QUESTIONS

1. Which of the following disorders does not increase in frequency in patients with Turner syndrome?
   a. Autoimmune thyroid disease
   b. Type 1 diabetes mellitus
   c. Chronic otitis media
   d. Celiac disease

Answer: b

2. Which of the following features is not attributed to haploinsufficiency for SHOX?
   a. Cubitus valgus
   b. Short stature
   c. Webbed neck
   d. Madelung deformity

Answer: c

3. A 36-year-old mother underwent amniocentesis to screen for Down syndrome, and the karyotype result showed mosaicism for 46,XY/45,X. The fetal ultrasound at 14 weeks showed an apparently normal male. Which of the following statements is accurate?
   a. The karyotype should be repeated after birth.
   b. The child has "male Turner syndrome."
   c. The likelihood of miscarriage is high.
   d. The mother has a higher than average risk for another gestation with sex chromosome anomaly.

Answer: a

4. A female newborn with neck webbing had a karyotype test showing nonmosaic 45,X. What should further evaluation include?
   a. Renal and cardiac ultrasound
   b. Skeletal x-ray series
   c. Molecular testing for occult Y chromosome sequences
   d. Thyroid autoimmunity screen

Answer: a

5. A karyotype analysis should be carried out for which of the following cases?
   a. A female newborn with neck webbing
   b. A 6-year-old girl with aortic coarctation
   c. An 11-year-old girl with short stature, no sign of puberty, and hypertension
   d. All of the above

Answer: d

6. Spontaneous pubertal development is most likely in Turner girls with which of the following conditions?
   a. Mosaicism for a cell line containing more than one X chromosome (e.g., 46,XX or 47,XXX)
   b. FSH in the age-specific normal range
   c. AMH in the age-specific normal range
   d. All of the above

Answer: d

7. What are the most common cardiovascular anomalies in Turner syndrome?
   a. Bicuspid aortic valve, coarctation, and ventricular septal defect
   b. Bicuspid aortic valve, coarctation, and mitral valve prolapse
   c. Bicuspid aortic valve, coarctation, and partial anomalous pulmonary veins
   d. Bicuspid aortic valve, partial anomalous pulmonary veins, and pulmonic stenosis

Answer: c

8. A girl that is found to have Y chromosome material on her peripheral blood karyotype may have which of the following?
   a. Spontaneous puberty and pregnancy
   b. A high risk for adenocarcinoma of the ovary
   c. A high risk for behavioral disorder
   d. All of the above

Answer: a

9. What is the best treatment for a 12-year-old girl recently diagnosed with Turner syndrome and menopausal FSH?
   a. GH, estrogen, and oxandrolone beginning immediately
   b. GH until age 15 and then pubertal induction
   c. GnRH analog and GH until age 15
   d. GH and low-dose estradiol until height is satisfactory and then full pubertal estrogen

Answer: d

10. What does an annual medical screening for the 10- to 12-year-old with Turner syndrome include?
    a. Blood pressure measurement
    b. Metabolic profile
    c. FSH and AMH levels
    d. Thyroid-stimulating hormone
    e. All of the above

Answer: e

11. Which of the following statements is justified?
    a. Girls need to have a DXA scan for bone mineral density prior to estrogen treatment.
    b. A normal cardiac echo is an adequate cardiac evaluation for the young woman with Turner syndrome who is considering pregnancy.
    c. Girls with surgically repaired coarctation need lifelong cardiovascular follow-up.
    d. Oral contraceptive pills should be used to induce puberty.
    e. All of the above
    f. a, b, and c

Answer: c

CHAPTER 17

Puberty and Its Disorders in the Male

Mark R. Palmert, MD, PhD • Leo Dunkel, MD, PhD • Selma Feldman Witchel, MD

CHAPTER OUTLINE

Puberty is a period during which children attain adult secondary sexual characteristics and reproductive capability.[1] In humans, two distinct processes of sexual maturation are recognized: gonadarche and adrenarche. Gonadarche is defined as the growth and maturation of the gonads associated with increased sex steroid secretion. Gonadarche requires an intact hypothalamic-pituitary-gonadal (HPG) axis, and any disruption of this axis can result in temporary or permanent disorders of reproductive endocrine function. Adrenarche is defined as maturation of the adrenal cortex associated with increased secretion of dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS), and androstenedione. Unlike gonadarche, adrenarche is a phenomenon limited to humans and some

great apes. The physiologic foundations for puberty begin in utero with the development of the neurobiologic structures that govern the hypothalamic-pituitary component of the HPG axis and with the differentiation and the development of the gonads. The entire process, extending from fetal life through achievement of reproductive competence, represents the dynamic and coordinated interactions of an expanding list of genes, proteins, signaling molecules, paracrine factors, and epigenetic events.

PRENATAL NEUROBIOLOGY OF PUBERTY

In postnatal life, the gonadotropin-releasing hormone (GnRH) neurons are located in the hypothalamus and constitute the GnRH pulse generator, which produces an intermittent discharge of GnRH into the hypophysial portal circulation to stimulate gonadotropin synthesis and secretion by the pituitary gonadotropes. The developmental progression of these neurons is governed by multiple regulatory factors; mutations in some of these factors have been associated with disorders of puberty.[2]

However, the 1000 to 2000 GnRH neurons originally differentiate in the olfactory placode and begin their migration along the vomeronasal nerves to the cribriform plate around the sixth week of gestation. This migration can be categorized into four stages. The first stage involves the differentiation of the GnRH neurons from a heterogenous stem cell population in the embryonic olfactory placode. Factors involved in these early stages include the proteins encoded by fibroblast growth factor 8 (*FGF8*), fibroblast growth factor receptor 1 (*FGFR1*), heparin sulfate 6-O-sulfotransferase 1 (*HS6ST1*), chromodomain helicase DNA-binding protein 7 (*CHD7*), and nasal embryonic luteinizing hormone (LH)–releasing hormone (*NELF*). The extracellular domain of FGFR1, a tyrosine kinase receptor, interacts with heparan sulfate proteoaminoglycan, which functions as its coreceptor. Nonrandom modifications of the sugar moieties associated with heparan sulfate proteoaminoglycans such as by HS6ST1 facilitate FGFR1 function. Binding of its cognate ligand, FGF8, to FGFR1, initiates signaling. The FGF8-FGFR1 signal transduction pathway plays an essential role in the neurobiology of GnRH neurons. Several additional genes show spatiotemporal expression patterns similar to *FGF8* and appear to modulate FGF8 signaling through FGFR1. These genes include fibroblast growth factor 17 (*FGF17*), interleukin 17 receptor D (*IL17RD*), dual specificity phosphatase 6 (*DUSP6*), sprout homologue 4 (Drosophila) (*SPRY4*), and fibronectin leucine rich transmembrane protein 3 (*FLRT3*).[3]

The second stage is the onset of GnRH neuron migration, which commences around the sixth week of gestation in humans. This process depends on guidance cues to ensure proper routing of the neurons. Several molecules such as anosmin-1, FGFR1, and prokineticin 2 (PROK2) appear to be involved in this process. Anosmin-1, encoded by the *KAL1* gene, is an extracellular matrix protein; it also binds to heparan-sulfate glycosaminoglycans. Although the precise function of anosmin-1 is unclear, potential functions include providing a guidance platform for migrating neurons, serving as a chemo-attractant for other factors, and interacting with FGFR1. Prokineticin-2 (PROK2), prokineticin receptor-2 (PROKR), NELF, and semaphorin-3A (SEMA3A) appear to influence GnRH neuron migration.

Eventually, these neurons reach the hypothalamus where they extend projections to the median eminence to form a network, which completes the third stage of GnRH neuron migration. The last stage comprises functional activity. By the 15th week of human gestation, the GnRH pulse generator is modulating the function of the fetal gonadotropes. The HPG axis is functionally active for the first time during fetal development, and it continues to function in infancy until it enters a relative quiescent state, often referred to as the juvenile pause or prepuberty. Likely sharing some similarities but also having some differences,[4] the molecular mechanisms responsible for the prepubertal inactivation of the HPG axis and its reactivation at the onset of puberty remain to be characterized.

TESTICULAR DIFFERENTIATION AND DEVELOPMENT

Prenatal Testicular Development

A brief summary of prenatal testicular differentiation and development follows; a more detailed description of testicular differentiation and sex development can be found in Chapter 4. Beginning at approximately 4 to 6 weeks of gestation, the primordial bipotential gonad arises from a condensation of the mesoderm of the urogenital ridge. Genes involved in the development of this bipotential gonad include the Wilms tumor (*WT1*) gene, *GATA4*, chromobox homologue 2 (*CBX2*), and steroidogenic factor-1 (*NR5A1*). During this time, the primordial germ cells proliferate and migrate from the hindgut to colonize the developing gonad. The bipotential gonad is composed of supporting cells, endothelial cells, steroid-secreting cells, and germ cells.

In the usual circumstance, the presence of a Y chromosome bearing the sex-determining region on the Y (*SRY*) gene promotes testicular differentiation. However, novel data emphasize the complexity of gonadal differentiation with involvement of signaling molecules—for example, SRY-box 9 (SOX9) and Forkhead transcription factor 2 (FOXL2)—that activate or repress gonadal determination factors involved in testicular and ovarian development. Sertoli cell differentiation is the earliest manifestation of testicular differentiation. At approximately 7 to 9 weeks of gestation in the human XY gonad, the Sertoli cells envelope the germ cells to form the seminiferous cords. Curiously, germ cells are not required for initial phases of testicular differentiation. Rather, the local environment directs the developmental fate of the primordial germ cells. During the migration though the hindgut, the primordial germ cells proliferate. The stem cell factor (Steel factor) and c-KIT receptor guide the primordial germ cells to the developing genital ridges. This signaling system ensures that viable primordial germ cells travel to their proper environmental niche and that misdirected primordial germ cells undergo apoptosis. Primordial germ cells that escape apoptosis and migrate to other physical locations, such as the mediastinum or central

nervous system, can develop into extragonadal germ cell tumors. Primordial germ cells that occupy the genital ridge become pluripotent gonocytes that express specific stem cell markers including placental/germ cell alkaline phosphatase (PLAP) and octamer binding transcription factor 3/4 (OCT3/4).

Internal genital structures are also bipotential. Sertoli cells secrete anti-Mullerian hormone (AMH), which induces regression of the Mullerian ducts through its actions on the type II AMH receptor. The fetal Leydig cells, initially stimulated by placental hCG, secrete testosterone which stabilizes the Wolffian ducts. In the human male fetus, the testicular compartments, tubular and interstitial components, and specific cell types, Leydig, Sertoli, and germ cells can be visualized by 11 weeks of gestation. The most rapid growth in Sertoli cell number appears to occur during the latter half of the first trimester and the second trimester.[5]

During early gestation, placental hCG governs Leydig cell proliferation and testosterone and insulin-like factor 3 (INSL3) secretion until endogenous LH regulates these activities in midgestation. Due to this role of placental hCG during early gestation, gonadotropin deficiency does not influence male sexual differentiation. LH secretion influences the number of fetal Leydig cells because the number is decreased in anencephalic fetuses and is increased in 46,XY fetuses, with elevated gonadotropin concentrations secondary to complete androgen insensitivity.[6] Follicle-stimulating hormone (FSH) secretion influences Sertoli cell differentiation and AMH and inhibin B secretion.[7]

Androgens induce the genital tubercle, urethral folds, and labioscrotal swellings to develop into the male external genital structures. In target tissues such as genital skin and prostate, testosterone is converted to dihydrotestosterone, which induces the urethral folds to fuse and form the corpus spongiosum and penile urethra. The genital tubercle develops into the corpora cavernosa of the penis and the labioscrotal folds fuse to form the scrotum. By 9 weeks of gestation, a cylindrical 2-mm phallus with genital swellings has developed. By 12 to 14 weeks of gestation, the urethral folds have fused to form the cavernous urethra and corpus spongiosum. By 14 weeks, the external genitalia are clearly masculine apart from testicular location. In the absence of sufficient androgen concentrations, the urethral folds and labioscrotal swellings do not fuse and develop into the labia minora and labia majora, respectively.

Testicular descent occurs in two phases. The transabdominal phase begins at approximately 12 weeks of gestation and is influenced by the Leydig cell product, insulin-like factor 3 (INSL3), and its cognate receptor, leucine-rich repeat-containing G protein–coupled receptor 8 (LGR8). The second androgen-dependent phase, descent of the testes through the inguinal canal, is usually accomplished by the end of week 35.[8]

Postnatal Testicular Development

Following a brief perinatal decline, the hypothalamic-pituitary-testicular axis is active during the first few months of life with testosterone concentrations peaking at 1 to 2 months of age.[9] By approximately 6 months of age, testosterone concentrations decline to prepubertal levels. Despite the increased neonatal HPG activity, sexual hair does not develop and gametogenesis does not occur due to limited androgen receptor (AR) signaling in certain tissues (e.g., Sertoli cells). Throughout infancy, AR is expressed in Leydig cells, but not in Sertoli cells.[10] During infancy and childhood, seminiferous cords are solid and generally filled with immature Sertoli cells. The germ cells are limited to spermatogonia and Leydig cells are rarely visualized.[11] After early infancy, which provides a window of opportunity to assess testicular function, hCG stimulation may be needed to assess Leydig cell function. Inhibin B and AMH continue to be secreted during childhood providing valuable markers of Sertoli cell function.

Reactivation of the GnRH pulse generator at the time of puberty stimulates pituitary LH and FSH secretion (Figure 17-1). The LH stimulation leads to increased testicular testosterone and INSL3 secretion. The increased testosterone acts as a paracrine factor to induce Sertoli cell maturation. Pubertal maturation of the seminiferous tubules is characterized by cytoskeletal rearrangements including development of tight junctions, Sertoli cell polarization, Sertoli cell proliferation, migration of spermatogonia toward the basement membrane, and decreased AMH secretion.[12] FSH stimulates Sertoli cells to secrete inhibin B, which from midpuberty onward serves as the major negative regulator of pituitary FSH secretion. Prior to puberty, inhibin B is germ cell independent. After puberty, inhibin B secretion becomes germ cell dependent and provides a marker of germ cell depletion in adults.[13]

The increase in Sertoli cell number contributes to the increase in testicular volume that marks the onset of gonadarche in boys. As puberty progresses, the seminiferous tubules are larger and develop a lumen; typical Leydig cells become apparent. Although much variation in chronologic age and testicular volume has been described, spermarche precedes peak pubertal linear growth velocity and generally occurs at a median testicular volume of 10 to 12 mL.[14] Beginning in early puberty, testosterone and AMH show an inverse relationship reflecting the paracrine actions of testosterone to repress AMH secretion by Sertoli cells. Intratesticular testosterone and AR expression in Sertoli cells are essential for the decline in AMH concentrations, meiosis, and spermatogenesis.[11] Hence, AMH concentrations provide an indication of Sertoli cell function and androgen action in the testes.

THE ANDROGEN RECEPTOR

The androgen receptor (AR) binds androgens to initiate a signal transduction cascade mediating the effects of testosterone and DHT. The *AR* gene is located at Xq11-q12. Similar to other members of the steroid-thyroid nuclear hormone receptor family, *AR* (also known as NR3C4) has a modular structure with N-terminal regulatory (NTD), DNA binding (DBD), and ligand binding (LBD) domains. The DBD contains the cysteine residues that coordinate zinc atoms to form the zinc finger

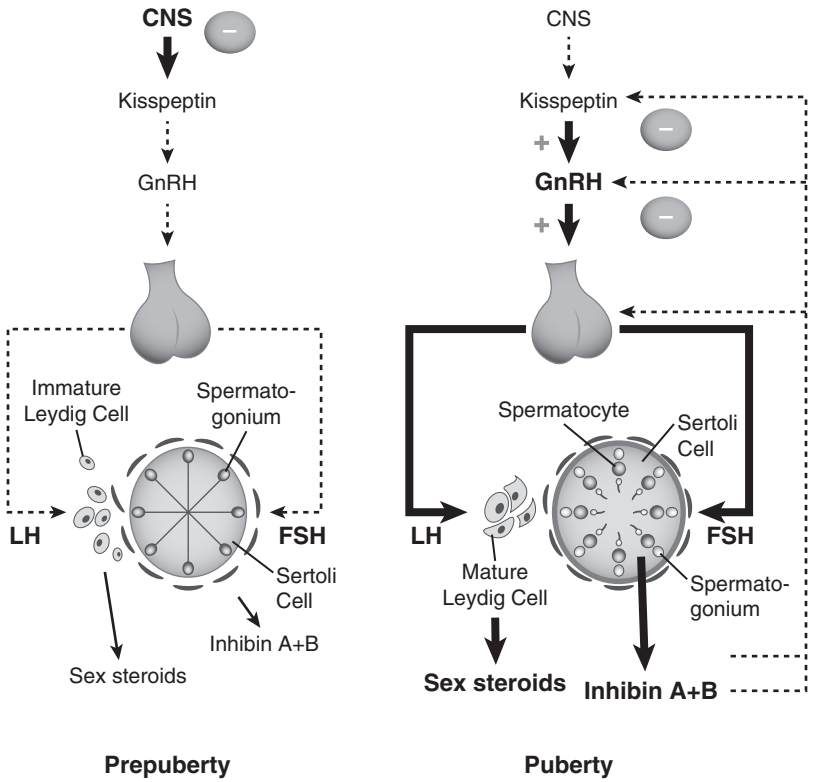

FIGURE 17-1 ■ Testicular products, such as inhibins, play a small role in regulation of the HPG axis prior to puberty, but most of the dampening of the HPG axis after infancy and until the onset of puberty (left panel) derives from central inhibition of the HPG axis. The basis for that inhibition is not fully understood nor is the basis for its diminution, which leads to emergence of central activation (right panel), increased gonadotropin releasing hormone (GnRH) secretion, and the onset of puberty. As pubertal development progresses, lumen develops in Sertoli cells. Inhibin B secreted from the mature testes (right panel) has a more substantial role in regulating/inhibiting hypothalamic-pituitary activity. Weight of lines (from dotted to thin solid to thick solid) indicates increasing strength of the particular signal. LH, luteinizing hormone; FSH, follicle-stimulating hormone.

domains, which bind to DNA. The LBD is composed of 12 α helixes associated with antiparallel β sheets, which form a tripartite sandwich structure.

The three-dimensional structure contains a hydrophobic pocket formed by helixes 4, 5, 7, 11, and 12. Helix 12 can fold like a lid on top of the hydrophobic pocket to capture the ligand and allow for interactions between the LBD and various co-regulator proteins. The AR protein contains several subdomains important for dimerization, protein-protein interactions, and transcriptional regulation. Interactions between the N-terminal domain and the C-terminal LBD stabilize the receptor-ligand complex to slow dissociation of the ligand from the receptor. DHT is a more potent androgen because it dissociates at a slower rate from the receptor than testosterone.

The unliganded receptor is located in the cytoplasm where it is associated with several heat shock proteins (HSPs) such as HSP70 and HSP90. Chaperone proteins such as FKBP52 also associate with this complex. Ligand binding induces dissociation of the cytoplasmic receptor-chaperone protein complex followed by translocation of the receptor-ligand complex into the nucleus where it binds as a homodimer to AR response elements. Additional proteins, coactivators and corepressors, also interact with this complex. Activation of transcription involves two subdomains known as activation function regions. The activation function-1 (AF1) region is located in the NTD. The activation function-2 (AF2) region is located in the LBD and interacts with steroid receptor coactivators through their LXXLL motifs. The LXXLL refers to the amino acids in this motif with L being leucine and X being any amino acid. Steroid receptor coactivators include SRC1, SRC2/TIF2, and SRC3.

PHYSIOLOGY OF PUBERTY

Endocrinology

The onset of puberty is heralded by an increase in the secretion of gonadotropin releasing hormone (GnRH) (see Figure 17-1) from a diffusely distributed network of hypothalamic neurons. Intermittent secretion of GnRH into the hypophysial portal circulation stimulates gonadotropes in the anterior pituitary to synthesize and secrete luteinizing hormone (LH) and follicle stimulating hormone (FSH) that, in turn, bind to ligand specific receptors in the Leydig and Sertoli cells of testes, respectively. Gonadotropin stimulation initiates gonadarche, and the production of sex steroids, most notably testosterone, and at later pubertal stages estradiol as well.[15] Testosterone and estradiol, together with inhibin, activin, and follistatin, provide signals that regulate the subsequent activity of the hypothalamus and pituitary gland. The transition from prepubertal quiescence to the adolescent pattern of

GnRH secretion is a gradual rather than abrupt process. LH and FSH pulsatility has been detected in normal children as young as 4 years of age.[16-19] Throughout childhood, GnRH secretion appears to undergo small but progressive increases until the onset of puberty, when GnRH secretion increases, first at night and eventually throughout the day.[20,21]

Neuroendocrine Regulation of Pubertal Onset

Understanding what factors contribute to the dampening of the HPG axis after infancy and what factors lead to the reemergence of GnRH secretion is critical to understanding the regulation of pubertal timing. Research into kisspeptin (Kiss1) and its receptor (Kiss1R, formerly G protein–coupled receptor 54, GPR54) in both animal and human studies has identified them as critical components of the HPG axis. The first indications of the importance of this signaling complex as a regulator of the HPG axis came in 2003 when two independent groups reported deletions and inactivating mutations of *GPR54* in patients with hypogonadotropic hypogonadism (HH).[22,23] Subsequently, activating mutations in this pathway were associated with central precocious puberty in the case of a female with an autosomal dominant mutation in *GPR54*.[24] Thus, it is clear that activation of Kiss1R by kisspeptins plays a pivotal role in the onset of puberty.

It is not yet known, however, whether this system is the initial trigger of puberty or whether it acts either as a downstream effector or in concert with other regulatory factors.[25,26] For example, the discovery that mutations in *TAC3* (encoding neurokinin B) or its receptor *TACR3* (encoding NK3R)[27] can cause HH has focused much attention on how hypothalamic neurons that coexpress kisspeptin, neurokinin B, and dynorphin (abbreviated as KNDy neurons) regulate the HPG axis in males and females.[28-30] Another excitatory factor in the hypothalamus is glutamate, an important stimulator of GnRH secretion through its actions at n-methyl, D-aspartate (NMDA) and kainate receptors. GnRH secretion is stimulated also by factors such as norepinephrine, dopamine, TGFα, neuregulin signaling via erbB4 receptors, leptin, and galanin-like peptide.[31-35] Many of these factors likely act via a complex, intricate communication network that exists between glial cells and neurons within the hypothalamus.[36] The potential roles that these and other compounds play in regulating the onset of puberty remains an area of active investigation.

Gamma-amino butyric acid (GABA) neurons appear to play a prominent role in inhibiting prepubertal GnRH release.[37] There is evidence that GABA can also stimulate GnRH secretion, but this variable action may be dependent on developmental stage, composition of GABA receptors, and expression of *KCC2* (a protein that can alter the inhibitory and excitatory properties of chloride channels).[38] The finding that neuropeptide Y (*NPY*) mRNA expression in the hypothalamus of juvenile monkeys is higher than neonatal animals suggests that NPY may play a role in the juvenile pause.[4] Other factors that likely inhibit GnRH release include endogenous opioids (i.e., β-endorphin) and melatonin, but neither of these compounds likely plays a major role in regulating the timing of puberty.[35]

Somatic Changes

In boys, the first marker for the onset of puberty is most often the change from Tanner genital stage G1 to stage G2, including enlargement of the testes (i.e., achievement of volume greater than 3 mL or testicular length greater than or equal to 25 mm). Originally Marshall and Tanner reported the mean (SD) onset of puberty in boys to be 11.64 (1.07) years.[39,40] These pubertal stages (Figure 17-2) were based on photographic observation of genital development of a longitudinal but still relatively small sample of 228 boys living in a children's home. Despite the probably poor representative nature of this sample, comparable studies in Switzerland,[41] the United States,[42] and Denmark[43] reported roughly similar mean ages of puberty onset. Although the mean age of onset may be fairly uniform, the onset of puberty occurs across a wide range of ages in normal, healthy adolescents. Several pathologic states influence the timing of puberty either directly or indirectly and contribute to this splay, but the great majority of the variation in pubertal timing cannot be attributed to any clinical disorder. Ninety-five percent of boys experience the onset of genital development between

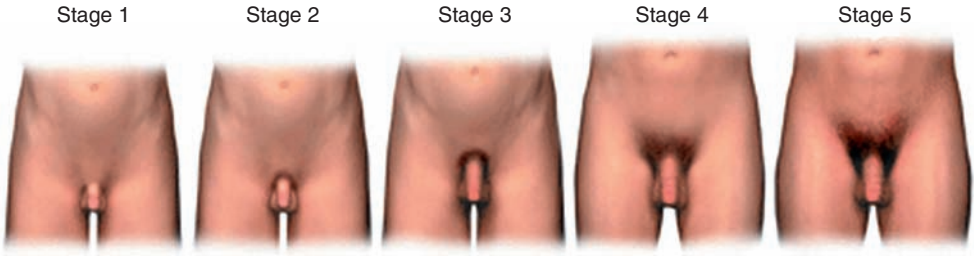

FIGURE 17-2 ■ In boys, genital development is rated from 1 (preadolescent) to 5 (adult); stage 2 marks the onset of pubertal development and is characterized by an enlargement of the scrotum and testis and by a change in the texture and a reddening of the scrotal skin. Pubic hair stages are rated from 1 (preadolescent, no pubic hair) to 5 (adult), and stage 2 marks the onset of pubic hair development. Although pubic hair and genital development are represented as synchronous in the illustration, they do not necessarily track together and should be scored separately. (Reproduced with permission from Carel, J. C., & Leger, J. [2008]. Clinical practice: precocious puberty. *N Engl J Med, 358*, 2366–2377.)

9.5 and 13.5 years,[44,45] data that have led to the traditional definition of sexual precocity in boys as development of secondary sexual characteristics before age 9 years and delayed puberty as lack of testicular enlargement by age 14 years.

Development of secondary sexual characteristics results from both gonadarche and adrenarche. Adrenarche refers to the maturation of the zona reticularis of the adrenal gland, resulting in increased production of adrenal androgens associated with secondary sexual characteristics, such as the development of pubic hair (pubarche), axillary hair, body odor, and acne. Like gonadarche, the onset of adrenarche appears to be a gradual, progressive maturational process that begins in early childhood and is marked by the further increases of production of adrenal androgens (DHEA, DHEA-S, and androstenedione) around the time of puberty.[46] Adrenarche sometimes precedes gonadarche by 1 to 2 years in boys and girls, but the timing of clinical signs can vary. Although adrenarche and gonadarche often overlap, they are separate processes that are independently regulated.[47,48] The triggers for adrenarche remain unknown; however, alterations in body weight and body mass index as well as in utero and neonatal physiology likely modulate this developmental process, perhaps along with intra-adrenal cortisol production.[49-51]

REGULATION OF THE TIMING OF PUBERTY

Genetics

The timing of puberty is influenced by both genetic and environmental factors.[52,53] Evidence for the genetic contribution is provided by correlations in timing within families and between monozygotic twins. These data derive mostly from studies of females and suggest that more than half of the variation in the most commonly used marker for the timing of puberty, age at menarche, is attributable to additive genetic effects and the rest appears to be attributable to nonshared environmental effects.[34,52,54-61] It is important to note that this genetic component does not preclude a significant role for environmental influences that may have changed over time. However, despite changing environmental and secular influences, genetic background still plays a significant role in regulating the variation of pubertal timing within a population at any particular point in time.

Genetic Disorders Causing GnRH Deficiency

The study of genetic disorders that cause GnRH deficiency, such as isolated hypogonadotropic hypogonadism (HH) and Kallmann syndrome (KS), has significantly increased our understanding of development and function of the hypothalamic pituitary gonadal (HPG) axis.[59,62-67] These studies have led to the identification of many genes that play critical roles in the HPG axis. For example, this work has defined roles for the genes that lead to HH (*GNRHR*, *GNRH1*, *GPR54*, *NELF*, *FGFR1*, *FGF8*, *PROK2*, *PROKR2*, *TAC3*, *TACR3*, *CHD7*, and *HS6ST1*), to X-linked (*KAL1*) and autosomal (*NELF*, *FGFR1*, *PROK2*, *PROKR2*, *FGF8*, *WDR11* and *CHD7*) forms of KS, to obesity and HH (*LEP*, *LEPR*, and *PC1*), and to abnormal HPG development (*DAX1*, *SF-1*, *HESX-1*, *LHX3*, and *PROP-1*). Moreover, research in this field permits recognition that, in some cases, HH and KS can be caused by mutations in the same genes and derive from a monogenic or oligogenic basis.[68] In contrast to this great progress, the specific genetic factors that regulate the variation in pubertal timing in the general population are just emerging. In addition to genes identified through genome wide association studies (discussed later), another factor may be the makorin RING-finger protein 3 (MKRN3). Loss-of-function mutations in *MKRN3* were associated with GnRH-dependent precocious puberty.[69]

Normosmic Hypogonadotropic Hypogonadism

Although several HH-related genes have been identified, HH with normal olfaction has been primarily associated with mutations in the genes for the gonadotropin-releasing hormone receptor (GNRHR) and the KISS1 (kisspeptin) receptor (*KISS1R*, formerly *GPR54)*.[22,23,70-74] Estimates regarding the frequency of *GNRHR* mutations in normosmic HH range from 3.5% to 10.4%.[75,76] Mutations in *GNRH1* have also been identified in patients with normosmic HH but only in rare case reports.[77,78] Although these individuals have normal olfaction, they can have other nonreproductive clinical features such as midline facial defects, renal agenesis, and skeletal abnormalities that may provide clues about the underlying pathophysiology.[67] Interestingly, a case of constitutional delay of growth and puberty (CDGP) has also been associated with a homozygous partial loss-of-function mutation in *GNRHR*,[79] and pedigrees of probands with HH can include individuals with delayed but otherwise normal puberty. However, more extensive analyses suggest that genetic variation in neither *GNRH1* nor *GNRHR* nor other HH-related genes is a common cause of late puberty in the general population[80,81]; whether combinations of rare variants in KS or HH-related genes is a cause of some cases of constitutional delay of growth and puberty remains to be determined.

Mutations in genes encoding neurokinin B and its receptor, *TAC3* and *TACR3*, have been identified in HH patients.[27] As noted earlier, these genes are highly expressed in the same neurons that express kisspeptin, further emphasizing the role of kisspeptin in the regulation of pubertal timing.

Kallmann Syndrome

HH associated with abnormal sense of smell (anosmia/hyposmia) is referred to as Kallmann syndrome. As with cases of HH and normal olfaction, other nonreproductive clinical features can be seen in individuals with KS, including ichthyosis, choanal atresia, horseshoe kidneys, and mirror movements of the hands (synkinesia).[67] Several genes critical to HPG axis function and olfactory development have been identified through investigation of Kallmann syndrome. In particular, mutations in Kallmann

syndrome 1 (*KAL-1)*[82,83] and fibroblast growth factor receptor 1 (*FGFR1)*[84] have been implicated in the X-linked and autosomal dominant forms of the disease, respectively, and appear to account for approximately 20% of patients with KS.[85] Mutations in the prokineticin receptor-2 gene (*PROKR2)*, a G protein–coupled receptor, and in its ligand prokineticin-2 *(PROK2)* have also been identified in patients with KS,[85] demonstrating that prokineticin signaling is important for olfactory and HPG axis development. One of the patients in this initial series was heterozygous for both a *PROKR2* mutation and a *KAL1* mutation, suggesting a possible digenic mode of inheritance.[85] Finally, mutations in the nasal embryonic luteinizing hormone releasing hormone factor (*NELF*), which plays a role in migration of GnRH neurons and olfactory axon outgrowth,[86] have also been implicated in the pathogenesis of KS.[87] A heterozygous deletion in *NELF* was initially reported as a component, along with *FGFR1*, of digenic KS,[88] but it has recently been reported that NELF can lead to HH or KS via monogenic as well as digenic inheritance.[89]

The distinction among the different abnormalities of pubertal development is not always clear cut. For example, a comprehensive study of *PROK2* and *PROKR2* in HH and KS patients found mutations in both genes distributed in both groups of patients.[90] Mutations in the *FGF8* gene, which encodes a ligand for FGFR1, have been observed in HH patients accompanied by variable olfactory phenotypes.[91] Mutations in *CHD7*, a gene responsible for CHARGE syndrome, which shares some developmental features with KS, have been identified in patients with both normosmic HH and KS.[92,93] More recently, mutations in *FGFR1*, *FGF8*, and *PROKR2* have been identified among subjects with combined pituitary hormone deficiency (CPHD) and septo-optic dysplasia (SOD), indicating that in some cases HH and CPHD/SOD can share genetic etiologies.[94,95] The distinction between HH and constitutional delay of growth and puberty (CDGP) is also not always clear. Variation in *FGFR1* does not appear to be a major cause of CDGP,[81] although loss-of-function mutations in *FGFR1* can cause delayed puberty in members of HH pedigrees.[96,97] Instances of reversible HH have also been reported,[98] raising the possibility that some cases of HH may represent severe versions of CDGP, further blurring the distinction between HH and CDGP.

Other Genes Associated with HH

Leptin appears to act as a permissive factor in pubertal maturation.[34] HH (accompanied by obesity) can result from defects in the leptin (*LEP*) or the leptin receptor (*LEPR*) genes, highlighting the importance of nutrition in modulating the HPG axis. The neuronal targets for leptin's action are incompletely explained because leptin receptors are not expressed by GnRH neurons, suggesting that the site of leptin action may be upstream of the GnRH neurons. However, association studies have found no substantial association between common polymorphisms in *LEP* and *LEPR* and constitutional delay of growth and puberty (CDGP) or age at menarche in the general population.[81,99]

Mutations in several pituitary transcription factors, including HESX-1, *LHX3*, and *PROP1*, can lead to combinedpituitary hormone deficiencies that include HH as a phenotype. The gene for prohormone convertase-1 (*PC-1*) has been associated with obesity and HH, possibly as a result of defective processing of neuropeptides or prohormones that are components of GnRH secretion.[66,100] Other causes of HH include mutations in genes that are critical to HPG development. This category includes the genes for the orphan nuclear receptors *DAX1* (dosage-sensitive sex reversal adrenal hypoplasia critical [DSS-AHC] region on the X chromosome, gene 1) and steroidogenic factor-1 (*NR5A1*).

Genetic Variation in Normal Puberty

Observations regarding the greater concordance in age at pubertal development in monozygotic twins and correlation at age of menarche in mothers and daughters emphasized the role of genetic influences in the timing of normal pubertal development.[101] Approaches utilized to identify specific genetic factors include candidate genes studies and genome-wide association (GWA) studies.

Candidate Gene-Based Studies

A commonly used approach for identifying the variants that affect complex traits, such as the timing of puberty, in the general population has been candidate gene-based association and sequencing studies.

In an association study that tested for associations between common variants in 10 HH-related genes (*GNRH1*, *GNRHR*, *KISS1R/GPR54*, *KISS1*, *LEP*, *LEPR*, *FGFR1*, *KAL1*, *PROK2*, and *PROKR2*) and age at menarche, only nominally significant associations between SNPs in several of the genes and age at menarche were identified, indicating that genetic variation in these 10 genes does not appear to be a substantial modulator of pubertal timing in the general population.[81]

Other work has also shown no evidence for substantial association between SNPs in *GNRH1* and *GNRHR*[80] or *LEP* and *LEPR*[99] and alterations in pubertal timing. In a direct sequencing study (which assessed variation in *FGFR1*, *GNRHR*, *TAC3*, and *TACR3* in 146 Finnish subjects), variants in the coding regions of these genes were not identified as likely causes of constitutional delay of growth and puberty in the general population.[102]

Genome-Wide Association (GWA) Studies

In large-scale GWA studies, the age of menarche has been the most commonly used marker of the timing of puberty. These studies provide important information regarding genes and pathways that regulate the timing of puberty, but it is unlikely that there is complete overlap among factors that regulate the timing of puberty in males and females. For the most part, further study is still needed in boys and men.

Common variants in *LIN28B* were associated with age at menarche in four independent GWA

studies and one meta-analysis.[103-107] *LIN28B* is a human homologue of *lin-28*, which in *C. elegans* controls the rate of progression from larval stages to adult cuticle formation, indicating conservation of specific microRNA regulatory mechanisms involved in developmental timing.[104] These GWA studies involved between 17,000 and 25,000 individuals, all of European descent. In each case, age at menarche (AAM) was analyzed, but in one study[107] additional phenotypes (breast development in girls, voice breaking and pubic hair development in boys, and tempo of height growth in both boys and girls) were found to associate with variants in *LIN28B*, suggesting that control of pubertal timing in boys and girls shares some common elements. One study found that the signal at *LIN28B* could be split into two haplotypes, suggesting that either multiple variants may associate with AAM at this locus or that a SNP that has not yet been tested for association may represent the true association signal.[106] Effect sizes were estimated at approximately 1.2 months earlier per effect allele for *LIN28B*.[105,107] A second menarche locus was identified in two of the four studies at 9q31.2.[103,105] The biology behind the locus at 9q31.2 remains unknown, but its effect size is similar to the locus in/near *LIN28B*.[105] The associated SNPs lie in an intergenic region with no obvious candidate genes nearby. The closest gene is *TMEM38B*, a transmembrane protein gene, which lies approximately 400 kb away from the signal at 9q31.2.[105] Although these studies were ground breaking, the *LIN28B* and 9q31.2 loci together explain only 0.6% of the variance in age at menarche.[103]

The genetic contribution to the variation in age at menarche was further investigated by a meta-analysis of 32 genome-wide association studies including 87,000 women.[104] Thirty new AAM-associated loci were identified, but pubertal timing among males was not assessed. Despite the large size of the meta-analysis, these loci explained only 3.6% to 6.1% of the variance in the age at menarche.[104] It is important to note that the small effect size does not negate the importance of the discovery. Findings from GWA studies have highlighted biologic pathways involved in a variety of phenotypes, both through "rediscovery" of genes known to be important and through identification of previously unsuspected pathways.[108] This principle also holds true for pubertal timing, with much new biology to explore as the mechanisms through which these newly identified genes modulate pubertal timing are investigated and as future studies determine whether the same genes regulate pubertal timing in boys and in girls.

GWA studies are designed to assess the contribution of common genetic variants to a particular phenotype. However, it is likely that other forms of inheritance also underlie CDGP, including rarer variants (frequency $< 5\%$ in the general population) with large or even small phenotypic effects; combinations of variants within a single gene or multiple genes (oligogenicity); structural variation, such as copy number variants; and epigenetics. Indeed, some of these mechanisms have been identified as causes of hypothalamic amenorrhea.[109]

External Factors and Secular Trends in the Timing of Puberty

Although these genetic advances are exciting, genetic factors cannot explain the reported secular changes in pubertal timing (discussed later) that have occurred since the late 20th century. Clearly, changes in lifestyle or environmental factors must be involved, likely as independent regulators but also as factors that mediate effects through gene by environment (G X E) interactions. Variables such as increased adiposity, insulin resistance, physical inactivity, psychological factors, and changed dietary habits have all been implicated as possible mediators of the observed change in pubertal timing.[52,110,111]

The mean age of menarche in mid-19th century Europe was likely between 17 and 18 years.[52] Starting from the late 19th century to the mid-20th century, a gradual decline in age at puberty has been reported, more convincingly in girls than in boys,[52,112] after which this trend may have slowed. The change in the timing in puberty has likely been the result of better hygiene and nutrition as well as increased stability in socioeconomic conditions.

The extent to which age at puberty has declined in males is controversial. In the mid-1990s, data from the Third National Health and Nutrition Examination Survey (NHANES III), where genital ratings were performed by visual inspection, reported earlier age at puberty in both boys and girls[113-116] than what previously had been reported from the United States.[44,115,117] Using the traditional cutoff of 9 years, these data suggest that an increased number of boys would be classified as having precocious puberty. However, due to lack of data on pubertal onset in the previous population-based study (Third National Health Examination Survey [NHES III]),[44] some controversy remained as how to interpret the NHANES III findings.[113,114,116] Furthermore, questions have been raised regarding the criteria used for genital staging in NHANES III.[118] A subsequent secular trend analysis between NHES III (which lacked data from the early pubertal stages) and NHANES III did not find clear evidence supporting earlier age at puberty, although some indications were present in non-Hispanic white boys.[115] These data were also reviewed by an expert panel, which concluded that the available data are insufficient in quality and quantity to confirm a change in pubertal timing in U.S. boys.[112] Conversely, at the same time in Europe, in comparison with NHANES III studies, some data were reported suggesting older ages at pubertal onset in boys.[41,119-121] Only a few European studies contained data to assess secular trend in the timing of puberty in Europe, and those do not support a substantial enough change in the age at pubertal onset in boys from the mid-1960s to the late 1990s to warrant a change in the age definitions for precocious and delayed puberty.[43,120]

Effect of BMI on Pubertal Timing

Among white American children aged 6 to 11 years, rates of obesity have increased from approximately 5% between 1963 and 1965 to 12% in 1999–2000.[122] The possibility that the increasing rates of obesity contributed to

the secular trend toward early puberty onset was originally highlighted in 1997.[123] However, despite strong evidence in support of a link between increased adiposity and early onset of pubertal markers in girls,[124,124] data in boys have remained somewhat ambiguous, with increased body mass index (BMI) being associated in general with earlier puberty but with obesity being associated with delayed puberty in some cases.[125,126]

Several population studies regarding pubertal timing and BMI have been conducted in boys. A retrospective study of 1520 men with serial height and weight measurements between the ages of 9 and 18 years reported that boys with high childhood BMI tended to have an earlier puberty, whereas boys with a later puberty tended to be taller and were less obese as adults than those who had experienced an earlier puberty.[127] Similarly, high BMI gain during childhood has been related to an earlier onset of puberty and reduced height gain during adolescence.[128]

In a study of 463 Danish choir boys, a significant downward trend in age at voice break was found over a 10-year period (from 14 years to 13.7 years).[129] Age at voice break was significantly different between boys in the different prepubertal BMI quartiles, and a trend toward earlier voice break was associated with increasing BMI SDS. Boys in the heaviest quartile at 8 years of age had an increased likelihood of earlier voice break compared with those in the thinnest quartile, suggesting a relationship between prepubertal BMI and the timing of puberty in boys.[129]

Another Danish study included an evaluation of secular trends in pubertal onset over a 15-year period and their relationship to BMI in boys.[121] In a total of 1528 boys, onset of puberty, defined as age at attainment of a testicular volume $>$ 3 mL, occurred 3 months earlier in 2006–2008 than in 1991–1993. Significantly higher levels of luteinizing hormone but not testosterone were found in boys between 11 and 16 years of age in 2006–2008 compared with boys of the same age in 1991–1993. BMI SD scores increased significantly from 1991–1993 to 2006–2008 as well. Interestingly, pubertal onset and levels of luteinizing hormone were no longer significantly different between study periods after adjustment for BMI. In this study, the estimated mean age at onset of puberty had, therefore, declined during the 15-year interval, and this decline was associated at least partly with an increase in BMI.[121]

In a study from Jamaica, the effects of birth size, growth rates throughout childhood, and body composition on the timing of onset of puberty were assessed in both boys and girls.[130] Fast weight gain from age 0 to 6 months and during childhood, but not large birth size, was associated with advanced puberty in both sexes. In addition, elevated fat mass at 8 years of age was associated with advanced puberty in both sexes. These data support the hypothesis that fast growth throughout childhood, especially with fat-mass accretion, is associated with advanced pubertal development.[130,131]

In a study from Germany, body weight, height, peak height velocity, and pubertal stages were evaluated in 1421 peripubertal children.[132] In contrast to the findings from other studies, the researchers found no significant differences in mean pubic hair stage in girls and boys with obesity when compared with either lean or normal-weight children and, when analysis was restricted to children at pubic hair stage 2, age at this stage was found not to differ significantly between normal-weight and obese individuals. In boys, testicular volume at a given age was also similar across all weight groups.[133]

In summary, research to date highlights inconsistencies in how obesity has been found to affect pubertal timing in boys and emphasizes the need for future research in this area.

Effect of Endocrine Disrupting Chemicals

Some evidence supports associations between human pubertal timing and exposure to environmental modifiers, although much of the data relate to girls. Earlier menarche and pubarche have been associated with exposure to polybrominated biphenyls (PBB) and dichlorodiphenyl dichloroethene (DDT), whereas delayed breast and pubic hair development as well as delayed menarche have been associated with lead exposure.[134,135] In addition, elevated serum levels of a mycotoxin (zearalenone) have been reported in girls with precocious puberty,[136] and phthalate exposure has been associated with changes in pubertal timing. A study in Denmark demonstrated that delayed pubarche, but not thelarche, was associated with high phthalate excretion in urine samples from healthy school girls, which may suggest antiandrogenic actions of phthalates.[137] Greater exposure to pesticides has been reported in boys with cryptorchidism or hypospadias.[138]

The extent to which these effects are associations versus cause-and-effect relationships is unknown as is full understanding of underlying mechanisms. To what extent any effects are shared versus different in girls compared to boys is also not known. Finally, what effects these exposures have in the general population as opposed to isolated examples of associated abnormalities is not clear. Certainly more research is this area is needed.[139,140]

PRECOCIOUS PUBERTY

Traditionally, the onset of secondary sexual characteristics in a boy prior to age 9 years has been defined as precocious, whereas lack of testicular enlargement by age 14 years has been classified as delayed puberty. In clinical settings boys present less often with precocious puberty than with delayed puberty, which is discussed more extensively later in the chapter.

GnRH-Dependent Forms of Precocious Puberty

The most common form of precocious puberty is the activation of pulsatile GnRH secretion 2 to 2.5 SDs earlier than average, recognizing that the normal limits for the onset of puberty can vary by geographic area and by ethnicity. This form of precocious puberty is called

central or gonadotropin-dependent precocious puberty, and it represents true pubertal development. Central precocious puberty (CPP) may result from hypothalamic tumors or central nervous system (CNS) lesions (neurogenic CPP) but in most cases remains unexplained (idiopathic CPP) (Table 17-1).[141,142]

Hypothalamic hamartomas are an example of a cause of neurogenic CPP. The hamartomas are congenital malformations characterized by heterotropic gray matter, neurons, and glial cells, and they are generally located on the floor of the third ventricle or attached to the tuber cinereum. On MR imaging, hamartomas exhibit an isodense fullness. Histologic examination has shown immunoreactivity for GnRH and for astroglial factors such as TGFα. Postulated potential mechanisms include increased GnRH secretion from neurons emancipated from suppression or that TGFα stimulates GnRH secretion from GnRH neurons. Most hypothalamic hamartomas are sporadic, but they may occur in association with Pallister-Hall syndrome, which is due to mutations in the *GLI3* gene. Optic gliomas, which can be associated with NF1, can also cause GnRH-dependent precocious puberty.[143] Other etiologies of neurogenic CPP include pineal tumors, suprasellar cysts, previous head trauma, CNS radiation, and static encephalopathy.[144]

Loss-of-function mutations of the makorin RING-finger protein 3 (MKRN3) located at chromosome 15q11-q13 have been associated with GnRH-dependent precocious puberty. All clinically affected individuals inherited the mutated allele from their fathers, which can be explained because this gene is imprinted and expressed only by the paternal allele. Curiously, almost half of these patients were boys; this differs from the typical female predominance of GnRH-dependent precocious puberty. The finding of MKRN3 as a cause of CPP is also interesting because it calls attention to the importance of inhibitory factors in the regulation of pubertal timing (see Figure 17-1) because loss of function of this gene (and loss of a presumed inhibitory role) leads to CPP.[69]

GnRH-Independent Forms of Precocious Puberty

Precocious development of secondary sexual characteristics may also be caused by mechanisms that do not involve activation of pulsatile GnRH secretion. These forms of precocity are called gonadotropin-independent or peripheral precocity and include gonadal and adrenal tumors, tumors producing human chorionic gonadotropin, mutations activating the gonadotropic pathway, and exposure to exogenous sex steroids (see Table 17-1). Familial male-limited precocious puberty (FMPP, OMIM ID: 176410), also known as testotoxicosis, is a rare dominant form of gonadotropin independent precocity caused by constitutively activating mutations of the human LH choriogonadotropin receptor (*LHCGR*).[145] This disorder usually presents by age 1 to 4 years with physical signs of puberty, rapid virilization, growth acceleration, skeletal (bone age) advancement, and elevated testosterone levels despite prepubertal levels of LH.[146,147] McCune-Albright syndrome (MAS, OMIM ID: 174800) is another rare cause of male sexual precocity of genetic origin. It is caused by a postzygotic somatic activating mutation of the *GNAS1* gene. The mosaic constitutive activation of the GSα protein signaling leads to autonomous cell proliferation and scattered hyperfunction in endocrine organs with a wide phenotypic spectrum.[148,149] The classical features include the clinical triad of bone fibrous dysplasia (BFD), café-au-lait skin spots, and precocious development of secondary sexual characteristics. In addition, excessive pituitary function (such as hyperthyroidism due to activation of thyroid-stimulating

TABLE 17-1 **Common Etiologies of Sexual Precocity in Boys**

Central (GnRH Dependent)	Peripheral (GnRH Independent)
Idiopathic	Congenital adrenal hyperplasia
Central nervous system tumors	McCune-Albright syndrome
—Hamartomas	Testosterone producing tumors
—Astrocytomas	—Adrenal carcinoma or adenoma
—Adenomas	—Leydig cell tumor
—Gliomas	Gonadotropin/hCG producing tumors
—Germinomas	—Choriocarcinoma
Central nervous system infection	—Dysgerminoma
Head trauma	—Hepatoblastoma
Iatrogenic	—Chorioepithelioma
—Low-dose CNS radiation	—Teratoma
—Chemotherapy	—Gonadoblastoma
—Surgical	Exogenous exposure to androgen
Malformations of central nervous system	Familial male limited precocious puberty
—Arachnoid or suprasellar cysts	Hypothyroidism (Van Wyk–Grumbach syndrome)
—Hydrocephalus	

Modified from Nathan BM, Palmert MR (2005). Regulation and disorders of pubertal timing. Endocrinol Metab Clin North Am 34:617-641, ix.

hormone [TSH] secretion and hypercortisolism due to constitutive activation of ACTH secretion), kidney phosphate wasting, cholestasis, and hypertrophic heart disease can be present.[148,150] For reasons that are not clear, MAS leads to sexual precocity more often in girls than in boys.

In 1960, Van Wyk and Grumbach first described a syndrome characterized by breast development, uterine bleeding, and multicystic ovaries in the presence of long-standing primary hypothyroidism.[151] A unique diagnostic feature of the Van Wyk–Grumbach syndrome is the combination of delayed bone age with apparent sexual precocity. Boys with this syndrome have macroorchidism without significant virilization. Testicular histology shows enlargement of the seminiferous tubules without an increase in Leydig cell number.[152,153] Typically, GnRH stimulation shows a prepubertal response with suppressed LH confirming gonadotropin-releasing hormone (GnRH)-independent precocious puberty. Most cases appear to originate from autoimmune thyroid disease, but there are some case reports where the syndrome is secondary to unrecognized congenital hypothyroidism.[154] The pathophysiology of Van Wyk–Grumbach syndrome involves a complex mechanism, which is, at least in part, mediated by the direct action of TSH on FSH receptors. Recombinant human TSH (Rec-hTSH) elicits a dose-dependent cAMP response in cells expressing the human FSH-receptor in vitro; however, the concentration of rec-hTSH required for half-maximal stimulation was several logs greater than that of hFSH.[152] Early recognition and initiation of thyroid hormone replacement can lead not only to resolution of symptoms and improvement in adult height but also to avoidance of further diagnostic procedures, fear of malignancy, and unnecessary surgery.

Another cause of GnRH-independent precocious puberty includes the virilizing forms of congenital adrenal hyperplasia (CAH). These are autosomal recessive disorders that present with premature pubic hair development, axillary hair development, accelerated linear growth, and phallic enlargement in the absence of testicular enlargement. The most common form is 21-hydroxylase deficiency due to loss-of-function mutations in *CYP21A2*. Mutations in 11β-hydroxylase (*CYP11B1*) and 3β-hydroxysteroid dehydrogenase type 2 (*HSD3B2*) account for 5% to 10% of cases. Long-term exposure to androgens in this condition can activate central precocious puberty even when the excessive androgen secretion from the adrenals is suppressed by appropriate cortisol and mineralocorticoid replacement.

Androgen secreting tumors are rare causes of GnRH-independent precocious puberty in boys. Leydig cell tumors secrete testosterone. Because these tumors are usually unilateral, testicular volume may be asymmetric. The majority of Leydig cell tumors are benign. Ultrasound may be useful because the tumor may be too small to palpate. Mutations in the *LHCGR* gene have been identified in some adenomas.[155] In boys, tumors secreting hCG stimulate testicular testosterone secretion. These tumors are generally hepatic in origin. Virilization is a common presentation for adrenal tumors in children.

The classification of precocious puberty is not always clear. As noted earlier, treatment of peripheral forms of sexual precocity, such as CAH or testicular or adrenal tumors, can lead to true central precocious puberty through subsequent activation of pulsatile GnRH secretion. In addition, in some cases of precocious pubertal development among girls, pubertal manifestations will regress or stop progressing, making treatment unnecessary; such cases are not as commonly seen in boys.[156,157] The mechanisms responsible for these nonprogressive forms of precocious puberty are not known. There is evidence that in some cases the HPG axis is intermittently but not fully activated.[157,158] Another form of early development of secondary sexual characteristics occurs when the hypothalamic-pituitary-adrenal (HPA) axis matures 1 to 2 years before the HPG axis, causing premature adrenarche. Premature adrenarche, more common among girls, is not associated with progressive pubertal development and is manifested by pubic and axillary hair with modest elevation of DHEA-S, but without substantial advancement in bone age and hence does not require treatment.

In cases of progressive central or peripheral precocity, the concerns include short adult stature due to early epiphyseal fusion and adverse psychosocial outcomes.[141,159] Several studies have assessed adult height in subjects with a history of precocious puberty. Mean heights range from 151 to 156 cm in boys and from 150 to 154 cm in girls in older patient series, which corresponds to a loss of more than 20 cm in boys and 12 cm in girls from predicted adult height.[160] Height loss due to precocious puberty is inversely correlated with the age at the onset of puberty, and treated patients today tend to have a later onset of puberty than did patients in historical series.[160] It is important to assess carefully the growth rate and skeletal maturation of individuals with central precocious puberty due to CNS lesions (e.g., tumors, cerebral malformations or injury from trauma or radiation) because these lesions may be associated with concomitant growth hormone (GH) deficiency, which can be masked by sex steroid–driven adequate growth rates. In such cases, undiagnosed and untreated GH deficiency may result in severely compromised adult height.

Although available data derive mostly from study of girls with early puberty, it has been suggested that a higher proportion of early-maturing adolescents engage in exploratory risky behaviors (sexual intercourse and legal and illegal substance use) at an earlier age than adolescents maturing within the normal age range or later.[161,162] However, available data regarding potential adverse psychosocial outcomes specific to patients with precocious puberty are limited, as it is not clear that data obtained from individuals with maturation at the early end of the normal spectrum are fully applicable to precocious puberty.

Pathologic entities leading to sexual precocity warrant treatment, but whether and at what ages one should initiate treatment for idiopathic central precocious puberty is less certain. Currently, robust data regarding the short-term and long-term psychosocial sequelae of CPP and data regarding whether treating CPP with gonadotropin releasing hormone analogues (GnRHa) alter these outcomes are lacking.[163] Thus, one needs to be cautious when using psychosocial outcomes as a rationale for

pharmacologic intervention to halt pubertal progression, especially among boys with the onset of puberty close to the normal range.

Evaluation of the Boy with Precocious Development of Secondary Sexual Characteristics

Boys with sexual precocity require careful evaluation because many have underlying disorders.[141] Those with premature pubarche (early development of pubic hair or body odor) need to be assessed for peripheral causes of precocity before determining that the premature pubarche stems simply from premature adrenarche. Premature adrenarche may be distinguished from true precocity over time by lack of progression. Conversely, progressive precocity is marked by significant bone age advancement (> 2 SD for age), a history of growth acceleration, and a progression of secondary sexual characteristics on physical examination.

The evaluation of a boy with sexual precocity is outlined in Box 17-1. Considerations include first verifying that the pubertal development is occurring outside the range of normal development prior to initiating an evaluation. It is also important to note that all tests are not appropriate in each case and that the diagnostic yield of each test is not known. Hence, it is important to allow history and physical examination to guide the evaluation. The child with bilateral enlarged testicles, for example, is most likely to have central precocious puberty, with FSH having led to the expansion of seminiferous tubule volume (although cases of hypothyroidism can also present with bilateral testicular enlargement). Conversely, the child with bilateral prepubertal sized testicles is more likely to have peripheral precocity, whereas the child with unilateral testicular enlargement may well have a testicular tumor. Testing should be directed accordingly.

BOX 17-1 Outline of the Evaluation of Sexual Precocity in Boys

Common Initial Screening Tests

- Careful history, physical exam, and assessment of growth velocity
- Bone age
- LH, FSH
- Testosterone (and in some cases estradiol)
- DHEA-S
- 17-hydroxyprogesterone
- TSH, T4

Secondary Tests to Consider

- Testicular or abdominal ultrasound
- MRI of pituitary and brain
- GnRH agonist stimulation test
- ACTH stimulation test

Modified from Nathan, B. M., & Palmert, M. R. (2005). Regulation and disorders of pubertal timing. Endocrinol Metab Clin North Am, 34, *617–641, ix.*

Peripheral causes of sexual precocity are characterized by suppressed LH and FSH values in the setting of elevated sex steroid levels. Testosterone levels will be elevated in instances of isosexual precocity (secondary sexual characteristics consistent with male gender), whereas estradiol levels may be elevated in the rare instances of contrasexual precocity (secondary sexual characteristics inconsistent with gender, such as marked breast development as the presenting sign in a boy). Determining the underlying mechanism for progressive peripheral precocity is important because all instances will result from pathologic conditions or exogenous exposures.[164] Levels of androgens that are elevated beyond the range expected for the pubertal stage suggest an adrenal or testicular cause of the precocity. DHEA-S is often used as a screen for adrenal tumors or adrenal pathology. Determination of the 17-hydroxyprogesterone concentration is used to screen for congenital adrenal hyperplasia due to 21-OH deficiency. Congenital adrenal hyperplasia and hormone secreting tumors of the adrenal are discussed in detail in Chapter 13.

Historically, the gold standard for the diagnosis of central precocious puberty was GnRH stimulation testing and the demonstration of pubertal gonadotropin responses. However, with the advent of ultrasensitive gonadotropin assays,[165] the recognition that these assays can identify individuals with CPP using unstimulated random samples,[166] and the unavailability of GnRH for testing has led some to forego stimulation testing. GnRH agonists can be used as an alternative to GnRH for stimulation testing, but again the diagnosis can often be made through the combination of clinical features and a baseline LH value in the pubertal range. Although determining the diagnostic cutoff for the basal LH level is difficult because of a lack of normative data and variability among assays, a value of ≥ 0.3 IU/L using an ultrasensitive assay with a detection limit near 0.1 IU/L is commonly cited.[163] If stimulation testing is done, a diagnostic cutoff of 5 IU/L for peak value has been suggested. LH values are more useful than FSH values in the diagnostic evaluation of precocious puberty, but stimulated LH/FSH values can help to identify patients with slowly progressive precocious puberty because these children tend to have FSH predominant responses.[157,167] Whether due to referral bias or to differences in underlying physiology, idiopathic central precocious puberty is a more common cause of precocious puberty among girls than among boys in endocrinology clinics.[168,169] Hence, all boys with CPP should have brain magnetic resonance imaging (MRI) to exclude underlying pathology.[163]

In summary, it is important for physicians evaluating patients with suspected precocious puberty to address these questions: Is pubertal development occurring outside the normal range of development? What is the underlying mechanism, and is that mechanism associated with a risk of a serious condition, such as an intracranial lesion? Is the pubertal development likely to progress, and may this impair the child's normal physical and psychosocial development?

Treatment of the Child with Precocious Puberty

Unless underlying pathology that requires intervention is present, whether the precocious pubertal development is likely to impair the boy's normal physical or psychosocial development is often the feature that determines if treatment is needed.

Central Precocious Puberty

A prerequisite for the consideration of therapy for CPP is the presence of documented, progressive pubertal development over a 3- to 6-month period, although this period of observation may not be necessary if the child is at or beyond Tanner stage 3 genital development. Documentation of progressive development is important because nonprogressive forms of precocious puberty do not require intervention.[163] Because epiphyseal fusion is an estrogen-dependent process, early and progressive production of sex steroids can cause rapid advancement of skeletal maturation and result in compromised adult height. Thus, preservation of adult stature is one of the main reasons to consider treatment of CPP with GnRH agonists, which down-regulate the pituitary-gonadal axis and limit pubertal progression. Although the data derive primarily from studies among girls, it appears that the risk of short stature is most pronounced in those children with earlier onset of symptoms and more shortened prepubertal growth periods.[170] Other factors, such as advanced bone age, may also contribute to poorer height outcomes.[170] In girls, available data suggest that the greatest height gain (preservation) occurs with onset of puberty prior to 6 years of age, with more moderate benefit being seen with onset between 6 and 8 years.[163] However, insufficient data exist to draw similar conclusions regarding age of onset and height outcomes among boys[171,172]; consequently, a consensus conference recommended considering initiation of GnRHa therapy for all boys with onset of CPP before age 9 years who have compromised height potential.[163]

The second main reason to consider therapy in CPP is to mitigate potential psychosocial effects of precocious puberty. However, as noted earlier, additional studies are needed to determine the effects of precocious puberty on quality of life and psychosocial functioning and to evaluate whether treatment with GnRHa therapies affects these outcomes. Thus, the consensus conference concluded that the use of GnRHa therapies solely to influence psychosocial consequences of precocious puberty needs to be considered carefully given the absence of convincing data.[163] These cautions are even more pertinent for boys because data regarding males are even more scarce.

Various formulations (intramuscular, subcutaneous, and intranasal) of short (daily) and long-acting GnRH agonists are available. The depot formulations are preferred, as they are easier for patients and families to administer regularly over a long treatment period. The initial depot medications were 1-month formulations, which have been shown to be well tolerated and effective.[173,174] Subsequently, 3-month depot formulations were developed,[163,175,176] and a 1-year depot formulation (histrelin-acetate) has also become available.[177-179] Which GnRHa to use depends on patient and provider preference, local regulatory approvals, and reimbursement systems.[163]

GnRH agonists are generally well tolerated. Occasionally, an initial, temporary flare of GnRH activity can occur and result in transient advancement of secondary sexual characteristics. Local reactions to the injection can occur in 10% to 15% of patients. If these reactions are persistent, a change in agent should be considered to try to prevent the development of sterile abscesses. Other considerations include long-term effects of GnRH agonists on bone mineral density and reproductive function. These outcomes have largely been studied among girls, but the available data are reassuring.[163] Whether GnRHa use is associated with increased obesity is less clear, and data among boys with CPP are sparse. However, in girls most studies are reassuring and indicate that this concern is not great enough to argue against use of GnRHa in cases of true central precocious puberty, especially because risk factors for obesity may be associated with CPP itself and not necessarily the use of GnRHa.[163]

Monitoring of GnRH agonist therapy should consist of assessment of Tanner stage and growth velocity every 3 to 6 months, with periodic assessment of skeletal maturation. Progression of pubertal development or of rapid skeletal maturation indicates a lack of efficacy, poor adherence, or a misdiagnosis. Such patients warrant reevaluation, including measurement of baseline or stimulated LH levels; conversely, the routine measurement of gonadotropins to monitor suppression during GnRHa treatment is controversial.[142,163] The optimal time to discontinue GnRH agonist therapy is unclear and difficult to determine because of variability in chronologic age, bone age, and degree and duration of secondary sexual characteristics prior to initiation of therapy. Data among boys are limited, but examination of clinical characteristics at the discontinuation of therapy—such as treatment duration, height, growth velocity, bone age, and chronologic age—has failed to identify clear predictors of adult height among girls. Thus, it seems reasonable to time discontinuation based on patient and family preference, often with the intent of having pubertal development resume in parallel with the patient's peers.[163]

Peripheral Precocity

In the past, treatment of GnRH independent causes of sexual precocity such as McCune Albright syndrome or familial male limited precocious puberty included using inhibitors of steroidogenesis (ketoconazole), weak antiandrogen agents (spironolactone), and, subsequently, first-generation aromatase inhibitors (AIs) (testolactone).[180-184] Although these therapies are to some extent effective in slowing growth velocity and reducing virilization,[185-188] the risk of hepatotoxicity and adrenal insufficiency with ketoconazole as well as the requirement of multiple daily dosing are obstacles to achieving a favorable therapeutic outcome.[189] Short-term combination therapy with a potent antiandrogen agent, bicalutamide, and third-generation AIs, anastrozole and letrozole, has also

suggested efficacy in reducing growth rate and virilization and improving predicted adult height.[190-193] This combination therapy provides a more convenient once-daily dosing regimen, although the therapy is more expensive than previous treatments. However, further controlled clinical trials using modern antiandrogens in combination with aromatase inhibitors are needed, including the evaluation of the long-term effects of such therapy on adult height, fertility, metabolic parameters, cognitive functions,[194] and bone health.[195] Until long-term data are available from a larger sample of patients, this combination therapy should be used judiciously and cautiously.

DELAYED PUBERTY

The etiologies, evaluation, and treatment of delayed puberty have been reviewed by the authors.[196] Delayed puberty is defined as the absence of testicular enlargement 2 to 2.5 standard deviations later than the population mean (traditionally age 14 years in boys). As noted previously, because of the downward trend in pubertal timing in some but not all reports from the United States[114,197,198] and other countries,[121,199] some advocate for younger age cutoffs for the general population or perhaps for particular countries or ethnic groups. However, the secular change in the onset of puberty has not been seen in the late developing boys,[121] and hence the need to readjust age definitions for delayed puberty in males may not be necessary. Unlike for sexual precocity, development of pubic hair is usually not considered in the definition of delayed puberty because pubarche may result from maturation of the adrenal glands (adrenarche) and the onset of pubic hair can be independent of HPG axis activation.

Delayed puberty is often quite concerning to patients and families. It can affect psychosocial well-being and peer relationships, and these issues are common reasons for initiating therapy. However, as with precocious puberty, further studies are needed to assess fully the psychosocial distress experienced by individuals with delayed puberty, whether this distress has long-term sequelae, and what impact sex steroid supplementation has on these outcomes.[196] Patients, families, and practitioners are also often worried that delayed puberty may affect adult stature, and many patients present with relative familial short stature along with delayed puberty, which accentuates concerns about adult stature. Adult height can indeed be affected by delayed puberty, but on average it is only slightly below the genetic target.[200] It remains unclear whether adult bone mass is adversely affected by pubertal delay[201] and whether concerns related to bone health represent a medical reason to initiate therapy.

Etiologies of Delayed Puberty

The most common cause of delayed puberty in boys is constitutional delay of growth and puberty (CDGP), which refers to an extreme of the normal spectrum of pubertal timing. In one large series, approximately 65% of boys and 30% of girls with delayed puberty had CDGP[202] (Figure 17-3). However, because the data derive from a tertiary referral center, these percentages likely underestimate of the frequency of CDGP encountered by primary care providers.

Although CDGP represents the single most common cause of delayed puberty in boys, it is a diagnosis of exclusion, and potential pathologic causes of delay must be excluded. Other causes of delayed puberty can be divided into three main categories[196,202] (Figure 17-3 and Table 17-2): permanent hypogonadotropic hypogonadism, which represents approximately 10% of cases among boys and is characterized by low LH and FSH levels due to hypothalamic or pituitary disorders; transient hypogonadotropic hypogonadism or functional hypogonadotropic hypogonadism, which represents approximately 20% of cases and where pubertal delay is due to delayed maturation of the HPG axis secondary to underlying conditions; and hypergonadotropic hypogonadism, which represents approximately 5% to 10% of cases and is characterized by elevated LH and FSH levels due to lack of negative feedback from the gonads.

CDGP

The etiology of CDGP is unknown. Suggested causes include increased total energy expenditure[203] and increased insulin sensitivity,[204] but no definitive etiology has been identified. CDGP does have a strong genetic basis. Fifty percent to 80% of variation of the timing of puberty in humans is due to genetic factors,[101] and 50% to 75% of individuals with CDGP have a family history of delayed puberty.[205,206] The inheritance patterns observed among pedigrees with CDGP are variable but most often consistent with an autosomal dominant pattern, with or without complete penetrance. Inheritance

TABLE 17-2 **Causes of Delayed Puberty Other Than Constitutional Delay of Growth and Puberty**

Hypergonadotropic Hypogonadism	Permanent Hypogonadotropic Hypogonadism	Functional Hypogonadotropic Hypogonadism
Genetic syndromes	CNS tumors/infiltrative diseases	Systemic illness/conditions
—Noonan syndrome and related disorders	—Astrocytoma	—Cystic fibrosis
Cryptorchidism	—Germinoma	—Asthma
Gonadal dysgenesis	—Glioma	—Inflammatory bowel disease
Vanishing testes syndrome	—Craniopharyngioma	—Celiac disease
Trauma/testicular torsion	—Prolactinoma	—Juvenile rheumatoid arthritis
Chemotherapy/radiation therapy	—Langerhans cell histiocytosis	—Anorexia nervosa/bulimia
Gonadal infection	Rathke's pouch cyst	—Sickle cell disease
—Mumps, Coxsackie	Genetic defects*	—Hemosiderosis
Autoimmune orchitis	—Kallmann syndrome *(KAL1, FGFR1, PROK2, PROKR2, FGF8, HS6ST1,* and *CHD7)*	—Thalassemia
Defects in steroidogenesis	—Isolated hypogonadotropic hypogonadism *(KAL1, GNRHR, GNRH1, GPR54, FGFR1, FGF8, PROK2, PROKR2, TAC3, TACR3. HS6ST1, NELF,* and *CHD7)*	—Chronic renal disease
—5-alpha reductase deficiency (SR5A2)	—HPG axis development *(DAX1, SF-1, HESX-1, LHX3,* and *PROP-1)*	—AIDS
—17, 20 lyase deficiency (CYP17A1)	—Obesity and hypogonadotropic hypogonadism (*LEP, LEPR,* and *PC1*) syndromes	Endocrinopathies
—Congenital lipoid adrenal hyperplasia (StAR)	—Prader-Willi	—Diabetes mellitus
—17-hydroxysteroid dehydrogenase deficiency (HSD17B3)	—Bardet-Biedl	—Hypothyroidism
Androgen insensitivity	—CHARGE	—Hyperprolactinemia
Sertoli cell only syndrome (Del Castillo syndrome)	Gaucher disease	—Growth hormone deficiency
	Postcentral nervous system infection	—Cushing syndrome
	Midline defects	Excessive exercise
	—Septo-optic dysplasia	Malnutrition
	—Congenital hypopituitarism	
	Chemotherapy/radiation therapy	
	Trauma	

*Some genes have been identified as causes of both Kallmann syndrome and isolated hypogonadotropic hypogonadism (IHH).
Table reproduced from Palmert, M. R., & Dunkel, L. (2012). Clinical practice. Delayed puberty. N Engl J Med, 366, *443–453 with permission.*

of CDGP is not sex-specific and is characterized by family members having either relatively delayed development (e.g., the average age at menarche among mothers of individuals with CDGP is 14.3 years compared to a mean of 12.7 among controls[19]) or evidence of pubertal timing that would have met clinical criteria for delayed puberty. Review of growth records often shows that linear growth during the first few years of life decelerates followed by growth velocity tracking along the lower percentiles during childhood. Skeletal maturation is usually delayed.

As previously discussed, the investigation of Kallmann syndrome (KS) and isolated hypogonadotropic hypogonadism (IHH) has led to the identification of genes that play critical roles in development and regulation of the HPG axis, but mutations in the genes identified to date do not cause CDGP, except in rare instances[81,102]; however, the genes causing 60% to 70% of cases of KS and IHH remain unknown.[62] Loci have also been identified that are associated with the age of menarche in the general population,[103-107] but these particular loci have likewise not yet been associated with CDGP.[207] Further studies are needed to identify the genes that cause CDGP, and it is likely that identification of these genes will also elucidate factors that regulate the timing of puberty in the general population.

Hypogonadotropic Hypogonadism

GnRH deficiency can be caused by mutations in many genes and is more common in boys than girls, affecting one in 7500 males and only one in 70,000 females.[208] Inheritance patterns include X-linked, autosomal dominant, and autosomal recessive. However, sporadic cases are more common than familial forms. Hypogonadotropic hypogonadism (HH) has been subclassified into three major categories: (1) Kallmann syndrome with anosmia, (2) HH without anosmia, and (3) acquired HH. However, with recognition of phenotypic heterogeneity within families, these classifications may need to be modified.

The classic form of Kallmann syndrome is characterized by isolated gonadotropin deficiency, anosmia, and X-linked inheritance. This disorder is due to mutations in anosmin 1 encoded by the *KAL1* gene resulting in failure of GnRH neurons to migrate to the hypothalamus. MR imaging can confirm the diminished presence or absence of the olfactory bulbs. Nonreproductive features include unilateral renal agenesis, sensorineural hearing loss, synkinesia, cerebellar ataxia, and cleft palate. *KAL1* mutations are also associated with a relatively high incidence of cryptorchidism, microphallus, and decreased inhibin B concentrations.

As noted earlier, the list of genes associated with HH is expanding. Nonreproductive clinical features of patients with *PROK2* and *PROK2R* mutations include fibrous dysplasia, obesity, synkinesia, and epilepsy.[90] To date, numerous mutations have been identified in the *FGFR1* gene; associated features can include skeletal anomalies and synkinesis. Mutations in *FGF8*, the ligand for FGFR1, have also been associated with holoprosencephaly, septo-optic dysplasia, and moebius syndrome.[209] Both normosmia and anosmia have been reported for these four genes.

Loss-of-function mutations in *HS6ST1*, *SEMA3A*, *WDR11*, and *NELF* have been identified in patients with HH.[89,210-212] In families carrying mutations in these genes, phenotypic heterogeneity for anosmia occurs and HH segregates as a complex trait found in association with mutations in other genes. Thus, it remains to be determined whether mutations in these genes are sufficient to lead to GnRH deficiency. Mutations in genes encoding proteins such as *FGF17* and *IL17RD* that modulate the signaling efficiency of FGF8 through FGFR1 have been identified, suggesting the existence of a FGF8 synexpression group that may form an oligogenic basis for HH.[3]

Mutations in genes encoding neurokinin B and its receptors, *TAC3* and *TACR3*, have been identified in HH patients.[27] As noted previously, these genes are highly expressed in the same neurons that express kisspeptin, emphasizing the role of kisspeptin in the regulation of pubertal timing. Mutations in *GNRH1*, *KISS1*, *KISS1R*, *TAC*, and *TACR3* affect GnRH secretion. Curiously, patients have been reported to have reversible HH despite carrying loss-of-function mutations in *FGFR1*, *CHD7*, *TAC3*, or *TACR3* genes. The biologic mechanism for this reversible gonadotropin deficiency remains unclear.[213,214]

Pituitary-Dependent Hypogonadism

Mutations in the GnRH receptor (*GNRHR*) gene have been reported. The phenotype ranges from neonatal presentation with microphallus and cryptorchidism to adolescent presentation for evaluation of delayed puberty.[215] Mutations in the FSH-beta and LH-beta have also been described. Developmental anomalies of pituitary development such as midline defects or septo-optic dysplasia can be associated with gonadotropin and other pituitary hormone deficiencies. Genes associated with developmental anomalies of the pituitary include *HESX1*, *SOX2*, *PITX2*, *LHX3*, and *PROP1* as well as some of the genes known to cause HH such as *FGFR1*, *FGF8*, and *PROKR2*. Nongenetic factors such as maternal cocaine abuse, valproate toxicity, and intrauterine vascular disruptive events may also cause CNS developmental anomalies.

Hypothalamic and Pituitary-Dependent Hypogonadism

Some disorders affect both the hypothalamus and pituitary. Congenital adrenal hypoplasia due to mutations in the DAX1/NROB1 gene is an X-linked disorder characterized by primary adrenal insufficiency and hypogonadotropic hypogonadism. In this disorder, the fetal adrenal cortex develops normally, but the adult zone of the adrenal cortex fails to develop. Affected males may present with adrenal insufficiency at 6 to 8 weeks of age. However, some may present in adolescence with delayed puberty. Decreased hypothalamic GnRH secretion or decreased pituitary responsiveness can occur leading to decreased LH, FSH, and testosterone concentrations. Mutations in this gene may be part of a contiguous gene deletion syndrome with Duchenne muscular dystrophy and glycerol kinase deficiency.[216]

Intracranial tumors can lead to delayed puberty. The most common neoplasm is a craniopharyngioma, which is thought to arise from remnants of Rathke's pouch. Other symptoms can include decreased growth velocity, headache, polyuria, and visual disturbances. Suprasellar or intracellular calcifications may be detected on CT scans. Other tumors include germ cell tumors, epidermoid and dermoid cysts, prolactinomas, and optic gliomas. Histiocytosis X is characterized by infiltration of lipid-laden histiocytes into skin, bone, or visceral organs. Although diabetes insipidus is the most common endocrine manifestation of histiocytosis X, other anterior pituitary hormone deficiencies may occur.

Hyperprolactinemia can lead to hypogonadism. Prolactin can directly suppress pulsatile GnRH secretion. Hyperprolactinemia can be due to microadenomas (adenomas < 10 mm) or macroadenomas (> 10 mm). MRI provides greater anatomic detail that CT scans. Patients with primary hypothyroidism or taking psychotropic medications may have hyperprolactinemia.

Several syndromes are associated with delayed puberty. These syndromes include Prader-Willi, Bardet-Biedl, Alström, and Bloom syndromes. Hereditary hematochromatosis leads to iron overload and iron deposition in endocrine organs leading to HH, impaired glucose tolerance, and diabetes mellitus.

Functional Hypogonadotropic Hypogonadism

Transient causes of hypogonadotropic hypogonadism or functional hypogonadotropic hypogonadism where pubertal delay is due to delayed maturation of the HPG axis secondary to underlying conditions may represent 20% of the etiology of delayed puberty (see Table 17-2). Examples of these conditions include anorexia nervosa, which is a chronic disorder characterized by decreased caloric intake, weight loss, and excessive physical activity. Although considered to be a disorder affecting females, approximately 10% of patients are male. Osteopenia and osteoporosis are potential consequences. In addition to low gonadotropin concentrations, cortisol, GH, and reverse T3 concentrations may be elevated. Chronic disorders such as sickle cell anemia, thalassemia, cystic fibrosis, and chronic renal disease may also be associated with delayed puberty. Intensive physical activity and the need to "make weight" in wrestlers may disrupt pubertal development. For wrestlers, these changes generally reverse within months of the end of the wrestling season.

Hypergonadotropic Hypogonadism

Primary gonadal failure leads to loss of negative feedback inhibition and hypergonadotropic hypogonadism. Although they represent only 5% to 10% of the causes of delayed puberty, etiologies within this category are broad and include sex chromosome anomalies, aberrant gonadal differentiation, gonadal injury, disorders of steroidogenesis, and disorders affecting steroid hormone action. Some disorders such as gonadal dysgenesis, Klinefelter syndrome, and Noonan syndrome affect both Leydig and Sertoli cell function (Figure 17-4). Disorders affecting steroidogenesis predominantly affect Leydig cell function.[11]

Klinefelter Syndrome

Klinefelter syndrome, which is associated with 47,XXY karyotype, is not a cause of delayed puberty per se but can be a cause of a prolonged or stalled pubertal course. The incidence is reported to be 1 in 667 when ascertained by prenatal cytogenetic analysis, but it is much lower when identified solely by clinical features. Thus, incomplete ascertainment of affected individuals likely occurs.[217] Parental origin of the extra X chromosome is approximately equal. In addition to the relative testosterone deficiency, it has been suggested that the extra copy of the short stature homeobox-containing (*SHOX*) gene in the pseudoautosomal region of the X chromosome contributes to the tall stature.[218]

The typical clinical features are small firm testes, tall stature, small penis, and gynecomastia. Both androgen secretion and spermatogenesis are impaired. Inhibin B concentrations are relatively normal during childhood but decline during puberty consistent with the progressive testicular failure. AMH levels follow the normal male pattern but progressively decline from mid-adolescence due to Sertoli cell dysfunction.

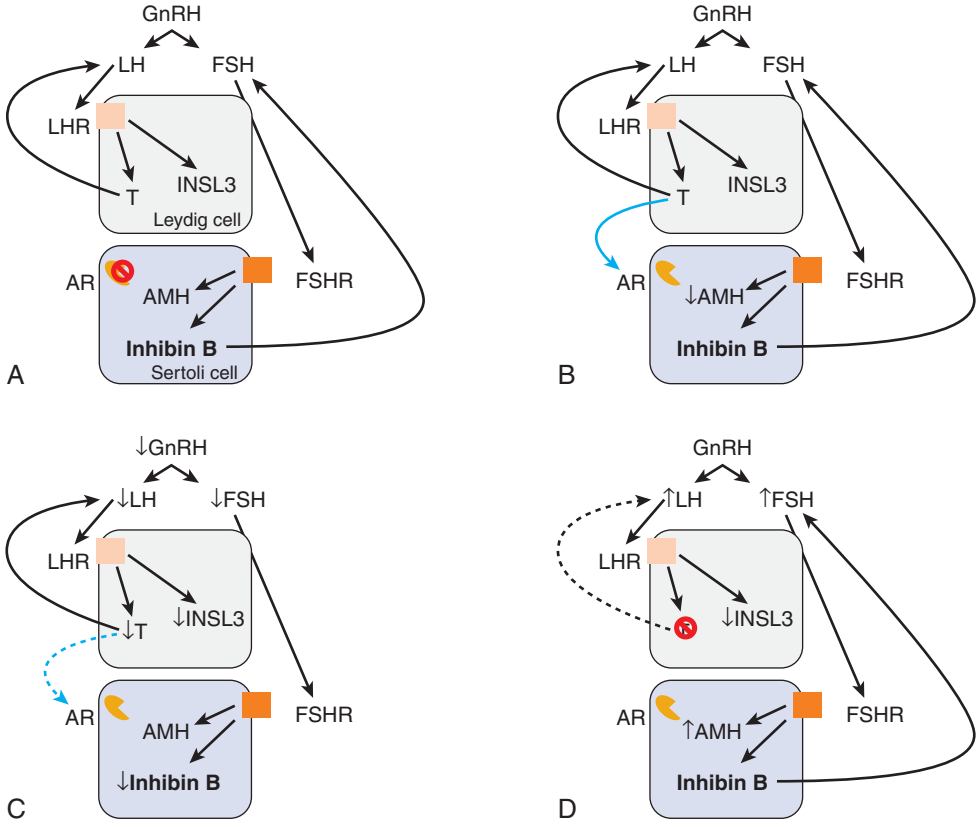

FIGURE 17-4 ■ Testicular compartments and hormone production. In the usual situation, hypothalamic GnRH secretion regulates pituitary LH and FSH secretion. LH acts on the LH receptor expressed on Leydig cells. The Leydig cell secretion of testosterone and INSL3 is influenced by LH secretion. FSH acts on the FSH receptor expressed on Sertoli cells and influences AMH and inhibin B secretion. **A**, Dynamics of HPG axis during gestation, infancy, and pubertal patients with CAIS. LH stimulates testosterone synthesis and FSH promotes AMH secretion. However, Sertoli cells do not express AR during fetal life and infancy. In patients with CAIS, AR is dysfunctional. The lack of Sertoli cell AR expression leads to high AMH production. Inhibin B levels reflect Sertoli cell function even when germ cells are absent. **B,** Dynamics of HPG axis at puberty. Upon reactivation of the GnRH pulse generator, increased LH secretion leads to increased testosterone secretion generating increased intra-testicular testosterone concentrations. INSL3 secretion also increases. Through its paracrine activity, testosterone promotes increased AR expression by Sertoli cells, which leads to decreased AMH secretion. FSH stimulates inhibin B secretion; inhibin B regulates FSH secretion. **C,** Dynamics of HPG axis in patients with hypogonadotropic hypogonadism. The lack of GnRH, LH, and FSH secretion results in testosterone deficiency. INSL3 and inhibin B secretion do not increase. During childhood AMH concentrations may have been lower than normal due to chronic lack of FSH stimulation, Due to the lack of testosterone's inhibitory effect on AMH production, AMH concentrations may be higher than normal during the adolescent years. **D,** Dynamics of HPG axis in patients with LHR mutations and defects in steroidogenesis. At puberty, in the absence of adequate testosterone production, AMH concentrations remain high.

The decreased testicular volume is secondary to degeneration of the seminiferous tubules. Boys with mosaic karyotypes with one normal 46,XY cell line tend to have a milder phenotype. The magnitude of testosterone deficiency and testicular failure varies among affected men. Treatment goals include development of secondary sexual characteristics, increased muscle mass, optimal bone density, and sexual function.

Academic and emotional difficulties are common. Some boys are detected through their learning disabilities. The cognitive phenotype is characterized by deficits in language and executive function. The executive dysfunction is characterized by poor decision making, problem solving, reasoning, and planning issues. Difficulties with self-control, increased distractibility, and reduced fine and gross motor skills are common.[219] Nonreproductive features can include an increased incidence of type 2 diabetes, breast cancer, mediastinal tumors, and vascular disease.[220]

Apart from decreased number of germ cells, testicular architecture is relatively normal in fetal and prepubertal testes. Loss of germ cells beginning in utero culminating in fibrosis and hyalinization of the seminiferous tubules is the proximate cause of the infertility associated with Klinefelter syndrome.[221] Fertility preservation is a relevant topic for the older adolescent boy. Some men with Klinefelter's have oligospermia and are able to father children without medical intervention. For others, paternity has been achieved with testicular sperm extraction combined with intracytoplasmic sperm injection (TESE-ICSI).[222]

XX Males

The frequency of XX males is approximately 1 in 25,000 males. These individuals may come to medical attention for evaluation of delayed puberty, infertility, gynecomastia, or a disorder of sexual development. XX males can be classified as *SRY*-positive or *SRY*-negative. In approximately 80% of XX males, the *SRY* gene can be detected by genetic analysis. In most instances, the *SRY* gene has been translocated to an X chromosome, but translocation to an autosome can occur. The typical phenotype for SRY-positive 46,XX males includes normal male external genital development, small testes, azoospermia, hypergonadotropic hypogonadism, and infertility.

Molecular etiologies are more variable for the SRY-negative 46,XX male. Duplication of *SOX9* was reported in one family.[223] Partial duplication of chromosome 22q13 leading to overexpression of *SOX10* was found in one 46,XX sex reversed patient in association with multiple congenital anomalies.[224] Another genetic etiology of 46,XX sex reversal are mutations in the R-spondin 1 (*RSPO1*) gene. This gene codes for a secreted furin-like domain protein that stabilizes β-catenin in the wingless-type mouse mammary tumor virus integration site-4 (WNT-4) signaling pathway. Patients with *RSPO1* mutations may also have palmoplantar hyperkeratosis with squamous cell carcinoma of skin.[225]

In rare instances, ovotesticular disorder with predominantly male phenotype can occur. This disorder can be diagnosed only with the presence of ovarian tissue containing follicles and testicular tissue containing seminiferous tubules present in the same individual, and often in the same gonad (ovotestis). Most patients with ovotesticular disorder have a 46,XX karyotype.

Gonadal Dysgenesis

This classification encompasses disorders characterized by atypical testicular determination and differentiation, and individuals can present with a disorder of sexual development, sex reversal, or delayed puberty. Approximately 15% of 46,XY patients with gonadal dysgenesis carry mutations in the *SRY* gene. The histologic appearance of the testes can include immature tubules with poorly differentiated Sertoli cells, poorly differentiated Leydig cells, and Sertoli cell only pattern. In some instances, gonadal differentiation appears to be a continuum with more or less differentiation along male or female direction. Carcinoma in situ may be identified. The clinical features are variable and related to the specific disorder and hormone status.

Pure gonadal dysgenesis, also known as Swyer syndrome, is characterized by complete male-to-female sex reversal. At birth, the external genitalia are normal female. Typically, a uterus and fallopian tubes are present, but Wolffian elements are usually absent. Affected individuals present with delayed puberty characterized by absent breast development and hypergonadotropic hypogonadism. Gonadal histology shows "streak" gonads and may show some evidence of testicular development. However, the testicular elements are aberrant. Due to the high risk for gonadal tumors, the gonads are best surgically removed.

Sex chromosome mosaicism is associated with gonadal dysgenesis. The clinical spectrum of internal and external genital development is highly variable. The correlation between the phenotypic appearance, the results of routine peripheral blood karyotyping, and gonadal histology is poor.[226]

The phenotypic spectrum for 45,X/46,XY mosaicism is broad, ranging from female with features of Turner syndrome to normal male appearance, and many live undiagnosed as normal males. However, ambiguous genitalia in a newborn but also mild undervirilization (e.g., hypospadias) in boys or even typical Turner syndrome in girls may be associated with 45,X/46,XY mosaicism.

Syndromes Associated with Delayed Puberty

Noonan syndrome is an autosomal dominant disorder characterized by short stature, ptosis, hypertelorism, mild intellectual disability, and congenital heart disease. Cryptorchidism is common in males. Approximately 50% of cases are due to mutations in the protein-tyrosine phosphatase, nonreceptor type 11 protein (*PTPN11*) gene (also known as *SHP2*). Other genes associated with Noonan syndrome include *KRAS*, *SOS1*, *NRAS*, and *RAF1*. The proteins encoded by these genes are members of the RAS-MAPK signaling pathway.

In one longitudinal study, LH, FSH, testosterone, AMH, and inhibin B concentrations were comparable to healthy boys prior to the onset of puberty. However,

some individuals with Noonan syndrome have delayed puberty, and the adult men with Noonan syndrome had higher LH, FSH, and testosterone concentrations and lower AMH and inhibin B concentrations compared to healthy controls.[227] Because these differences were observed in the total group of men with Noonan syndrome as well as the group with history of cryptorchidism, both Sertoli cells and Leydig cells show impaired function (see Figure 17-4).

Prader-Willi syndrome can also be associated with delayed puberty. Cryptorchidism is common in boys with Prader-Willi syndrome. Inhibin B concentrations are generally normal in infants and prepubertal boys. As puberty progresses, inhibin B concentrations decline and FSH concentrations increase. Testicular histology is variable and is reported to range from normal to complete absence of spermatogonia (Sertoli cell only syndrome).[228] Longitudinal data indicate that the hypogonadism among boys with Prader-Willi syndrome is likely due to primary testicular dysfunction involving both Sertoli and Leydig cell compartments. However, inadequate HPG axis function may also contribute to the hypogonadism.[229]

Defects in Steroidogenesis or Steroid Hormone Action

Although often not among the cardinal manifestations of defects in steroid hormone synthesis or steroid hormone action, delayed puberty can be associated with a broad range of these disorders. Complete loss-of-function mutations may present in the newborn period as a disorder of sexual development or apparent normal female external genital development with labial masses (testes). Importantly, milder variants can be associated with male sex development and delayed or incomplete puberty development.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal disorder due to mutations in the 7-dehydrocholesterol (*DHCR7*) gene. Clinical features include undervirilization, congenital heart disease, renal anomalies, failure to thrive, and developmental delay. Syndactyly of the second and third toes and proximally placed thumbs are characteristic features of this defect in cholesterol biosynthesis. The diagnosis can be confirmed by finding elevated 7-dehydrocholesterol concentrations.

Steroidogenic factor-1 (*NR5A1)* plays a major role in steroidogenesis, male sexual differentiation, and the development of the hypothalamus, pituitary, adrenal glands, and testes. Two patients were reported to have 46,XY karyotype, female external genitalia, presence of Mullerian structures, and adrenal insufficiency.[230] Haploinsufficiency of *NR5A1* can also manifest as a predominantly gonadal phenotype characterized by hypergonadotropic hypogonadism with normal adrenal function. Penoscrotal hypospadias, bilateral anorchia, and testicular regression syndrome have been described. The phenotypic spectrum extends to 46,XY girls who present with delayed puberty, primary amenorrhea, and low testosterone concentrations in the absence of adrenal insufficiency. Haploinsufficiency of *NR5A1* can also present with delayed puberty or premature ovarian failure in 46,XX individuals. The inheritance pattern is variable, including both autosomal recessive and sex-linked dominant as well as de novo cases. The SF-1 protein contains two zinc finger structures and appears to bind to DNA as a monomer.[230]

Inactivating LH receptor (*LHCGR*) mutations are associated with Leydig cell hypoplasia, testosterone deficiency, undervirilization, and delayed puberty. The phenotype for this autosomal recessive disorder ranges from female external genitalia presenting with absence of puberty to normal male development with hypospadias and microphallus. Mullerian structures are absent because Sertoli cell function and AMH secretion are normal. In the severe forms, microscopic and ultrastructural findings show seminiferous tubules, normal Sertoli cells, and decreased germ cells. Poorly differentiated cells appear in the interstitial spaces; Leydig cells are rare. Mullerian duct derivatives are absent. As would be anticipated, LH concentrations are elevated and testosterone concentrations are low.[231]

Mutations in the steroidogenic acute regulatory protein (*StAR*) gene are associated with congenital lipoid adrenal hyperplasia. In this disorder, loss-of-function *StAR* mutations lead to failed steroidogenesis and accumulation of cholesterol esters in the cytoplasm of steroidogenically active cells. The accumulated lipid droplets cause physical engorgement and chemical damage from the accumulated cholesterol auto-oxidation products. This lipid accumulation damages the fetal Leydig cells but does not affect AMH secretion by the fetal Sertoli cells such that Mullerian duct derivatives are absent. This autosomal recessive disorder is often identified in the neonatal period due to the associated undervirilization and adrenal insufficiency. Milder phenotypes with normal male sex development and non-autoimmune adrenal insufficiency have been described; the magnitude of overt mineralocorticoid deficiency varies.[232] Ethnic groups in which higher incidence of *StAR* mutations occur include Japanese, Korean, and Palestinian Arabs.

Patients with loss-of-function cholesterol side chain cleavage (*CYP11A1*) mutations have been recognized. The phenotype ranges from prematurity associated with undervirilization and early-onset adrenal failure to presentation with adrenal insufficiency in children with normal sexual development.[233] Typically, the normal sized adrenal glands differentiate this genetic disorder from congenital lipoid adrenal hyperplasia. However, *StAR* mutations were detected in sibs with neonatal adrenal insufficiency and normal sized adrenal glands.[234]

Loss-of-function mutations in the 17α-hydroxylase/17, 20-lyase (*CYP17A1*) gene are associated with glucocorticoid and sex steroid deficiencies. Patients may be hypertensive and have hypokalemia because mineralocorticoid biosynthesis is unaffected. Affected males manifest complete or partial male-to-female sex reversal and may seek medical attention for delayed puberty.[235] Characteristic laboratory findings include low or absent 17-hydroxylated C_{21} and C_{19} steroids. There is a subnormal response to cosyntropin (ACTH) stimulation. Because mineralocorticoid secretion is unaffected, serum levels of DOC, corticosterone, 18-hydroxycorticosterone, and

18-hydroxy DOC are elevated and suppress with glucocorticoid treatment.

P450 oxidoreductase (POR) is a protein that functions as an electron donor to microsomal P450 cytochrome (CYP) enzymes. Thus, several enzymes involved in steroidogenesis such as 17α-hydroxylase (P450c17), 21-hydroxylase (P450c21), and P450 aromatase depend on this protein. Mutations that act as loss of function in *POR* are associated with congenital adrenal hyperplasia with combined glucocorticoid and sex steroid deficiency. Although this disorder typically presents in the newborn period with undervirilization, skeletal anomalies (Antley-Bixler syndrome), and glucocorticoid deficiency, males may present with a milder phenotype such as delayed puberty. The skeletal anomalies found in both P450 oxidoreductase deficiency and Antley-Bixler syndrome include brachycephaly and joint contractures.[236]

In 1972, Zachmann and colleagues reported Swiss families with undervirilized males and hormone concentrations suggestive of isolated 17,20-lyase deficiency.[237] No *CYP17A1* mutations were identified when members of the original families were evaluated using the tools of molecular genetics. Rather, deleterious mutations were identified in the aldo-keto reductase family 1, member C2 (*AKR1C2*), and the aldo-keto reductase family 1 member C4 (*AKR1C4*) genes. Further investigations revealed an alternative pathway in which DHT can be synthesized without androstenedione or testosterone as intermediary hormones. This alternative or "backdoor" pathway had been previously described in the tammar wallaby.[238] Thus, loss-of-function mutations in the dihydrodiol dehydrogenase type 2 (*AKR1C2*) and dihydrodiol dehydrogenase type 4 (*AKR1C4*) genes can be associated with undervirilization of males.[239] Typically, adrenal insufficiency does not occur.

In the autosomal recessive 17β-Hydroxysteroid dehydrogenase deficiency, conversion of androstenedione to testosterone in the Leydig cell is impaired. This disorder is due to mutations in the 17β-hydroxysteroid dehydrogenase type 3 (*HSD17B3*) gene. The extent of external genital virilization is variable, ranging from genital ambiguity to microphallus. Wolffian duct development is impaired. At puberty, the increased peripheral conversion of sex steroids (androstenedione) to testosterone induces virilization of affected individuals. Affected "girls" may convert to male gender during puberty. When the diagnosis is made in the newborn period, male gender of rearing is appropriate. Although increased basal androstenedione to testosterone ratios would be expected, hCG stimulation tests and molecular genetic analysis may be necessary to confirm this diagnosis.

Testosterone is converted to dihydrotestosterone (DHT) in specific target cells including the prostate and developing external genitalia. Loss-of-function mutations in the 5α-reductase gene (*SRD5A2*) lead to impaired peripheral conversion of testosterone to DHT. The phenotype of affected 46,XY individuals ranges from varying degrees of male-to-female sex reversal at birth. The classic description of the genitalia is perineoscrotal hypospadias, bilateral labial masses (testes), and absence of Mullerian structures. At puberty, affected individuals typically virilize with phallic enlargement and, if raised as females, may change to a male gender. Thus, patients may present with primary amenorrhea, mild virilization, no breast development, absent uterus, and 46,XY karyotype. Spermatogenesis is often impaired. This autosomal recessive disorder is prevalent in the Dominican Republic, southern Lebanon, southern Turkey, and the eastern highland region of Papua, New Guinea. Curiously, this disorder has been detected in several elite female athletes identified by having primary amenorrhea and elevated testosterone concentrations.[240] Females homozygous for *SRD5A2* mutations generally have no reproductive phenotype. Random testosterone to DHT ratios may be elevated. However, hCG stimulation testing is often necessary to confirm the diagnosis. Urinary steroid metabolite ratios (androsterone/etiocholanolone, 5α-tetrahydrocortisol/tetrahydrocortisol, and 5β-tetrahydrocorticosterone/tetrahydrocorticosterone) may be helpful.[241]

Chemotherapy, Radiation Therapy, and Cancer Survival

Treatment of childhood cancers can lead to gonadal failure, delayed puberty, and infertility. Quality-of-life concerns have become increasingly relevant because many young cancer patients are long-term cancer survivors. Multiple components of the hypothalamic-pituitary-gonadal axis may be affected by chemotherapy and radiation therapy with specific consequences depending on the drugs and fields of irradiation. The germ cells of the gonads are particularly vulnerable to radiation. Discussions regarding fertility preservation are crucial for pediatric patients with cancer and their parents; however, detailed discussion of this relevant subject is beyond the scope of this chapter.

OTHER DISORDERS OF THE MALE REPRODUCTIVE ENDOCRINE AXIS

Several other disorders deserve discussion, albeit not necessarily associated with alterations in pubertal timing.

Androgen Receptor (*AR*) Mutations

The classic presentation of 46 XY individuals with complete androgen insensitivity (CAIS) is primary amenorrhea, breast development, and lack of sexual hair. Labial masses (testes) may be palpated on physical exam. Imaging shows an absence of Mullerian structures because in utero Sertoli cell secretion of AMH is normal. Inheritance is X-linked recessive. Some individuals with CAIS are detected when a gonad is found during repair of an inguinal hernia in a phenotypic female child. As bilateral inguinal hernias are unusual in girls, the diagnosis of androgen insensitivity should be assessed by obtaining a karyotype and checking for the presence of a Y chromosome by fluorescent in situ hybridization (FISH).

The phenotype of 46,XY individuals carrying mutations in *AR* ranges from the classic CAIS to partial forms presenting with undervirilization and male infertility. Individuals with partial androgen insensitivity (PAIS)

may present with gynecomastia, hypospadias, cryptorchidism, micropenis, decreased sexual hair, and infertility. Mild isolated hypospadias has rarely been associated with *AR* mutations; missense mutations were detected in exon 1 that encodes an important regulatory region for the receptor.[242] Phenotypic heterogeneity occurs even within a family. Despite classic features of CAIS, *AR* mutations may not be detected in some individuals. It is speculated that these patients may carry mutations in receptor cofactors or distant regulatory regions of the *AR*.

As noted earlier, the *AR*, located at Xq11-q12, has a modular structure with N-terminal regulatory (NTD), DNA binding (DBD), and ligand binding (LBD) domains. Ligand binding is impaired for mutations located in the ligand binding domain. Mutations located in the DNA binding domain do not affect ligand binding; rather the ligand-receptor complex fails to bind to the promoter region of the gene and shows impaired transcriptional activity. To date, more than 800 *AR* mutations have been described (http://androgendb.mcgill.ca).[243]

Exon 1 of *AR* contains two trinucleotide repeat regions. The CAG repeat encodes for a homopolymeric stretch of glutamines. In vitro studies have demonstrated that the number of CAG repeats is inversely proportional to the transcription activity of the protein. Expansion of the polyglutamine repeat (> 40 repeats) is associated with Kennedy disease, a form of spinal and bulbar muscular atrophy (SBMA). Kennedy disease is an adult-onset lower motor neuron disease characterized by slowly progressive muscle weakness and atrophy of the bulbar, facial, and limb muscles. Men with Kennedy disease may have signs of mild androgen insensitivity. The other trinucleotide repeat encodes a homopolymeric stretch of glycines.

The typical hormone findings during adolescence include elevated LH and testosterone concentrations. Inhibin B and FSH concentrations are usually normal. Estradiol concentrations are elevated due aromatization of testosterone. Sex hormone binding globulin (SHBG) concentrations are generally in normal female range. Surprisingly, testosterone concentrations are not elevated during early infancy in children with CAIS. No explanation for this apparent lack of negative feedback is available.

Once the diagnosis of CAIS is confirmed, full disclosure to the patient and her family is essential. Mothers may feel guilty for transmitting this X-linked disorder. One essential discussion relates to gonadectomy. Some individuals and families prefer to delay gonadectomy until late adolescence to allow for spontaneous breast development. Additional topics for discussion include implications of the 46,XY karyotype, infertility, sexual function, and what information to share with nonfamily members. Individuals with CAIS usually have a blind vaginal pouch, and vaginal dilatation may be the only therapy necessary to create a functional vagina.

Persistent Mullerian Duct Syndrome

Persistent Mullerian duct syndrome (PMDS) is characterized by persistence of Mullerian duct derivatives in the presence of otherwise normal male sex development. PMDS is an autosomal recessive disorder due to loss-of-function mutations in the *AMH* gene or the *AMHRII* gene. Measurement of AMH can be helpful. Low AMH levels are consistent with AMH deficiency and high levels suggest a mutation in the *AMHRII* gene. Common presentations include discovery of a uterus during inguinal hernia repair or orchidopexy. Transverse testicular ectopia with both testes on the same side is virtually pathognomonic for this disorder. Testicular torsion is not uncommon because the testes may not be anchored properly to the bottom of the processus vaginalis.

Testicular differentiation is usually normal, but the male excretory ducts may be embedded in the Mullerian duct remnants or incompletely developed. Infertility may ensue secondary to cryptorchidism, intertwining of vas deferens and uterine wall, or lack of proper communication between the testes and excretory ducts. The close physical relationship of the vas and the uterine wall complicates the surgical excision of the Mullerian remnants. However, because malignancy (adenocarcinoma) has been reported to arise in the Mullerian remnants, surgical excision by experienced surgeons should be considered.[244]

Testicular Regression Syndrome (Anorchia), Cryptorchidism, and Hypospadias

Testicular regression syndrome affects approximately 5% of boys with cryptorchidism.[245] In this instance, one or both testes are nonpalpable despite normal-appearing male external genitalia. Bilateral nonpalpable testes with a normal appearing but small phallus may be considered to be a variant of this syndrome. During early infancy and adolescence, elevated gonadotropin and unmeasurable inhibin B and AMH concentrations indicate anorchia. The lack of a testosterone response to hCG stimulation in the older infant and prepubertal boy is consistent with anorchia. Random inhibin B and AMH concentrations may more helpful than hCG stimulated testosterone concentrations.[246] Imaging studies are generally not informative. Hence, the combination of undetectable plasma AMH and inhibin B, an elevated plasma FSH, and 46,XY karyotype may be sufficient to diagnose anorchia and obviate the need for an hCG stimulation test.[247] Nevertheless, thorough clinical reevaluations are indicated and when warranted hCG stimulation may still be helpful to confirm diagnosis of anorchia.

At operation, nubbins of discrete vascularized fibrosis are found in close proximity to a blind-ending spermatic cord structure. Although the precise etiology is unclear, the testicular regression syndrome has been attributed to in utero testicular torsion. The finding of hemosiderin-laden macrophages and dystrophic calcifications supports a vascular accident etiology.

Cryptorchidism (undescended testes) is the most common disorder of sex development affecting 3% of males. The prevalence decreases to 1% by 6 months of age due to spontaneous descent during infancy. Many conditions are associated with cryptorchidism including hypogonadotropic hypogonadism, aberrant testicular differentiation,

impaired testosterone biosynthesis, androgen insensitivity, holoprosencephaly, abnormal AMH production or action, abnormalities affecting INSL3/LGR8 function, and possibly environmental factors. Other associations include prune belly syndrome, bladder extrophy, and renal anomalies. Cryptorchidism is also a feature of many syndromes (see Chapter 5). Maternal diabetes mellitus, including gestational diabetes, and environmental exposures may be risk factors as well.

In male fetuses, urethral closure occurs during 8 to 14 weeks' gestation. This process reflects continuous ventral fusion in the proximal to distal direction. Hypospadias represents an aberration of this process resulting in abnormal penile and urethral development. Physical examination reveals an abnormal position of the urethral meatus along the ventral portion of the penis, ventral curvature of the penis (chordee), and an abnormal foreskin. Hypospadias can be associated with disorders of sex development and chromosomal anomalies. Hypospadias can be classified into hormone-independent and hormone-dependent etiologies. Genes associated with hypospadias include *FGF8*, *FGFR2*, *BMP4*, and *BMP7*. Insufficient androgen exposure can lead to hypospadias.[248]

Epidemiologic data suggest a possible role for environmental factors in the etiology of both cryptorchidism and hypospadias. Potential mechanisms include binding to hormone receptors, interference with postreceptor signaling pathways, and effects on hormone synthesis, activity, and degradation. Suspected environmental factors include phthalates, bisphenol A, pesticides containing *DDE* (1,1-dichloro-2, 2-bis(p-chlorophenyl)ethylene) and DDT (dichlorodiphenyltrichloroethane), maternal smoking, phytoestrogen intake, low birth weight, and maternal progestin exposure during gestation. Maternal DES exposure is of historical interest. However, studies confirming a causal relationship for environmental disruptors report inconsistent findings.[249]

Testis Tumors

Testis tumors are rare among the pediatric population. Tumors can arise from one of three principal cell types: germ cells, Sertoli cells, and Leydig cells. Rarely, tumors can develop from other elements such as endothelium (hemangioma), muscle (rhabdomyosarcoma), or fibrous tissue (fibroma). Germ cells tumors in children include yolk sac tumor, embryonal carcinoma, seminoma, nonseminoma, dysgerminoma, and gonadoblastoma. For patients with DSDs or undervirilization, the type II germ cell tumors are the most relevant and will be the only type of germ cell tumor discussed in this section.

Germ Cell Tumors

Type II germ cells tumors include seminoma, nonseminoma, and dysgerminoma; these invasive tumors arise from primordial germ cells and occur with increased frequency in patients with DSDs who carry Y chromosomal material. The noninvasive premalignant precursors for type II germ cells tumors are the intratubular germ cell neoplasia unclassified (ITGCNU), previously known as carcinoma in situ (CIS), and the gonadoblastoma. Both reflect delayed germ cell maturation and express the germ cell transcriptional factor, OCT 3/4. A locus mapped to Yp, the testis specific protein Y-encoded (*TSPY*) gene, plays a major role in the pathogenesis of germ cell tumors. Hence, germ cells tumors residing in unfavorable environments may have prolonged expression of OCT 3/4, *TSPY*, placental/germ cell alkaline phosphatase (PLAP), and fail to undergo apoptosis.

ITGCNU is characterized by the presence of germ cells in the seminiferous tubules. Gonadoblastomas are composed of immature germ cells and sex cord–stromal cells. One major difference between these lesions is the local microenvironment. Some degree of Sertoli cell/testicular differentiation favors ITGCNU development, whereas gonadoblastomas develop in streak gonads or poorly differentiated gonadal tissue. Thus, these lesions may represent a continuum with the phenotype reflecting the degree of Sertoli cell differentiation.[250] On histologic examination of the tissue, the origin of the cell, granulosa versus Sertoli, may be indeterminate. Staining of gonadoblastoma for FOXL2 and SOX9 can differentiate granulosa from Sertoli cell, respectively, regarding cell of origin.[251] Dysgerminoma (ovary) and seminoma (testis) are the end-stage invasive tumors.

The risk for the development of germ cell tumors varies among patients with DSD. The risk is negligible for the virilized XX patient with CAH. For patients with complete androgen insensitivity, the risk for germ cell tumors is low in childhood but increases during adulthood. Due to the low risk for neoplastic changes, individuals with CAIS may choose to postpone gonadectomy.[252] Germ cell number generally decreases with advancing age. A retrospective review of MRI findings in 25 patients with CAIS identified benign paratesticular simple cysts in 80%. Histologic evaluation of the testes from these same individuals showed premalignant lesions in 12%; these lesions were too small to be detected on MRI. Until a sensitive and specific screening tool is available, gonadectomy after puberty likely remains the safest option for individuals with CAIS.[253]

In contrast, the risk for a type II germ cell tumor is high in dysgenetic gonads such as in patients with 46,XY gonadal dysgenesis, Frasier syndrome, and partial androgen insensitivity. Curiously, boys with Klinefelter syndrome have an increased risk for mediastinal germ cell tumors, but not testicular germ cell tumors. Intra-abdominal location of the dysgenetic gonad increases the risk for germ cell tumors. Thorough discussion with the patient, if older, and the parents is essential to choose the optimal management ranging from observation to prophylactic gonadectomy.

Nongerm Cell Tumors

As noted previously, Leydig cell tumors may present with peripheral precocious puberty and asymmetry of testicular volume. Reported median age at presentation was 6.5 years. Gonadotropin concentrations are typically low. An activating mutation in the *LHCGR* has been found in some boys.[254]

Tumors can also develop in Sertoli cells. Large cell calcifying Sertoli cell tumors can be found in prepubertal

boys, adolescents, and young adult males. Aromatase expression may be increased such that growth acceleration, advanced skeletal maturation, and gynecomastia may occur. Large cell calcifying Sertoli cell tumors may be bilateral with palpable calcifications due to macrocalcifications within the tumor. The calcifications can be detected on testicular ultrasound. Malignancy occurs in approximately 17% and usually in older men. Peutz-Jeghers syndrome and Carney complex are associated with large cell calcifying Sertoli cell tumors.[255]

Testicular adrenal rest tumors (TARTs) are hypoechoic, well-circumscribed lesions believed to arise from adrenal stem cells that were misdirected and descended into the scrotum with the testes during gestation. These cells express adrenal steroidogenic enzymes. Typically, suppressive glucocorticoid doses decrease the size of the tumor, but TARTs can occur despite ACTH-suppressive glucocorticoid doses. Although more common in men with classical forms of CAH, TARTs have been reported in men with nonclassic CAH. In one pediatric series, the youngest patient was 7 years old.[256] The typical location is in the rete testis. TARTs can obstruct the seminal ducts, with subsequent permanent testicular damage, infertility, decreased sperm count, and decreased testicular testosterone production. Testicular ultrasound screening is helpful to detect TARTs. Importantly, TARTs must be differentiated from other testicular mass lesions to avoid unnecessary surgery.

Gynecomastia

Physical examination is extremely important in the evaluation of gynecomastia to distinguish among true gynecomastia, pseudogynecomastia, and pathologic gynecomastia. With the patient lying supine with his hands clasped beneath his head, the examiner can slowly compress the breast area between forefinger and thumb beginning from the sides of the breast. In true gynecomastia, the breast tissue is located concentrically under the nipple-areolar complex, feels rubbery or firm, and is often bilateral. During the early phase, ductal and epithelial proliferation occurs. This early proliferation is associated with periductal inflammation and edema, which correspond to the tenderness noted by the patient.[257]

The differential diagnosis includes lipomastia or pseudogynecomastia that is characterized by breast fullness and the absence of a nipple-areolar complex mound. Lipomas and neurofibromas can occur in the breast. Although extremely rare in adolescents, the tissue mound in the breast cancer patient feels firm or hard and is located outside the nipple-areolar complex. Nipple discharge, skin dimpling, and nipple retraction do not occur in physiologic gynecomastia.

Pubertal or physiologic gynecomastia is a common midpubertal finding noted at Tanner stage 3 to stage 4 for pubic hair.[258] Pubertal gynecomastia has been attributed to a relative and transient imbalance in testosterone to estradiol ratio. With the progression of puberty and rising testosterone concentrations, the gynecomastia typically resolves.

Medications, exposures, and rare hormone disorders are associated with pathologic gynecomastia. Medications associated with gynecomastia include spironolactone, cimetidine, ketoconazole, estrogens, anti-androgens, growth hormone, GnRH analogs, and 5α-reductase inhibitors.[259] Exposures to estrogen-containing substances, lavender and tea tree oils, and phytoestrogens have been considered to be etiologies. Other drugs associated with gynecomastia include tricyclic antidepressants, chemotherapeutic agents, and cardiovascular medications (e.g., digitalis). Drugs of abuse associated with gynecomastia include marijuana, ethanol, heroin, and amphetamines.

Estrogen excess can cause pathologic gynecomastia. Autosomal dominant mutations in the aromatase (*CYP19A1*) gene result in constitutively increased gene transcription and overexpression of the aromatase enzyme.[260] Feminizing tumors can directly secrete estrogen. Peutz-Jeghers syndrome (PJS) is characterized by mucocutaneous pigmentation, multiple gastrointestinal polyps, and a variety of neoplasms. Gynecomastia was described in prepubertal boys secondary to large cell calcifying Sertoli cell tumors associated with PJS or Carney complex syndrome.[255] Gynecomastia can occur in men with hyperthyroidism and with hypogonadism including Klinefelter syndrome, androgen insensitivity, ovotesticular disorder.[261] Additional associations include obesity, liver disease, radiation exposure, and other causes of hypogonadism.

Gynecomastia in a prepubertal boy is pathologic and warrants investigation. Gynecomastia occurring in a midpubertal boy who is otherwise healthy most likely represents physiologic gynecomastia for which an extensive laboratory evaluation is unwarranted. Physiologic gynecomastia is typically self-limited. If present, treatment of the underlying disorder or removal of environmental causes is appropriate and may lead to regression of the breast tissue. Aromatase inhibitors and estrogen receptor blockers have been used. An open label study concluded that anastrozole reduced breast size.[262] However, the single randomized double placebo controlled pediatric trial noted that anastrozole was no more effective than placebo to reduce gynecomastia.[263]

EVALUATION OF THE CHILD WITH DELAYED PUBERTY

Whether due to a referral bias or to differences in underlying biology that result in a slightly skewed distribution of ages of pubertal timing in boys compared to girls,[52] delayed puberty in general and CDGP in particular are also seen more commonly in boys in endocrinology clinics.[202]

Initial Evaluation

The aim of the initial evaluation is to rule out causes of delayed puberty other than CDGP (Table 17-3 and Figure 17-5). Pubertal development is assessed clinically and biochemically, providing information important for counseling and predicting further pubertal development. Eventual normal progression of puberty verifies a diagnosis of CDGP, whereas absent or slow

TABLE 17-3 **Investigations for Delayed Puberty**

First Line Investigations		
VARIABLE	REQUIREMENTS AND LIMITATIONS	INTERPRETATION
Growth rate	Two or more height measurements, preferably 6-12 months apart.	In early adolescence in both sexes a growth rate less than 3 cm/year is suggestive of a disease specifically inhibiting growth (e.g., GH deficiency, hypercortisolism, hypothyroidism), but such rates can also be seen in CDGP. Boys with delayed puberty who are overweight tend to have height and predicted adult consistent with the genetic height potential.[125,265]
Tanner stages	Pubic hair stages and genital stages should be scored separately because they do not necessarily track together.	Testicular volume of $>$ 3 mL is a more reliable indicator of the onset of puberty than Tanner stage 2 genital development.
Testis volume	Prader's orchidometer or a ruler.	Testicular volume of $>$ 3 mL ($\geq$ 2.5 cm in length) indicates central puberty. Most healthy boys with a testicular volume 3 mL or greater will have a further increase in testicular volume, pubic hair stage, or both, at repeated examination 6 months later.[117]
Bone age	X-ray of left hand and wrist. Greulich and Pyle Atlas. Bone age is also used to predict adult height.	A bone age delay of more than 2 years has arbitrarily been used as a criterion for CDGP but is not specific to that condition. A bone age delay of 4 years has been associated with an average of 8 cm over prediction of adult height, whereas in short stature with no bone age delay, adult height is usually underestimated by the Bayley-Pinneau tables.[293]
Biochemistry	Evaluation varies but common tests include complete blood count, erythrocyte sedimentation rate, creatinine, electrolytes, bicarbonate, alkaline phosphatase, albumin, thyrotropin, and free thyroxine.	To rule out chronic disorders. Should be directed based on history and physical examination. Additional investigations may be necessary based on family history, symptoms, and signs, including screening for celiac disease and inflammatory bowel disease.
Serum luteinizing hormone (LH)	Morning sample. Use immunochemiluminometric (ICMA) or immunofluorometric (IFMA) assays with a lower limit of detection at or below 0.1 IU/L	At low levels, values obtained on ICMA are at least 50% lower than those by IFMA.[270] Values $<$ 0.1 IU/liter are not specific for hypogonadotropic hypogonadism. Value $>$0.6 (IFMA) or 0.2 (ICMA) IU/L are specific but not sensitive markers for the initiation of central puberty, because in early puberty some adolescents have lower values.[270] In delayed puberty, elevated values suggest primary hypogonadism.
Serum follicle-stimulating hormone (FSH)	Morning sample. Use ICMA or IFMA assays with a lower limit of detection at or below 0.1 IU/L if possible.	At low levels, values obtained on ICMA are $\sim$50% lower than those by IFMA. Values $<$0.2 (ICMA) or $<$ 1 (IFMA) IU/L suggest hypogonadotropic hypogonadism but are not diagnostic.[269,270] In delayed puberty, a value above the upper limit of normal for the assay is a marker of inhibin B deficiency and of primary gonadal failure with high sensitivity and specificity.
Serum insulin-like growth factor 1 (IGF-1)	Blood samples should be processed within 2 h to avoid an artifactual increase in results. Only assays that recognize IGF-1 without any interference from IGF binding proteins provide reliable results.	IGF-1 level is used to screen for GH deficiency. An increase in the levels during follow-up or during or after treatment with sex steroids makes the diagnosis of GH deficiency less likely. The IGF-1 concentration shows the greatest change during childhood and puberty and then changes more slowly with advancing age. Therefore, normal values for children and adolescents should include narrow age ranges and Tanner stages. GH provocation tests are needed to diagnose GH deficiency.
Serum testosterone	Morning sample is ideal. Use an assay with a lower limit of detection at or below 10 ng/dL (0.35 nmol/L) if possible. Concentrations show diurnal variation.	An 8 am serum testosterone value of $\geq$ 20 ng/dL (0.7 nmol/L) often predicts the appearance of pubertal signs within 12 to 15 months.[294]

Second-Line Investigations

VARIABLE	REQUIREMENTS AND LIMITATIONS	INTERPRETATION
Gonadotropin-releasing hormone (GnRH) test*	Assay requirements are the same as for basal LH and FSH. Test can be performed any time of day. LH and FSH values vary according to assay used and with the stimulating agent (GnRH or GnRH agonist).	A predominant LH over FSH response after GnRH stimulation or peak LH levels of 5 to 8 IU/L (depending on assay) suggests onset of central puberty. There is an overlap between prepubertal and early pubertal post-GnRH values.[270] A prepubertal response is seen in some patients with CDGP as well as in hypogonadotropic hypogonadism, but a post-GnRH LH value $<$ 0.8 IU (IFMA) and FSH value $<$ 1.1 IU/L (IFMA) may be more consistent with hypogonadotropic hypogonadism in boys.[270]
Human chorionic gonadotropin (hCG) test*	IM or SC injections on several days. There are number of different protocols available. Results vary by the protocol.	Peak testosterone concentrations to both 3-d and 19-d hCG tests have been reported to be significantly lower in patients with hypogonadotropic hypogonadism compared with CDGP. A combination of the GnRH test and hCG test [peak LH cutoff, 2.8 U/L; peak 19-d testosterone cutoff, 275 ng/dL (9.5 nmol/liter)] gave a sensitivity and a specificity of 100% in a small study of CDGP and hypogonadotropic hypogonadism.[295]
Serum inhibin B*	Can be measured any time of day. Has diagnostic value only in boys.	Measurement is used in differentiation of hypogonadotropic hypogonadism from CDGP. Boys with higher baseline inhibin B levels had a higher likelihood of CDGP in one study.[271] In prepubertal boys, sensitivity and specificity of 100% was obtained at concentration of $>$35 pg/mL. With Tanner stage 2 genitalia, sensitivities were 86% and 80%, and specificities 92% and 88%, respectively, for CDGP with an inhibin B value of $>$ 65 pg/mL. In boys, unmeasurable inhibin B indicates primary germinal failure.
Serum prolactin	Measurement is indicated only in some cases. Physiologic states including stress, exercise, and sleep can increase prolactin levels, as can hypothyroidism and some medications.	Elevated levels may indicate hypothalamic-pituitary tumors causing hypogonadotropic hypogonadism. In such cases, additional pituitary-hormone deficiencies may be present. Macroprolactin (physiologically inactive form of prolactin) measurement is recommended in patients with asymptomatic hyperprolactinemia.
Brain magnetic resonance imaging (MRI)	Indicated in any suspicion of CNS pathology (e.g., headache, changes in vision, changes in behavior).	Imaging is performed to rule out underlying disorders of the central nervous system. Imaging in patients with the Kallmann syndrome commonly shows olfactory bulb and sulcus aplasia or hypoplasia and thus may help differentiate the Kallmann syndrome from isolated hypogonadotropic hypogonadism in patients with an apparently normal or difficult-to-evaluate sense of smell. In hypogonadotropic hypogonadism there is a moderate agreement between the MRI of the olfactory bulbs and the UPSIT (overall Kappa 0.5), but in presence of aplastic bulbs and anosmia, there is good agreement (Kappa 0.9).
Olfactory function test	One test, UPSIT,[296] uses microencapsulated odorants, which are released by scratching standardized odor-impregnated test booklets.	Used to assess for hyposmia and anosmia as part of evaluation for Kallmann syndrome.
Genetic testing	In more than 60% of patients with Kallmann syndrome or isolated hypogonadotropic hypogonadism no specific gene defect is found.	Genotyping for known monogenic causes is currently a research procedure and not warranted in routine clinical practice. It may be warranted when there is a positive family history or the patient has phenotypic signs suggestive of a specific mutation. If performed, genetic testing should be accompanied by genetic counseling.
GH testing	Various protocols both for testing and priming are available. The choice of GH stimuli to be used is variable.	Response in GH provocation test is greater after the administration of exogenous (aromatizable) androgens or estrogens (priming). Reliable assay performance and appropriate normative data are critical for appropriate use of GH and IGF-1 measurements.
Karyotype		Diagnostic of Klinefelter syndrome.

*These tests are used to try to differentiate CDGP and IHH. However, validation in larger, independent studies is needed before they can be endorsed for routine clinical use.[267,268] Clinical follow-up is often needed to confirm the diagnosis; no endogenous puberty by age 18 years is diagnostic of IHH.

Table modified and reprinted with permission from Palmert, M. R., & Dunkel, L. (2012). Clinical practice. Delayed puberty. N Engl J Med, 366, *443–453.*

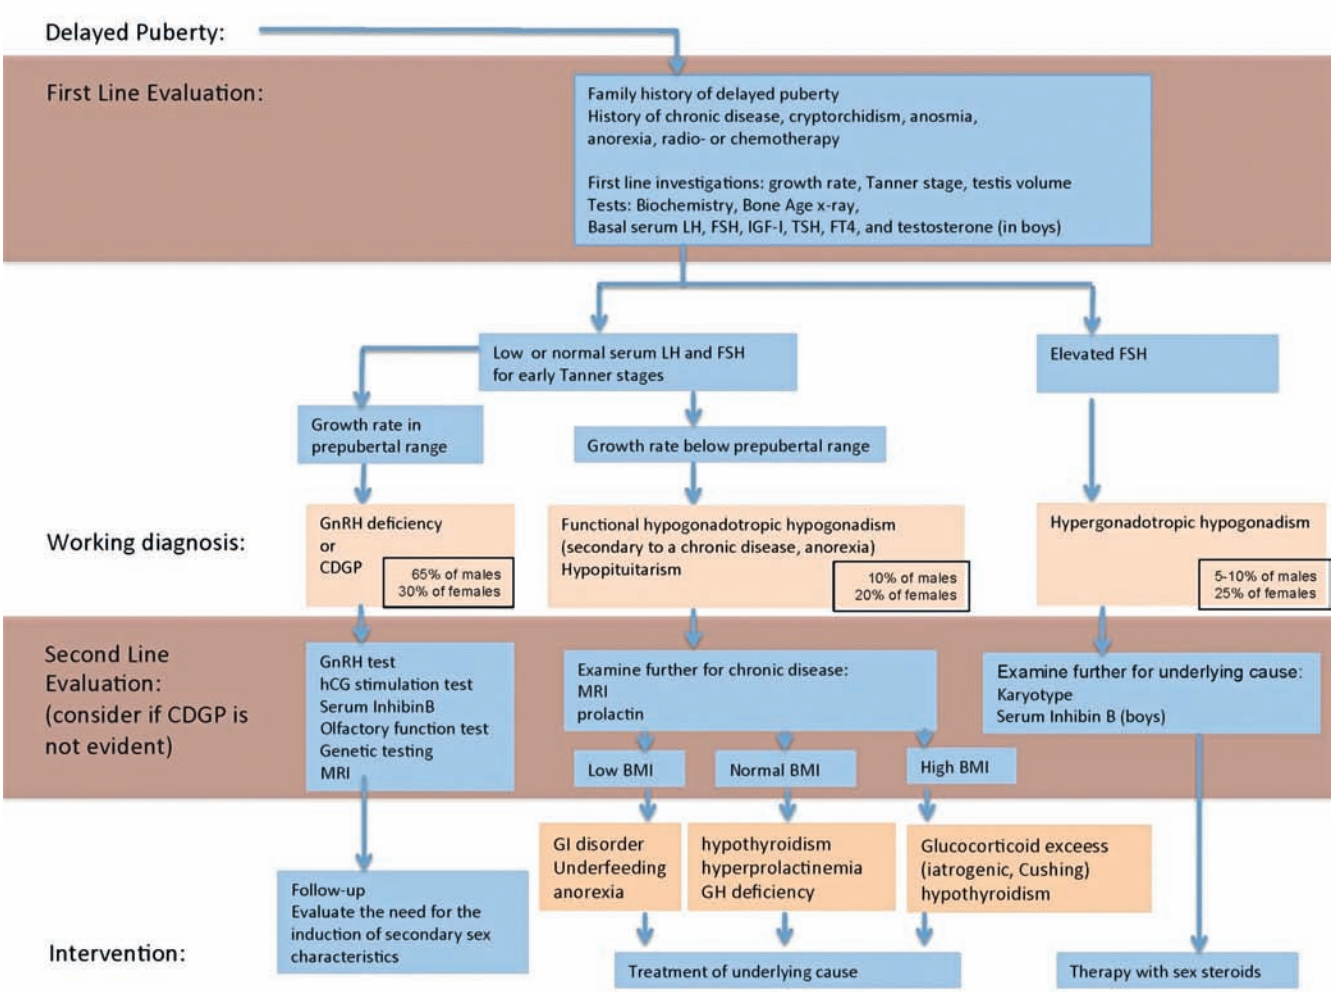

FIGURE 17-5 ■ Flowchart for the evaluation of a patient with delayed puberty. CDGP, constitutional delay of growth and puberty; FSH, follicle stimulating hormone; GH, growth hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone. Percentages are from reference 202; they do not add up to 100% because of rounding and because a small percentage of patients have disorders that cannot be classified using this schema. (Reprinted with permission from Palmert, M. R., & Dunkel, L. [2012]. Clinical practice: delayed puberty. *N Engl J Med, 366,* 443–453.)

development, or cessation of development after onset, is consistent with permanent hypogonadism.

History

A family history—including childhood growth patterns, age at pubertal onset of the parents, and infertility—should be obtained. Delayed puberty in a parent or sibling, regardless of gender, followed by spontaneous onset of puberty suggests CDGP. However, if pubertal development was induced by sex steroids in family members, IHH is also possible, as reversal of hypogonadism is noted after discontinuation of sex steroids in about 10% of IHH cases.[98,213]

Chronic diseases, such as inflammatory bowel disease, sickle cell disease, celiac disease, asthma, chronic renal failure, cardiac disease, endocrine disorders such as hypothyroidism and poorly controlled diabetes mellitus, and chronic therapy with glucocorticoids,[264] may delay both linear growth and puberty. Inadequate nutritional intake, when associated with conditions such as cystic fibrosis, anorexia nervosa or excessive energy utilization[203] due to vigorous exercise in athletes or ballet dancers, may result in pubertal delay. Successful intervention in such situations can be followed by catch-up growth and pubertal progression.

Delayed cognitive development associated with obesity or dysmorphic features may suggest an underlying genetic syndrome. Cryptorchidism or small penis at birth, hyposmia, or anosmia may suggest hypogonadotropic hypogonadism. A history of chemo- or radiotherapy may indicate primary gonadal failure. However, some patients receiving treatment for malignancy may have elevated gonadotropin levels during and initially after therapy, but subsequently the gonadotropin levels decrease as these patients experience varying degrees of gonadal recovery. Of special note, although Klinefelter syndrome is a type of hypergonadotropic hypogonadism, males with this condition commonly present with unusually small testes, lack of pubertal progression, or infertility rather than pubertal delay.

Physical Examination

Previous height and weight measurements should be obtained and plotted so that longitudinal growth can be carefully assessed. Height, weight, and body proportions should be determined. Compared with previous data, height and weight can be used to calculate annual growth rates preferably based on a 12-month interval, as intervals less than 4 to 6 months can be inadequate. Delayed puberty is often associated with short stature and slow growth for age, although height and growth rate may be within the prepubertal normal range. Individuals who are underweight for height have a higher likelihood of an underlying condition delaying HPG axis activation. Conversely, in boys, unlike girls, being obese can be associated with later pubertal development.[125,265] Upper-to-lower segment ratio can be determined by measuring sitting height or lower segment (from top of pubic symphysis to floor) and compared with normal for age: ratio decreases with age to 1 or lower depending on racial group. Arm span (finger tip to finger tip) should be within 5 cm of the standing height. Longer limbs or eunuchoid habitus suggest hypogonadism.

The physical examination should also concentrate on identifying markers of chronic disease, malnutrition, neurologic abnormalities, thyroid and other endocrinopathies, and syndromic features. In boys, in addition to determining height, weight, and skeletal proportions, documentation should include stretched penile length, position of urethral opening, testicular size, and whether both testes are present in a normally developed scrotum. Cryptorchidism, bifid scrotum, micropenis, or perineoscrotal hypospadias may indicate defects in gonadal steroidogenesis and disorders of sex development. Small testes, eunuchoid habitus, and gynecomastia suggest Klinefelter syndrome. Obesity and delayed puberty may suggest defects in the prohormone convertase 1 (*PC1*), leptin, or leptin receptor genes. When obesity is associated with delayed puberty and dysmorphic features, it suggests Prader-Willi, Bardet-Biedl, or other genetic syndromes.

In boys, Tanner stage 2 genitalia mark the onset of pubertal development and are characterized by enlargement of scrotum and testes and by a change in the texture and color of the scrotal skin (see Figure 17-2). Testicular volume should also be measured; a volume $>$ 3 cc indicates the initiation of central puberty. In patients with CDGP, both adrenarche and hormonal activation of the gonads often occur later than average, but in isolated hypogonadotropic hypogonadism, adrenarche usually occurs at a normal age.[202,266]

Testing

The history and physical examination should direct the laboratory studies so that a parsimonious, cost-effective evaluation is performed. Certainly, not all tests need to be performed in all individuals.

An individual who is experienced in interpreting these x-rays should review the bone age. A delay in bone age is characteristic but not diagnostic of CDGP and also may occur in individuals with chronic illness, hypogonadotropic hypogonadism, or gonadal failure. Adult height prediction is an important part of counseling if short stature is a component of the presentation, and practitioners need to be aware that the Bayley Pinneau tables overestimate adult height in patients with CDGP if bone age is delayed by more than 2 years (see Table 17-3).

Pubertal onset is characterized by accentuation of diurnal gonadotropin and testosterone secretion before apparent phenotypic changes. Basal LH and FSH levels are low in CDGP and in hypogonadotropic hypogonadism, whereas they are usually elevated in gonadal failure. In general, LH is a better marker of pubertal initiation than FSH, and FSH is a better marker of gonadal failure than LH. Serum IGF-1 concentrations can help in the evaluation of growth hormone deficiency but must be interpreted carefully because levels are often low for chronologic age but within normal range for bone age in patients with delayed puberty. Thyroid function tests are routinely obtained.

Brain and pituitary MRI may be indicated when there are signs or symptoms to suggest a CNS lesion; otherwise, although some clinicians obtain brain imaging routinely, a reasonable strategy is to defer this test until age 15, at which point many patients with CDGP will have spontaneously begun puberty and will require no further evaluation. Full neuroendocrine testing is warranted in patients with hypothalamic-pituitary tumors causing hypogonadotropic hypogonadism, as they may have additional pituitary hormone deficiencies. Assessment of olfactory bulbs on MRI may be helpful in patients with hypogonadotropic hypogonadism and anosmia.

Additional Evaluation

Most boys will not have an apparent alternative cause for delayed puberty on initial evaluation, suggesting CDGP as the likely diagnosis. However, no test can reliably distinguish CDGP from IHH, so the diagnosis of CDGP cannot be made with certitude.[267,268] Observation usually resolves this conundrum; IHH is diagnosed if endogenous puberty has not begun by age 18 years. Several tests have been proposed to distinguish CDGP from IHH (see Table 17-3). If basal gonadotropin levels are inconclusive, some have suggested that stimulation by GnRH or a GnRH agonist may be helpful.[269,270] Stimulated LH levels in the pubertal range indicate reactivation of the HPG axis and suggest that secondary sexual development is likely to occur within 1 year. However, the GnRH test alone often cannot differentiate CDGP from HH because prepubertal values may be observed in HH or in individuals with CDGP who have not yet activated the HPG axis. Data suggest that baseline inhibin B levels may facilitate discrimination between these conditions.[271,272] Low inhibin B levels may predict IHH, but replication is needed before this or other tests can be adopted routinely.[273]

Growth hormone secretion in the basal state, as well as after provocative testing, may be decreased in CDGP. If concerns about growth are sufficient to warrant growth hormone stimulation testing, sex steroid priming with estrogen or testosterone is necessary for

reliable results in patients with delayed puberty; estrogen stimulates endogenous growth hormone secretion, and sex steroid priming facilitates separation of true growth hormone deficiency from physiologic low GH secretion that stems from low estrogen levels. Another strategy of assessing for true growth hormone deficiency is to remeasure IGF-1 levels after the initiation of testosterone therapy. If IGF-1 increases appropriately with administration of testosterone, then true growth hormone deficiency is less likely. If a patient has normal growth rate, GH provocation tests are not necessary, whereas low IGF-1 levels together with reduced growth velocity warrant testing.

TREATMENT OF DELAYED PUBERTY

The options for management of CDGP include expectant observation or therapy with low-dose testosterone (Table 7-4). If puberty has started, clinically or biochemically,

TABLE 17-4 **Medications Used for the Treatment of CDGP and Permanent Hypogonadism**

Drug and Formulation	Treatment of Boys Recommended Dose		Side Effects and Cautions
	CDGP	HYPOGONADISM	
Testosterone*			Erythrocytosis, weight gain, prostate hyperplasia. High doses can cause premature epiphyseal closure. Not for use in boys with bone age < 10 years.
Testosterone enanthate, cypionate, and propionate. Testosterone enanthate has longer duration of effect than testosterone propionate. Intramuscular injection.	Not recommended before 14 years of age. Initial dose 50-100 mg every 4 weeks for 3 to 6 months. Repeated treatment with 25-50 mg increment in dose (not exceeding 100 mg)	Can initiate after age 12 years of age at 50 mg every 4 weeks. Increase with 50 mg increments every 6 to 12 months. After reaching 100-150 mg monthly, decrease interval to every 2 weeks. Adult dose ~200 mg every 2 weeks.	All intramuscular preparations: local side effects (pain, erythema, inflammatory reaction and sterile abscess). Priapism can occur in patients with sickle cell disease.
Testosterone undecanoate. Intramuscular injection	No data available.	Adult dose is 1000 mg every 10-14 weeks.	
Testosterone gel. Transdermal preparations, applied topically at bedtime.	No data available.	Can be started when ~ 50% adult dose with intramuscular testosterone has been achieved. Adult dose 50-80 mg daily.	Local irritation. After applying, avoid close skin contact with others
Aromatase Inhibitors			Not yet approved for this indication. After onset of puberty, may increase gonadotropin secretion and circulating T levels.[297]
Letrozole PO	2.5 mg daily	Not recommended	Decreased level of high-density lipoprotein cholesterol, erythrocytosis, vertebral deformities have been reported.[195]
Anastrozole PO	1 mg daily	Not recommended	Less potent than letrozole.
Pulsatile GnRH Subcutaneous pump†	Not recommended routinely	Initial: 5-25 ng/kg/pulse every 90-120 min; increase to 25-600 ng/kg/pulse	Requires extensive experience. Most physiologic form of replacement.
hCG plus recombinant FSH. Subcutaneous or intramuscular hCG injections Subcutaneous rhFSH injections†	Not recommended routinely	hCG: Dose 500 to 3000 IU twice weekly, increased to every 2 days. Dose adjusted based on serum T levels. rhFSH: Dose 75 to 225 IU 2-3 times weekly.	hCG: Inflammation locally in the testis, may induce apoptosis of germ cells. In hypogonadotropic hypogonadism with prepubertal onset it is necessary to add FSH to induce testicular growth and spermatogenesis. No data on effects on future fertility.

*Testosterone undecanoate tablets or anabolic steroids are not recommended for the induction of secondary sexual characteristics.
†Induction of fertility may be less successful in men who have lower baseline testicular volumes, have received previously testosterone treatment,[288] and have not previously received treatment with GnRH[285,286] or gonadotropins.[285]
CDGP, Constitutional delay of growth and puberty.

and stature is not a major concern, reassurance with realistic adult height prediction is frequently all that is needed. If therapy is initiated, it is usually to assuage psychosocial difficulties that may derive from negative interactions with peers, decreased self-esteem, and anxiety about growth rate or body habitus.[196] Therapy is usually not initiated solely for medical reasons, such as accrual of bone mass. However, data regarding the effect of pubertal timing on bone mass suggest that additional data are needed to determine definitively whether medical reasons to initiate therapy should be given more consideration.[201]

Since the 1980s, there have been numerous studies of treatment of CDGP in boys, mostly involving treatment with short courses of low-dose androgens. There are limited randomized controlled trials, most with small numbers of subjects,[274-276] but data from these and other studies strongly suggest that treatment leads to increased growth velocity and sexual maturation and positively affects psychosocial well-being without significant side effects, rapid advancement of bone age, or reducing adult height. For boys who elect to be treated, we initiate supplementation with 50 mg testosterone ester intramuscular each month for 3 to 6 months, which can be repeated for another 3 to 6 months with dose escalation (see Table 17-4). Testosterone patches and gels are alternative treatment options, but their use during the initiation of secondary sexual characteristics has been limited by the requirement for low doses that can be delivered reproducibly. If spontaneous puberty has not occurred after 1 year, other diagnoses, such as permanent hypogonadotropic hypogonadism, should be reconsidered, and an MRI of the brain may be indicated.

For a subset of patients with CDGP, short stature can be more concerning than delayed puberty, and indeed in idiopathic short stature (ISS) there is a component of delay in many of the subjects.[277] Although the U.S. Food and Drug Administration (FDA) has approved the use of GH for the treatment of ISS and height SDS ≤ 2.25 for age, this therapy has at best a modest effect on adult height in adolescents with CDGP, and its routine use in CDGP is not recommended.[278] Nor do we use anabolic steroids, such as oxandrolone, for treatment of delayed puberty. Its use for treatment of ISS was not endorsed by the Consensus Statement,[277] and it is rare that boys after age 14 years are not concerned about the lack of pubertal changes, which cannot be induced by oxandrolone because of its weak androgenic effects.

In boys with CDGP and short stature, another potential therapeutic approach is aromatase inhibition, but this treatment requires further study before it should be incorporated into routine practice.[279,280] Aromatase inhibitors (AIs) inhibit conversion of androgens to estrogens. Because estrogen is the predominant hormone needed for epiphyseal closure, AIs could prolong linear growth and potentially increase adult height.[281] In controlled trials in boys with short stature or delayed puberty[279,280] or GH deficiency,[282] AIs have been shown to delay bone maturation and increase predicted adult height. However, adult heights have not yet been reported from all studies, and characteristics of patients who respond and those who do not as well as the optimal timing, dose, and duration of AI treatment remain unresolved.[283]

A complete profile of the potential side effects associated with the use aromatase inhibitors has not been established. Testosterone levels are elevated during AI therapy, and erythrocytosis has been observed in pubertal boys treated with AIs and in men with aromatase deficiency. Theoretical risks include a decline in adiponectin and subsequent development of nonalcoholic hepatic steatosis. Letrozole has no apparent adverse effects on bone mineral density in adolescents. However, estrogen deficiency and letrozole treatment have been associated with impaired trabecular bone development in boys with ISS, and letrozole treatment during prepuberty or early puberty has also been associated with increased risk of vertebral body deformities.[195] Thus, the use of aromatase inhibitors, even in adolescents with compromised predicted adult height, requires further careful study.[284]

In boys with permanent hypogonadism, the initial sex steroid therapy is the same as for CDGP. The difference is that testosterone doses are gradually increased to full adult replacement levels over approximately 3 years (see Table 17-4). During the last year of dose escalation, the interval is decreased from once each month to once every 2 weeks with a typical regimen for adult replacement being 200 mg every 2 weeks. Transdermal preparations can be initiated during the final stages of dose escalation, if preferred. In hypogonadotropic hypogonadism, exogenous testosterone does not induce testicular growth or spermatogenesis. Thus, if male patients with permanent hypogonadotropic hypogonadism wish to father a child or achieve increased testicular volume, gonadotropin therapy can be utilized; induction of testicular growth and fertility can be accomplished through treatment with exogenous gonadotropins[285] or, in hypothalamic disorders, pulsatile GnRH, if available, can be also be used[285-288] (see Table 17-4).

In some cases of hypergonadotropic hypogonadism, individuals may still be able to father children using assisted reproductive technologies, such as intracytoplasmic sperm injection (ICSI), although this technology may be associated with a small increased risk of birth defects.[289] In cases where ICSI is not desired or not feasible, in vitro fertilization using donor sperm and adoption provide additional options for those wanting to have children. As noted earlier, fertility preservation is an important topic for boys with Klinefelter syndrome and malignancies.

TESTOSTERONE: THE HYPOGONADAL MALE ATHLETE AND THE INDIVIDUAL WITH A DSD

Treating the competitive athlete with hypogonadism or a DSD is a potentially problematic issue. Studies by Bhasin and colleagues provided experimental evidence confirming that exogenous testosterone improved athletic performance.[290] These studies ultimately led to a ban on the use of exogenous testosterone in Olympic competition. The World Anti-Doping Agency (WADA) currently maintains a list of substances banned for use by competitive athletes.

Yet it is essential to replace testosterone in the hypogonadal male. The complete ban on testosterone

does make an exception for men with definitive diagnoses of primary gonadal failure and hypogonadotropic hypogonadism. Potential concerns include wrongly accusing an athlete of doping and abuse of testosterone treatment by athletes. Hence, maintaining normal testosterone concentrations is essential for the hypogonadal male athlete.[291]

To prevent men from competing as women, obligatory gender verification testing was conducted from the 1960s until 1999. Such testing confounded the situation, had a negative impact on participation in competitive sports, and exposed some individuals to public humiliation.[292]

CONCLUSION

The pubertal process begins during gestation with the differentiation and development of the components of the hypothalamic-pituitary-gonadal axis. The tools of molecular biology and molecular genetics have repositioned a relatively stagnant conundrum regarding the factors governing the timing and tempo of puberty to the forefront of reproductive endocrinology. The identification of novel genes associated with pubertal disorders has generated more questions regarding the elusive critical components governing GnRH and gonadotropin secretion. Additional new discoveries about HPG axis regulation will further enhance our understanding of normal variation in pubertal timing and provide further insight into the etiology and treatment of pubertal disorders.

QUESTIONS

1. Genetic defects have been identified that cause many cases of all *except* which of the following conditions?
   a. Kallmann syndrome
   b. Constitutional delay of growth and maturation
   c. Isolated hypogonadotropic hypogonadism
   d. McCune-Albright syndrome
   e. Familial male limited precocious puberty

Answer: b

2. The traditional definition of delayed puberty in a boy includes which of the following?
   a. Lack of testicular enlargement by age 13 years
   b. Lack of pubic hair by age 14 years
   c. Lack of testicular enlargement by age 14 years
   d. Lack of pubic hair by age 13 years

Answer: c

3. Among patients seen in pediatric endocrinology clinics, which of the following is true?
   a. Idiopathic central precocious puberty is more common among boys and constitutional delay of growth and puberty is more common among girls.
   b. Idiopathic central precocious puberty is more common among girls and constitutional delay of growth and puberty is more common among boys.

Answer: b

4. GnRH dependence underlies which of the following?
   a. Testicular tumor producing large amounts of testosterone
   b. Adrenal tumor producing large amounts of androgens
   c. Idiopathic central precocious puberty
   d. All of the above

Answer: c

5. Obesity has been associated with earlier onset of puberty in girls. In boys,
   a. The same relationship exists.
   b. There is no relationship between overweight/obesity and pubertal timing.
   c. The relationship between overweight/obesity and onset of puberty is not clear.

Answer: c

6. The decision to treat idiopathic central precocious puberty is based on which of the following considerations?
   a. Preserving growth potential and optimizing adult height
   b. Mitigating psychosocial distress associated with early development
   c. Both
   d. Neither

Answer: c

CHAPTER 18

Disorders of Mineral Homeostasis in Children and Adolescents

Allen W. Root, MD • Frank B. Diamond, Jr., MD

CHAPTER OUTLINE

Disorders of calcium, magnesium, and phosphate metabolism and of bone formation, accrual, and maintenance during the first two decades of life result from suboptimal ingestion, absorption, or retention of constituent nutrients, abnormal vitamin D metabolism or bioactivity, disorders of parathyroid hormone (PTH) synthesis, secretion, or action, and intrinsic aberrations in cartilage and bone cells. The origins of these illnesses may be intrinsic due to pathologic variations in the genes controlling these processes or to acquired insults (Table 18-1). For an integrated overview of calcium, mineral, and skeletal homeostasis and changes in this system through the life cycle, see Chapter 8.

HYPOCALCEMIA

Hypocalcemia in the Neonate and Infant

Clinical manifestations of hypocalcemia occurring in the neonate—defined as values of total calcium < 7.5 to 8 mg/dL and ionized calcium (Ca^{2+}) < 4.4 mg/dL (1.1 mmol/L) in newborns with birth weights > 1500 g and < 7 mg/dL and Ca^{2+} < 3.6 mg/dL (0.9 mmol/L) in newborns with birth weights < 1500 g—are principally those of neuromuscular hyperexcitability: irritability, hyperacusis, jitteriness, tremulousness, facial spasms, tetany, laryngospasm, and focal or generalized seizures.[1,2] Nonspecific symptoms such as apnea, tachycardia, cyanosis, emesis, and feeding problems may also occur. Causes of neonatal hypocalcemia may be considered in relation to the age of onset (before or after 72 hours of life) (Table 18-2).

Early Neonatal Hypocalcemia

In the absence of hypoproteinemia, hypocalcemia occurring within the first 72 hours after birth is considered "early neonatal hypocalcemia." It occurs most commonly in prematurely delivered or small-for-gestational-age, low-birth-weight, or asphyxiated neonates, or in those born to women with gestational or permanent forms of diabetes mellitus, and it is the consequence of impaired PTH secretion and delayed renal tubular phosphaturic response to PTH characteristic of the neonate, prolonged secretion of calcitonin, or hypomagnesemia.[2] Total calcium and Ca^{2+} concentrations decline more rapidly from high intrauterine values to lower nadir levels in preterm than in term neonates. In low-birth-weight (LBW) neonates, hypocalcemia may be further attributed to the rapid accretion of skeletal calcium in the presence of relative resistance to the calcium absorptive and reabsorptive effects of calcitriol on the intestinal tract and bone, respectively. Offspring of severely vitamin D–deficient mothers may become hypocalcemic shortly after birth. Hypocalcemia develops in approximately one third of asphyxiated newborns

who are products of complicated and compromised deliveries. In these infants, increased phosphate load due to cellular injury, reduced calcium intake, and hypercalcitonemia are important pathogenetic factors in the development of hypocalcemia. Neonates with severe infections (sepsis) or other critical illness are often hypocalcemic.

Fifty percent of infants of mothers with diabetes mellitus develop early neonatal hypocalcemia; the incidence may be reduced by strict maternal glycemic control.[3] Its causes are multifactorial and include reduced placental transfer of calcium due to substantial maternal urinary excretion of calcium and magnesium, decreased neonatal secretion of PTH, hypercalcitonemia, hypomagnesemia (occurring in 40% of offspring of diabetic women), and limited intake and impaired absorption of ingested calcium.[4] Maternal hypercalcemia due to unsuspected hyperparathyroidism leads to increased transfer of calcium to the fetus and still further increase in the in utero serum calcium concentrations that suppress fetal PTH synthesis and release and stimulate calcitonin secretion, aberrations in homeostatic mechanisms that persist postpartum and may result in hypocalcemic tetany/seizures in offspring. Suppression of PTH secretion may persist for several months and be undetected until symptomatic hypocalcemia develops after weaning of the infant from breast milk to higher phosphate containing cow milk formula. Maternal ingestion of large quantities of calcium carbonate in antacids has also led to neonatal hypocalcemia.[5]

Hypocalcemia has occurred in neonates with hyperbilirubinemia undergoing exchange transfusion due to complexing of calcium by citrate used to store blood and avoid clotting, and in those exposed to phototherapy. Neonates with acute rotavirus infection and severe diarrhea may present with hypocalcemic seizures. Aminoglycoside antibiotics (e.g., gentamycin) increase urinary excretion of calcium and magnesium, thereby facilitating the development of neonatal hypocalcemia. Compounds that complex with and sequester calcium such as citrate (present in transfused blood), phosphates (that alter the calcium × phosphate product), and fatty acids (given as caloric supplements) lower Ca^{2+} levels. Bicarbonate administered to correct acidosis increases calcium binding to albumin and thus lowers Ca^{2+} values. Hypocalcemia may also occur in hyperventilated infants with severe respiratory alkalosis as well as in those with other causes of metabolic alkalosis. Phytates in soy milk bind calcium and phosphate and interfere with their absorption. Neonates and infants with malignant osteopetrosis type II and impaired osteoclastogenesis may present with either early or late neonatal hypocalcemia.[6-8]

Late Neonatal Hypocalcemia

Hypocalcemia developing after 72 hours of postnatal age may be due to an increased intake of phosphate, hypomagnesemia, hypoparathyroidism, or vitamin D deficiency (see Tables 18-2A and B). Often neonatal hypocalcemia develops after 3 days of age in offspring born in the late winter-early spring of the year to multiparous women of lower socioeconomic status with an inadequate intake of vitamin D or exposure to sunlight. Ingestion of excessive phosphate in evaporated milk or modified cow milk formulas forms poorly soluble calcium salts,

TABLE 18-2A Causes of Hypocalcemia

I Neonatal

A Maternal Disorders

1 Diabetes mellitus
2 Toxemia of pregnancy
3 Vitamin D deficiency
4 High intake of alkali or magnesium sulfate
5 Use of anticonvulsants
6 Hyperparathyroidism

B Neonatal Disorders

1 Low birth weight: prematurity, intrauterine growth restriction
2 Peripartum asphyxia, sepsis, critical illness
3 Hyperbilirubinemia, phototherapy, exchange transfusion
4 Hypomagnesemia, hypermagnesemia
5 Acute/chronic renal failure
6 Nutrients/medications: high phosphate intake, fatty acids, phytates, bicarbonate infusion, citrated blood, anticonvulsants, aminoglycosides
7 Hypoparathyroidism
8 Vitamin D deficiency or resistance
9 Osteopetrosis type II

II Hypoparathyroidism

A Congenital

1 Transient neonatal
2 Congenital hypoparathyroidism (see also Table 18-2B)
  a Familial isolated hypoparathyroidism
    (1) Autosomal recessive hypoparathyroidism (*GCMB*, *PTH*)
    (2) Autosomal dominant hypoparathyroidism (*CASR*)
    (3) X-linked hypoparathyroidism (*SOX3*)
  b DiGeorge syndrome (*TBX1*)
  c Sanjad-Sakati syndrome (short stature, retardation, dysmorphism; HRD)
    Kenny-Caffey syndrome 1 (short stature, medullary stenosis) (*TBCE*)
  d Barakat syndrome (sensorineural deafness, renal dysplasia; HDR) (*GATA3*)
  e Lymphedema-hypoparathyroidism-nephropathy, nerve deafness
  f Mitochondrial fatty acid disorders (Kearns-Sayre, Pearson, mitochondrial encephalopathy, lactic acidosis, stroke-like [MELAS])
3 Insensitivity to parathyroid hormone
  a Blomstrand chondrodysplasia (*PTHR1*)
  b Pseudohypoparathyroidism type IA (*GNAS*)
    Pseudohypoparathyroidism type IB
    Pseudohypoparathyroidism type IC
    Pseudohypoparathyroidism type II
    Pseudopseudohypoparathyroidism
  c Acrodysostosis with hormone resistance (*PRKAR1A*)
  d Hypomagnesemia (see Tables 18-7A and B)

B Acquired

1 Autoimmune polyglandular syndrome type I (*AIRE*)
2 Activating antibodies to the calcium sensing receptor
3 Post surgical, radiation destruction
4 Infiltrative—excessive iron (hemochromatosis, thalassemia) or copper (Wilson disease) deposition; granulomatous inflammation, neoplastic invasion; amyloidosis, sarcoidosis
5 Maternal hyperparathyroidism
6 Hypomagnesemia/hypermagnesemia

III Vitamin D Deficiency

IV Other Causes of Hypocalcemia

A Calcium Deficiency

1 Nutritional deprivation
2 Hypercalciuria

B Disorders of Magnesium Homeostasis (see Tables 18-7A and B)

1 Congenital hypomagnesemia
2 Acquired
  a Acute renal failure
  b Chronic inflammatory bowel disease, intestinal resection
  c Diuretics

C Hyperphosphatemia

1 Renal failure
2 Phosphate administration (intravenous, oral, rectal)
3 Tumor cell lysis
4 Muscle injuries (crush, rhabdomyolysis)

D Miscellaneous

1 Hypoproteinemia
2 Hyperventilation
3 Drugs: furosemide, bisphosphonates calcitonin, anticonvulsants, ketoconazole, antineoplastic agents (plicamycin, asparaginase, cisplatinum, cytosine arabinoside, doxorubicin), citrated blood products
4 Hungry bone syndrome
5 Acute and critical illness: sepsis, acute pancreatitis, toxic shock
  a Organic acidemia: propionic, methylmalonic, isovaleric

TABLE 18-2B **Gene Mutations Associated with Hypoparathyroidism**

Disorder	MIM	Gene(s)	Chromosome MIM	Pathophysiology	Inheritance
Familial isolated hypoparathyroidism	146200	*GCM2*: Glial cells missing, Drosophila, homologue of, 2	6p24.2 603716	Transcription factor essential for parathyroid gland development	AR, AD
		PTH: Parathyroid hormone	11p15.2 168450	Peptide that increases serum Ca^{2+} concentration	AR, AD
		CASR: Calcium sensing receptor	3q21.1 601199	GPCR that monitors ambient Ca^{2+} concentration	AD
Familial isolated hypoparathyroioidism	307700	(*SOX3*: SRY box 3)	Xq26-27 (Xq27.1 313430)	Factor(s) expressed in the developing parathyroid gland	X-linked recessive
DiGeorge syndrome 1 (chromosome 22q 11.2 deletion syndrome)	188400	Continuous gene deletion disorder or mutation in *TBX1*: T-box 1	22q11.21 602054	TBX1: Transcription factor that regulates *GCM2* expression	AD, Sporadic
DiGeorge syndrome 2	601362	Deletion of 10p	10p14-p13		
Chromosome 22q11.2 duplication syndrome	608363	Microduplication involving the same interval deleted in DiGeorge syndrome 1	22q11.2		AD
Barakat syndrome (HDR)	146255	*GATA3*: GATA binding protein 3	10p14 131320	Transcription factor that regulates expression of *GCM2* and development of otic vesicles and kidneys	AD, AR
Sanjad-Sakati syndrome (HRD)	241410	*TBCE:* Tubulin-specific chaperone E	1q42.3 604934	Chaperone protein necessary for formation of the cytoskeleton, protein transport and secretion	AR
Kenny-Caffey syndrome 1 (KCS1)	244460	*TBCE*: Tubulin-specific chaperone E	1q42.3 604934	Chaperone protein necessary for formation of the cytoskeleton, protein transport, and secretion	AR
Kenny-Caffey syndrome 2 (KCS2)	127000	*FAM111A*: Family with early seqence similarity 111	615292	Restriction factor	AD
Kearns-Sayre syndrome	530000	*ATP8*: ATP synthase 8	516070	Mitochondrial gene	Transmitted primarily by females
		MTTL1: Transfer RNA, mitochondrial leucine, 1	590050	Mitochondrial gene	
		RRM2B: Ribonucleotide reductase, M2 B	8p22.3 604712	Enzyme essential for mitochondrial DNA synthesis	AR

Mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes (MELAS)	540000	*MTTKL*: Transfer RNA, mitochondrial, lysine	590060	Mitochondrial genes	Transmitted primarily by females
		MTTQ: Transfer RNA, mitochondrial, glutamine	590030		
Pearson marrow-pancreas syndrome	557000	Continuous gene deletion/duplication syndrome involving several mtDNA genes		Mitochondrial genes	Transmitted primarily by females
Blomstrand chondrodysplasia	215045	*PTH1R*: Parathyroid hormone 1 receptor	3p21.31 168468	GPCR for parathyroid hormone	AR
Pseudohypoparathyroidism type IA	103580	*GNAS*: GNAS complex locus	20q13.32 139320	Gsα transmits ligand-bound GPCR stimulus to adenylyl cyclase	AD
Pseudohypoparathyroidism type IB	603233	*GNAS*: GNAS complex locus	20q13.32 139320	Gsα transmits ligand-bound GPCR stimulus to adenylyl cyclase	AD
		STX16: Syntaxin 16	20q13.32 603666	Regulates epigenetic control of *GNAS* expression	AD
Pseudohypoparathyroidism type IC	612462	*GNAS*: GNAS complex locus	20q13.32 139320	Gsα transmits ligand-bound GPCR stimulus to adenylyl cyclase	AD
Progressive osseous heteroplasia	1166350	*GNAS*: GNAS complex locus	20q13.32 139320	Gsα transmits ligand-bound GPCR stimulus to adenylyl cyclase	AD
Pseudohypoparathyroidism type II	203330			Biochemical lesion distal to generation of cyclic AMP	
Acrodysostosis	101800	*PRKAR1A*: Protein kinase, cAMP-dependent, regulatory, type I, alpha	17q24.2 188830	Regulatory alpha subunit of protein kinase A controls peripheral cyclic AMP response to PTH and TSH	AD
Autoimmune polyglandular syndrome type 1 (APS1)	240300	*AIRE*: Autoimmune regulator	21q22.3 607358	Transcription factor expressed in medulla of thymus that enables differentiation of self- from foreign antigens	AD
Immunodysregulation, polyendocrinopathy and enteropathy	304790	*FOXP3*: Forkhead box P3	Xp11.23 300292	Transcription factor essential for normal development of naturally occurring T regulatory cells	X-linked recessive

GPCR, G protein–coupled receptor; AD, autosomal dominant; AR, autosomal recessive.

limiting the intestinal absorption of calcium while raising serum phosphate values. Premature introduction of fiber-containing cereals into the infant's diet also decreases calcium absorption. Affected infants may have an associated defect in renal phosphate excretion or coexisting vitamin D deficiency. Hyperphosphatemia and hypocalcemia may initially suggest hypoparathyroidism, but serum PTH concentrations are high in infants with excessive phosphate loading in response to a reciprocal reduction in serum calcium values. Newborns and infants with chronic renal insufficiency due to renal hypoplasia or obstructive nephropathies often are hypocalcemic and hyperphosphatemic with elevated serum PTH levels as well, but they are also azotemic. Hypomagnesemia leads to impaired secretion of PTH and decreased peripheral responsiveness to PTH and may be transient or related to congenital abnormalities of intestinal absorption or renal tubular reabsorption of magnesium.[3] Hypermagnesemia may occasionally be associated with neonatal hypocalcemia.

Hypocalcemia due to fetal/neonatal deficiency of vitamin D occurs in offspring of mothers deprived of vitamin D (either for cultural or socioeconomic reasons); impaired renal 25-hydroxyvitamin D-1α hydroxylase activity or loss-of-function mutations of the vitamin D receptor also lead to hypocalcemia (and hypophosphatemia). Hypovitaminosis D may develop in the breastfed infant of a vegetarian mother who shields herself from sunlight and ingests a diet low in vitamin D. Marginal deficiency of vitamin D in neonates and infants is much more common than has been recognized heretofore.[9-12] "Late-late" neonatal hypocalcemia occurs in premature infants with osteopenia at 3 to 4 months of age in whom the intake of calcium, phosphate, and vitamin D has been marginal; it is perhaps due to an avid deposition of available calcium into bone.[3] Hypocalcemia due to vitamin D deficiency may develop rather acutely and in the absence of clinical or radiographic signs of rickets in the older infant or young child who has ingested an elimination diet low in vitamin D because of severe allergies or who has been maintained indoors with limited exposure to sunlight.

Hypoparathyroidism

Hypoparathyroidism presenting in infancy is often transient and related to delayed developmental maturation of parathyroid gland function; it frequently resolves within the first several weeks of life (see Tables 18-2A and B). When prolonged, hypoparathyroidism is often due to an error in the embryogenesis of the parathyroid glands or in the synthesis or secretion of parathyroid hormone (PTH) or to peripheral unresponsiveness to PTH. Familial isolated congenital hypoparathyroidism may be transmitted as an autosomal recessive, autosomal dominant, or X-linked recessive trait that has been associated with loss-of-function mutations of *GCM2* and *PTH* and possibly *SOX3*, respectively, and gain-of-function mutations in *CASR*. *GCM2* is a gene with five exons that encodes a 506-amino-acid DNA-binding transcription factor whose expression is restricted to the parathyroid glands. "Knockout" of *Gcm2* in mice leads to agenesis of the parathyroid glands and hypoparathyroidism. Intragenic deletions or homozygous missense mutations in exons 2, 3, and 5 of *GCM2* result in hypoparathyroidism in humans.[13-17] Mutations in *GCM2* exons 2 and 3 (encoding DNA binding and transactivation domain 1) lead to impaired protein synthesis and stability and autosomal recessive transmission of congenital hypoparathyroidism, whereas those in exon 5 (encoding transactivation domain 2) lead to mutations with a dominant negative effect and autosomal dominant transmission of this disorder.[17] (Expression of *GCM2* is dependent on normal transcriptional function of *GATA3*, the gene mutated in patients with the Barakat syndrome of hypoparathyroidism-deafness-renal dysplasia [HDR].[18]) Inactivating mutations in *PTH* that interfere with the processing of preproPTH to active PTH result in functional hypoparathyroidism that may be transmitted as an autosomal dominant or recessive characteristic.[15] Depending on the specificity of the immunoassay for PTH, serum levels of PTH may be low, normal, or even high in these patients. Hypoparathyroidism due to heterozygous activating mutations in *CASR* have been found in hypocalcemic neonates.[19] X-linked hypoparathyroidism is associated with agenesis of the parathyroid glands; the disorder has been mapped to Xq26-q27 and may involve a deletion-insertion mutation that adversely affects the position of *SOX3*.[20] Because *Sox3* is expressed in embryonic mouse parathyroid glands, it is likely an important transcription factor for normal embryologic development of these structures.

Hypercalciuric hypocalcemia is an autosomal dominantly transmitted form of hypoparathyroidism that is due to gain-of-function mutations in *CASR* that result in enhanced "sensitivity" to Ca^{2+}. A lowered "set point" enables PTH secretion to be suppressed and renal tubular reabsorption of calcium to be depressed by extremely low concentrations of Ca^{2+}; this disorder may present in the newborn period.[19,21] Mutations may be scattered throughout the gene but occur predominantly in the extracellular domain of the CaSR. Activating mutations (Cys141Trp) of *CASR* may also inhibit function of the renal outer medullary potassium channel (*KCNJ1*, MIM 600359), leading to a Bartter-like syndrome with hypokalemic metabolic alkalosis, hyperreninemia, and hyperaldosteronism as well as hypercalciuric hypocalcemia; the paired metabolic defects are partially responsive to treatment with hydrochlorothiazide and low doses of calcitriol.[22] Children with hypercalciuric hypocalcemia due to gain-of-function mutations in *CASR* are very sensitive to even low doses of calcitriol that can lead to even more marked hypercalciuria and to nephrocalcinosis. Thus, management of these patients has been quite difficult. Administration of recombinant human PTH[1-34] to a 14-month-old hypocalcemic male infant with a de novo nonsense mutation in *CASR* (Leu727Gln) for 17 months partially restored calcium homeostasis with increased but still subnormal serum levels of calcium, whereas urinary excretion of calcium decreased into the normal range.[19] During treatment the child was clinically asymptomatic, did not develop nephrocalcinosis, and tolerated the drug well. Long-term treatment of

children with activating mutations of *CASR* may be feasible.[23,24]

The most common form of dysgenesis of the parathyroid glands in neonates and infants is that associated with the DiGeorge syndrome (DGS), a disorder that occurs with a frequency of 1:4000 births and is present in approximately 70% of children with isolated hypoparathyroidism.[25,26] The DGS is a neurocristopathy that results from the disturbed migration of cervical neural crest cells and consequent maldevelopment of tissues of neural crest origin derived from the third and fourth pharyngeal pouches and first to fifth branchial arches. It is usually associated with microdeletions of chromosome region 22qll.2 (del22q11.2: DGCR), a segment on which more than 35 genes are sited and thus considered a contiguous gene syndrome (a disorder caused by deletion of several adjacent genes that when individually mutated may result in a distinctive clinical feature but when collectively lost lead to a group of apparently unrelated clinical findings). The chromosome 22q11.2 microdeletion is contained within regions of low copy number repeats, and it is this characteristic that results in an unequal segmental exchange between the paired 22nd chromosomes during meiosis.[26] DGS may occur sporadically or be transmitted as an autosomal dominant trait. Although the clinical severity and phenotype of patients with this chromosomal anomaly are variable, characteristically subjects with DGS have the triad of hypocalcemia due to hypoplasia of the parathyroid glands often manifest in the neonatal period but which may not be detected until the child reaches an older age, defective T-lymphocyte function and impaired cell-mediated immunity due to partial or complete absence of thymic differentiation leading to increased frequency of viral and fungal infections, and conotruncal defects of the heart or aortic arch (tetralogy of Fallot, ventricular septal defect, interrupted or right aortic arch, truncus arteriosus, vascular ring).[3,26,27] Immune deficiency is common as are velopharyngeal insufficiency, cleft palate, and developmental challenges.[26] Other features of the DGS include gastrointestinal malformations (esophageal atresia, anal atresia), dysplastic kidneys, cervical spine instability, impaired vision, and ocular malformations.

In addition to the DGS, deletion of chromosome 22q11.2 has been associated with the conotruncal anomaly face and velocardiofacial syndromes. Collectively, these syndromes are associated with similar facial features (ocular hypertelorism, lateral displacement of inner canthi, short palpebral fissures, swollen eyelids, dysmorphic "segmented" nose, small mouth, low-set ears with abnormally folded pinnae, short philtrum, micrognathia, malar hypoplasia, velopharyngeal insufficiency with/without cleft palate), olfactory dysfunction, short stature, nonverbal learning disabilities, and various psychological maladies.[25,28] Takao velocardiofacial syndrome (included in MIM 188440) consists primarily of the typical cardiac defects described earlier that may also be associated with hypocalcemia; Shprintzen velocardiofacial syndrome (MIM 192430) is characterized by craniofacial and palatal defects and cardiac anomalies; Cayler cardiofacial syndrome (MIM 125520) is associated with partial unilateral facial paresis due to hypoplasia of the depressor anguli oris muscle and anomalies of the heart and aorta. These syndromes have been grouped as the CATCH-22 syndromes of *C*ardiac defects, *A*bnormal face, *T*hymic hypoplasia, *C*left palate, *H*ypocalcemia. In addition to the anomalies and clinical findings listed, a litany of additional abnormalities may be seen in patients with del22q11.2.[29] Disparate manifestations of these syndromes may be observed in different members of the same family, indicating the variable clinical expressions that accompany deletions of chromosome 22q11.2.[30]

A two-megabase microdeletion at chromosome 22q11.2 leads to loss of several contiguous genes within this region including *HIRA* (histone cell cycle regulation, MIM 600237), a transcription factor that is expressed in developing heart and upper body neural crest elements and is necessary for normal cardiac development. Also within this region is *TBX1* encoding T-box 1, a transcription factor with a highly conserved DNA binding sequence (the T-box) that is essential for organogenesis and pattern formation and is expressed in the pharyngeal arches and pouches. Experimental disruption of *Tbx1* impairs development of the pharyngeal arch arterial vasculature, whereas introduction of null mutations in *Tbx1* results in anomalies of the cardiac outflow track and hypoplasia of the thymus and parathyroid glands. The transcription factor encoded by *TBX1* is part of a network of gene products (including those encoded by *ISL1*, *SHH*, *FOXA2*, *FOXC2*) that controls development of the parathyroid glands and thymus by regulating expression of *GATA3*, *GCM2* and *PAX9*.[26] Evaluation of patients with clinical characteristics of the CATCH-22 syndromes but intact chromosome 22q11.2 has revealed heterozygous loss-of-function mutations (Phe148Tyr, Gly310Ser) in *TBX1* in patients with the DGS and Shprintzen velocardiofacial syndrome.[25,31] Thus, haploinsufficiency of *TBX1* alone can account for the cardiac defects, abnormal face, thymic and parathyroid hypoplasia, and velopharyngeal insufficiency with cleft palate but not for the developmental delay characteristic of CATCH-22. Another candidate gene for the DGS sited at chromosome 22q11.2 is *UFD1L* (ubiquitin fusion degradation 1-like, MIM 601754), whose product is important for the posttranslational processing of proteins or their degradation by interaction with the ubiquitin fusion protein. Experimentally, the DGS and related disorders have also been linked to genes encoding endothelin-1, vascular endothelial growth factor, and fibroblast growth factor-8 (a target gene for *TBX1*), and to genes within the DGCR at chromosome 22q11.2—*CRKL*—(MIM 602007) and *DGCR6* (MIM 601279). In the mouse hypomorphic for *Fgf8*, there are cardiovascular, craniofacial, parathyroid, and thymic defects—an experimental phenocopy of the human del22q11.2 syndrome.[32] Fgf8 functions through stimulation of transcription of *Crkl*—its product is an adaptor protein that transduces intracellular signals from several tyrosine kinase receptors, one of which is the receptor for Fgf8; interestingly, Fgf8 interacts with Tbx1 as well. The DGS has also been associated with microdeletions of chromosomes 10p13 (DGS2), 18q21.33, and 4q21.2-q25, indicative of the cascade of genes likely involved in the generation of this phenotype. The presence of the DGS should be considered when fetal

ultrasonography reveals an interrupted aortic arch or truncus arteriosus and may be confirmed by appropriate studies (microarray, fluorescent in situ hybridization [FISH]) on samples of chorionic villi or amniotic fluid.

Hypocalcemia has been observed in some subjects with microduplication of chromosome 22q11.2, a copy number variant; clinical characteristics of individuals with this genetic anomaly vary from those who are entirely normal to patients with multiple congenital anomalies, severe developmental delay, autism, and schizophrenia.[33,34] The duplication chromosome 22q11.2 syndrome appears to be transmitted as an autosomal-dominant characteristic whose expression is modified by other factors. The pathophysiology of hypocalcemia in affected subjects is uncertain. In one family in which the proband had the DGS associated with del22q11.2, the normal father had the same anomaly on one of his 22nd chromosomes and dup22q11.2 on his other 22nd chromosome; paternal quantitative expression of the genes located on chromosome 22q11.2 was normal, indicating that the adverse effects of the 22q11.2 deletion were compensated by the 22q11.2 duplication.[35]

Several other syndromes exhibit multisystem involvement and hypoparathyroidism. The Barakat or HDR syndrome of *H*ypoparathyroidism, sensorineural *D*eafness, and *R*enal disease (dysplasia, steroid-resistant nephrosis with progressive renal failure) has been attributed to haploinsufficiency of *GATA3*, a zinc-finger transcription factor that regulates expression of *GCM2* and thus is critical for the embryonic development of the parathyroid glands as well as for the kidneys, otic vesicles, and thymus.[15,18,36] The parathyroid glands of these children are dysgenetic—hypoplastic or absent. Hypocalcemia may be present in the newborn period or unrecognized until later childhood. Malformations of the female genital tract (didelphic uterus, septate vagina) may also occur in patients with HDR.[37] Heterozygous deletions, insertions, missense, and nonsense mutations in *GATA3* have been identified in patients and families with HDR.[38,39] Patients with an isolated loss of *GATA3* function do not have other features common to patients with larger terminal deletions of chromosome 10p such as growth and developmental retardation, dysmorphic facial features, or congenital heart disease.

Biallelic mutations in the gene encoding tubulin-specific chaperone E (*TBCE*) have been identified in the Sanjad-Sakati syndrome of *H*ypoparathyroidism-mental *R*etardation-*D*ysmorphism (HRD) and the Kenny-Caffey syndrome type 1 (KCS1) of hypocalcemia, cortical thickening, medullary stenosis, dysmorphic face, and growth retardation. Children with HRD are short, developmentally delayed, and seizure prone; they have medullary stenosis and other skeletal anomalies; they are microcephalic with faces characterized by deeply recessed eyes or microphthalmia, depressed nasal bridge, beaked nose, long philtrum, thin upper vermillion border, micrognathia, and large earlobes. The HRD syndrome often presents in infancy with symptomatic hypocalcemia associated with low serum concentrations of PTH and normal phosphaturic responses to exogenous PTH. The cardiovascular system of these patients is intact, but as infants they are susceptible to life-threatening pneumococcal infections.[40] Neonates with the closely related disorder KCS1 are often severely hypocalcemic early in the neonatal period. As children they are short, with craniofacial anomalies due to the absence of diploic space in the skull, osteosclerosis, and thickening of the cortices of the long bones with narrowing of the medullary compartment, normal or mildly delayed development, and increased susceptible to recurrent bacterial infections. TBCE is essential for formation of microtubules—cytosolic structures composed of heterodimeric α- and β-tubulin subunits that form the cytoskeleton, mitotic apparatus, cilia, and other cellular components; this chaperonin assists in the correct folding of α- and β-tubulin subunits and the formation of α-β-tubulin heterodimers. The α- and β-tubulin subunits and TBCE are necessary for normal embryogenesis of the parathyroid glands. Mutations in *TBCE* result in lowered microtubule formation and consequently in a decrease in subcellular components such as the Golgi apparatus and endosomal compartments required for normal intracellular movement of proteins. Interestingly, the identical mutation in *TBCE*—a homozygous 12 bp deletion in exon 2—may result in either the HRD or KCS1 phenotype in a specific family.[41] A child with autosomal recessive HRD syndrome and intact TBCE has been identified, suggesting that this disorder is likely to be genetically heterogeneous.[42] In KCS type 2, the phenotype is similar to that of KCS1 but transmission is as an autosomal dominant trait attributable to heterozygous loss-of-function mutations in *FAM111A* (MIM 615292).

Neonates with loss-of-function mutations in *PTH1R*, the gene encoding the GPCR for PTH and PTHrP, are functionally hypoparathyroid despite elevated serum concentrations of PTH.[43] Because of subresponsiveness to PTHrP in utero, fetal bone formation is abnormal, resulting in Blomstrand chondrodysplasia—an osteochondrodystrophy characterized by short extremities and advanced skeletal and dental maturation—abnormalities detectable in utero by fetal ultrasonography. Histologically the proliferative zone of the cartilage growth plate is narrowed with relatively few resting and proliferating chondrocytes, whereas the hypertrophic zone is composed of irregular columns of chondrocytes. Transmitted as an autosomal recessive trait, its clinical characteristics include polyhydramnios, hydrops fetalis, short-limbed dwarfism, facial anomalies, aberrant tooth development, aplasia of the nipples and breasts, hypoplastic lungs, and preductal aortic coarctation. Although Blomstrand osteochondrodysplasia is usually lethal, skeletal malformations may be more (type I) or less severe (type II). Mutations in *PTH1R* that result in complete absence of normal protein (e.g., Arg104Ter) are designated type I, whereas mutations that permit some PTH1R synthesis (Pro132Leu) result in type II Blomstrand osteochondrodysplasia.[44] Heterozygous inactivating mutations of *PTH1R* (Glu155Ter) result in autosomal dominant nonsyndromic failure of tooth eruption (MIM 125350).[45] Eiken chondrodysplasia (MIM 60002) is also due to biallelic loss-of-function mutations in *PTH1R* but is clinically and radiographically distinct from Blomstrand osteochondrodysplasia as affected subjects have mild growth retardation, markedly delayed ossification,

multiple epiphyseal dysplasia, and persistent islands of cartilage in the pelvis.[46] The *PTH1R* mutations in patients with Eiken skeletal dysplasia occur in the carboxyl terminal (e.g., Arg485Ter).

GNAS encodes the stimulatory alpha subunit (Gαs) of G-proteins coupled to seven transmembrane receptors. After activation by its GPCR, the guanosine diphosphate (GDP) moiety on Gαs is replaced by guanosine triphosphate (GTP), Gαs dissociates from its βγ companion subunit complex, and stimulates membrane-bound adenylyl cyclase activity generating cyclic adenosine monophosphate (AMP) and activating protein kinase A, which phosphorylates serine and tyrosine residues of further signal transduction proteins. *GNAS* is composed of 13 exons; it has four major transcripts that arise through splicing of unique first exons onto shared exons 2 to 13 (Figure 18-1).[47] The four transcripts of *GNAS* encode (1) the Gαs transcript is a protein that stimulates adenylyl cyclase and generates cyclic AMP; Gαs is expressed by both maternal and paternal alleles in most tissues; in the proximal renal tubule, thyroid, gonads, and adenohypophysis, however, only the maternal allele of *GNAS* is expressed; (2) XLαs yields a Gαs isoform that is specifically expressed in neuroendocrine and nerve tissues and is identical to Gαs except that it has a very long amino terminal sequence of amino acids; it is expressed only by the paternally acquired allele; (3) the NESP55 (neuroendocrine secretory protein-55) transcript is a chromogranin-like protein that is expressed in neuroendocrine tissues but only by the maternal *GNAS* allele; (4) the alternative first exon A/B (exon 1A) transcript is expressed ubiquitously but only by the paternal GNAS allele and is not translated. The promoters of XLαs, NESP55, and exon 1A transcripts lie within the 5′ differentially methylated region (DMR) of *GNAS*. Methylation of the promoter usually silences expression of that GNAS transcript.

Loss-of-function mutations in *GNAS* or epigenetic aberrations that lead to failure of expression of the Gαs transcript of *GNAS* result in pseudohypoparathyroidism (PHP). PHP type IA is manifested by resistance to protein hormones that signal though GPCRs; resistance to PTH results in hypocalcemia, hyperphosphatemia, and elevated serum concentrations of PTH and impaired urinary excretion of cyclic AMP and phosphate after administration of exogenous PTH. (Resistance to thyroid-stimulating hormone, the gonadotropins, and growth hormone releasing hormone also occurs in patients with PHP IA. PHP IA may be suspected in the neonate with hypocalcemia in whom hyperthyrotropinemia has been detected in the neonatal screening study for congenital hypothyroidism.[48]) When maternally transmitted, PHP IA is coupled with the phenotype of Albright's hereditary osteodystrophy (AHO; short stature; brachydactyly of the 3rd, 4th, and 5th metacarpals; round face; and heterotopic intramembranous subcutaneous calcifications).[49] Although both maternal and paternal *GNAS* alleles are expressed in most tissues including bone, in renal tissue only the maternal *GNAS* allele is expressed. Thus, in renal tissue *GNAS* expression is "imprinted"—that is, there is differential gene expression depending on the parent of origin of the allele. Therefore, clinical manifestations of PHP IA in the affected patient depend on which parent donated the inactive *GNAS* allele. Loss-of-function mutations of the maternal *GNAS* allele result in PHP type IA with end-organ resistance to PTH and the skeletal defects of AHO. PHP IA patients have subnormal expression of Gsα in their erythrocytes. Inactivating mutations of paternal *GNAS* result in the abnormal AHO skeletal phenotype due to haploinsufficiency of *GNAS* expression in bone but intact proximal renal tubular responses to PTH where maternal GNAS is expressed; this clinical complex is designated pseudopseudohypoparathyroidism (PPHP). More than 80 heterozygous loss-of-function mutations in *GNAS* have been described. A four base pair deletion in exon 7 (codons 188 to 189) in *GNAS* that leads to a frameshift and premature stop codon has been found in a number of families with PHP IA and appears to be a "mutational hot spot" as it impairs DNA polymerization and replication. Other mutations alter intracellular movement of GNAS protein (Leu99Pro, Ser250Arg), increase the rate of release of GDP (Arg258Trp, Ala366Ser), or impair coupling of G-protein to PTH1R (Arg385His).

PHP type IB occurs only in the offspring of obligate female carriers in whom loss of maternal *GNAS* expression

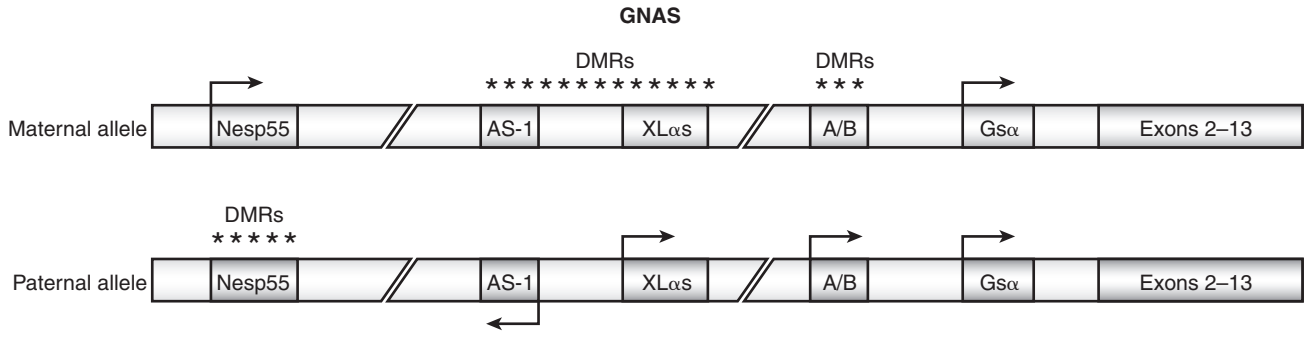

FIGURE 18-1 ■ Schematic view of the *GNAS* gene complex. Three alternate exons 1—NESP55, XLαs, and AS-1—are upstream of the start codon. DMR refers to the differentially methylated region. The pattern of methylation and hence the expression of the alternate exons is dependent on the parent of origin of the allele and the specific tissue in which *GNAS* is expressed. (From Shore, E. M., & Kaplan, F. S. (2010). Inherited human diseases of heterotopic bone formation. *Nat Rev Rheumatol, 6*, 518–527.)

is present in the renal proximal tubule, resulting in selective proximal renal tubular resistance to PTH; skeletal expression of both maternal and paternal *GNAS* is intact and hence bone formation is normal. In some patients, PHP type IB is due to deletions within the DMR (NESP55, XLas, or alternative first exons A/B) of *GNAS* or to loss of a 5′ cis-acting imprinting control center that is essential for methylation of the *GNAS* differentially methylated region that regulates expression of maternal *GNAS* in the proximal renal tubule.[47,49] Within the 5′ upstream region of *GNAS* is *STX16*, a gene that is partially deleted in some patients with PHP IB; mutations of this gene are associated with loss of methylation of *GNAS* exons A/B. Thus, defects in *STX16* and within the DMR of *GNAS* prevent expression of maternal *GNAS* in the proximal renal tubule. Paternal uniparental isodisomy of the long arm of chromosome 20 (site of *GNAS*) may be the cause of PHP IB in some patients. Patients with PHP IB are often resistant to thyroid-stimulating hormone (TSH) as well as to PTH.[49] The phenotype of subjects with PHP type Ic is similar to that of those with PHP IA including AHO, but these patients usually express normal quantities of functional Gsα in their erythrocytes; in some PHP Ic subjects, however, inactivating mutations in *GNAS* have been reported.[49] It must be remembered that there may be overlap in mechanisms that down-regulate expression of *GNAS* in various tissues and that PHP types 1 are heterogeneous in their genetic origins. Indeed, imprinting defects are present in patients with clinical manifestations of either PHP IA or PHP IB, indicating the pathogenetic overlap of these two disorders.[50] Despite elevated levels of PTH and radiographic evidence of bone responsiveness to PTH in patients with PHP IA, bone mineralization is normal in these subjects.[51] In patients with PHP type II, the skeletal phenotype is normal but patients are partially resistant to the renal effects of PTH; after administration of PTH, the urine excretion of cyclic AMP increases but that of phosphate does not; its pathogenesis is unknown as yet. Progressive osseous heteroplasia (MIM 166350) is an autosomal dominant disorder due to loss-of-function mutations in paternal *GNAS*, characterized by dermal ossifications, that begins in infancy and progresses to diffuse bone formation in skeletal muscle and deep fascia.[49,52,53] This disease may lie at one end of the spectrum of PPHP. Although not as yet clinically described, an inactivating mutation in *LRP6* (encoding lipoprotein receptor-related protein 6; MIM 603507) might also be associated with resistance to the biologic effect of PTH. In addition to its primary role in receptor-mediated endocytosis of lipoproteins, LRP6 is essential for the movement of Gαs to the plasma membrane and for its coupling to PTH1R.[54] Experimentally, in vitro "knockdown" or inactivating mutations of *Lrp6* decrease the cellular response to PTH.

Acrodysostosis is a chondrodysplasia with many features of PHP IA (short stature, obesity, brachydactyly, abnormal face with nasal and maxillary hypoplasia, advanced skeletal maturation) that is due to a mutation in *PRKAR1A*. This gene encodes the cyclic AMP–dependent regulatory alpha subunit of protein kinase A (PKA), the protein kinase that is downstream of Gαs and cyclic AMP and whose activation leads to cascades of intracellular signal transduction pathways that regulate cell division, differentiation, metabolism, and apoptosis. Paradoxically, prolonged activation of the regulatory alpha subunit of PKA results in a decline in the functional activity of the catalytic subunit of PKA. In a patient with acrodysostosis, a de novo germline gain-of-function mutation (Arg368Stop) in *PRKAR1A* was identified that led to functional resistance to PTH and TSH.[55] Mutant PRKAR1A was a shortened protein whose binding avidity to the catalytic subunit of PKA was increased because it lacked one of two cyclic AMP binding domains; hence, it could only be slowly released from the catalytic subunit of PKA by cyclic AMP, thereby maintaining the catalytic subunit of PKA in the inactive state.

Deletions and mutations of the (maternal) mitochondrial genome (composed of 16,569 base pairs) have been associated with hypoparathyroidism. Patients with the Kearns-Sayre syndrome manifest ophthalmoplegia, retinal pigmentation, and cardiomyopathy; muscle biopsy may reveal ragged red fibers. Hypoparathyroidism has been observed in patients with the syndromes of *M*itochondrial encephalopathy, *L*actic *A*cidosis, and *S*troke-like episodes (MELAS), *M*itochondrial *T*rifunctional *P*rotein *D*eficiency *S*yndrome (MTPDS, MIM 609015), and Pearson marrow-pancreas syndrome.[15,43,56] Point mutations, duplications, and deletions of various length of the mitochondrial genome have been found in these patients.

Evaluation and Management

Evaluation of the neonate with hypocalcemia begins with review of the maternal, gestational, peripartum, postnatal, and family histories and physical examination (Figure 18-2).[1-3] Historical data include those related to maternal parity and complications of pregnancy such as maternal diabetes mellitus (gestational, types I or II), toxemia of pregnancy or ingestion of agents that may cause maternal hypercalcemia (excessive alkali), intrauterine growth restriction, abnormalities of delivery, neonatal sepsis, or other early postpartum illnesses. The family history is examined for members with abnormalities of mineral metabolism such as renal calculi, rickets, or hypocalcemia (e.g., seizure disorders). The social history provides information about the socioeconomic status of the mother and her cultural milieu that may have impacted maternal diet and exposure to sunlight during gestation. Physical examination of the neonate (abnormal face, cardiac murmur) may suggest a complex form of hypocalcemia. Determination of a complete blood count, serum concentrations of total calcium, Ca^{2+}, magnesium, phosphate, creatinine, intact PTH, calcidiol, and calcitriol, and urinary calcium and creatinine concentrations in a spot urine should precede initial therapy of the hypocalcemic newborn whenever possible. Decreased serum concentrations of PTH are common in neonates with early onset hypocalcemia, but persistently low PTH levels suggest impaired PTH secretion. High PTH concentrations are present in patients with vitamin D deficiency or insensitivity, PTH resistance due to loss-of-function mutations in *PTH1R*, *GNAS*, or *PRKAR1A* or impaired renal function. Low levels of calcidiol signify decreased maternal (and hence fetal) vitamin D stores or

Hypoparathyroidism in the adult: epidemiology, diagnosis, pathophysiology, target-organ involvement, treatment, and challenges for future research. *J Bone Mineral Res, 26,* 2317–2337.)

rarely a defect in vitamin D-25 hydroxylase, whereas calcitriol concentrations are inappropriately low in subjects with severely compromised renal function, hypoparathyroidism, or those with a deficiency of 25OHD-1α-hydroxylase. Elevated calcitriol values suggest vitamin D resistance due to an abnormality in *VDR*, a disorder that may be associated with alopecia. Skeletal radiographs may disclose osteopenia, whereas chest x-ray may not identify a thymic shadow (although this is an unreliable sign in a severely ill or stressed neonate). Serum levels of calcium, Ca^{2+} phosphate, and intact PTH should be measured in the mothers of neonates with unexplained hypocalcemia.

In neonates with hypocalcemia not otherwise explained, evaluation for possible DGS should be undertaken, particularly when physical examination reveals an abnormal face, and a congenital anomaly of the outflow tract of the heart is present. The white blood and T (CD4) lymphocyte counts are low in DGS and the thymic shadow often absent. The diagnosis of the DGS is confirmed by the presence of a microdeletion of chromosome 22q11.2 as demonstrated by microarray or fluorescent in situ hybridization (FISH). Occasionally, sequence analysis of *TBX1* may be needed to establish this diagnosis, if the other studies are normal. Because the DGS may be heritable, examination of the karyotype of the parents of a DGS infant is indicated as well as those of the siblings if the parent also has deletion of chromosome 22q.11.21. It should be noted that the majority of neonates and infants with DGS are recognized primarily because of cardiac anomalies and that subjects without these lesions may not be identified until mid or late childhood or adolescence.[57] Neonates with PHP IA may present with elevated serum levels of TSH in the neonatal metabolic screening survey but usually do not have the characteristic skeletal phenotype (brachymetacarpals) of AHO; if no cause of congenital hypothyroidism is identified, the diagnosis of PHP IA should be suspected, and measurement of serum calcium levels and, if appropriate, genotyping and methylation studies of *GNAS* are indicated.[49]

Early neonatal hypocalcemia is often asymptomatic, but nevertheless treatment is indicated when the total serum calcium concentration is below 6 mg/dL in the preterm infant and less than 7 mg/dL in the term infant.[3] Asymptomatic neonates are most easily managed by increasing the oral intake of calcium and establishing an overall ratio of calcium:phosphate intake of 4:1 (including that in feedings with a low phosphate formula such as Similac PM 60/40^{R}—calcium:phosphate ratio 1.6:1) with calcium glubionate or calcium carbonate administered in divided doses every 4 to 6 hours (Table 18-3). Eucalcemia is almost always restored in these subjects within 3 weeks after birth and often earlier. In hypocalcemic infants with tetany or frank seizures, 10% calcium gluconate

TABLE 18-3 **Preparations of Vitamin D, Calcium, Magnesium, and Phosphate**

Content	Elemental Mineral	
Vitamin D		
Vitamin D		
Calciferol	8000 IU/mL	
	50,000 IU/capsule	
Calcidiol	20 or 50 μg/tablet	
Calcitriol		
Rocaltrol	1 μg/mL (oral solution)	
	0.25 μg or 0.5 μg/capsule	
Vectical	3 μg/g (ointment)	
Dihydrotachysterol		
Hytacherol	0.2 mg/5 mL 0.125, 0.2, 0.4 mg/tablet	
Calcium		
Calcium acetate		
Phoslyra	667 mg/5 mL	667 mg/capsule
Calcium gluconate (iv)	93 mg/10 mL	93 mg/g
	500, 650 mg/tablet	
Calcium glubionate (solution)	64 mg/g	115 mg/5 mL
Calcium carbonate	400 mg/g	500, 600, 750, 1250 mg/ tablet
Titralac	420 mg tablet	168 mg/tablet
	780 mg tablet	300 mg/tablet
Oscal	650 mg tablet	260 mg/tablet (vitamin D)
	1250 mg tablet	500 mg/tablet (vitamin D)
Tums	500 mg tablet	200 mg/tablet
	750 mg tablet	300 mg/tablet
	1000 mg tablet	400 mg/tablet
	1250 mg tablet	280 mg/tablet
Caltrate	1500 mg tablet	600 mg/tablet (vitamin D)
Calcium carbonate (suspension)	1250 mg/5 mL	500 mg/5 mL
Calcium chloride	100 mg/mL	
Calcium citrate	200 mg/g	210 mg/tablet
Citracal	950 mg tablet	200 mg/tablet
Calcium lactate	84 mg/g	130 mg/tablet
Magnesium		
Magnesium sulfate	49 mg/mL (50% intramuscular solution)	
	0.32, 0.64, 4 mEq/mL (intravenous solution)	
Magnesium oxide	603 mg/g	241 mg/tablet
Magnesium gluconate	54 mg/g	27 mg/tablet
Magnesium chloride	120 mg/g	64 mg/tablet
Phosphorus		
Sodium phosphate (Phospha-Soda)		127 mg/mL
Sodium/potassium phosphate (Phos-NaK)		250 mg/packet (powder)
Potassium phosphate (Neutraphos-K)		250 mg/packet (powder)
Potassium phosphate (K-Phos Original)		114 mg/tablet
Sodium/Potassium phosphate (K-Phos #2)		250 mg/coated tablet
Sodium/Potassium phosphate (K-Phos Neutral)		250 mg/tablet

(elemental calcium 9.3 mg/mL) at a dose of 1 to 3 mg/kg and at a rate of less than 1 mL/minute with the total dose not to exceed 20 mg of elemental calcium/kg may be administered by intravenous infusion over 15 minutes; often seizures will cease after 1 to 3 mL of 10% calcium gluconate have been administered.[3,58] Cardiac rate and rhythm must be carefully monitored to prevent bradycardia and asystole. Further intravenous bolus doses of calcium (~10 mg/kg at 6-hour intervals) should be used sparingly, as they result in wide excursions in serum calcium values. After initial treatment of neonatal hypocalcemia, 500 mg of calcium gluconate/kg/24 hours may be administered by continuous intravenous infusion taking care to prevent extravasation or infiltration as extracellular calcium will precipitate in soft tissues.[59] These infants may receive supplemental oral calcium if necessary (as discussed previously). Depending on the cause of the hypocalcemia, supplemental vitamin D or calcitriol may also be needed. In a neonate with hypocalcemia due to hypoparathyroidism, administration of synthetic PTH[1-34] may occasionally be required to restore eucalcemia.[60] Serum and urine calcium and creatinine levels should be determined frequently and treatment modified to maintain eucalcemia and the urine calcium/creatinine ratio < 0.2 - < 0.5 in an effort to avoid iatrogenic hypercalcemia, hypercalciuria, nephrocalcinosis, and renal insufficiency. In neonates who require parenteral alimentation, 50 mg of elemental calcium/kg/24 hours should be incorporated into the infused solution; elemental phosphate must also be administered as permitted and indicated.

After restoration of eucalcemia in the infant with DGS, other components of this disorder must be addressed. Cardiac anomalies often require surgical correction, as do palatal clefts. In DGS infants who are immunocompromised and experience recurrent infections due to thymic aplasia, appropriate anti-infectious therapy is mandatory. Transplantation of fetal or cultured postnatal thymic tissue, bone marrow, or peripheral blood mononuclear cells has restored immune function in infants with the DGS. Supplemental calcitriol (20 to 60 ng/kg/day) and calcium are necessary for restoration and maintenance of eucalcemia in infants with hypoparathyroidism. Poor growth due to feeding difficulties and learning disabilities due to developmental delay must be managed on an individual basis and illustrate the need for a multidisciplinary approach to the care of DGS patients.[57] Hypocalcemia due to hypomagnesemia is managed acutely by the intravenous infusion over 1 to 2 hours or by the intramuscular injection of 50% magnesium sulfate at a dose of 0.1 to 0.2 mL/kg while carefully monitoring cardiac status.

Hypocalcemia in the Child and Adolescent

Etiology

Causes of hypocalcemia in the child and adolescent include many that also result in neonatal hypocalcemia and are listed in Tables 18-2A and B. Hypocalcemia is defined by the norms of the analytic laboratory and its parameters dependent on the age of the subject (total calcium concentrations: 1 to 5 years 9.4 to 10.8; 6 to 12 years 9.4 to 10.2; $>$ 20 years 8.8 to 10.2 mg/dL).[58] Total calcium levels are low in the hypoalbuminemic patient; a correction for hypoalbuminemia may be calculated by adding 0.8 mg/dL to the recorded total calcium concentration for every decrease in albumin concentration of 1 g/dL. Thus, it is appropriate to measure both total and Ca^{2+} values when evaluating the hypocalcemic child, but reliance on Ca^{2+} determinations alone is discouraged given the technical difficulties with this assay. Hypocalcemia develops as a consequence of either too little inflow of calcium from the gastrointestinal tract, bone, or kidney into the extracellular and vascular spaces or an excessive loss of calcium from these spaces into urine, stool, or bone. Thus, hypocalcemia may be due to decreased intake or absorption or excessive loss of calcium, decreased production of bioactive PTH due to congenital abnormalities of parathyroid gland development or PTH synthesis or of the CaSR, destruction of parathyroid glands by autoantibodies, metal overload (copper, iron), surgical or radiation insults, granulomatous infiltration, or impaired cellular responsiveness to PTH. Restricted exposure to sunlight or reduced intake, absorption, metabolism, or activity of vitamin D leads to hypocalcemia. Hypomagnesemia impairs the secretion (but not the synthesis of PTH) and blunts tissue responsiveness to PTH. Hypocalcemia occurs in the very ill child and after exposure to a number of drugs and medications. Hypocalcemic tetany may develop after the administration of phosphate containing enemas by rectum or laxatives by mouth.[61] At times, the hypocalcemic child or adolescent may be asymptomatic and identified by chemical screening for an unrelated problem, or she or he may present with intermittent muscular cramping either at rest or during exercise (when the increase in systemic pH due to hyperventilation further lowers the concentration of Ca^{2+}); paresthesias of fingers, toes, or circumoral regions; tetany (carpopedal spasm, laryngospasm, bronchospasm); or seizures (grand mal, focal, petit mal, adynamic, or syncopal). Prolonged and severe hypocalcemia may lead to congestive heart failure.[62] Physical examination often reveals a positive Chvostek or Trousseau sign (carpopedal spasm) and hyperreflexia. However, a Chvostek sign is commonly present in normal adolescents also.

Hypoparathyroidism may occur as a solitary disorder, as part of a multidimensional autoimmune polyendocrinopathy, or as one manifestation of a group of complex congenital anomalies (DGS, HDR, HRD, KCS1, Blomstrand, and other syndromes).[62] There are sporadic and familial forms of hypoparathyroidism; when familial, hypoparathyroidism may be transmitted as an autosomal dominant, autosomal recessive, or X-linked recessive trait (see Tables 18-2A and B). Abnormalities in the development of the parathyroid glands, in the transcription of *PTH*, and in the processing of the translated product have been associated with inherited forms of hypoparathyroidism. Autosomal dominant dyshormonogenic hypoparathyroidism due to a monoallelic T $\Rightarrow$ C transition in codon 18 (Cys18Arg) of the 25 amino acid signal peptide of prepro-PTH impaired efficient transport of protein from the ribosome and interaction of prepro-PTH with the signal

recognition particle, movement of the precursor peptide into and exit from the rough endoplasmic reticulum, its cleavage by a signal peptidase, and its incorporation into a secretory granule.[63] Autosomal recessive dyshormonogenic hypoparathyroidism has been associated with a homozygous G ⇒ C transversion in nucleotide 1 of intron 2 of *PTH* within the signal sequence that prevented normal cleavage of prepro-PTH and decreased secretion of PTH. However, inactivating mutations in *PTH* are uncommon in patients with sporadic idiopathic hypoparathyroidism.[64] Isolated hypoparathyroidism may be found in patients with deletion of chromosome 22q11.2 without other signs or symptoms of the DGS or the velocardiofacial syndrome.

Autosomal dominant hypoparathyroidism (MIM 146200) due to heterozygous gain-of-function mutations in the extracellular, transmembrane, and intracellular domains of *CASR* that transcribe a CaSR that is not intrinsically constitutively active but is exceptionally sensitive to and easily activated by very low serum Ca^{2+} concentrations may be identified in infancy or in older subjects (Figure 18-3). Even at hypocalcemic levels, Ca^{2+} binds avidly to the CaSR and activates phospholipase C-β1, increasing cytosolic levels of inositol phosphate and Ca^{2+} and stimulating the mitogen-activated protein kinase (MAPK) signal transduction pathway in parathyroid chief cells—suppressing PTH synthesis and secretion—and in the kidney—decreasing renal tubular calcium and magnesium resorption leading to urinary wasting of these cations (hypercalciuric hypocalcemia); urinary concentrating ability is also depressed. In these subjects, serum levels of phosphate are increased and magnesium values decreased; PTH concentrations are low or inappropriately normal. Affected patients frequently have symptomatic hypocalcemia such as tetany and seizures. They are very sensitive to vitamin D; the dose of calcitriol must be limited to that which raises serum calcium to asymptomatic values even if not within the normal range, as larger doses lead to hypercalciuria (sometimes even when serum calcium levels remain subnormal), nephrocalcinosis, and functional renal insufficiency. Administration of recombinant human (rh)PTH[1-34] restores calcium homeostasis in this disorder but does not necessarily prevent nephrocalcinosis.[19,23,24] Although there has been reluctance to administer rhPTH to children because there is an increased incidence of bone tumors in young rats receiving very large amounts of this agent, primates appear to be less susceptible to PTH-induced bone tumor formation than do rodents.[65] Development of stimulatory autoantibodies to the CaSR results in an acquired variant of spontaneous hypoparathyroidism that may be isolated or part of a complex autoimmune endocrinopathy.[66] Indeed, in perhaps as many as one third of patients with acquired isolated idiopathic hypoparathyroidism, antibodies directed against epitopes in the extracellular domain of the CaSR may be present. This form of acquired hypoparathyroidism may be reversible, as these antibodies do not destroy the parathyroid glands. In patients with other forms of autoimmune hypoparathyroidism, the antibodies are cytotoxic and accompanied by lymphocytic infiltration, atrophy, and fatty replacement of parathyroid tissue.

In mid-childhood and adolescence, acquired hypoparathyroidism may be a late manifestation of a congenital abnormality (e.g., DGS), but it is also likely to be the result of destruction of the parathyroid glands by autoimmune disease or surgical removal or operative trauma to the vascular supply of these structures. Unusual causes of acquired hypoparathyroidism in this age group include infiltration by iron (hemochromatosis, thalassemia) or copper (Wilson's hepatolenticular degeneration), granulomatous diseases, or radiation (mantle radiation for Hodgkin/non-Hodgkin lymphoma or radioiodine therapy of hyperthyroidism).[2,67] Autoimmune hypoparathyroidism may occur as an isolated disorder or as part of the complex of autoimmune polyendocrinopathy syndrome type I.[67,68] Development of an autoimmune endocrinopathy is initiated by failure to recognize a peptide specific for a target organ by a subgroup of regulatory T cells that ordinarily recognize that peptide. When immunologic tolerance for that peptide is lost, clones of CD4 regulatory T cells for the peptide expand; type 1 helper T cells secrete inflammatory cytokines such as interferon-γ, whereas type 2 helper T cells stimulate B cell function and lead to autoantibody-mediated inflammation. Loss of immune tolerance may be the consequence of the postinfectious inflammatory state due to activation of the innate immune system or due to a gene mutation that depresses immune tolerance and permits expansion of a CD4+ regulatory T cell clone after exposure to quantitatively small amounts of antigen. Genetic variations within the major histocompatibility complex (HLA-DQ, HLA-DR) that determine peptide (antigen) presentation to CD4+ regulatory T cells join with genetic abnormalities in immune regulation to induce autoimmune disease. In 30% of patients with isolated idiopathic hypoparathyroidism; the disorder is due to antibodies to the extracellular domain of the CaSR and thus is functionally inhibitory but potentially reversible; in approximately 33% of patients, serum antibodies to other components of the parathyroid chief cell may be present.[66] There are several types of autoimmune polyendocrine syndromes (APS), but only in type I is hypoparathyroidism a major component. Autoimmune polyendocrine syndrome type II is a polygenic disorder manifested by hypoadrenalism, type 1 diabetes mellitus, and autoimmune thyroid disease (and gastritis, celiac disease, vitiligo) and is related to the major histocompatibility complexes.[69] The syndrome of *I*mmunodeficiency, *P*olyendocrinopathy, and *E*nteropathy—X-linked (IPEX) is associated with autoimmune enteropathy, insulin dependent neonatal diabetes mellitus, autoimmune thyroid disease, eczema, glomerulonephritis, thrombocytopenia, and hemolytic anemia that occurs only in males as it is due to loss-of-function mutations in *FOXP3* (MIM 300292; chromosome Xp11.23). FOXP3 is a transcription factor that is essential for normal development of naturally occurring T regulatory cells.

Autoimmune polyendocrinopathy syndrome type I is an autosomal recessive disorder with the classic triad of *A*utoimmune *P*olyendocrinopathy, mucocutaneous *C*andidiasis, and *E*ctodermal *D*ystrophy (APECED) that is due to loss-of-function mutations in *AIRE* encoding the autoimmune regulator.[69] In a Finnish cohort of 91 patients with APS1/APECED, the cardinal manifestations were mucocutaneous candidiasis involving the nails

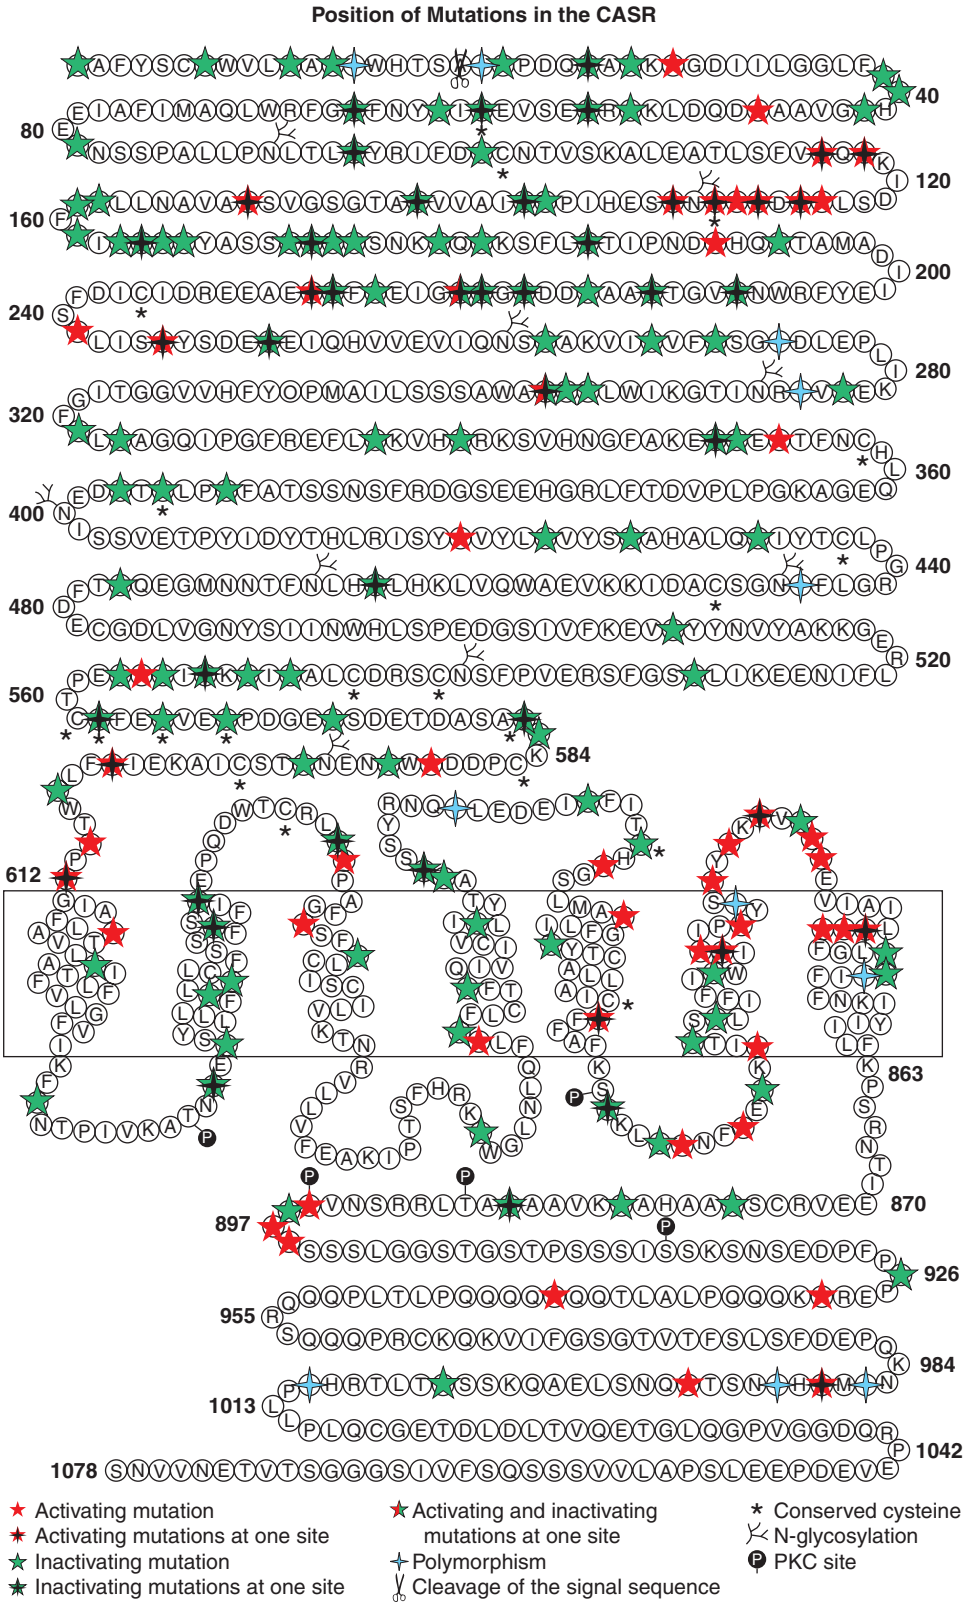

FIGURE 18-3 ■ Schematic view of the calcium sensing receptor (CaSR) depicting inactivating (hereditary/familial hypocalciuric hypercalcemia) and activating (autosomal dominant hypoparathyroidism) mutations. Note that mutations at adjacent codons may result in either a gain or a loss of function of the mutant *CASR* product (e.g., codons 565, 567, 568). (Courtesy of Drs. Lilia D'Souza-Li and Geoffrey N. Hendy, McGill University, Montreal, Quebec, www.casrdb.mcgill.ca/?Topic=CasrGraph2&v=new.) *This image can be viewed in full color online at ExpertConsult.*

and mouth occurring in 100% of patients (often in the first 2 years of life), hypoparathyroidism, and hypoadrenocorticism, both of which illnesses developed in 80% to 90% of affected subjects.[70] Hypoparathyroidism occurred most often in patients who were between 2 and 10 years old, and hypoadrenocorticism developed in patients who were between 5 and 15 years of age. Almost all females with APECED developed hypoparathyroidism, whereas 80% of affected males did so. Hypomagnesemia, often severe and recalcitrant to therapy, was common in patients with hypoparathyroidism due to APECED. The most frequent presenting manifestations of APECED were mucocutaneous candidiasis (60%), hypoparathyroidism (32%), and hypoadrenocorticism (5%); the disease first became apparent when patients were between 2 months and 18 years of age. However, 10% of patients presented with another manifestation of APECED. In addition to hypoparathyroidism and hypoadrenocorticism, other endocrinopathies encountered in APECED included autoimmune oophoritis leading to ovarian failure (70%), orchitis resulting in testicular failure (30%), diabetes mellitus (30%), thyroiditis (30%), and hypophysitis (4%). Besides mucocutaneous candidiasis, dermatologic manifestations and complications of APECED in the Finnish cohort included alopecia (40%), vitiligo (30%), and rashes with fever (15%). Keratoconjunctivitis developed in 20% of affected subjects, pernicious anemia in 30%, hepatitis in 20%, and chronic diarrhea in 20%. In a Norwegian population of 36 patients with APECED, 13 had clinical evidence of disease at or before 5 years of age and an additional 15 subjects presented at or before 15 years of age.[71] In a Russian population of 46 patients, mucocutaneous candidiasis was present in 70%, hypoparathyroidism in 83%, and adrenal insufficiency in 54%.[72] Other common problems were alopecia (27%), thyroid dysfunction (20%), and malabsorption syndromes (18%). Unusual findings in this cohort were retinitis pigmentosa and metaphyseal dysplasia, both occurring in 7% of patients. Clinical manifestations of APS1/APECED and their age of onset vary among subjects and even among siblings. Later manifestations of APECED include esophageal and oral squamous cell carcinoma, asplenia, and interstitial nephritis. The diagnosis of APECED usually requires the presence of two of three of its major diseases (mucocutaneous candidiasis, hypoparathyroidism, hypoadrenocorticism), but occasionally chronic candidiasis, hypoparathyroidism, or primary adrenal insufficiency alone may be the only manifestation of an inactivating mutation in *AIRE*.[72] In patients with autoimmune hypoparathyroidism, antibodies to PTH and to the CaSR have been identified; some CaSR antibodies have been activated, leading to a clinical picture that mimics that of patients with activating mutations in *CASR*.[73] Antibodies to NACHT leucine-rich-repeat proteins (NALP5), another antigen present in the parathyroid gland, have also been found in patients with autoimmune hypoparathyroidism and APS1.[74]

Autoimmune polyendocrinopathy syndrome type I is the result of homozygous or compound heterozygous loss-of-function mutations in *AIRE* (autoimmune regulator), a 14-exon gene encoding a 545-amino-acid protein with two zinc-finger motifs that is expressed in nuclei of thymic medullary epithelial cells and in lymph nodes, spleen, monocytes.[69] AIRE also serves as an E3 ubiquitin ligase, an essential component of the ubiquitin-proteasomal system for protein modification and destruction involved in cellular division and differentiation, protein transport, and intracellular signaling.[75] Structurally, AIRE contains two plant homeodomains: an amino acid sequence composed of an octet of cysteines and histidines that coordinate two zinc ions; the first plant homeodomain is essential for the E3 ubiquitin ligase activity of the protein and the second plant homeodomain is required for its transcription-regulating action. AIRE also contains a SAND domain, a structure that permits it to bind DNA. Functionally, AIRE promotes expression of peripheral antigens in the thymus, thereby increasing immune tolerance.[68]

Development of an immune system that is capable of distinguishing between "self" and "foreign" antigens is essential in order to prevent autodestruction of an organism's cells and tissues. To this end, thymic stromal medullary epithelial cells locally transcribe the majority of protein encoding genes expressed in various peripheral tissues in order to permit their recognition by developing T cells prior to their release from the thymus and thus prevent an autoimmune response when these proteins are encountered by T cells in the periphery. The autoimmune regulatory gene *AIRE* enables the thymic transcription and expression of these genes by interacting with nuclear transporters (e.g., exportin), chromatin binding proteins (e.g., histones), transcription factors, and postinitiation transcription processes (e.g., cyclic AMP response element binding protein; complex of DNA-dependent protein kinase-polymerase- topoisomerase), and pre-mRNA splicing and processing factors.[76] AIRE does not function as a specific transcription factor. Inasmuch as nuclear AIRE binds to the unmethylated tails of histone-3 in chromatin, it has been proposed that AIRE activates quiescent genes by attracting to their site the transcription apparatus that enables initiation of transcription, elongation, and pre-mRNA processing.[76] In the Finnish and Russian populations with APS1, the most common loss-of-function mutation in *AIRE* was a homozygous truncating mutation at codon 257 (Arg257Ter). Pathogenic mutations in *AIRE* detected in patients with APECED include missense, nonsense (Arg139Ter), insertions, and deletions (e.g., 13 base pair deletion; 964del13, NT 1094, exon 8) that alter the subcellular distribution of AIRE or decrease its transcriptional activation capacity or its E3 ubiquitin ligase activity.[72,75,77]

Pseudohypoparathyroidism is a disorder with variable clinical manifestations associated with resistance to the action of PTH, classified as types IA, IB, IC, and II, and pseudopseudohypoparathyroidism (PPHP), whose clinical manifestation and pathophysiology were discussed previously. Deficiency of vitamin D intake, aberrant metabolism of cholecalciferol, or decreased biologic responsiveness of the vitamin D receptor (VDR) may result in hypocalcemia.[56] In the subject with skeletal demineralization due to marked vitamin D deficiency, serum calcium concentrations may fall precipitously after administration of even small amounts of vitamin D as renewed mineralization of bone matrix due to accelerated osteoblastic

activity consumes calcium and phosphate (the "hungry bone" syndrome). After parathyroidectomy for primary hyperparathyroidism, calcium concentrations often decline rapidly by the same mechanism. Drugs that inhibit PTH secretion (excessive magnesium), osteoclast resorption of bone (bisphosphonates), or renal resorption of calcium (furosemide) may lead to hypocalcemia. Intravenous infusion or rectal administration of phosphate (in enemas), acute cellular destruction by tumor cell lysis or rhabdomyolysis, and acute and chronic renal failure increase serum phosphate levels and lead to reciprocal decline in calcium values. Serum calcium concentrations decline in patients receiving multiple transfusions of citrated blood or during plasmapheresis. In subjects with acute pancreatitis, calcium complexed with free fatty acids generated by pancreatic lipase is deposited in necrotic tissue.[78] Acute severe illness of diverse pathogenesis is often associated with hypocalcemia; this has been attributed to hypoalbuminemia, functional hypoparathyroidism, hypercalcitonemia, hypomagnesemia, decreased calcitriol synthesis, alkalosis and increased serum concentrations of free fatty acids (the latter increase binding of Ca^{2+} to albumin), and increased cytokine activity.

Evaluation

Figure 18-2 outlines the evaluation of the child/adolescent with hypocalcemia. Hypocalcemia may be asymptomatic until detected by a multiassay chemical profile obtained for another purpose. It may be first identified during evaluation of a long QT interval noted by electrocardiography obtained for evaluation of a functional heart murmur or arrhythmia.[79] Clinical symptoms that suggest hypocalcemia include paresthesias, circumoral numbness, muscular cramping (particularly during vigorous exercise), tetany (uncontrollable muscular contractions including laryngospasm and bronchospasm), muscle twitching, carpal-pedal spasm (flexion of the elbow and wrist, adduction of the thumb, flexion of the metacarpal/metatarsal-phalangeal joints, and extension of the interphalangeal joints), and seizure.[62] Review of the past medical history may reveal symptoms consistent with or illnesses associated with hypocalcemia (recurrent infections, congenital cardiac anomalies, surgical procedures in the neck, cervical radiation, infiltrative diseases), or the family history may identify members with hypoparathyroidism, dysmorphic physical characteristics, autoimmune endocrinopathies, or hypomagnesemia. Physical examination will disclose characteristic abnormalities in children with PHP type IA in whom the AHO phenotype is present (short stature, round face, subcutaneous hard nodules, brachymetacarpals), the DGS (typical face, recurrent infections, cardiac murmur), and familial autoimmune polyendocrinopathy syndrome type I (chronic mucocutaneous candidiasis and other ectodermal abnormalities such as vitiligo, alopecia, keratoconjunctivitis), whereas rachitic deformities in the hypocalcemic child imply the presence of a form of hypovitaminosis D. Most commonly, however, the physical examination reveals no striking abnormality in the hypocalcemic child other than those of increased neuromuscular irritability such as hyperreflexia, positive Chvostek sign (twitching of the circumoral muscles when tapping lightly over the seventh cranial nerve) or Trousseau sign (carpal pedal spasm when maintaining the blood pressure cuff 20 mm Hg above the systolic blood pressure for three minutes) and occasionally cataracts, papilledema, or abnormal dentition. (Tetany also occurs in subjects with hypo- and hypernatremia, hypo- and hyperkalemia, and hypomagnesemia, and a positive Chvostek sign may be found in many normal adolescents.)

After confirmation of the hypocalcemic state (by measuring serum total calcium and Ca^{2+} levels, the latter to exclude hypoalbuminemia as a cause of a low total calcium value), urine calcium excretion is determined; in most hypocalcemic patients, urine calcium excretion is low (see Figure 18-2). If the urine calcium excretion is inappropriately normal or high, disorders such as autosomal dominant (gain-of-function mutation in *CASR*) hypoparathyroidism may be considered; *CASR* may then be analyzed or antibodies to CaSR determined as clinically indicated. The frequency with which antibodies to the CaSR are detected in patients with autoimmune hypoparathyroidism depends on the method employed for their identification. Thus, antibodies to the CaSR have been found in 86% of subjects with APS1/APECED employing an immunoprecipitation assay with the full-length CaSR expressed in human embryonic kidney cells and in 50% of the same subjects utilizing a flow cytometry assay but in none of these patients applying a radiobinding assay.[73,80] The serum levels of intact PTH, calcidiol, magnesium, phosphate, creatinine, and alkaline phosphatase are also to be measured. Determination of the serum concentration of intact PTH (by ultrasensitive assay) permits differentiation between low (or inappropriately "normal") and high PTH secretory states. The child/adolescent with hypocalcemia, hypocalciuria, hyperphosphatemia, and low or undetectable serum PTH concentration (and normal or only slightly low serum magnesium level) likely has hypoparathyroidism due to a primary defect in PTH synthesis or secretion related to congenital malformation or acquired destruction of the parathyroid glands. Patients with hypoparathyroidism often have low serum concentrations of calcitriol, normal levels of calcidiol, decreased excretion of urinary nephrogenous cyclic AMP, and increased renal tubular reabsorption of phosphate.[67] The DGS may be identified by microarray or FISH analysis of chromosome 22q11.2 or *TBX1* genotyping. Analysis of *GCM2* or *SOX3* and genes associated with syndromic hypoparathyroidism (*TBCE GATA3*) is indicated in the appropriate clinical context (see Table 18-2B). The diagnosis of autoimmune polyendocrinopathy syndrome type I is based on clinical and laboratory findings and genotyping of *AIRE*. The presence of two of three of its major manifestations (candidiasis or ectodermal dystrophy, hypoparathyroidism, hypoadrenocorticism) is the accepted criterion for its clinical diagnosis, but isolated hypoparathyroidism, adrenal insufficiency, or chronic mucocandidiasis may occasionally be its only manifestation.[72] Antibodies to the CaSR or other cellular components of the parathyroid glands, the adrenal glands (side-chain cleavage, 21-hydroxylase, 17α-hydroxylase enzymes), neurotransmitters (aromatic

L-amino acid decarboxylase, tryptophan hydroxylase), and interferons-α and -ω may be determined; antibodies to interferon-ω are commonly present in patients with APS1/APECED.[71,81] Genotyping of *AIRE* and identification of the mutations confirm the diagnosis of APECED. There is wide variability in the clinical expression of APECED both between families and among siblings, as the phenotype is not directly related to the genotype. In patients with isolated, idiopathic hypoparathyroidism, a search for antibodies to the CaSR or to parathyroid tissue is warranted. In hypomagnesemic subjects, magnesium and PTH levels are quite low, and PTH secretion increases rapidly after intravenous administration of magnesium. Primary hypomagnesemia should be considered when hypocalcemia and hypercalciuria coincide and serum PTH and magnesium values are low; urinary magnesium excretion should then be quantitated and *CLDN16* genotyped (see Tables 18-7A and B, presented later in the chapter). Because hypomagnesemia may also be due to a selective small intestinal defect in magnesium absorption, mutations in *TRPM6* should be examined as warranted. Primary hypomagnesemia must be differentiated from that due to the Gittleman and Bartter syndromes.

An elevated serum concentration of PTH in a hypocalcemic subject suggests that the patient is either secreting an abnormal PTH molecule or is resistant to PTH or there is a compensatory (secondary) PTH secretory response to hypocalcemia (see Figure 18-2). Physicochemical characterization of the PTH molecule and analysis of *PTH* enable one to define the abnormality in PTH synthesis, posttranslational processing, secretion, or activity leading to the functionally hypoparathyroid state. Analysis of *GNAS* and its pattern of imprinting permits identification of the specific genetic defect in the majority of patients with clinical PHP type IA and PPHP. Skeletal and renal responsiveness to PTH may be assessed if warranted by measurement of changes in serum calcium, phosphate, cyclic AMP, and calcitriol concentrations and urinary nephrogenous cyclic AMP and phosphate excretion following administration of biosynthetic $PTH^{1\text{-}34}$ (Elsworth-Howard test). In the normal subject and in the patient with primary hypoparathyroidism, urinary cyclic AMP excretion increases 10- to 20-fold and that of phosphate several fold; in the patient with PHP types IA and IB there is less than a 3-fold increase in the excretion of cyclic AMP after administration of $PTH^{1\text{-}34}$. The diagnosis of PHP type IB may be established by examining the imprinting patterns of *GNAS* and analyzing *STX16* and the 5′ sequences of *GNAS* as indicated. In the child with vitamin D deficiency, serum levels of calcidiol are low. In patients with decreased renal $25OHD_3$-1α-hydroxylase activity, serum concentrations of calcidiol are normal, whereas those of calcitriol are inappropriately low. Increased concentrations of calcitriol suggest the presence of a defect in the nuclear vitamin D receptor. The patient with renal failure is recognized by an increased serum creatinine value. Other findings in hypocalcemic subjects include prolongation of the Q-T interval by electrocardiography and calcification of the basal ganglia by cranial computerized tomography.

Management

The primary goal in the care of the hypocalcemic child and adolescent is to increase serum calcium concentrations to levels at which the patient is asymptomatic and as close to the lower range of normal as possible; the secondary goal is to identify the cause of hypocalcemia as quickly as possible in order to provide disease-specific management.[56,62,67] Asymptomatic hypocalcemia (total calcium > 7.5 mg/dL) may not require immediate intervention. With lower serum calcium levels or when hypocalcemia is symptomatic (tetany, seizures, laryngospasm, bronchospasm), acute management may require the intravenous administration of calcium gluconate (93 mg of elemental calcium/10 mL vial) at a slow rate (not greater than 2 mL [1.86 mg of elemental calcium]/kg over 10 minutes) while closely monitoring pulse rate (and the QT interval). Acutely, intravenous administration of calcium is intended to ameliorate the more serious consequences of hypocalcemia such as seizures, bronchospasm, or laryngospasm, not to restore and maintain the eucalcemic state. Intravenously, calcium should not be administered with phosphate or bicarbonate, because these salts may coprecipitate. Extravascular extravasation of calcium is to be avoided, as it may precipitate and cause local tissue injury. After the acute symptoms have resolved, calcium gluconate (10 mL = 93 mg of elemental calcium in 100 mL 5% dextrose/0.25 normal saline) may be infused intravenously at a rate sufficient to maintain calcium levels in the asymptomatic low-normal range while the cause of the hypocalcemia is identified and more specific therapy for persistent hypocalcemia prescribed. The evaluation should proceed as rapidly as possible, and oral therapy should begin reasonably quickly. In the child with marked hyperphosphatemia as a cause of hypocalcemia, in addition to parenteral calcium administration, infusion of normal saline sufficient to maintain urine output at or above 2 mL/kg per hour is necessary.[61] Frequent measurement of serum calcium and phosphate concentrations permits rapid adjustment of fluid and electrolyte therapy.

After stabilization, patients with hypoparathyroidism or PHP may be treated with calcitriol (20 to 60 ng/kg/day) and supplemental calcium (calcium glubionate or calcium citrate 30 to 75 mg elemental calcium/kg/day in divided doses; see Table 18-3) to restore and maintain eucalcemia. The serum calcium concentration should be maintained within the low-normal range. Each patient must be carefully monitored to avoid hypercalcemia, hypercalciuria (calcium excretion greater than 4 mg/kg/24 hours), nephrocalcinosis, and nephrolithiasis. Basal and periodic measurements of serum concentrations of calcium, phosphate, and creatinine and urinary calcium and creatinine excretion and renal sonography are mandatory. Children with autosomal dominant hypoparathyroidism due to gain-of-function mutations in *CASR* are extremely sensitive to vitamin D and its metabolites. Even small doses of calcitriol may lead to hypercalciuria with a minimal increase in serum calcium levels; in that instance, the addition of hydrochlorothiazide (0.5 to 2.0 mg/kg/day) may increase renal tubular reabsorption of calcium and lower the calcitriol requirement. Administration of

recombinant human PTH[1-34] has been beneficial in individual subjects with this disorder.[19,23,24] In adults and children with hypoparathyroidism due to a variety of causes, the use of rhPTH[1-34] (0.4 to 0.5 μg/kg every 12 hours subcutaneously) together with calcium carbonate and vitamin D (1200 mg/day of elemental calcium and 800 IU/day of cholecalciferol in four equally divided doses) has proven effective and safe for as long as 3 years.[24] rhPTH[1-34] led to an acceleration of bone turnover as reflected by increases in serum alkaline phosphatase and osteocalcin and urinary excretion of pyridinoline and deoxypyridinoline, whereas accrual of bone mineral mass, linear growth, and weight gain were not adversely impacted in treated children.[24] Continuous infusion of rhPTH[1-34] has also proven effective in maintaining reasonable serum calcium concentrations in adults with postsurgical hypoparathyroidism with fewer fluctuations in calcium levels and lower urine calcium values when compared to twice-daily subcutaneous injections of rhPTH[1-34].[82]

Because PHP type IA is associated with resistance to a number of peptide hormones that act through GPCRs, periodic assessment of pituitary-thyroid and pituitary-ovarian function and growth hormone secretion is necessary and hormone replacement therapy should begin as indicated.[49] In general the short stature of patients with PHP type IA reflects the AHO phenotype and not GH deficiency. Transient hypoparathyroidism of infancy may be the initial manifestation of later onset hypoparathyroidism; thus, it is important to assess calcium homeostasis in such subjects throughout childhood. Patients with apparently isolated hypoparathyroidism of unknown etiology should be reevaluated periodically to identify the development of autoimmune disorders in the patient or family. Assessment of thymic function is important in subjects with findings suggestive of the DGS. The management of patients with vitamin D deficiency or resistance is discussed in subsequent sections.

When hypomagnesemia is symptomatic, administration of magnesium sulfate parenterally may be necessary (50% solution—0.1 to 0.2 mL/kg intramuscularly—repeated after 12 to 24 hours if needed). The patient with primary hypomagnesemia may require daily parenteral (intramuscular, intravenous) doses of magnesium sulfate in order to prevent tetany, seizures, and other neurologic symptoms (slurred speech, choreoathetoid movements, weakness) and to enable normal growth and development.[83] Calcitriol alone raises serum calcium levels in hypomagnesemic subjects but is ineffective in the prevention of tetany. Continuous overnight nasogastric infusion of magnesium may help alleviate the gastrointestinal side effects of multiple large doses of oral magnesium. More mild and transient forms of hypomagnesemia may be treated with oral magnesium gluconate or tribasic magnesium citrate (see Table 18-3).

HYPERCALCEMIA

Hypercalcemia in the Neonate and Infant

Hypercalcemia in neonates and very young infants is defined as total blood calcium concentration > 10.8 to 11.3 mg/dL (depending on the analytic laboratory). However, substantial symptoms (impaired growth, anorexia, gastroesophageal reflux and emesis, constipation, and lethargy and hypotonia or irritability and seizures) usually do not occur until the total calcium level exceeds 12.5 to 13 mg/dL.[2,58,84,85] These infants frequently have polyuria and may become dehydrated because of renal resistance to antidiuretic hormone if oral fluid intake is restricted. Due to the vasoconstrictive effect of calcium, the hypercalcemic infant may be hypertensive. Hypercalcemia also shortens the S-T segment and can lead to heart block and ultimately asystole. In older infants and young children with chronic hypercalcemia, poor growth and failure to thrive are often presenting manifestations. Hypercalcemia also leads to polyuria due to hypercalciuria, nephrocalcinosis, and nephrolithiasis.

Etiology

Neonatal/infantile hypercalcemia may be iatrogenic in origin, e.g., administration of excessive calcium or vitamin D (at times to the mother who secretes cholecalciferol in her breast milk); use of thiazide diuretics that increase renal tubular absorption of calcium; or purposeful restriction of phosphate (Tables 18-4A and B). Hypercalcemia, hypophosphatemia, hyperphosphatasemia, and radiographic evidence of rickets may develop in very premature infants receiving intravenous alimentation deficient in phosphate or in those fed only human breast milk, the phosphate content of which is low. In this situation, hypophosphatemia leads to increased synthesis of calcitriol by two mechanisms: (1) direct stimulation of renal tubular 25OHD-1α hydroxylase activity and (2) depressing secretion of fibroblast growth factor 23 (FGF23), a factor that inhibits its activity of this enzyme—the two processes additively increase 25OHD-1α hydroxylase activity, calcitriol synthesis, and intestinal calcium absorption.[85] The problem may be circumvented by increasing the amount of parenteral phosphate administered to the extent possible or by the use of breast milk fortified with phosphate. (Adequate extrauterine mineralization of the preterm skeleton requires intakes of both calcium and phosphate of approximately 200 mg/kg/day.) Extracorporeal membrane oxygenation may also be associated with hypercalcemia in neonates.[86,87]

Hypervitaminosis D may be due to prolonged feeding of an improperly prepared formula or commercial dairy milk containing excessive vitamin D, iatrogenic prescription of vitamin D, calcidiol, or calcitriol, or increased endogenous production of calcitriol from inflammatory sites.[84] In infants with severe birth trauma or perinatal asphyxia, subcutaneous fat necrosis may develop in tissues that have sustained direct trauma and be manifested by indurated, extremely firm, violaceous nodules on the cheeks, trunk, buttocks and legs.[58] Hypercalcemia may be present when the lesions first appear or develop as the nodules resolve several weeks later. Histologically, the skin lesions are composed of adipocytes, an inflammatory lymphohistiocytic infiltrate, and multinucleated giant cells in a bed of calcium crystals. The hypercalcemia of subcutaneous fat necrosis is attributable not only to

TABLE 18-4A **Causes of Hypercalcemia**

I Neonate/Infant

A Maternal Disorders
1 Excessive vitamin D ingestion, hypoparathyroidism, pseudohypoparathyroidism

B Neonate/Infant
1 Iatrogenic: excessive intake of calcium, vitamin D, vitamin A
2 Phosphate depletion
3 Subcutaneous fat necrosis
4 Williams-Beuren syndrome (del7q11.23/*BAZ1B*)
5 Neonatal severe hyperparathyroidism (*CASR*)
6 Metaphyseal chondrodysplasia, Murk-Jansen type (*PTH1R*)
7 Idiopathic infantile hypercalcemia (*CYP24A1*)
8 Persistent parathyroid hormone related protein
9 Lactase/disaccharidase deficiency (*LCT*)
10 Infantile hypophosphatasia (*TNSALP*)
11 Mucolipidosis type II (*GNPTAB*)
12 Blue diaper syndrome
13 Antenatal Bartter syndromes types 1 and 2 (*SLC12A1*, *KCNJ1*)
14 Distal renal tubular acidosis
15 IMAGe syndrome (*CDKN1C*)
16 Post bone marrow transplantation for osteopetrosis
17 Endocrinopathies: primary adrenal insufficiency, severe congenital hypothyroidism, hyperthyroidism

II Hyperparathyroidism

A Sporadic
1 Parathyroid hyperplasia, adenoma, carcinoma

B Familial
1 Neonatal severe hyperparathyroidism (*CASR*)
2 Multiple endocrine neoplasia, type I (*MEN1*)
3 Multiple endocrine neoplasia, type IIA (*RET*)
4 Multiple endocrine neoplasia, type IIB (*RET*)
5 Multiple endocrine neoplasia, type IV (*CDKN1B*)
6 McCune-Albright syndrome (*GNAS*)
7 Familial isolated hyperparathyroidism 1(*CDC73*)
8 Familial isolated hyperparathyroidism 2 (jaw tumor syndrome) (*CDC73*)
9 Familial isolated hyperparathyroidism 3
10 Jansen's metaphyseal dysplasia (*PTH1R*)

C Secondary/Tertiary
1 Postrenal transplantation
2 Chronic hyperphosphatemia

D Hypercalcemia of Malignancy
1 Ectopic production of PTHrP
2 Metastatic dissolution of bone

III Familial Hypocalciuric Hypercalcemia

A Familial Hypocalciuric Hypercalcemia I (CASR)
1 Loss-of-function mutations in *CASR*
a Monoallelic: familial benign hypercalcemia
b Biallelic: neonatal severe hyperparathyroidism

B Familial Hypocalciuric Hypercalcemia II (GNA11)
C Familial Hypocalciuric Hypercalcemia III, Oklahoma Variant (AP2S1)
D CASR blocking autoantibodies

IV Excessive Calcium or Vitamin D

A Milk-Alkali Syndrome
B Exogenous Ingestion of Calcium or Vitamin D or Topical Application of Vitamin D (calcitriol or analog)
C Ectopic Production of Calcitriol Associated with Granulomatous Diseases (sarcoidosis, cat scratch fever; tuberculosis, histoplasmosis, coccidioidomycosis, leprosy; human immunodeficiency virus; cytomegalovirus; chronic inflammatory bowel disease)
D Neoplasia
1 Primary bone tumors
2 Metastatic tumors with osteolysis
3 Lymphoma, dysgerminoma
4 Tumors secreting PTHrP, growth factors, cytokines, prostaglandins, osteoclast activating factors

E Williams-Beuren Syndrome (del7q11.23)

V Immobilization
VI Other Causes

A Drugs: Thiazides, Lithium, Vitamin A and Analogs, Calcium, Alkali, Antiestrogens, Aminophylline
B Total Parenteral Nutrition
C Endocrinopathies: Hyperthyroidism, Hypoadrenocorticism, Pheochromocytoma
D Vasoactive Intestinal Polypeptide-Secreting Tumor
E Acute or Chronic Renal Failure/Administration of Aluminum
F Hypophosphatasia
G Juvenile Rheumatoid Arthritis: Cytokine Mediated

reabsorption of precipitated calcium but also to extrarenal synthesis of calcitriol by local macrophages and resultant hyperabsorption of ingested calcium. The 25OHD-1α-hydroxylase activity of these inflammatory macrophages is not under the control of PTH, calcium, or phosphate, but it is suppressible by glucocorticoids.[58] Excessive production of prostaglandin E and interleukins (IL)-1 and -6 further contributes to hypercalcemia in this disorder by increasing the rate of bone turnover. Hypercalcemia attributable to subcutaneous fat necrosis is managed by the ingestion of a low-calcium formula, avoidance of vitamin D, and administration of fluids, furosemide, calcitonin, glucocorticoids, or bisphosphonate (etidronate, pamidronate) as needed.[2] Hypercalcemia due to subcutaneous fat necrosis has also been observed in older children with major trauma or disseminated varicella.[84] Congenital lactase and other disaccharidase deficiencies have been associated with infantile hypercalcemia, likely due to increased intestinal absorption of calcium promoted by disaccharides.

TABLE 18-4B **Gene Mutations Associated with Hypercalcemia**

Disorder	OMIM	Gene(s)	Chromosome OMIM	Pathophysiology	Inheritance
Hyperparathyroidism					
Multiple endocrine neoplasia type 1 (MEN1)	131100	*MEN1*	11q13.1 613733	Menin: inhibitor of transcription; tumor suppressor	Germline and somatic inactivating mutations sum to produce MEN1, AD
Multiple endocrine neoplasia type 2A	171400	*RET*	10q11.21 164761	Tyrosine kinase receptor mediating cell differentiation and growth	AD
Multiple endocrine neoplasia type 2B (3)	162300	*RET*	10q11.21 164761	Tyrosine kinase receptor mediating cell differentiation and growth	AD
Multiple endocrine neoplasia type 2C (isolated: medullary carcinoma of thyroid)	155240	*RET*	10q11.21 164761	Tyrosine kinase receptor mediating cell differentiation and growth	AD
Multiple endocrine neoplasia type 4	610755	*CDKN1B*	12p13.1 600778	Inhibitor of cyclin dependent kinase-mediated cell division, tumor suppressor	AD
Familial isolated primary hyperparathyroidism (FIHP) type 1	145000	*CDC73*	1q31.2 607393	Cell division cycle protein	AD
Hyperparathyroidism jaw tumor syndrome (FIHP type 2)	145001	*CDC73*	1q31.2 607393	Cell division cycle protein	AD
Familial isolated primary hyperparathyroidism (FIHP) type 3	610071		2p14-p13.3		AD, AR
Familial isolated primary hyperparathyroidism (FIHP)		*MEN1*	11q13.1 613733	Menin: inhibitor of transcription; tumor suppressor	AD
Neonatal severe hyperparathyroidism	239200	*CASR*	3q13.3-q21 601199	GPCR for Ca^{2+}	AD, AR
Familial hypocalciuric hypercalcemia, type I	145980	*CASR*	3q21.1 601199	GPCR for Ca^{2+}	AD
Metaphyseal chondrodysplasia, Murk-Jansen type	156400	*PTH1R*	3p21.1 168468	GPCR for PTH and PTHrP	AD
Williams-Beuren syndrome (WBS)	194050		Delq7q11.23	Contiguous gene deletion syndrome	AD with variable manifestations
Williams-Beuren syndrome (WBS)	194050	*BAZ1B*	7q11.23 605681	WBS transcription factor (WSTF) complex regulates transcriptional responses to VDR	
Williams-Beuren syndrome (WBS)	194050	*ELN*	7q11.23 130160	Elastin required for normal formation of supravalvular aorta

Williams-Beuren syndrome (WBS)	194050	*GTF21RD1*	7q11.23 604138	TF influences neurocognition and behavior	
Dup7q11.23 syndrome	609757		Duplication of chromosome 7q11.23	Contiguous gene duplication syndrome	AD with variable penetrance
Idiopathic infantile hypercalcemia	143880	*CYP24A1*	20q13.2 126065	Renal enzyme that hydroxylates vitamin D metabolites at C-24	AR
Intrauterine growth retardation, metaphyseal dysplasia, adrenal hypoplasia, congenita, genital anomalies (IMAGE syndrome)	614732	*CDKN1C*	11p15.4 600856	Inhibitor of G1 cyclin/cyclin dependent kinase (Cdk) complexes that interferes with cell cycle	AD through mother; imprinted with expression of only the maternal allele

TF, transcription factor.

Neonatal severe hyperparathyroidism (NSHPT) is a potentially lethal form of familial (hereditary) hypocalciuric hypercalcemia (HHC). It is most commonly due to homozygous or compound heterozygous inactivating mutations of *CASR* that greatly increase the serum concentration of Ca^{2+} needed to suppress PTH synthesis and secretion. However, in several infants with NSHPT, there have been heterozygous inactivating mutations of *CASR* (e.g., Arg185Gln, Arg227Leu), suggesting that the products of these mutations exert a dominant-negative effect on normal CaSR, perhaps by interfering with the migration of wild-type receptor to the cell surface or inactivation of wild-type receptor by linking to the mutated CaSR once embedded in the cell membrane, or by sequestration of G-proteins.[88] In addition, the fetus bearing a heterozygous mutation in *CASR* that has been inherited from an affected father but residing in the womb of a normal mother may be relatively "hypocalcemic" in utero leading to hyperplasia of the fetal parathyroid glands that persists after birth giving rise to NSHPT. Occasionally, NSHPT may be transmitted as an autosomal recessive disorder by clinically and biochemically normal parents.[89,90] Subjects with homozygous mutations near the amino terminal of *CASR* (e.g., Leu13Pro) may not become manifest until mid-childhood or even adulthood.[91] The clinical spectrum of NSHPT ranges from mild (constipation, polyuria) with calcium concentrations ranging from 11 to 13 mg/dL to severe and life-threatening (dysrhythmia, respiratory distress due to hypotonia, demineralization and fractures of the ribs) when calcium levels exceed 15 mg/dL.[85,92] NSHPT may present within the first few days of life to several months of age depending on the degree of hypercalcemia. Search of the family history may identify members with mild hypercalcemia due to autosomal dominant HHC1. Physical examination often reveals hypotonia, difficulties swallowing, and respiratory distress. The serum calcium concentration is frequently markedly elevated (average 14 mg/dL, range 11 to > 20 mg/dL) as is the PTH value (average 540 pg/mL, range 55 to > 1000 pg/mL).[93] There is hypophosphatemia, hypermagnesemia, hyperphosphatasemia, and elevated calcitriol values, low renal tubular reabsorption of phosphate, and relative hypocalciuria. Radiographically, there is evidence of hyperparathyroid bone disease: osteopenia, metaphyseal widening and irregularity, subperiosteal resorption, varus angulation of the hips, and fractures. Lowering of the elevated serum calcium concentration present in NSHPT may be effected by induction of sodium diuresis by infusion of fluids and by administration of furosemide to increase urinary calcium excretion, and calcitonin and a bisphosphonate (e.g., pamidronate) to suppress resorption of bone calcium. The allosteric calcimimetic cinacalcet hydrochloride that acts directly on the CaSR has also been effective for lowering serum calcium concentrations in infants with NSHPT.[94] (However, in 2013 the U.S. Food and Drug Administration suspended clinical trials of cinacalcet in children because of safety concerns.) Parathyroidectomy may be a requisite lifesaving measure at times. Children with NSHPT who remain hypercalcemic are anorectic, fail to thrive, and are at risk for developmental delay.[58]

Secondary hyperparathyroidism in the neonate may be the result of maternal hypocalcemia due to hypoparathyroidism, PHP, renal tubular acidosis, or vitamin D deficiency.[58,85] Maternal hypocalcemia reduces placental transport and net delivery of calcium to the fetus, resulting in relative fetal hypocalcemia and leading to hyperplasia of the fetal parathyroid glands and secondary hyperparathyroidism proportional to the maternal calcium deficit. Although only 25% of infants of hypocalcemic mothers are hypercalcemic, most have skeletal changes that reflect PTH excess that vary from severe demineralization with fractures to osteopenia detectable only by bone mineral densitometry. Secondary hyperparathyroidism usually resolves within a few weeks after birth as the infant ingests adequate calcium and phosphate. Mucolipidosis type II (MIM 252500) is a second cause of neonatal secondary hyperparathyroidism; this Hurler-like disorder is characterized by facial abnormalities (asymmetry, flat nasal bridge), hepatosplenomegaly, skeletal deformities (dysostosis multiplex), and developmental delay and is due to inactivating mutations in a gene (*GNPTAB*) encoding N-Acetyglucosamine-1-phosphotransferase, α/β subunits, a lysosomal phosphotransferase required for synthesis of mannose 6-phosphate.[95,96] In this disease, maternal calcium concentrations are normal, but placental histology is abnormal, suggesting impaired placental transport of calcium and fetal hypocalcemia leading to compensatory increase in the in utero PTH generation. In turn, skeletal evidence of PTH excess (osteopenia, fractures) develops; secondary hyperparathyroidism and its adverse effects remit within the first several weeks to months after birth. Transient neonatal distal renal tubular acidosis has also been associated with hypercalcemia due to secondary hyperparathyroidism.

Murk-Jansen metaphyseal chondrodysplasia is an autosomal dominant chondrodystrophy associated with marked hypercalcemia as a consequence of heterozygous mutations that lead to constitutive, ligand-independent activation of *PTH1R* expressed in the kidney, bone, and growth plate chondrocytes.[84,85] Phenotypically, there is short-limbed dwarfism; deformities of the long bones, digits, spine, and pelvis; choanal atresia; highly arched palate; micrognathia; widely open cranial sutures (in infancy); sclerosis of the basal cranial bones; disorganization of the metaphyses (delayed chondrocyte differentiation, irregularly calcified cartilage protruding into the diaphysis); and excessive loss of cortical bone but normal trabecular bone. Interestingly, birth length and physical appearance are often normal in these neonates, although radiographic evidence of the chondrodysplasia is present. In affected neonates and infants, there are hypercalcemia, hypophosphatemia, increased serum concentrations of calcitriol, and elevated urinary excretion of nephrogenous cyclic adenosine monophosphate but low or undetectable serum levels of PTH and PTHrP. (Adults with this disorder are very short [adult height 100 cm], skeletal maturation is delayed, metaphyses of the long bones are long and histologically disorganized, and cranial bones are sclerotic.) Constitutively activating mutations of *PTH1R* in these subjects include His223Arg at the junction of the first intracellular loop and second transmembrane domain and Thr410Pro in the sixth transmembrane domain—sites that are specifically important

in conferring ligand-independent activity upon PTH1R.[84] Excessive secretion of PTHrP and resultant hypercalcemia have been observed in infants with neonatal iron storage disease and embryonal renal tumors (Wilms, mesoblastic nephroma).

Williams-Beuren syndrome (WBS) is a hemizygous contiguous gene deletion syndrome (involving 26 to 28 genes on chromosome 7q11.23) that is transmitted as an autosomal dominant disorder and whose prevalence is 1:7500 to 1:15,000 live births.[97,98] WBS is characterized by intrauterine and postnatal growth retardation, hypercalcemia in infancy in 15% of patients that usually resolves by 2 years of age but may occasionally persist into adulthood; consistent hypercalciuria; supravalvular aortic stenosis in 30% of subjects; narrowing and stenoses of the pulmonary, renal, mesenteric, and celiac arteries; microcephaly; "elfin" face (epicanthal folds, stellate iris pattern, esotropia, short nose with full nasal tip, arched upper and prominent lower lips, long philtrum, full cheeks with flattened malar eminences, dental malocclusion); hoarse voice; hyperacusis in childhood leading to nerve deafness, radioulnar synostosis, renal hypoplasia or unilateral agenesis; hypertension, and developmental delay (poor visual-motor integration, attention deficit disorder, mean IQ 58, range 20 to 106).[58] Although most patients with WBS are developmentally challenged, they have unique and proficient verbal skills with a large vocabulary and enhanced auditory memory particularly for names, adept social language skills, and exceptional musical aptitude including the ability to memorize and sing many musical compositions and play many instruments.[84] Children with WBS prefer to be in the company of adults rather than with their peers and are not shy or fearful of strangers.[97]

Hypercalcemia in WBS subjects may be pathogenetically related to a loss of function of the Williams syndrome transcription factor (WSTF) encoded by *BAZ1B*. WSTF is a nuclear protein that is part of a multimeric, ATP-dependent, chromatin remodeling complex termed WINAC (WSTF including nucleoside assembly complex).[99] Independently of ligand-binding, the VDR interacts with WINAC. Under usual circumstances, binding of calcitriol to the VDR-WINAC complex (1) represses expression of renal tubular *CYP27B1*, the gene encoding 25-hydroxyvitamin D-1α-hydroxylase, and (2) enhances transcription of *CYP24A1*, the gene encoding 25-hydroxyvitamin D-24-hydroxylase. Hence, haploinsufficiency of WSTF leads to an increased and relatively unregulated synthesis of calcitriol while slowing its rate of degradation; in response to the increase in calcitriol generation, the intestinal absorption of calcium increases and hypercalcemia ensues. Other endocrinopathies associated with WBS include glucose intolerance and hypothyroidism.[100]

WBS is the consequence of the deletion of chromosome 7q11.23 due to unequal meiotic recombination (unequal crossover of genes between chromosome 7 homologues during meiosis); this genetic error occurs with equal frequency in the gametes of both parents and results in the loss of 26 to 28 genes.[97] Hemizygosity of *ELN* (MIM 130160) encoding elastin is the likely cause of the cardiovascular malformations and hypertension observed in WBS, as partial loss of *ELN* leads to a compensatory increase in the number of rings of smooth muscle and elastic lamellae resulting in arterial thickening and increased risk of obstruction as well as softening of the skin and an aged appearance. Functional hemizygosity for *GTF2I* (MIM 601679) and *GTF2IRD1* (MIM 604318) may underlie the neurocognitive deficits and strengths that characterize WBS and the distinctive personalities of these patients.[97] Hemizygous loss of *STX1A* (MIM 186590) may be pathogenetically related to development of glucose intolerance in WBS subjects.[98] The WBS phenotype has also been associated with interstitial deletion of chromosome 6q22.2-q23 as well as defects in chromosomes 4, 11, and 22, implying that the syndrome is genetically heterogeneous involving a number of genetic systems. Diagnosis of the WBS syndrome is suspected on the basis of the characteristic clinical phenotype (with/without hypercalcemia) and confirmed by demonstration of the microdeletion at chromosome 7q11.23 by microarray or FISH, although a normal chromosome analysis does not entirely eliminate this diagnosis. Specific genotyping may also prove diagnostically useful on occasion. Hypercalcemia is managed by ingestion of a low-calcium, vitamin D–free formula; occasionally short-term glucocorticoid therapy may be necessary to restore eucalcemia.

Duplication of chromosome 7q11.23 results in a syndrome characterized by heart defects, diaphragmatic hernia, cryptorchidism, and neurocognitive and behavioral aberrations.[101] Additional findings in patients with dup7q11.23 include short stature and minor dysmorphic facial features (prominent forehead, long nasal tip, short philtrum, thin lips, retrognathia, folded ear helices). Neurocognitively, there is severe speech delay and often autistic behavior but intact visuocognitive skills—characteristics that are opposite to those present in WBS patients. Interestingly, duplication of *GTF2I*, one of the genes lost in del7q11.23 (WBS), reportedly results in separation anxiety in mice and humans.[102]

Idiopathic infantile hypercalcemia is manifested clinically by impaired growth, febrile episodes, polyuria and vomiting leading to dehydration, hypercalciuria, and nephrocalcinosis associated with hypercalcemia in the presence of decreased serum concentrations of PTH.[103] *CYP24A1* encodes 24-hydroxylase, an enzyme to which heme is bound that converts 25-hydroxyvitamin D to 24,25 dihydroxyvitamin D and 1,25-dihydroxyvitamin D to 1,24,25-trihydroxyvitamin D and increases their excretion in bile and urine. In some infants with idiopathic infantile hypercalcemia, biallelic loss-of-function mutations in *CYP24A1* have been demonstrated.[103] Delaying the degradation of 1,25-dihydroxyvitamin D prolongs its effective biologic life. Inactivating mutations in *CYP24A1* have also been found in adults with hypercalcemia, hypercalciuria, and nephrolithiasis.[104,105] *CYP24A1* mutations may either decrease the binding of the enzyme to its substrate or interfere with the interaction of heme and enzyme protein; either type of mutation decreases function of the enzyme protein.[106] In most patients hypercalcemia resolves within the first several years of life, but it may persist to older ages. Avoidance of vitamin D, low dietary calcium intake, and glucocorticoids to reduce

intestinal absorption of calcium are therapeutic modalities for this disorder.

Antenatal Bartter syndromes, type 1 (MIM 601678) and type 2 (MIM 241200) are clinically and biochemically identical and are due to biallelic loss-of-function mutations in genes controlling transepithelial transport of chloride (*SLC12A1*) and potassium (*KCNJ1*), respectively, into the lumen of the renal tubular thick ascending limb of the loop of Henle (TALH). Affected fetuses develop polyhydramnios leading to premature delivery with postnatal salt wasting, hypokalemic metabolic acidosis, hypercalciuria and occasionally hypercalcemia, nephrocalcinosis, osteopenia, failure to thrive, and often death. The type 1 disorder is due to inactivating mutations of the gene encoding sodium/potassium/chloride cotransporter-2 (*SLC12A1*), the mediator of active reabsorption of sodium chloride in the TALH, whereas the type 2 syndrome is due to an inactivating mutation in the gene encoding an inwardly rectifying apical potassium channel (*KCNJ1*).[107] Hypokalemia (occasionally transient hyperkalemia in the type 2 syndrome), reduced intravascular volume, and increased levels of angiotensin sum to increase renal and systemic production of prostaglandin E2 that further inhibits sodium and chloride reabsorption in the TALH and enhances juxtaglomerular renin release. Hypochloremic, hypokalemic alkalosis, hyperprostaglandin E, hypercalciuria leading to nephrocalcinosis and osteopenia, and hypercalcemia suggest neonatal Bartter syndrome. Replacement of fluid and electrolytes and administration of potassium sparing diuretics and the cyclooxygenase inhibitors (indomethacin or a specific inhibitor of cyclooxygenase type 2) may be effective in ameliorating the biochemical and clinical manifestations of the disease.

The "blue diaper" syndrome (MIM 211000) is named for the color noted on the diaper of affected infants; it is due to a defect in intestinal absorption of tryptophan that is then metabolized to indoles by bacteria, absorbed, excreted in urine, and turned blue when oxidized. It is associated with hypercalcemia and nephrocalcinosis, but its pathogenesis has not as yet been elucidated.

Infantile hypophosphatasia (MIM 241500) is an often fatal, autosomal recessive disorder that is recognized clinically by 6 months of age and is characterized by rickets, demineralization of the calvarium and peripheral skeleton, increased intracranial pressure (due to premature cranial synostosis), flail chest, vitamin B_6-dependent seizures, hypercalcemia, and hypercalciuria.[108,109] Radiographically, spurs of cartilage and bone extend from the sides of the knee and elbow joints.[110] The disease is due to defective osteoblast synthesis of tissue nonspecific alkaline phosphatase because of loss-of-function missense, nonsense, and donor splice site mutations of *ALPL*. The lethal homozygous or compound heterozygous mutations of *ALPL* are located within or near the enzyme domain or the homodimer and tetramer interfaces.[109] Decreased alkaline phosphatase activity results in a deficit in phosphate ions and impaired hydroxyapatite formation resulting in rickets, whereas continued intestinal calcium absorption leads to hypercalcemia. Inappropriately low serum bone alkaline phosphatase activity differentiates this condition from other rachitic or osteopenic states (osteogenesis imperfecta congenita or achondrogenesis type 1A) in which alkaline phosphatase activity is usually normal or elevated. Increased urine phosphoethanolamine and serum inorganic pyrophosphate (an inhibitor of hydroxyapatite crystallization that also impairs skeletal mineralization) and pyridoxal-5′-phosphate values are consistent with the diagnosis of hypophosphatasia, whereas analysis of *ALPL* identifies the gene mutation(s) itself. Hypophosphatasia can be diagnosed prenatally by *ALPL* genotyping.[108] The hypercalcemia of infantile hypophosphatasia is managed by hydration, diuretics that act at the TALH (e.g., furosemide), and the administration of bisphosphonates (pamidronate), calcitonin, or glucocorticoids as necessary. Dietary calcium intake should be restricted and vitamin D and its metabolites avoided. Bone marrow transplantation and "stem cell boosts" of transfused donor osteoblasts have also been used to treat affected patients. Administration of recombinant TNSALP has been employed successfully to treat life-threatening hypophosphatasia.[111] A clinical trial (NCT00744042) of the efficacy and safety of biosynthetic human recombinant tissue nonspecific alkaline phosphatase fusion protein in 1-year-old patients with infantile hypophosphatasia has been completed; 9 of 11 subjects demonstrated radiographic response after 24 weeks of treatment, but many adverse effects were recorded in this study.

Evaluation and Management

After historical review (the family history is explored for members with mineral disorders and maternal status considered in depth, and the infant's intake of calcium, phosphate, and vitamin D is estimated) and physical examination (nonspecific manifestations of hypercalcemia include hypertension, subnormal growth, hypotonia, weakness, lethargy, stupor, occasionally seizures; specific findings associated with hypercalcemia include facial and cardiovascular signs of WBS, subcutaneous nodules consistent with fat necrosis, deformities of metaphyseal chondrodysplasia or infantile hypophosphatasia) have been completed, evaluation of the hypercalcemic neonate and infant continues with total serum calcium and Ca^{2+}, phosphate, alkaline phosphatase, PTH, calcidiol, and calcitriol measurements and determination of urine calcium and creatinine levels (see Table 18-6, presented later in the chapter, and Figure 18-4). Hypocalciuria in the presence of hypercalcemia suggests the presence of NSHPT. Occasionally one may encounter a neonate in whom the total calcium concentration is elevated due to hyperproteinemia but the Ca^{2+} value is normal, a state termed "pseudohypercalcemia" by some authors.[85,112] In infants with suspected WBS, microarray or FISH analysis searching for deletion of chromosome 7q11.23 should be undertaken. In those in whom NSHPT is suspected, determination of parental serum and urine calcium and creatinine values is often helpful unless the disorder has been transmitted as an autosomal recessive disease.[89,90] Genotyping of CASR should be undertaken when *NSHPT* is being considered.

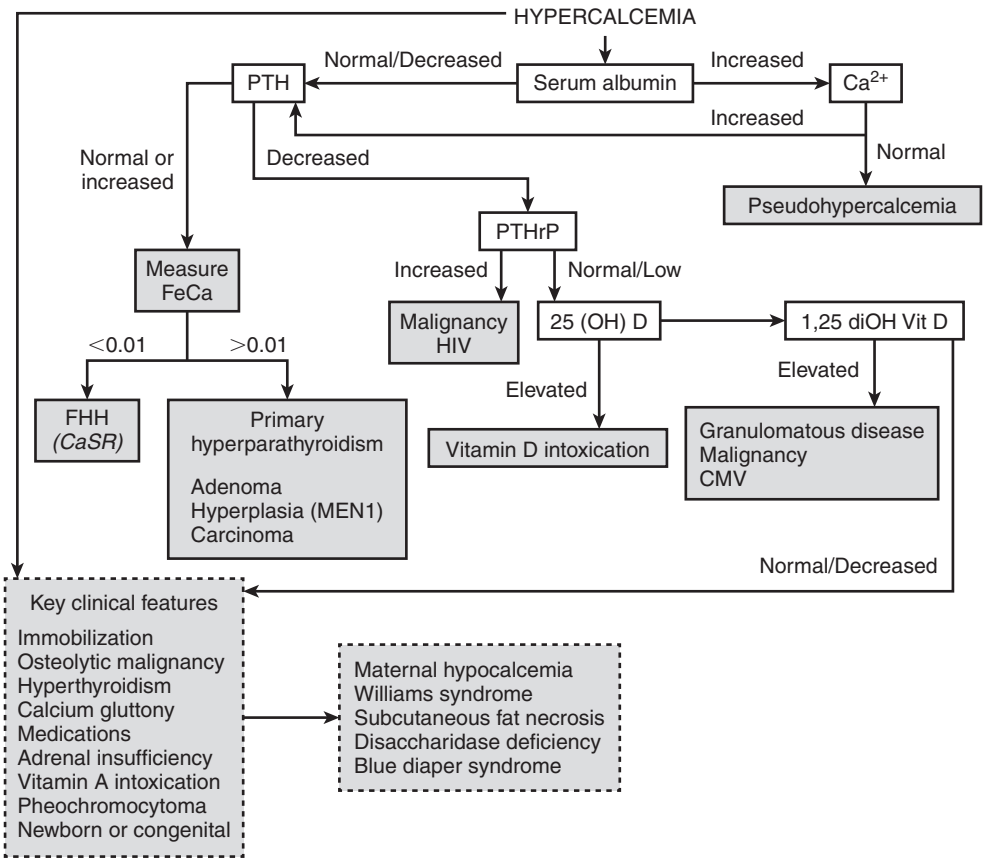

FIGURE 18-4 ■ Evaluation of hypercalcemia. FeCa, fractional excretion of urinary calcium. (From Lietman, S. A., Germain-Lee, E. L., & Levine, M. A. (2010). Hypercalcemia in children and adolescents. *Curr Opin Pediatr*, *22*, 508–515.)

Treatment of hypercalcemia in neonates and infants focuses on preventing its progression, identifying its cause, and assessing its severity. Use of a formula low in calcium and avoidance of vitamin D (excessive intake or sunlight) are helpful in the majority of neonates with modest hypercalcemia.[58] Infants with significantly elevated serum calcium levels, particularly if long standing, are often dehydrated. Immediate treatment consists of infusion of 0.9% sodium chloride with 30 mEq/L of potassium chloride (10 to 20 mL/kg over 1 hour); after dehydration has been corrected and adequate urine flow established, and if substantial hypercalcemia persists, an intravenous bolus injection of furosemide (1 to 2 mg/kg) may be administered. Currently, bisphosphonates, analogs of pyrophosphate that adsorb to the surface of hydroxyapatite crystals and are incorporated into and then disable the osteoclast and thereby inhibit osteoclast dissolution of bone mineral and matrix, are the agents of choice for the treatment of substantial hypercalcemia in infants. Etidronate (5 mg/kg twice daily orally) and pamidronate (0.5 to 2 mg/kg in 30 mL normal saline intravenously over 4 hours) have been successfully employed in infants with hypercalcemia due to vitamin D intoxication, subcutaneous fat necrosis, NSHPT, and other causes.[85,113,114] The effects of bisphosphonate last for several weeks to months and when administered in excess can lead to hypocalcemia, hypophosphatemia, and hypomagnesemia.[85] Other agents that may be considered in the treatment of a hypercalcemic infant include hydrocortisone (l mg/kg intravenously every 6 hours) to reduce intestinal calcium absorption and salmon calcitonin (2 to 4 units/kg subcutaneously every 12 hours) to inhibit calcium mobilization from bone. Inasmuch as the type II calcimimetic—cinacalcet—has been demonstrated experimentally to improve the function of many inactive mutant forms of the CASR and to be of clinical benefit in an older subject with familial hypocalciuric hypocalcemia, a therapeutic trial of this agent may be considered in a patient with NSHPT with appropriate safeguards and permissions.[85,115] In the newborn with life-threatening NSHPT, total parathyroidectomy may be urgently required.[114] Postoperatively, the patients may become hypocalcemic—as calcium is avidly deposited in bone ("hungry bone syndrome")—and require large amounts of supplemental calcium until stabilized.

Infants with hypercalcemia due to WBS (and other forms of hypercalcemia as well) may be managed by ingestion of a low-calcium formula (Calcilo XD, < 10 mg of calcium per 100 calories; no vitamin D) and withholding of supplemental vitamin D. Hypercalcemia in WBS subjects usually remits by 2 years of age. Infants with "idiopathic" hypercalcemia of infancy due to inactivating mutations of *CYP24A1* should receive the low-calcium formula and supplemental vitamin D should be withheld.

Mineral homeostasis must be monitored closely in infants receiving a low-calcium formula and from whom vitamin D is being withheld in order to prevent deficiencies of both nutrients.

Hypercalcemia in the Child and Adolescent

Etiology

Causes of hypercalcemia in infants, children, and adolescents are listed in Tables 18-4A and B. In the presence of a normal serum protein concentration, hypercalcemia occurs when the "set point" for serum Ca^{2+} is increased due to a loss-of-function mutation in *CASR* or the set point is reversibly increased by lithium, or when the rate of entry of calcium into the extracellular and circulatory compartments from bone, the intestinal tract, or the kidney exceeds its rate of loss.[112] The resorption rate of bone mineral may be increased by excessive secretion of PTH or PTHrP, constitutive activation of PTH1R, excessive vitamin D or metabolites, increased production of osteoclast-activating inflammatory cytokines or localized osteolytic processes such as metastatic neoplasms, and dissociation of the rates of bone formation and resorption (e.g., immobilization). The absorption rate of intestinal calcium may be increased by excessive intake of calcium, by hypervitaminosis D of exogenous or endogenous origin, or by increased secretion of PTH or PTHrP. Augmented renal tubular reabsorption of filtered calcium may occur with the administration of calcium-sparing diuretics such as thiazides, an effect that may "unmask" hypercalcemia in a previously eucalcemic patient with hyperparathyroidism.[116] The total serum calcium concentration but not the Ca^{2+} concentration increases in the presence of hyperalbuminemia (pseudohypercalcemia). Venous stasis (e.g., by tourniquet) results in spuriously altered local pH and Ca^{2+} values.

Familial hypocalciuric hypercalcemia type 1 (HHC1) is an autosomal dominant disorder with 100% penetrance at all ages characterized by PTH-dependent usually asymptomatic (total and ionized) hypercalcemia with hypocalciuria (and, therefore, an absence of nephrocalcinosis or calcium-containing renal calculi), hypermagnesemia, hypomagnesuria, and hypophosphatemia that is due to heterozygous loss-of-function mutations in *CASR*.[117-119] Consequently, higher serum concentrations of Ca^{2+} are required to inhibit synthesis and secretion of PTH and to suppress renal tubular reabsorption of calcium. Serum concentrations of PTH may be normal or slightly elevated but inappropriately high for the Ca^{2+} level; calcidiol and calcitriol values are normal. In children, HHC1 is most commonly suspected initially by the presence of unexpected hypercalcemia (11 to 13 mg/dL) in a chemistry profile or through family screening of a parent or other relative with hypercalcemia. Older subjects with HHC1 may complain of fatigue, weakness, or polyuria; there is a slightly increased incidence of relapsing pancreatitis, cholelithiasis, chondrocalcinosis, and premature vascular calcification in subjects with HHC1, but bone mass and fracture rate are normal. Because of decreased parathyroid chief cell membrane CaSR number or function, the set point for Ca^{2+} suppression of PTH secretion is reset upward.[115,117] The parathyroid glands are slightly hyperplastic. In renal tubular cells, decreased CaSR number and activity lead to increased renal tubular reabsorption of filtered calcium and relative hypocalciuria (ratio of calcium clearance/creatinine clearance < 0.01 in 80% of patients with HHC1); renal tubular reabsorption of magnesium is also increased; urinary concentrating ability and other measures of renal function are normal; in hypercalcemia of other pathogenesis, urinary calcium excretion is increased and renal concentrating ability depressed. Usually, HHC1 requires no therapy but must be differentiated from mild primary hyperparathyroidism in which hypomagnesemia and hypercalciuria are present. Subtotal parathyroidectomy in HHC1 does not lower calcium levels as the residual parathyroid glands hypertrophy; total parathyroidectomy is unnecessary except in some infants with NSHPT. More than 100 nonsense, missense, insertion, and deletion mutations in *CASR* associated with HHC1 or NSHPT have been identified, mostly in the receptor's extracellular Ca^{2+} binding domain; these mutations either decrease receptor affinity for Ca^{2+} or alter intracellular processing of the CaSR (glycosylation, dimerization [e.g., Arg66His, Asn583Stop]) in the endoplasmic reticulum, preventing its translocation to the surface of the cell membrane[115,119,120] (Figure 18-5). Many of the mutations are located in the extracellular domain of CaSR between codons 39 to 300, a region rich in aspartate and glutamate residues in which Ca^{2+} may nestle.[43] Glycosylation is necessary for both dimerization and trafficking of the CaSR. Missense mutations involving arginine at codon 66 (Arg66His, Arg66Cys) result in a product that is able to be only partially glycosylated; it can form homodimers in the endoplasmic reticulum but cannot enter the Golgi apparatus and be transported to the cell plasma membrane.[120] Experimentally, approximately 50% of the products of inactivating mutations of *CASR* can be "escorted" to the plasma membrane and functionally stabilized by the allosteric calcimimetic cinacalcet (NPS R-568), proffering a potentially therapeutic agent for the management of patients with symptomatic hypercalcemia due to loss-of-function *CASR* mutations, especially those with NSHPT, if it proves safe to do so (as noted earlier).[115] Mutations in *CASR* tend to be unique to the affected family. In approximately one third of families with HHC1, no mutations in the coding region of *CASR* have been identified; they may have a mutation in a noncoding region of *CASR* or an abnormality in genes associated with the HHC1 phenotype that have been identified on chromosomes 19p13.3 (HHC2, MIM 145981) and 19q13 (HHC3, MIM 600740).[117] Autoantibodies against the amino terminal extracellular domain of the CaSR that reversibly inhibit receptor activity have been identified in patients with acquired HHC1; this disorder may be responsive to glucocorticoid therapy.[73,121] In some patients with primary or uremic secondary hyperparathyroidism, there is reduced expression of *CASR* and an increased set point for suppression of PTH secretion.

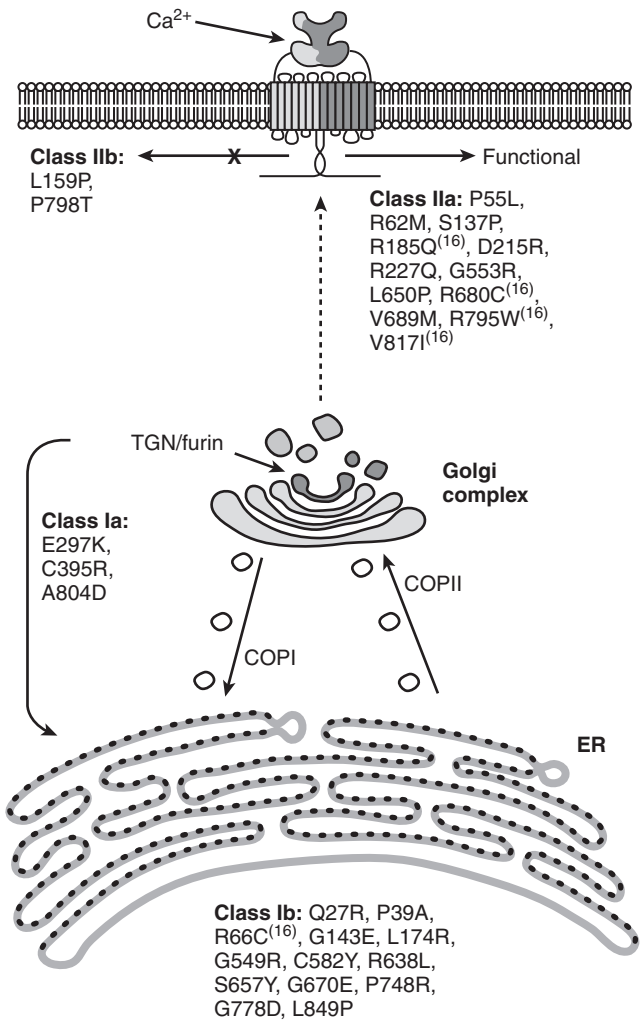

FIGURE 18-5 ■ Movement of the calcium sensing receptor through the endoplasmic reticulum (ER) and Golgi complex to the cell membrane. Inactivating mutations of *CaSR* may arrest movement of CaSR at various sites along this pathway including the cell membrane. Depending on the site of arrested movement, the mutations are designated classes Ia (Golgi), Ib (endoplasmic reticulum), and II (plasma membrane). Functional activity of class IIa CaSR mutants can be "rescued" by a pharmacochaperone inserted into the plasma membrane and attain functionality, whereas class IIb CaSR mutants are resistant to pharmacochaperone administration and remain inert. (From White, E., McKenna, J., Cavanaugh, A., & Breitwieser, G. E. (2009). Pharmacochaperone-mediated rescue of calcium sensing receptor loss-of-function mutants. *Molec Endocrinol, 23,* 1115–1123.)

Primary hyperparathyroidism is an unusual childhood disorder with an incidence of 2 to 5/100,000 as compared with that in adults of approximately 100/100,000.[122,123] In adults with hyperparathyroidism, females outnumber males 3:1; in children the female-to-male ratio is closer to 1. In older children and adolescents, primary hyperparathyroidism is most often a sporadic disease and usually the result of a single parathyroid adenoma. It also occurs as an autosomal dominant disorder in familial isolated primary hyperparathyroidism (MIM 145000) due to germline mutations in the genes responsible for multiple endocrine neoplasia (MEN) type I (*MEN1*) or the hyperparathyroidism-jaw tumor syndrome (*CDC73*).[84,85,114,122,124,125]

The majority of children and adolescents with hypercalcemia due to hyperparathyroidism are symptomatic at the time of diagnosis (personality and behavioral changes, particularly depression, headache, malaise, proximal muscle weakness, anorexia, abdominal cramping, nausea and vomiting, constipation, polydipsia and polyuria) or present with symptoms reflecting the consequences of this disorder such as flank pain and hematuria due to renal calculi (hypercalciuria), abdominal pain (pancreatitis), or pathologic fractures (through areas of osteopenia or lesions of osteitis fibrosa cystica).[93,114,123] Although the physical examination may reveal slight weakness of proximal musculature, it is unusual to palpate a cervical mass in these patients. Hypercalcemia, hypophosphatemia, and elevated serum concentrations of intact PTH are present in the majority of children with hyperparathyroidism. Ultrasonography, magnetic resonance imaging, computed tomography, three-dimensional imaging, and radionuclide scans (^{99m}Technetium-labeled sestamibi-single photon emission CT scan) have been employed to localize the abnormal parathyroid gland(s) prior to surgical excision (as discussed earlier). (Sestamibi is methoxyisobutyl isonitrile, a lipophilic cation.) Occasionally, the parathyroid tumor may be located ectopically in the thymus, thyroid gland, or mediastinum.

In subjects with primary hyperparathyroidism, hypercalcemia is the result of increased secretion of PTH due to loss of the normal relationship between the set point of serum Ca^{2+} and PTH synthesis and release and to Ca^{2+}-independent (constitutive) PTH secretion related to the mass of parathyroid tissue.[122] Pathologically, hyperparathyroidism in children is most often due to a chief cell adenoma involving one parathyroid gland, but adenomas in several parathyroid glands and diffuse hyperplasia (particularly in patients with multiple endocrine neoplasia type 1) and rarely carcinoma of the chief cells may also occur.

The majority of parathyroid adenomas are monoclonal in origin—that is, a single mutant cell develops into a tumor. In adolescents, parathyroid tumors may rarely develop after external radiation of the neck for treatment of lymphoma. In some parathyroid tumors, increased expression of cyclin D1 (encoded by *CCND1*, MIM 168461, chromosome 11q13.3) has been demonstrated; cyclins are intracellular proteins that regulate cyclin-dependent protein kinases that control the rate of cellular transition from G1 to S in the cycle of cell division.[43] Overexpression of *CCND1* in parathyroid chief cells is at times the result of a somatic chromosome mutation—inversion (rotation) of regions 11p15 and 11q13 in which the promoter region of *PTH* is repositioned to serve as a promoter for *CCND1*, thereby increasing the rate of chief cell division whenever the (hypocalcemic) stimulus for PTH generation is received and leading ultimately to (benign) tumor formation. However, in many parathyroid adenomas there is increased activity of cyclin D1 without this chromosomal rearrangement.[122] In patients with parathyroid adenomas and carcinomas, overexpression of the retinoblastoma and p53 tumor-suppressor genes, whose products normally inhibit the cell cycle at

the G1/S step, has also been demonstrated as have somatic mutations in *CDC73*.[126] In approximately 35% of sporadic parathyroid adenomas, a somatic loss-of-function mutation of the tumor suppressor factor menin—the germline mutation in patients with MEN type 1—can be identified together with loss of heterozygosity on chromosome 11.[127] Germline loss-of-function mutations in *MEN1* and *CASR* have also been detected in patients with isolated primary hyperparathyroidism in association with multiglandular involvement; in this instance, patients with *CASR* mutations did not have the typical biochemical findings of HHC1 (Table 18-4B).[124,128] Chronic renal insufficiency leads to secondary hyperparathyroidism due to hyperplasia of the parathyroid glands and also to monoclonal parathyroid tumors (tertiary hyperparathyroidism) associated with somatic chromosomal deletions in some instances.

Isolated autosomal dominant familial primary hyperparathyroidism (HRPT1) or in association with multiple ossifying fibromas of the jaw (HRPT2) is due to loss-of-function heterozygous germline mutations in the tumor suppressor gene encoding parafibromin *(CDC73R)*.[114,129] Hyperparathyroidism occurs in 80% of subjects with a mutation in *CDC73* at a mean age of 32 years, but it may also appear in children younger than 10 years of age.[130] In these patients, the parathyroid lesion may be an atypical, potentially premalignant cystic adenoma (65%), hyperplasia (20%), or even carcinoma (15%); the parathyroid tumor may be an isolated finding or it may be associated with maxillary or mandibular bone tumors composed of ossified fibrous tissue; renal (Wilms tumor, papillary renal cell carcinoma, hamartoma, polycystic kidney), pancreatic (carcinoma), and uterine (tumor) lesions may also develop in these patients.[43,124] Lesions within the parathyroid glands may develop asynchronously. *CDC73* is a 17 exon gene that encodes parafibromin, a 531-amino-acid nuclear protein that is a component of a complex of accessory factors that modulates the activity of RNA polymerase II and of a histone methyltransferase (SUV39H1) and hence regulates gene expression and cell proliferation—functioning as both a transcriptional activator and repressor.[131,132] Parafibromin is also a component of the WNT signaling system; experimentally, overexpression of *CDC73* increases WNT signaling activity through β-catenin.[133] For a parathyroid tumor to develop, a "second hit" must occur that results in a loss of heterozygosity—that is, the germline inactivating mutation of *CDC73* on one allele must be matched by a mutation in or deletion of *CDC73* in the remaining normal allele.[134] When a germline mutation in *CDC73* has been detected, screening of family members for this mutation and longitudinal evaluation of affected subjects is recommended as asymptomatic individuals with atypical adenoma or carcinoma of the parathyroid glands may be so identified.[135] Somatic mutations in *CDC73* have also been identified in atypical parathyroid adenomas and many parathyroid carcinomas (MIM 608266), but they are unusual in the typical sporadic parathyroid adenoma.[136] Familial isolated hyperparathyroidism type 3 (HRPT3, MIM 610071) has been linked to chromosome 2p14-p13.3, but a specific mutated gene in this region has not as yet been identified.

The syndromes of multiple endocrine neoplasia (MEN) are familial autosomal dominant diseases of high penetrance associated with the development of tumors in two or more endocrine glands within a single individual.[124,125] There are four defined MEN syndromes: 1, 2A, 2B, and 4 (Table 18-5). MEN1 is characterized by development of tumors of the parathyroid glands (adenoma), pituitary (prolactinoma, somatotropinoma), and enteropancreatic unit (gastrinoma, insulinoma, pancreatic polypeptide-oma, carcinoid). In addition, neoplasms of the adrenal cortex, neuroendocrine tumors of the bronchopulmonary tree and thymus, lipomas, angiofibromas, collagenomas, and meningiomas develop in affected subjects.[125] The postmortem incidence of MEN1 is 0.25%; in hyperparathyroid subjects it is 1% to 18%; in patients with gastrinoma it is 16% to 38%.[125] Hyperparathyroidism (due to a solitary parathyroid adenoma or tumors within several parathyroid glands or hyperplasia of all four parathyroid glands) is the most common manifestation of MEN1 occurring in more than 90% to 95% of affected patients; it is the most frequent endocrinopathy in children with MEN1, at times developing before the child is 10 years of age. Unlike other forms of hyperparathyroidism, equal numbers of males and females are affected in MEN1. Pituitary tumors secreting prolactin or growth hormone often (30% to 40% of MEN1 subjects) develop as do gastrin- (Zollinger-Ellison syndrome), insulin-, and glucagon-secreting tumors of the pancreatic islets and gastrointestinal system (30% to 70% of patients); these neoplasms also occur in children and adolescents with MEN1.[43,124] Hypercortisolemia in patients with MEN1 may be due to excessive secretion of adrenocorticotropin by a pituitary adenoma or ectopically by a neoplasm or to a primary adrenal tumor. Thyroid neoplasms occur in 25% of patients with MEN1. Nonendocrine tumors such as lipomas (34%), intestinal and bronchial carcinoids, and other intestinal neoplasms are reasonably common in subjects with MEN1. Indeed, the dermatologic manifestations of MEN1 (angiofibromas, 85%; collagenomas, 70%; more than three angiofibromas and any collagenomas) are extremely sensitive and specific indicators of this disease.[137] Patients with MEN1 may also develop a schwannoma or a pheochromocytoma, the latter a tumor most often present in patients with MEN types 2A and 2B. Although most of the tumors that develop in MEN1 are benign but functionally hyperactive, those of pancreatic, intestinal, and foregut origin may be malignant.

Germline mutations in *MEN1*, a 10 exon gene that encodes a 610-amino-acid cytoplasmic and nuclear protein termed menin, have been demonstrated in the majority of patients with familial and sporadic forms of MEN1. Menin regulates cell growth, division, and demise in two sites and through multiple pathways. In the cytoplasm, menin binds AKT1 (protein kinase B—MIM 164730, chromosome 14q32.33), preventing its translocation to the cell membrane where it is ordinarily activated by phosphorylation enabling AKT1 to exert proliferative and antiapoptotic effects; by binding of menin to AKT1, both the cytosolic level of AKT1 and its kinase activity are depressed, thereby suppressing its effects on cell division and survival, a property lost when

TABLE 18-5 **Multiple Endocrine Neoplasia Syndromes**

Subtype	Gene	Chromosome	Site of Frequent Tumors	Mutations
MEN 1	*MEN1*	11q13.1	Parathyroid (90%)	Intron 4 N:5168 G->A (10%)
			Enteropancreatic (30%-70%): gastrinoma,	Codons 83-84 (4%)
			Insulinoma, pancreatic polypeptide,	Codons 119 (3%)
			nonfunctional	Codons 209-211 (8%)
			Anterior pituitary (30%-40%): prolactinoma	Codon 418 (4%)
			GH, ACTH, nonfunctional	Codon 516 (7%)
			Adrenocortical (40%): diffuse and nodular hyperplasia, adenoma, carcinoma	
			Intestinal: gastric neuroendocrine (10%),	
			Thymic neuroendocrine (2%)	
			Other: facial angiofibroma (85%), collagenoma (70%),	
			lipoma (30%), meningioma (8%)	
MEN 2	*RET*	10q11.21		
MEN 2A			MCT (90%)	Codon 634 (Cys->Arg, 85%)
			Pheochromocytoma (50%)	
			Parathyroid hyperplasia (20%-30%)	
			Cutaneous lichen amyloidosis	
MEN 2B (3)			MCT (> 90%)	Codon 918 (Met->Thr, > 95%)
			Pheochromocytoma (40%-50%) Associated:	
			Marfanoid habitus	
			Mucosal neuromas (90%)	
			Medullated corneal nerves	
Megacolon				
MEN 2C			MCT (100%)	Codon 618 (> 50%)
MEN 4	*CDKN1B*	12p13.1	Parathyroid	
			Pituitary	
			Testicular/cervical	
			Renal/adrenal	

MCT, medullary carcinoma of thyroid.

(2012). Clinical practice guidelines for multiple endocrine neoplasia type 1 (MEN1).* J Clin Endocrinol Metab, 97, *2990–3011.*

MEN1 sustains an inactivating mutation.[138] Menin enters the nucleus with the guidance of two nuclear localization signals in its carboxyl terminus (amino acids 479 to 498, 589 to 608) where it is involved directly in the regulation of transcription, replication, and survival. By binding directly to JunD, menin blocks JunD-mediated inhibition of transcription of activating protein-1 (and consequently cell division); many of the mutations in *MEN1* in patients with MEN1 cluster in exon 4 and interrupt the binding of these two proteins (between menin amino acids 139 to 142 and 323 to 428). By interacting with SMAD3 (MIM 603109, chromosome 15q22.3), menin inhibits signaling by transforming growth factor (TGF) β and impairs TGFβ-mediated inhibitory control of cell replication.[139] Interaction of menin with the SMAD 1/5 complex inhibits signaling by bone morphogenetic protein (BMP) 2; menin also inhibits the transcription regulating protein—nuclear factor κB (NFκB).[43,140] Further, menin interacts directly with a histone methyltransferase complex and with genes that regulate DNA repair and cell replication and apoptosis such as tumor suppressor *TP53* (p53), *CDKN1A*, *CDKN1B*, *GADD45A*, *POLR2A*, *BBC3*, *TP5313*, and *FAS*.[141]

In subjects with heterozygous germline loss-of-function mutations in *MEN1*, unregulated cell growth and tumor formation occur when a second insult leads to loss of *MEN1* on the normal allele within susceptible tissues. As with *CDC73* (discussed previously), the "two hit"

hypothesis of tumorigenesis in MEN1 denotes that the patient inherits germline susceptibility to neoplasia superimposed on which is a second insult leading to loss of heterozygosity for chromosome segment 11q13 and biallelic loss of *MEN1*; the "second hit" may be deletion of a segment of chromosome 11 that includes 11q13 or a mutation (missense, frameshift) within the wild-type *MEN1* allele itself, an observation that also extends to MEN type 1 tumors with somatic mutations in *MEN1*.[124] Several hundred germline mutations in *MEN1* have been identified in patients with MEN1; 25% have been nonsense mutations, 15% missense mutations, 45% frameshift insertions or deletions, with more than 80% leading to the synthesis of an inactive product due to loss of the nuclear localization signal or the ability to bind to JunD or other downstream factor. Especially susceptible germline mutational "hot spots" in *MEN1* are nucleotide 5168 G ⇒ A transitions, which result in a novel splice site in intron 4, codons 83 to 84, 118 to 119, 209 to 211, 418, and 516 where collectively mutations have been identified in 37% of patients with MEN1.[142] On either side of many of these sites are segments of repeat DNA sequences of single nucleic acids or of dinucleotides to octanucleotides; this configuration may lead to increased susceptibility to "replication-slippage" because of misalignment of the nucleotide repeat segments during DNA replication permitting deletion or insertion of nucleotides at inappropriate sites. Mutations within the exonic/intronic splice site coding region of *MEN1* have been detected in approximately 70% of patients with familial MEN1; likely in the remaining 30% of subjects there is either deletion of one *MEN1* allele or a mutation in one of its noncoding regions.[143] New mutations of *MEN1* occur sporadically in 10% of patients with MEN1. In only 7% of patients with a variant of MEN1 in which only tumors of the parathyroid gland and the adenohypophysis are present has a mutation in *MEN1* been identified.[144] Familial autosomal dominant, isolated primary hyperparathyroidism has been variably associated with germline mutations (e.g., Val184Glu, Glu255Lys, Gln260Pro) in *MEN1* as well. Somatic mutations in *MEN1* have also been identified in patients with sporadic, isolated tumors of the parathyroid glands, pancreatic islet cells, anterior pituitary, and adrenal cortex.[43] Clinically apparent disease due to mutations in *MEN1* increases with advancing age: at 10 years of age, 7% of children with a mutation in *MEN1* have a detectable endocrinopathy (primarily hyperparathyroidism); 52% of affected 20-year-old subjects manifest one or more tumors; penetrance increases to 87% by 30 years, to 98% by 40 years and to 100% by 60 years.[125]

There are three forms of multiple endocrine neoplasia type 2: types 2A, 2B (also termed type 3), and 2C. Medullary carcinoma of the thyroid (MCT) is the most common neoplasm encountered in MEN 2A occurring in 90% of patients (MIM 171400) (see Table 18-5).[125,143] It evolves from antecedent parafollicular C-cell hyperplasia within the thyroid gland. These subjects also develop adrenal medullary pheochromocytomas (50%), parathyroid hyperplasia or adenoma (20% to 30%), localized cutaneous lichen amyloidosis (suprascapular pruritic deposits of subepidermal keratin), and partial or complete megacolon. Calcitonin, the secretory product of thyroid C cells, is also produced in large amounts by MCT; its measurement aids in the diagnosis of MCT and in monitoring the response of this tumor to therapy. In addition to MCT and pheochromocytoma, patients with MEN 2B (MIM 162300) have a marfanoid habitus, mucosal neuromas of the lips and tongue, gastrointestinal ganglioneuromas, medullated corneal nerve fibers, and megacolon, but they do not develop parathyroid disease.[124,125,143] Familial isolated MCT is a variant of these disorders. Germline heterozygous gain-of-function mutations in the *RET* proto-oncogene underlie the pathogenesis of the type 2 hereditary multiple endocrine neoplasias (Figure 18-6). *RET* is a 20-exon gene encoding an 860 amino acid glycosylated cell membrane tyrosine kinase receptor with extracellular, transmembrane, and intracellular domains that is expressed in tissue of neural crest origin (sympathetic ganglia, adrenal medulla, thyroid parafollicular cells). The natural ligand of this receptor is glial cell line–derived neurotrophic factor (GDNF—MIM 600837, chromosome 5p13.2). Constitutively activating mutations of one of six cysteine residues in the extracellular domain of RET—codons 609, 611, 618, 620, 630, and particularly codon 634 (Cys -> Arg)—are present in patients with MEN 2A. Loss of but one cysteine residue facilitates receptor homodimerization without ligand binding, thereby activating the RET intracellular tyrosine kinase domain resulting in autophosphorylation of critical tyrosine residues (particularly at codons 1015 and 1062) and subsequent signal transduction.[124] An activating mutation has been identified at codon 918 (Met -> Thr) in more than

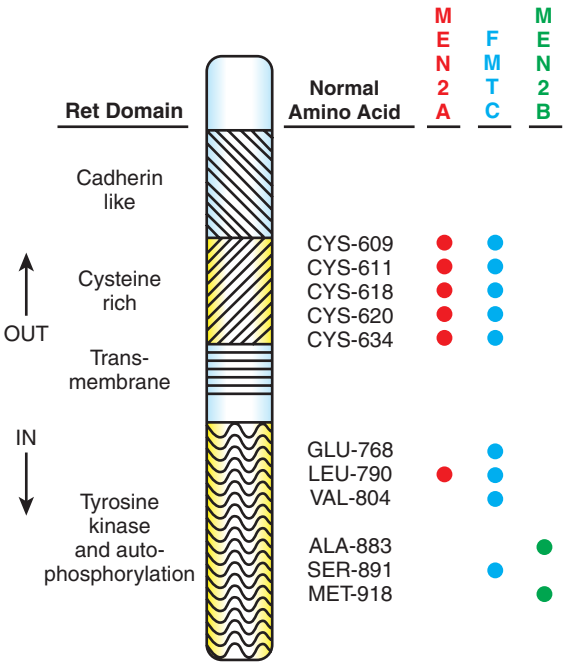

FIGURE 18-6 ■ Schematic depiction of the domains of the *RET* protooncogene with sites of activating mutations in *RET* associated with multiple endocrine neoplasia types 2A and 2B and familial medullary carcinoma of the thyroid. (From Marx, S. J., & Simonds, W. F. (2005). Hereditary hormone excess: genes, molecular pathways, and syndromes. *Endocr Rev, 26*, 615–661.) *This image can be viewed in full color online at ExpertConsult.*

95% of patients with MEN 2B; this site lies within the tyrosine kinase domain and this mutation permits signal transduction and neural cell transformation and differentiation in the absence of both ligand binding *and* receptor homodimerization. The Met918Thr MEN 2B-associated *RET* mutation often arises de novo from sporadic mutations that occur in the germline of an older father, because this mutation confers a "selective advantage" upon the mutated spermatocyte.[145] Other missense mutations of *RET* associated with MEN 2B have been identified at codons Val804, Ala883, and Ser904. Missense mutations at *RET* codons 609, 611, 618, 620, and 634 within the extracellular domain and at codons 768, 790, 804, and 891 within the intracellular tyrosine kinase domain have been found in patients with familial MCT. Two coreceptors, GFRA1 and GFRA2, interact with RET protein, but no role of the coreceptors in the pathogenesis of MEN 2 has yet been identified. In addition to the disorders designated "multiple endocrine neoplasia," other familial syndromes associated with the development of tumors of the endocrine and other systems include Von-Hippel-Lindau (adrenal medulla, pancreas, neuroendocrine), Beckwith Wiedemann (adrenal cortex, rhabdomyosarcoma, Wilms, hepatoblastoma), Carney complex (adrenal cortex, testes, pituitary, thyroid), Cowden (thyroid, endometrial, breast), McCune-Albright (pituitary, adrenal cortex), neurofibromatosis type I (adrenal medulla, thyroid, pancreatic, carcinoid), tuberous sclerosis (pituitary, parathyroid, pancreatic, adrenal medulla, carcinoid), Peutz-Jeghers (thyroid, ovarian, Sertoli cell, pancreas), Li-Fraumeni (adrenal cortex, bone, breast, brain), and familial polyposis coli (thyroid, pancreatic, adrenal cortex, hepatoblastoma, sarcoma, medulloblastoma).[124,146] In children, hyperparathyroidism is an unusual manifestation of the McCune-Albright syndrome due to a postzygotic activating mutation of *GNAS*.[147]

Ingestion of excessive amounts of vitamin D or calcitriol for therapeutic reasons (treatment of rickets, hypoparathyroidism, or other causes of hypocalcemia), megavitamin intake, manufacturing errors in the preparation of vitamin supplements, or inappropriate fortification of milk are major causes of hypervitaminosis D.[148,149] Topical application of creams containing vitamin D or an analog (e.g., 22-oxacalcitriol) for treatment of psoriasis might also lead to hypercalcemia, particularly if the urinary excretion of calcium is compromised.[150] Patients with granulomatous diseases (noninfectious: sarcoidosis, berylliosis, eosinophilic granuloma, subcutaneous fat necrosis, inflammatory bowel disease; infections: tuberculosis, histoplasmosis, coccidioidomycosis, candidiasis, cat-scratch disease) and neoplastic disorders (B-cell lymphoma, Hodgkin disease, dysgerminoma) develop hypercalcemia due to the associated monocytic (macrophage and other cells) expression of $25OHD_3$-1α-hydroxylase activity and the production of calcitriol.[151] Unlike renal tubular cells in which this enzyme is within mitochondria and the transcription of *CYP27B1* is closely regulated by PTH, calcitriol, calcium, and phosphate, in monocytes $25OHD_3$-1α-hydroxylase is microsomal in location and its gene is constitutively expressed and calcitriol synthesis quantitatively determined by the amount of substrate. The monocytic expression of *CYP27B1* is sensitive to stimulation by interferon-γ and its postreceptor signal transducer nitric oxide, as well as by leukotriene C_4; it is easily suppressed by glucocorticoids, ketoconazole, and chloroquine. Subjects with acquired immunodeficiency disease may become hypercalcemic by infection with granuloma-forming organisms or by osteoclast-activating cytokines elaborated during the course of this disorder. Elevated serum calcium concentrations have also been recorded in children with congenital hypothyroidism, primary oxalosis, congenital lactase deficiency, trisomy 21, and juvenile idiopathic (rheumatoid) arthritis.[152] In some hypercalcemic children, excessive prostaglandin production may be of pathogenetic significance. Hypercalcemia develops frequently in small subjects with the infantile form of hypophosphatasia, likely a consequence of the dissociation of the rates of low bone formation and normal bone resorption. Hypercalcemia may follow successful bone marrow transplantation in infants with osteopetrosis as functional osteoclasts rapidly reabsorb excess bone mineral.

Oncogenic or malignancy-associated hypercalcemia may be the consequence of synthesis and secretion of osteoclast activating agents such as PTHrP (rarely PTH), calcitriol, or cytokines (interleukins, TNF, TGFβ), or it may be due to direct invasion and destruction of bone by the neoplasm.[85,114,153] Although hypercalcemia occurs in less than 1% of children with cancer, it may develop even in very young patients with acute lymphatic and monocytic leukemias, Hodgkin and non-Hodgkin lymphoma, rhabdomyosarcoma, hepatoblastoma, neuroblastoma, and Ewing sarcoma.[154] Acute immobilization of the rapidly growing child with a femoral fracture or a spinal cord injury results in decreased bone mineral accretion and uncoupling of the interaction of osteoblasts and osteoclasts with increased rate of bone resorption leading to hypercalciuria and "acute disuse osteoporosis."[155] When the rate of bone resorption exceeds the renal tubular capacity for excretion of calcium, hypercalcemia ensues. Acute disuse osteoporosis and hypercalcemia can even occur in the immobilized hypoparathyroid or vitamin D depleted individual. Increased intake of calcium and absorbable alkali (milk or calcium containing antacids such as calcium carbonate) for peptic ulcer disease or as dietary supplements lead to absorptive hypercalcemia, hypercalciuria, and nephrocalcinosis. Parenteral nutrition with excessive calcium or aluminum or too little phosphate can also result in hypercalcemia. Hypophosphatemia of various etiologies leads to hypercalcemia as the body attempts to maintain the calcium x phosphate product over 30. Drugs causing hypercalcemia include: thiazide diuretics increase renal tubular resorption of calcium and decrease plasma volume; vitamin D and analogs increase intestinal absorption of calcium; vitamin A and its retinoic acid analogues stimulate bone resorption; lithium increases the set point for PTH secretion, thereby increasing serum calcium concentrations while lowering urinary calcium excretion and thus mimicking HHC1. In the thyrotoxic subject, hypercalcemia is the result of thyroid hormone-mediated stimulation of osteoclast function and the subsequent increase in the rate of bone resorption.[114] Pheochromocytomas and some islet cell tumors may be associated with hypercalcemia, in some instances

because of cosecretion of PTHrP. Hypercalcemia in the hypoadrenal patient is of uncertain pathogenesis but is not related to increased serum concentrations of PTH, calcidiol, or calcitriol, or with augmented bone resorption.

During recovery from acute renal failure, serum calcium levels may increase due to mobilization of calcium from ectopic sites such as muscle in which it had been deposited during the hyperphosphatemic phase of the illness from which it is released by rhabdomyolysis.[114] Hypercalcemia can develop in patients with chronic renal failure due to a combination of factors including immobilization, aluminum toxicity, excessive ingestion of calcium antiacids or vitamin D or its analogs, and secondary hyperparathyroidism. After renal transplantation hypercalcemia is often the result of secondary hyperparathyroidism due to hypertrophy and hyperplasia of parathyroid chief cells that occurred in response to the PTH stimulatory effects of hyperphosphatemia, hypocalcemia, and decreased synthesis of and response to calcitriol during the period of chronic renal insufficiency. In patients with compromised renal function, mild hypocalcemia and calcitriol deficiency develop when the glomerular filtration rate falls below 80 to 60 mL/min/1.73 m^2, whereas phosphate retention occurs after the glomerular filtration rate has fallen to 60 to 30 mL/min/1.73 m^2.[156,157] The secretion of PTH rises in these patients in an effort to increase the synthesis of calcitriol, raise calcium levels, and lower phosphate values. Prolonged, uncontrolled secondary hyperparathyroidism can lead to relatively autonomous parathyroid hyperfunction ("tertiary hyperparathyroidism") and hypercalcemia, primarily in patients with chronic renal failure. Hyperplasia of chief cells is followed by defects in function of the CaSR and loss of effective down-regulation of PTH secretion refractory to increased serum concentrations of Ca^{2+}. There is an expanded number of monoclonal chief cells in which the expression of *CASR* and the number of vitamin D nuclear receptors have declined. Secondary and tertiary hyperparathyroidism have occurred in patients with prolonged nutritional vitamin D deficiency rickets and in subjects with X-linked hypophosphatemic rickets receiving large amounts of phosphate.[156] Secondary hyperparathyroidism (in which by definition serum calcium concentrations are normal) also develops in patients with inadequate dietary calcium, impaired intestinal absorption of calcium (lactose intolerance, ingestion of phytates, malabsorption syndromes due to pancreatic insufficiency or celiac disease), or excessive calcium loss in the urine or soft tissues.[156] Enhanced but transient secretion of PTH may accompany the administration of GH to adolescents with chronic renal failure, likely the result of superimposing upon a high basal rate of PTH secretion further increase in the rate of bone remodeling related to GH and sex hormones. In acutely ill adults, GH administration has been associated with hypercalcemia as well.[155]

Isolated hypercalciuria in the eucalcemic child may be idiopathic or due to renal medullary or tubular dysfunction or increased intestinal absorption of calcium including mutations in genes encoding the vitamin D and calcium sensing receptors and soluble adenylyl cyclase (MIM 605205), demineralizing disorders such as juvenile idiopathic (rheumatoid) arthritis, hyperalimentation, metabolic acidosis, excessive protein ingestion, and diabetes mellitus; hypercalciuria with/without hypercalcemia may be observed in patients with familial forms of hypomagnesemia, several types of Bartter syndrome, distal renal tubular acidosis, and other disorders.[158]

Evaluation

When hypercalcemia is mild (total calcium concentration < 12 mg/dL), there may be few, if any, symptoms; affected children and adolescents are often identified by a multichannel screening study obtained for some other purpose. Hypercalcemia may also be detected during studies for renal calculi, abnormal bone mass, pathologic fractures, or during screening of families for associated problems. It should also be recognized that an elevated serum (total or ionized) calcium concentration in a single specimen may reflect assay variability and must be verified by repeated determinations in a reliable laboratory. Pseudohypercalcemia is the presence of persistently elevated total calcium concentrations in the presence of normal Ca^{2+} values and is found in hyperalbuminemia and other dysproteinemic states.[152] Symptoms attributable to hypercalcemia are independent of its cause, are related to the degree of hypercalcemia, and include intestinal symptoms such as anorexia, nausea, vomiting, abdominal pain (peptic ulceration, acute pancreatitis), and constipation; urinary symptoms such as polydipsia, nocturia, and polyuria (calcium acts as an osmotic diuretic while hypercalcemia impairs the concentrating function of the distal renal tubule); skeletal conditions such as bone pain; and neural symptoms such as headache, muscular weakness, impaired ability to concentrate, increased requirement for sleep, and altered consciousness (ranging from lethargy and confusion to irritability, delirium, stupor, and coma); on occasion, depression may be the major presenting concern in an adolescent with hypercalcemia.[112,114,116] In the toddler and young child, hypercalcemia is manifested by anorexia, constipation, poor weight gain, and impaired linear growth ("failure to thrive"). In a series of 52 children and adolescents with hypercalcemia due to primary hyperparathyroidism, 80% were symptomatic; the most common symptoms were fatigue/lethargy (35%), headache (35%), nausea (29%), vomiting (23%), and polydipsia (21%).[123] Bone involvement (low bone mass, fractures) was present in 30%, and 14% of these subjects were depressed. All of the children (N = 17) with nephrolithiasis in this series were symptomatic. In another series of 44 children and adolescents (26 girls) with primary hyperparathyroidism, mean age at diagnosis was 13 years (ranging from 6 to 18 years), overall 37 were symptomatic (anorexia, weight loss, malaise, depression), and there were 18 patients with nephrolithiasis.[93] At surgery, 29 patients had a parathyroid adenoma and 11 had hyperplastic parathyroid glands, two of whom had MEN.

Evaluation of the hypercalcemic child begins with the historical review during which the family/patient is queried not only about symptoms related to hypercalcemia and its consequences (renal calculi) but also about possibly excessive intake of vitamin D, vitamin A and related

compounds (such as Retin A for treatment of acne), calcium (perhaps to "prevent" osteoporosis), and alkali, or drugs that affect calcium metabolism (thiazide diuretics may "unmask" hyperparathyroidism by increasing renal tubular resorption of calcium and thereby raising borderline calcium concentrations into the hypercalcemic range) (see Figure 18-4). The family history is explored for members with known disorders of calcium metabolism (HHC1, hyperparathyroidism, renal calculi) or familial neoplasms (galactorrhea as a sign of a prolactinoma, severe peptic ulcer disease as an indicator of a gastrinoma and the Zollinger-Ellison syndrome). Except in extreme instances when hypertension (if normally hydrated) or bradycardia, dehydration, decreased muscular strength, or altered consciousness may be present or in the "marfanoid" subject with MEN 2B, physical examination of the hypercalcemic child and adolescent is usually normal. Rarely is a paratracheal (parathyroid) mass palpable in the hyperparathyroid patient. (Subjects with hypercalcemia due to subcutaneous fat necrosis have firm to hard, irregular, movable masses scattered about the trunk and extremities. Those with WBS have a typical face, whereas those with Jansen metaphyseal chondrodysplasia have characteristic skeletal deformities.)

After confirming the presence of total and ionized hypercalcemia, the urinary excretion of calcium is measured (Table 18-6). If the PTH concentration is normal or elevated and the calcium excretion is low, it is most probable that the patient has HHC1; this diagnosis can be substantiated by the finding of asymptomatic hypocalciuric hypercalcemia in one of the parents and further defined by identification of the inactivating mutation in *CASR*. If the patient is hypercalciuric, other causes of hypercalcemia should be sought. With highly sensitive and specific immunoradiometric and immunochemiluminometric assays for "intact" PTH[1-84] in comparison to serum calcium values, separation of patients with hyperparathyroidism from those with other causes of hypercalcemia in whom PTH values are low or normal is usually possible. In the absence of secondary hyperparathyroidism (chronic renal insufficiency, malabsorption syndromes, ingestion of thiazide diuretics or lithium), consistently elevated PTH concentrations in the hypercalcemic, hypophosphatemic, hypercalciuric child or adolescent are consistent with primary hyperparathyroidism. Although the diagnosis of primary hyperparathyroidism is usually apparent in children and adolescents, there is an occasional patient in whom serum calcium or PTH values may not be elevated in a single specimen and in whom repeated measurements of serum and urine calcium and PTH values are necessary before this diagnosis can be established. In a series of 52 children/adolescents with hyperparathyroidism, serum calcium values were normal in 10% and PTH levels in 15%; however, in all subjects the PTH concentration was inappropriately increased relative to the calcium level.[123] Hypercalcemia, hypophosphatemia, and elevated PTH concentrations were recorded in all 44 children and adolescents (6 to 18 years of age at diagnosis) with primary hyperparathyroidism in another series.[93] Osteitis fibrosa cystica, brown tumors (localized non-neoplastic areas of bone resorption composed of osteoclast-like multinuclear giant cells, fibroblast-like spindle shaped cells, and hemorrhagic infiltrates), and subperiosteal and endosteal bone resorption can be detected radiographically in most children with hyperparathyroidism, whereas cortical (distal radial) bone mineral density is likely to be decreased in these subjects. Nonspecific findings in the hypercalcemic subject of diverse etiology include shortening of the QT interval by electrocardiography because the rate of cardiac repolarization is accelerated by increased calcium levels, bradycardia, and first-degree atrioventricular block, and nephrocalcinosis and renal calculi detected by abdominal ultrasonography. Serum concentrations of PTHrP should be measured when clinical and laboratory findings are consistent with primary hyperparathyroidism, but PTH values are low and humoral hypercalcemia of malignancy is suspected. When PTH concentrations are low in the hypercalcemic patient, metabolites of vitamin D (calcidiol, calcitriol) should be measured and other causes of hypercalcemia sought (discussed later).

Preoperatively, a parathyroid adenoma may be localized by high-resolution ultrasonography, computed tomography, magnetic resonance imaging, or radionuclide scanning with ^{99m}Tc-sestamibi. The latter radionuclide is taken up by both the thyroid and parathyroid glands but quickly "washed out" from the thyroid gland; thus, two scans obtained 2 hours apart permit differentiation of parathyroid from thyroid tissue (Figure 18-7).[122] Alternatively, a simultaneously administered second radionuclide selectively accumulated by the thyroid (^{123}iodine) may be employed to visualize parathyroid tissue. Scans may be obtained by conventional two-dimensional or computed tomographic techniques, the latter offering a three-dimensional image. Rarely is it necessary to undertake selective venous catheterization with sampling of local PTH levels or arteriography to identify the site of a parathyroid adenoma. Evaluation for associated endocrine tumors is necessary if the family history suggests the possibility of MEN 1 or MEN 2A or if there are clinical findings (galactorrhea, excessive growth, hypertension) to suggest the presence of a prolactinoma, somatotropinoma, or pheochromocytoma. Patients at risk for MEN may be screened by determining basal and stimulated serum concentrations of prolactin, GH, IGF-I, gastrin, glucagon, pancreatic polypeptide, calcitonin, catecholamines, and other substances as warranted. Indeed, it is reasonable to consider screening children with hyperparathyroidism preoperatively for an associated pheochromocytoma or tumors of the maxilla and mandible and for mutations in *RET*, *MEN1*, and *CDC73*.[124]

In the patient with hypercalcemia due to ingestion of excessive amounts of vitamin D, serum concentrations of calcidiol are markedly elevated; in those receiving exogenous calcitriol or in hypercalcemic patients with granulomatous, chronic inflammatory, and lymphomatous diseases, serum levels of calcitriol are increased. Other disorders associated with hypercalcemia (see Tables 18-4A and B) should be eliminated by appropriate historical findings and laboratory and genetic studies.

Management

Appropriate management of the patient with hypercalcemia depends on the severity and the cause of the high calcium levels. It is important to distinguish the patient with pseudohypercalcemia (due to hyperproteinemia) from one with a pathologic cause of hypercalcemia so that effective medical and surgical therapy may be initiated promptly. It is equally important to recognize the child/adolescent with HHC1 so that aggressive therapy is avoided. When the calcium concentration is < 12 mg/dL in the asymptomatic subject, treatment may be delayed until the cause of the hypercalcemia is understood; in the interim, it is reasonable to recommend that the patient increase fluid intake, avoid calcium and vitamin D supplements, and discontinue drugs associated with hypercalcemia if relevant. The child with HHC1 often has serum total calcium concentrations between 11 to 13 mg/dL but no clinical symptoms and requires no therapy under usual circumstances. In the absence of HHC1, if the total serum calcium concentration exceeds 12 mg/dL or if the child is symptomatic (anorexia, nausea, altered sensorium, polydipsia, polyuria, dehydration, muscular weakness), efforts to lower its level are usually necessary because of the adverse effects of hypercalcemia on cardiac, central nervous, renal, and gastrointestinal function. In these children and adolescents, diagnostic studies as outlined here and treatment to lower the serum calcium concentration should begin simultaneously. The tools of therapy of severe hypercalcemia are usually employed sequentially as follows: (1) hydration—with 0.9% saline (twice maintenance volume over 24 to 48 hours)—restores intravascular volume, dilutes and decreases serum Ca^{2+} levels, increases glomerular filtration of Ca^{2+}, decreases reabsorption of Ca^{2+} in the proximal and distal renal tubules, and promotes calciuresis; hydration alone usually lowers the total serum calcium concentration 1 to 3 mg/dL; (2) calciuresis—intravenous infusion of the loop diuretic furosemide (1 mg/kg slowly) initiated only

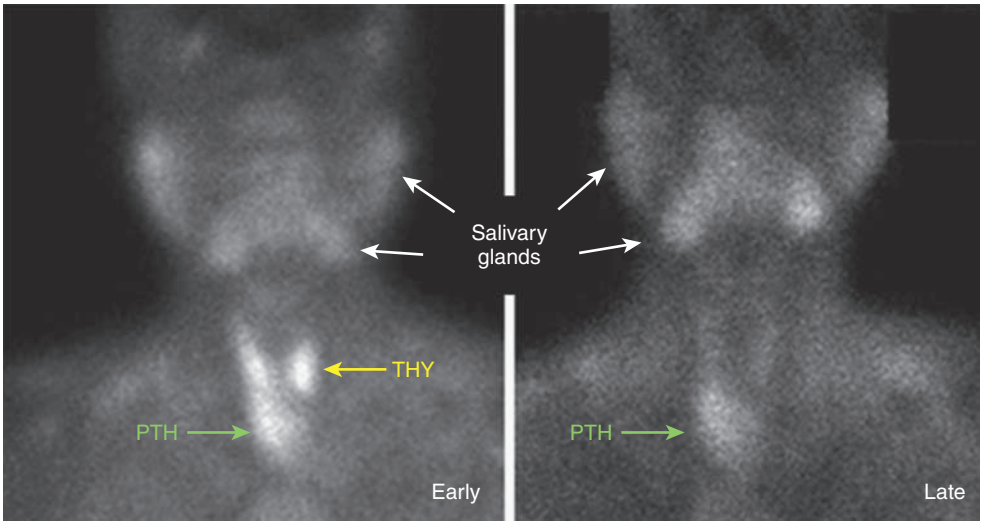

FIGURE 18-7 ■ Visualization of a parathyroid adenoma with technetium-99m sestamibi scanning. (From Steenkamp, D., & Lee, S. L. (2011). Hypercalcemic crisis in a young woman. Endocrine Today, October. Reprinted with permission from SLACK Incorporated.) *This image can be viewed in full color online at ExpertConsult.*

after restoration of extracellular fluid volume with saline—further lowers calcium levels by inhibiting resorption of calcium (and sodium) by the TALH (thiazide diuretics are to be avoided as they increase renal tubular reabsorption of calcium and increase serum calcium concentrations and are clearly contraindicated in the management of hypercalcemia); (3) inhibition of bone resorption—if hypercalcemia does not respond to the preceeding measures, specific inhibitors of osteoclast function may be employed. Bisphosphonates (pamidronate, zoledronic acid) are the agents of choice in the acute management of hypercalcemia in children and adolescents. Bisphosphonates are nonhydrolyzable, phosphatase-resistant analogues of pyrophosphate; in vivo by binding to and coating the hydroxyapatite crystal beneath the osteoclast, they interfere with osteoclast attachment, and by incorporation into the osteoclast, they interfere with its cellular metabolism thereby inhibiting its functional ability to dissolve bone and hastening its death. Pamidronate (0.5 to 1 mg/kg/dose by intravenous infusion over 4 to 6 hours) effectively lowers serum calcium concentrations in hypercalcemic infants and children.[85,113] The hypocalcemic effect of bisphosphonates is variable in duration (days to weeks); transient systemic side effects (fever, myalgia) may accompany the administration of pamidronate and other bisphosphonates. Salmon calcitonin also acts rapidly but transiently to lower serum calcium concentrations by inhibiting osteoclast activity and increasing urinary calcium excretion; it must be administered by multiple daily subcutaneous injections (2 to 4 U/kg/injection every 6 to 12 hours). However, calcitonin tachyphylaxis develops several days after its administration, thus limiting its usefulness.[159] Calcitonin may be paired with a bisphosphonate at the beginning of treatment of hypercalcemia in order to lower serum calcium levels more rapidly.[116] Glucocorticoids do not lower calcium levels in patients with hyperparathyroidism or solid tumor malignancies but are quite effective in the management of hypercalcemia due to excess vitamin D ingestion or calcitriol production by activated monocytes or hematologic malignancies. In adults with hypercalcemia of malignancy, gallium nitrate has also been employed to lower serum calcium values, but it must be administered over 5 days; gallium inhibits osteoclastic bone resorption directly.[159] Rarely, it may be necessary to dialyze (peritoneal or hemodialysis with low- or zero-calcium dialysate) the severely hypercalcemic patient resistant to conventional therapy. During acute treatment of hypercalcemia, Ca^{2+} concentrations may be assessed indirectly by monitoring the (shortened) Q-T interval by electrocardiography, but serial measurements of total and Ca^{2+} are necessary to monitor the efficacy of therapy and to prevent hypocalcemia.

Although in older adults (> 50 years) with asymptomatic primary hyperparathyroidism (without bone disease or renal stones), no immediate intervention may be advised at times, in younger adults, children, and adolescents with hyperparathyroidism, surgical intervention is recommended when the diagnosis is established. Although hyperparathyroidism in youth is most often (> 60%) due to an adenoma, hyperplasia of the parathyroid glands is also common (~30%).[93,123] As discussed, prior to surgical intervention in the pediatric population with hyperparathyroidism it is important to localize a parathyroid adenoma employing one of several imaging techniques such as echography with Doppler analysis, magnetic resonance, computed tomography, or ^{99m}Technetium-sestamibi combined with computed tomography. It is also possible to construct a three-dimensional virtual model of the neck by pairing iodine contrast with thin-slice computed tomographic imaging with color contrast enabling clear definition of the cervical vasculature and its normal and abnormal structures.[160] The operating surgeon must be experienced and expert in parathyroid surgery. In adults and older adolescents, minimally invasive focused procedures to remove an anatomically identified parathyroid adenoma(s) may be employed utilizing ^{99m}Technetium-sestamibi administered 2 hours before surgery with dissection directed by insertion of a hand-held gamma probe until the adenoma is located and removed. Video assistance is an alternative method for localization of a parathyroid adenoma. A complementary technique for assessing the completeness of the removal of the adenoma intraoperatively is to measure peripheral levels of PTH by rapid immunoassay before and 10 minutes after removal of the adenoma; a 50% decline in PTH levels indicates complete excision; if the PTH concentration does not decline following removal of suspected abnormal parathyroid tissue, further exploration is undertaken and additional tissue removed as guided by the serum PTH level. These procedures are reported to be cost effective as they decrease operative time and patient morbidity; many patients return home within hours after leaving the operating suite. These techniques have been applied to the surgical management of the child and infant with a parathyroid adenoma or hyperplasia of multiple parathyroid glands. If there is parathyroid hyperplasia, total parathyroidectomy is performed and autotransplantation of small fragments of one gland to a forearm pocket undertaken. Following removal of a parathyroid adenoma, many patients develop transient hypocalcemia that may be managed by the administration of supplemental oral calcium. When there is severe osteitis fibrosa cystica and marked demineralization, substantial hypocalcemia may occur as a result of the "hungry bone" syndrome. Other complications of surgery include (transient or permanent) vocal cord dysfunction and the need for further operations because of the development of a second adenoma. If permanent hypoparathyroidism develops postoperatively, it is treated by the administration of calcitriol and supplemental calcium as needed.

Calcimimetic agents (phenylalkylamines; e.g., cinacalcet) bind to and activate the membrane CaSR on the parathyroid chief cell and thereby increase cytosolic levels of $Ca^{2+}{}_I$ and depress secretion of PTH in adults with mild primary hyperparathyroidism.[122] The use of these agents in children and adolescents with this disorder offers a potential treatment pathway for subjects with diffuse parathyroid hyperplasia. Indeed, this agent has been useful in the management of infants with milder forms of NSHPT. (However, in early 2013 the Food and Drug Administration suspended the use of cinacalcet in children and adolescents pending further evaluation of its safety in this population.) The secondary hyperparathyroidism of

chronic renal disease is best managed by lowering serum phosphate concentrations to the extent possible by limiting intake, administering oral phosphate binding agents, and maintaining serum Ca^{2+} levels within the low-normal range by the administration of calcitriol or analog; calcimimetic agents (e.g., cinacalcet) may also be useful in this situation with the caveat noted previously.[161] Parathyroidectomy may be necessary for effective management of refractory secondary and tertiary hyperparathyroidism as manifested by severe renal osteodystrophy, hypercalcemia, and systemic symptoms such as pruritus and bone pain.[156]

Hypercalcemia due to hypervitaminosis D or excessive production of calcitriol by granulomatous and chronic inflammatory tissues may be treated with glucocorticoids to suppress activity of $25OHD_3$-1α-hydroxylase. Ketoconazole (3 to 9 mg/kg/day in three divided doses) is an antifungal agent that also inhibits renal $25OHD_3$-1α-hydroxylase activity and promptly lowers calcitriol and calcium values in children and adults with similar disorders. Side effects of therapy with ketoconazole include nausea, vomiting, abdominal pain, depressed secretion of gonadal steroids, and adrenal production of cortisol. Therefore, careful monitoring of patients receiving ketoconazole is essential. Glucocorticoids ameliorate the hypercalcemia related to excessive interleukin-1β production in adolescents with juvenile rheumatoid arthritis. An attempt should be made to prevent hypercalcemia in the immobilized child or adolescent by ingestion of a low-calcium diet, avoidance of vitamin D, copious fluid intake, and early mobilization. Serum and urine calcium levels should be monitored frequently and fluids increased still further if hypercalciuria occurs. Once present, hypercalcemia is best treated by mobilization; saline diuresis or bisphosphonate administration may be necessary until eucalcemia is restored. Restriction of dietary calcium and limitation of exposure to sunlight may be appropriate in the long-term management of some patients with hypercalcemia not amenable to more specific treatment. Antiprostaglandin agents may be useful in the child with hypercalcemia associated with excessive production of these compounds. Specific treatment of diseases accompanied by hypercalcemia (thyrotoxicosis, hypoadrenocorticism) restores the eucalcemic state.

DISORDERS OF MAGNESIUM METABOLISM

In serum, magnesium is presented complexed to proteins and ionized or free. Approximately 50% of body magnesium stores are deposited within bone adsorbed to the surface of hydroxyapatite. The CaSR recognizes and responds to magnesium (Mg^{2+}) as well as calcium. In the kidney, 10% to 20% of filtered Mg^{2+} is reabsorbed in the proximal renal tubule and 65% to 70% of filtered Mg^{2+} is reabsorbed in the thick ascending limb of the loop of Henle by a passive paracellular process; 10% to 20% of filtered Mg^{2+} is reabsorbed in the distal convoluted tubule by an active transcellular system.[162] In the distal convoluted tubule, Mg^{2+} reabsorption occurs through a cation channel encoded by *TRPM6* and supporting components (discussed later). Mg^{2+} regulates the secretion but not the synthesis of PTH and the generation of calcitriol.[3]

Hypomagnesemia

Hypomagnesemia (serum total magnesium concentration < 1.5 mg/dL) leads to hypocalcemia by inhibiting the release of PTH and by interfering with its peripheral action. Hypomagnesemia may be congenital or acquired (Tables 18-7A and B). It occurs in infants born to mothers deficient in magnesium, those with preeclampsia or gestational or type 1 diabetes mellitus, and neonates with low birth weight due to prematurity or intrauterine growth restriction.[163] Prolonged nasogastric suctioning, malabsorptive disorders due to extensive intestinal resection ("short gut" syndrome), intestinal fistulas, or other

TABLE 18-7A **Disorders of Magnesium Homeostasis**

I Hypomagnesemia

A Congenital

1 Neonates of mothers with diabetes mellitus, eclampsia, magnesium deficiency
2 Intrauterine growth restriction, prematurity
3 Gene mutations (see Table 18-7B)

B Acquired

1 Drugs: loop and thiazide diuretics, antibiotics (amphotericin, gentamycin), sympathomimetic agents, proton pump inhibitors (omeprazole), digitalis, antineoplastic agents (cisplatin), cyclosporin
2 Nasogastric suction
3 Intestinal malabsorption (celiac disease, intestinal resection)
4 Secretory diarrhea (inflammatory bowel disease)
5 Acute pancreatitis
6 Hypermagnesuria due to diabetes mellitus or alcoholism or following renal tubular necrosis or renal transplantation
7 In association with hypokalemia

II Hypermagnesemia

A Acquired

1 Renal insufficiency
2 Excessive intake of magnesium salts or laxatives/antacids that contain magnesium
3 Diabetic ketoacidosis, adrenocortical insufficiency, hyperparathyroidism, lithium intoxication

*MODY, maturity onset diabetes of youth.
AR, autosomal recessive; AD, autosomal dominant.

diseases associated with chronic diarrhea and steatorrhea also lead to infantile hypomagnesemia. In renal tubular disorders such as Gitelman and Bartter syndromes (discussed later) as well as in subjects exposed to diuretics and nephrotoxic (cisplatin, cyclosporin, mercury, gentamycin) agents, hypermagnesuria leads to hypomagnesemia. In infants, children, and adolescents, hypomagnesemia may be clinically silent or it may be manifested by heightened neuromuscular irritability (carpal pedal spasm, tetany, seizures) and when prolonged and profound by muscle wasting, weakness, apathy, and tachycardia with prolonged PR and QT intervals by electrocardiography. In these age groups, hypomagnesemia may be primary and due to a specific defect in the intestinal absorption of Mg^{2+} or in the renal tubular resorption of filtered Mg^{2+} (discussed later) or secondary and due to gastrointestinal losses (chronic vomiting or diarrhea or malabsorptive states due to inflammatory bowel disease, bowel resection or fistulas, or pancreatitis), associated renal tubulopathies (Gitelman and Bartter syndromes), exposure to alcohol, diuretics, and chemotherapeutic agents, and specific endocrinopathies (diabetes mellitus, primary hyperparathyroidism, hyperaldosteronism).[2,164]

Gene mutations that lead to hypomagnesemia are listed in Table 18-7B.[162,165] Type 1 hypomagnesemia with hypocalcemia is an autosomal recessive disorder pathophysiologically due to a selective small intestinal defect in transcellular absorption of Mg^{2+}. The disease presents with hypocalcemic tetany or seizures in the neonatal period and can lead to myocardial, renal, and arterial calcinosis. Renal excretion of Mg^{2+} is normal in subjects with this disease. Hypocalcemia is attributable to decreased secretion of and peripheral insensitivity to PTH. This disorder is due to biallelic loss-of-function mutations in *TRPM6* (transient receptor potential cation channel, subfamily M, member 6), encoding a 2,022 amino acid protein with two functional domains: a Ca^{2+}- and Mg^{2+}-permeable ion channel domain and a protein tyrosine kinase domain that is expressed in the intestinal tract and kidney.[166] For full functional activity, TRPM6 must team with its homologue TRPM7 (MIM 605692) and form a functional TRPM6/TRPM7 complex at the surface of the cell.[167] Although most mutations of *TRPM6* associated with this disease (nonsense, deletion) have resulted in extensive loss of product, the naturally occurring missense mutation Ser141Leu specifically disrupts formation of the complex and hence the transcellular absorption of Mg^{2+}. Oral ingestion of large quantities of magnesium is effective therapy for this illness. Monoallelic inactivating mutations in *FXYD2* result in autosomal dominant hypomagnesemia type 2. *FXYD2* encodes a gamma subunit of a Na^+/K^+-ATPase expressed in the renal distal convoluted tubule. Loss-of-function mutations of *FXYD2* result in misrouting of its protein product to the basolateral membrane of the nephron's epithelial cells and leads to increased urinary

loss of Mg^{2+} but paradoxically to increased renal tubular reabsorption of Ca^{2+} in the loop of Henle. Type 3 primary hypomagnesemia is an autosomal recessive disorder due to decreased renal tubular paracellular reabsorption of filtered Mg^{2+} linked to biallelic loss-of-function mutations in *CLDN16*. This disease often presents in infancy and is associated with tetany, hypermagnesuria, hypercalciuria, mild hypocalcemia, nephrocalcinosis, impaired renal function, and secondary hyperparathyroidism. Claudin 16 (also termed paracellin 1) is a 305-amino-acid protein with four transmembrane domains and intracellular amino and carboxyl terminals that is expressed within the intercellular tight junctions of renal epithelial cells in the TALH and distal convoluted tubule where it facilitates paracellular transport and reabsorption of Mg^{2+} and Ca^{2+} from the renal tubule. The first extracellular loop of claudin 16 bridges the intercellular space and is the site of paracellular conductance of ions; a number of missense mutations in *CLDN16* have been identified, particularly at leucine 151 (Leu151Phe, Leu151Trp, Leu151Pro).[168] Most of the mutations in CLDN16 impair its normal movement to the renal epithelial cell's lateral surface; in other mutations (Ala62Val, His71Asp), products localize to the tight junctions but are functionally defective.[169] Oral administration of 20 times the normal daily requirement of magnesium has been successful therapy in these subjects. Biallelic inactivating mutations in *EGF* result in type 4 hypomagnesemia, a disorder associated with seizures and developmental delay but in which serum and urine levels of calcium are normal.[170] EGF is necessary for normal distal renal tubular Mg^{2+} resorption by TRPM6. The complex of hypomagnesemia, hypercalciuria, and visual impairment (macular colobomata, myopia, nystagmus) is designated type 5 hypomagnesemia and is due to biallelic loss-of-function mutations in *CLDN19*, a second renal epithelial tight junction protein that is localized to the distal renal tubule and eye and is necessary for paracellular transport of calcium and magnesium.[171] In addition to ocular anomalies (colobomata, nystagmus, severe myopia), mutations in *CLDN19* result in hypomagnesemia, hypercalciuria, nephrocalcinosis, and renal failure. Hypomagnesemia type 6 is an autosomal dominant disorder that presents in childhood or adolescence and is due to heterozygous loss-of-function mutations in *CNNM2*.[172] Despite hypomagnesemia, urine excretion of Mg^{2+} is inappropriately normal; serum and urine calcium values are normal in these subjects. *CNNM2* encodes a protein localized to the basolateral membrane of the renal thick ascending loop of Henle and the distal convoluted tubule where its expression is up regulated by Mg^{2+} deficiency. One function of CNMM2 may be to "sense" ambient Mg^{2+} concentrations.

Hypomagnesemia associated with myokymia (quivering of muscles) has been related to a heterozygous loss-of-function mutation (Asn255Asp) in *KCNA1* encoding a renal potassium channel that colocalizes with TRPM6 in the renal distal convoluted tubule.[173] Mutated KCNA1 may impair the ability of TRPM6 to reabsorb Mg^{2+} from the distal convoluted tubule leading to hypermagnesuria and hypomagnesemia. Hypomagnesemia has also been associated with mutations in *HNF1B* encoding hepatocyte nuclear factor 1 homeobox B, a transcription factor necessary for normal embryogenesis of the kidney and pancreas.[174] Inactivating mutations in HNF1B lead to malformations of the kidney (cysts, renal malformations) and early onset of diabetes mellitus. Hypomagnesemia is encountered in patients with hypokalemic metabolic acidosis in association with the SESAME syndrome (seizures, sensorineural deafness, ataxia, mental retardation, and electrolyte imbalance due to inactivation mutations in a gene—*KCNJ10*—encoding a potassium channel), antenatal Bartter syndrome type 2 (polyhydramnios, prematurity, poor postnatal growth, salt wasting, and hypercalciuria due to inactivating mutations in a gene encoding a second potassium channel—*KCNJ1*), and Gitelman syndrome, a variant of Bartter syndrome that presents in later childhood or adolescence or young adulthood (muscle weakness, potassium wasting, and hypocalciuria due to loss-of-function mutations in a gene encoding a thiazide-sensitive Na^+ Cl^- cotransporter—*SLC12A3*) (Table 18-7B).

The presence of hypomagnesemia is identified by measurement of serum Mg^{2+} concentrations, whereas its pathophysiologic etiology is determined by concurrent assay of calcium, phosphate, sodium, potassium, chloride, bicarbonate, creatinine, PTH, and vitamin D levels and assessment of its urinary loss and intestinal absorption.[163] Hypomagnesemic, hypocalcemic seizures are only transiently responsive and sometimes resistant to parenteral administration of elemental calcium alone. Intravenous or intramuscular administration of a 50% solution of magnesium sulfate ($MgSO_4.7H_20$, 0.05 to 0.1 mL/kg or 2.5 to 5 mg/kg elemental magnesium with cardiac monitoring) is often necessary to control convulsions in the hypomagnesemic neonate.[2,163] Oral magnesium supplements may also be helpful (50% $MgSO_4.7H_20$, 0.2 mL/kg/day). Chronic hypomagnesemic states are treated with oral magnesium supplements as tolerated, as excessively large doses may lead to diarrhea.

Hypermagnesemia

Hypermagnesemia (total magnesium > 2.5 mg/dL) is frequently recorded in the neonatal period after magnesium sulfate has been administered to the pregnant women with hypertension, preeclampsia, or toxemia of pregnancy. Most neonates with hypermagnesemia are asymptomatic; however, when serum Mg^{2+} concentrations are exceptionally high, hypotonia and depression of the central nervous system may be present and when extensive, metabolic bone disease may develop.[163] Thus, prolonged (9 to 10 weeks) administration of intravenous magnesium sulfate to women with multiple fetuses who have entered labor prematurely has been associated not only with hypermagnesemia but also with marked hypocalcemia in the offspring as well as significant osteopenia.[175] Hypermagnesemia may also result from its parenteral administration or oral ingestion of magnesium-containing antacids or enemas. In large amounts, magnesium sulfate suppresses secretion of PTH and decreases renal tubular reabsorption of calcium, factors contributing to hypocalcemia. The

hypermagnesemic neonate is most appropriately managed by adequate hydration to permit urinary excretion of the high magnesium load; if the newborn is also hypocalcemic and osteopenic administration of calcium and calcitriol is indicated. Hypermagnesemia may also develop in patients with renal insufficiency receiving magnesium-containing antacids. Mg^{2+} concentrations are modestly increased in patients with familial hypocalciuric hypercalcemia due to loss-of-function mutations in *CASR*.

DISORDERS OF SKELETAL MINERALIZATION

Disorders of Bone Mineralization in the Neonate and Infant

Low Bone Mass/Rickets

Rickets is a disorder of bone mineralization in the growing infant, child, and adolescent due to lack of vitamin D or its functional efficiency, calcium or phosphate, or decreased activity of alkaline phosphatase (Table 18-8).

TABLE 18-8 **Disorders of Bone Mineralization: Rickets**

I Vitamin D Deficiency

A Decreased Intake, Endogenous Synthesis, Retention, or Sequestration
1 Maternal vitamin D deficiency: breastfeeding
2 Reduced skin synthesis: sunlight deprivation, sunscreen use, increased skin pigmentation
3 Malabsorption: celiac disease, hepatobiliary dysfunction, short gut syndrome, cystic fibrosis, inflammatory bowel disease, gastric bypass surgery
4 Drugs: anticonvulsants, glucocorticoids, cholestyramine, antiretroviral agents
5 Nephrotic syndrome
6 Obesity

B Metabolic Errors
1 Deficiency of 25-hydroxylase
a Loss-of-function mutation of *CYP2R1*
b Hepatic dysfunction
2 Deficiency of 25OH-vitamin D_3-1-hydroxylase
a Loss-of-function mutation of *CYP27B1*
b Decreased renal mass: hypoplasia, chronic renal insufficiency
3 Impaired response to vitamin D
a Loss-of-function mutation of *VDR*
b Excessive heterogeneous nuclear ribonucleoprotein C1/C2 (*HNRNPC*)

II Calcium Deficiency, Primary

A Nutritional Deprivation
B Hypercalciuria: Hyperprostaglandin E2 Syndromes

III Phosphate Deficiency/Hypophosphatemia

A Transcellular Shifts
1 Glucose or insulin infusion
2 Refeeding
3 Respiratory alkalosis; hyperventilation
4 Salicylate poisoning
5 Catecholamines

B Decreased Intestinal Absorption
1 Nutritional deprivation
a Low-birth-weight infant
2 Decreased intestinal absorption
a Vitamin D deficiency: nutritional, synthetic error, insensitivity
b Aluminum, magnesium, or calcium-containing antacids
c Malabsorption due to chronic diarrhea, steatorrhea

C Hyperphosphaturia
1 X-linked dominant familial hypophosphatemic rickets (*PHEX*)*
2 X-linked recessive hypophosphatemic rickets (*CLCN5*)
3 Autosomal dominant hypophosphatemic rickets (*FGF23*)*
4 Autosomal dominant hypophosphatemia with urolithiasis 1 (*SLC34A1*)†
5 Autosomal dominant hypophosphatemia with urolithiasis 2 (*SLC9A3R1*)
6 Autosomal recessive hypophosphatemic rickets 1 (*DMP1*)*
7 Autosomal recessive hypophosphatemic rickets 2 (*ENPP1*)*
8 Autosomal recessive hypophosphatemic rickets with hypercalciuria (*SLC34A3*)
9 Hypophosphatemic rickets with hyperparathyroidism (*KL*)
10 Hypophosphatemic rickets with Fanconi renotubular syndrome (*SLC34A1*)‡
11 Oncogenic hypophosphatemic rickets/osteomalacia (*FGF23*, *sFRP4*, *MEPE*, *FGF7*)
12 FGF23 excess of uncertain pathogenesis—McCune-Albright syndrome (*GNAS*),* Jansen-type metaphyseal chondrodysplasia (*PTH1R*),* osteoglophonic dysplasia (*FGFR1*),* linear nevus sebaceous syndrome,* iron polymaltose*
13 Renal tubular acidosis/Fanconi syndrome
a Heritable: cystinosis, tyrosinemia, hereditary fructose intolerance, galactosemia, idiopathic
b Acquired: nephrotic syndrome, vitamin D deficiency, renal vein thrombosis, renal tubular insult due to cadmium, lead, bismuth, outdated tetracycline, 6-mercaptopurine, valproic acid, ifosfamide

D Other Causes
1 Hyperparathyroidism
2 Medications: diuretics (thiazides, acetazolamide, loop diuretics); antiretroviral agents (tenofovir, adefovir); antineoplastic drugs (ifosfamide, cisplatin); aminoglycosides, imatinib

IV Hypophosphatasia (*ALPL*)

A Perinatal, infantile, childhood, adult forms
B Odontohypophosphatasia
C Pseudohypophosphatasia

V Inhibitors of Mineralization

A Aluminum, Parenteral
B Bisphosphonates
C Fluoride

*Associated with increased expression of FGF23.
†Monoallelic.
‡Biallelic.

Minireview: fibroblast growth factor 23 in phosphate homeostasis and bone metabolism.* Endocrinology, 152, *4–10; Imel, E. A., & Econs, M. J. (2012). Approach to the hypophosphatemic patient.* J Clin Endocrinol Metab, 97, *696–706.*

Impaired deposition of hydroxyapatite onto collagen type I fibers in bone matrix leads to skeletal deformations (craniotabes, genu valgum, genu varum, metaphyseal flaring) and fractures. In the adult, deficiencies of vitamin D, calcium, or phosphate result in osteomalacia and increased fracture risk. Osteopenia may be defined as too little bone tissue with decreased thickness of bone cortex or diminished thickness or number of bone trabeculae that may be due either to suboptimal mineralization or to decreased quantity of bone matrix collagen type I. Osteoporosis is primarily a disorder of bone matrix formation with bone mass that is so low that fractures may occur after minor trauma.[176] Osteoporosis is the consequence of decreased synthesis or excessively rapid degradation of bone matrix proteins, particularly collagen type I that results in osteopenia because of a decreased collagen scaffold upon which to deposit hydroxyapatite.

Approximately 80% of total bone calcium in the full-term neonate is accrued in the last trimester of pregnancy as the in utero rate of calcium deposition increases more than twofold between 28 and 36 weeks, gestation. Infants with a low birth weight (LBW < 1500 g) or very low birth weight (VLBW < 1000 g) are particularly vulnerable to the development of osteopenia of prematurity (defined as postnatal bone mineral content that is less than the bone mineral content of the intrauterine fetus at the same postconceptual age), because they are unable to maintain the in utero rate of synthesis of organic bone matrix (osteoid) and the rate of calcium (third trimester, 100 to 130 mg/kg/day) and phosphate deposition into osteoid from the minerals provided via the gastrointestinal tract or by parenteral nutrition.[176-179] In this neonatal population, decreased calcification of bone matrix results in low bone mineral content, whereas depressed calcification of the cartilage growth plate can lead to rickets and its characteristics deformities. Postpartum, hypocalcemia and decrease in spontaneous movement against the force exerted by the muscular wall of the uterus also depress the rate of bone mineral acquisition, whereas an increased rate of bone resorption further decreases skeletal mass in premature infants.[179,180] Approximately 30% of preterm infants with birth weights of less than 1500 grams develop osteopenia.[181] Birth weight and rate of postnatal weight gain as well as umbilical cord concentrations of IGF-I are important determinants of bone mass in premature infants.[182] Necrotizing enterocolitis, a disorder that affects approximately 10% of LBW infants, increases the rate of bone resorption as assessed by measurement of serum (carboxyl telopeptide of collagen type I = ICTP) and urinary (deoxypyridinoline [Dpd]) markers of this process.[183] Malrotation of the intestinal tract or catastrophic necrotizing enterocolitis leading to intestinal infarction requiring extensive small bowel resection substantially increases the risk of malabsorption and subsequent low bone mass. Parenteral alimentation of LBW or VLBW neonates restricts administration of fluid, calcium, and phosphate (in part, because of the incompatibility of the coinfusion of these ions in high concentrations); excessive aluminum in parenteral fluids also adversely affects bone formation. Increased maternal parity, male gender, severe systemic disease (bronchopulmonary dysplasia), immobility, and pharmacologic agents (glucocorticoids, methylxanthines such as theophylline, diuretics such as furosemide) also adversely impact bone formation in these neonates.[180,184] Theophylline and furosemide increase urinary excretion of calcium.[185] Prenatal factors that contribute to low bone mass in VLBW and LBW neonates are intrauterine growth restriction (possibly by reducing placental transport of calcium and decreasing the rate of bone formation) and prenatal exposure to large amounts of magnesium sulfate, which when administered repeatedly to the mother in preterm labor leads to hypocalcemia and osteopenia by suppressing PTH secretion through its interaction with the CaSR and by competing with calcium for deposition at bone surfaces, respectively.[175]

In preterm neonates, serum levels of total and bone specific alkaline phosphatase, carboxyl terminal propeptide of collagen type I (PICP), and osteocalcin (markers of osteoblast activity and bone formation) are elevated relative to full-term neonates and older infants and continue to rise over the first 10 weeks of life.[186] Urinary hydroxyproline and Pyr/Dpd values (markers of osteoclast activity and bone resorption) are also increased, although serum concentration of ICTP, another marker of bone resorption, decline during the first 10 weeks after premature delivery. Overall, the data indicate that intrauterine and postnatal rates of bone turnover in preterm newborns are rapid and persistently elevated through 40 weeks postconceptual age, a conclusion confirmed by bone histomorphometry.[184] By photon absorptiometry and quantitative ultrasonography, bone mass of preterm infants appears to decline during the first several weeks after birth.[187] Serum levels of alkaline phosphatase and osteocalcin and urinary excretion of Pyr and calcium may remain elevated in LBW infants with osteopenia of prematurity relative to values in LBW infants without bone disease for the first year of life even though radiographic improvement in skeletal mineralization is usually evident by 6 months of age.[181]

Because standard roentgenograms may not detect low bone mineralization before deficits of 20% to 30% or greater have occurred in the second month of life, estimation of bone mineral content (BMC) by dual energy x-ray absorptiometry (DEXA) has become the preferred method to assess bone mineralization in infants because of its accuracy, reproducibility, rapidity of performance, and low radiation exposure (2 to 3 mrem).[179] Mean whole body BMC in the first 2 days of life ranges from 21.7 g in newborns with birth weights of 1001 to 1500 g to 78.8 g in neonates with birth weights of 3501 to 4000 g, whereas whole body bone mineral density (BMD) varies from 0.146 mg/cm^2 (1001 to 1500 g) to 0.234 g/cm^2 (3501 to 4000 g). In full-term healthy neonates, the mean whole body BMC measured by fan beam DEXA is 89.3 g (SD ± 14.1).[188] BMC and BMD increase through the first year of life and beyond as measured by DEXA. No racial, gender, or seasonal factors affect bone mineralization at this age; body weight is best correlated with bone mass. Quantitative ultrasonography (QUS) may also be employed to assess bone integrity and strength in preterm and other LBW infants; QUS may be performed at the crib side, there is no exposure to radiation, and it may be repeated as frequently as necessary.[189] QUS measures the

speed of sound (SOS) through a bone (humerus, tibia, radius, patella, os calcis, metacarpal, phalanx), a measurement that is correlated with the strength of the bone; mineral content is but one of several skeletal components (elasticity, cortical thickness, microstructure) that collectively contribute to bone strength. QUS also permits calculation of bone transmission time, a measurement that determines the difference in the velocity of sound as it travels through bone and surrounding soft tissue. There is considerable overlap of SOS values at various ages and somatic sizes; however, bone transmission times may discriminate to a greater extent between these parameters. Humeral and tibial QUS measurements are lower in preterm than term infants and correlate positively with gestational age, birth weight, postnatal length, and weight.[190] In neonates with intrauterine growth restriction, tibial SOS levels may be appropriate for gestational age or lower or even elevated.[189] The relationships between bone mineral density determined by DEXA and bone strength estimated by QUS in preterm and term newborns are weak but significant.[178]

With prolonged deprivation of calcium, phosphate, and vitamin D, not only does the LBW infant lag in accumulation of bone mass, but clinical and radiographic evidence of rickets also develops—usually between the sixth and twelfth postnatal weeks—and fractures may occur in as many as 24% of VLBW infants.[187] The LBW neonate at risk for low bone mass or rickets is best managed preventively by maintaining serum calcium concentrations between 8 and 11 mg/dL and serum phosphate values between 5.8 and 9 mg/dL and by providing by daily enteral administration of as much of the needed amounts of calcium (140 to 160 mg/100 kcal), phosphate (95 to 108 mg/100 kcal of formula), and vitamin D (400 U) as well as protein (for collagen synthesis) and energy (carbohydrates, lipids) as possible. When parenteral administration of nutrients is necessary in the LBW or VLBW neonate, an attempt should be made to administer the maximum amounts of calcium and phosphate safely attainable. The solubility of calcium and phosphate depends not only on their quantities but also on the forms selected for infusion (i.e., calcium chloride, gluconate, glycerophosphate, monobasic phosphate, or dibasic phosphate). Utilizing monobasic phosphate and glycerophosphate, it is possible to infuse as much as 86 mg of calcium/kg/dL and 46 mg/kg/dL of phosphate. However, these preparations increase the risk of metabolic acidosis and hypercalciuria.[179] Infusion of parenteral nutrition solutions containing 60 to 80 mg/kg/day of calcium and 40 to 50 mg/kg/day of phosphate provides only 60% to 70% of the estimated in utero bone mineral accretion rates.[179] Therefore, enteral feeding should begin as soon as possible in the VLBW infant by fortification of human breast milk with calcium 150 to 220 mg/kg/day and phosphate 75 to 140 mg/kg/day).[177,179] Prepared formulas for feeding of LBW neonates providing 200 mg/kg/day of calcium and 100 mg/kg/day of phosphate can result in up to 90 mg/kg/day of retained calcium and 40 mg/kg/day of retained phosphate.[177] The type of prepared formula (sources of protein, fat and carbohydrates) and its lipid and mineral additives determine the rate of intestinal calcium absorption and retention; therefore, the choice of formula must be carefully considered before it is selected. Nevertheless, parenteral nutrition, fortified human milk, and available preterm formulas are unable to provide the amounts of calcium and particularly phosphate that would normally accrue to the fetus in utero. Vitamin D 400 IU/day should also be provided to the preterm infant either enterally or parenterally. Monitoring of serum levels of calcium, phosphate, creatinine, and alkaline phosphatase and urinary excretion of calcium, phosphate, and creatinine is essential in order to prevent hypercalcemia and hypercalciuria and nephrocalcinosis. It is also important to avoid hypocalcemia because of the avidity of bone matrix for calcium once remineralization has commenced ("hungry bone syndrome"). Passive physical activity (daily range of motion with extension/flexion of all joints of each extremity in the supine infant for 4 weeks beginning after the neonate has been stabilized between 2 and 6 weeks of postnatal age) with or without gentle massage of the prone infant from head to toe increases serum levels of markers of bone formation as well as bone mineralization by DEXA and QUS changes consistent with augmented bone strength.[184,187,190] The efficacy and safety of bisphosphonates or of PTH[1-34] (discussed later) in the management of osteopenia of prematurity remain to be examined. Although in the prematurely born infant bone mass may remain low through infancy and early childhood, bone mineralization eventually catches up to the norms.[191,192]

Osteogenesis imperfecta congenita (OIC), or type II (MIM 166210), is a perinatal lethal disorder most commonly associated with heterozygous spontaneous loss-of-function mutations in the genes encoding collagen-α1(I) (*COL1A*) or collagen-α2(I) (*COL1A2*) (discussed later). The mutations may be partial gene deletions resulting in decreased synthesis of the triple helix of type I collagen or missense mutations that lead to amino acid substitutions (e.g., arginine, aspartic acid, cysteine) for the glycine residues that are essential for the normal three-dimensional conformation of collagen-α1(I)/collagen-α2(I) and synthesis of the triple helix and structural integrity of type I collagen in extracellular matrix of bone on which hydroxyapatite is deposited. Osteogenesis imperfecta type II may rarely be transmitted as an autosomal dominant trait by a parent who is mosaic for a heterozygous mutation in either collagen-α1(I) or -α2(I).[193] Clinical manifestations of OIC are variable and include fractures present at birth (which may also occur in newborns with osteogenesis imperfecta types I and III), deformities of the long bones, osteopenia of the skull with large fontanelles, intrauterine growth restriction, premature delivery, and death usually in infancy due to respiratory insufficiency. Radiologically, OIC has been categorized into three subgroups: A, characterized by short, broad, and "crumpled" long bones, angulation of the tibia, and continuous beading of the ribs; B, characterized by similar femoral and tibial configurations but incomplete beading of the ribs; and C, characterized by thin long bones with many fractures and thin beaded ribs. The diagnosis of OIC is most often made clinically and by its differentiation from achondrogenesis type I, thanatophoric dysplasia, and perinatal hypophosphatasia, and it is confirmed by quantitation of subnormal amounts of collagen

synthesized by fibroblasts in vitro and identification of the mutation in *COL1A1* or *COL1A2* by direct genotyping. The lethal mutations in collagen α1(I) are clustered at sites at which the collagen monomer binds integrins, matrix metalloproteinases, fibronectin, and cartilage oligomeric matrix protein; other mutations impair posttranslational processing of collagen α1(I) and thereby interfere with association of collagen chains or propagation of the triple helix configuration.[194] Mutations in *COL1A2* encoding collagen α2(I) coincide with binding sites for proteoglycans. Indeed, the lethal mutations in *COL1A1* leading to OIC are more functionally incapacitating to the protein than is complete absence of one COL1A1 allele that leads to the less clinically severe osteogenesis imperfecta type I.[195] Although administration of the bisphosphonate pamidronate has been helpful in infants with severe manifestations of osteogenesis imperfecta types III and IV, it has been ineffective in the lethal form of osteogenesis imperfecta type II (discussed later).[196,197] Lethal forms of osteogenesis imperfecta transmitted as autosomal recessive disorders are also attributable to inactivating mutations in *CRTAP* (MIM 605497), *PPIB* (MIM259440), or *LEPRE1* (MIM 610339) (discussed later)—three factors necessary for hydroxylation of proline-986 in COL1A1 and proline-707 in COL1A2, essential modifications of these proteins.[198,199]

Lysinuric protein intolerance (MIM 222700) is an autosomal recessive disorder of hepatic and renal tubular transport of dibasic amino acids (lysine, arginine, ornithine) that manifests itself in infancy and childhood by vomiting, diarrhea, failure to thrive, developmental delay, hepatomegaly, and cirrhosis. Affected infants and children have impaired urea synthesis due to decreased hepatic uptake of ornithine but are episodically hyperammonemic with increased urinary excretion of the dibasic amino acids; there is extremely low bone mass due to marked protein deprivation and perhaps due to increase in cytokine induced bone resorption. Administration of citrulline has been reported to increase growth and bone mass in some of these patients. Lysine protein intolerance is due to loss-of-function variants in *SLC7A7* encoding an amino acid transporter including deletion of multiple exons, duplications, missense, nonsense, and splice-site mutations dispersed throughout the gene; patients with the largest deletions had the most severe phenotypes.[200,201] Osteopenia may also be observed in infants with infantile hypophosphatasia (MIM 241500) and in those with muscular disorders restricting movement such as the Prader-Willi syndrome (MIM 176270), glycogen storage disease type II (Pompe disease, MIM 232300), and forms of arthrogryposis.

Increased Bone Mass

Increased bone mass may be generalized or localized; osteosclerosis refers to thickening of trabecular bone and hyperostosis to increase in cortical bone mass.[8] The infantile "malignant" form of osteopetrosis (MIM 259700) is one of several autosomal recessive disorders due to abnormal osteoclast differentiation or function resulting in defective reabsorption of the mineral phase of bone (discussed later). Infantile osteopetrosis is clinically manifested in affected infants by failure to thrive; delayed development; nasal obstruction; loss of sight, hearing, and other cranial nerve functions; and intense bone overgrowth leading to pancytopenia and increased susceptibility to infection, hepatosplenomegaly as sites of extramedullary hematopoiesis, increased susceptibility to fracture because of decreased bone strength despite high bone mass, mandibular osteomyelitis, and death often within the first several years of life due to sepsis, anemia, or hemorrhage. Physical examination reveals impaired linear growth, enlarged head circumference, frontal bossing, nystagmus, delayed eruption of primary teeth, ecchymoses, and hepatosplenomegaly. The radiographic hallmark of infantile osteopetrosis is relatively uniform increase in bone density of the skull, vertebrae, and axial skeleton with thickened cortical and trabecular bone; "Erlenmeyer flask" deformities at the distal ends of the long bones in older children; and alternating bands of sclerotic and lucent bone in the iliac wings and metaphyses.[8] Biomarkers for osteopetrosis are increased serum levels of acid phosphatase and the brain isoform of creatine kinase. Usually lethal infantile osteopetrosis may be due to homozygous or compound heterozygous loss-of-function mutations in one of three genes: *TCIRG1* encodes a subunit of the vacuolar proton pump within the osteoclast ruffled border through which hydrogen ions are transported from the cytosol into the subosteoclast resorption lacuna; *CLCN7* encodes a chloride channel required for movement of this cation into and acidification of the resorption lacuna; *OSTM1* encodes a subunit of CLCN7 necessary for its normal posttranslational processing (discussed later). In selected subjects bone marrow transplantation providing osteoclast precursor cells has been effective in arresting progression of this disorder, albeit often with substantial residual deficits. Transient but substantial hypercalcemia may occur after this procedure. Osteopetrosis due to deficiency of *CA2* encoding carbonic anhydrase II (osteopetrosis, autosomal recessive type 3, MIM 259730) may present in infancy with failure to thrive or fracture with insignificant trauma (discussed later). Disproportionate short stature is the cardinal manifestation of pycnodysostosis (MIM 265800) and is manifest during infancy or early childhood.[8] There is a relatively large head circumference with open fontanelles and cranial sutures, dysmorphic facial features (fronto-occipital prominence, proptosis, bluish sclerae, hypoplastic maxilla, micrognathia, highly arched palate, malocclusion, beaked nose), stubby and clubbed fingers with hypoplastic nails, narrow thorax, pectus excavatum, lumbar lordosis, kyphoscoliosis, and increased fracture risk. Radiographically, there is marked osteosclerosis that increases with age, open fontanelles and cranial sutures, thin clavicles with hypoplastic lateral ends, erosion and hypoplasia of the distal phalanges and ribs, and dense vertebrae yet normal transverse processes. Histologically, there is decreased osteoblastic and osteoclastic activity. Pycnodysostosis is due to homozygous or compound heterozygous loss-of-function mutations (stop, missense, nonsense) in *CTSK*, the gene encoding cathepsin K, a lysosomal cysteine protease expressed in osteoclasts; loss of cathepsin K activity impairs degradation of collagen and the resorption of organic matrix but not that of the mineral component of bone.

Disorders of Bone Mineralization and Formation in the Child and Adolescent

Bone formation may be impaired because of lack of minerals (calcium or phosphate) or because of deficient production of bone matrix. Bone mineralization may be excessive because of an increase in the rate of mineral deposition or a decrease in the rate of resorption of the mineral phase of bone. Ectopic calcification of extraskeletal tissues may occur when local calcium and phosphate levels are high, whereas extraskeletal ossification may ensue when the regulation of skeletal bone formation is deranged.

Rickets

Rickets and osteomalacia are disorders that result from decreased mineralization of the growth plate and bone matrix, respectively, and are due to deficiencies of calcium or phosphate[202,203] (Tables 18-8 and 18-9). During endochondral bone formation in children, cartilage matrix is elaborated and subsequently mineralized. When endochondral matrix is not fully mineralized, cartilage accumulates and there is thickening of the growth plate and disorganization of the chondrocytes; the ends of the long bones (particularly those that are weight bearing) distort, and rachitic deformities ensues.[203] During the

TABLE 18-9 **Disorders of Mineralization: Rickets and Osteomalacia**

Gene Chromosome MIM	Pathophysiology	Mutation: Clinical Manifestations
Disorders of Vitamin D Metabolism		
CYP2R1: cytochrome P450, subfamily IIR, polypeptide 1 11p15.2 608713	Hepatic 25-hydroxylase: enzyme that converts vitamin D3 to 25OHD3 (calcidiol)	Biallelic loss-of-function mutation leads to vitamin D hydroxylation-deficient rickets type 1B (also termed vitamin D–dependent rickets type 1B), AR
CYP27B1: cytochrome P450, subfamily XXVII, polypeptide 1 12q14.1 609506	25OHD3-1α hydroxylase: enzyme that converts 25OHD3 to 1,25(OH)2D3 (calcitriol)	Biallelic inactivating mutations result in vitamin D–dependent rickets type 1A, AR
VDR: vitamin D receptor 12q13.11 601769	Vitamin D receptor: transcription factor that transduces the effects of calcitriol on gene activation or repression	Biallelic loss-of-function mutations lead to resistance to calcitriol and vitamin D–dependent rickets type 2A, AR
HNRNPC: heterogeneous nuclear ribonucleoprotein C 14q11.2 164020	Encodes a ribonucleoprotein that regulates gene transcription by reciprocally and transiently occupying the VDRE in the upstream promoter region of vitamin D–responsive target genes	Overexpression in vitamin D–responsive tissues leads to prolonged occupancy of the VDRE that interferes with interaction of the VDR/RXR with the VDRE resulting in vitamin D–dependent rickets type 2B
Disorders of Phosphate Metabolism		
SLC34A1: solute carrier family 34 (sodium phosphate cotransporter), member 1 5q35.3 182309	Encodes NPT2a: sodium/phosphate cotransporter expressed on the apical membranes of epithelial cells of the proximal renal tubule; under the inhibitory control of PTH	Loss-of-function mutation results in hypophosphatemic rickets with nephrolithiasis, type 1, AD; Fanconi syndrome type 2, AR
SLC34A2: solute carrier family 34 (sodium phosphate cotransporter), member 2 4p15.2 604217	Encodes NPT2b: sodium/phosphate cotransporter expressed in the small intestine, lung, and testes	Loss-of-function mutations associated with pulmonary alveolar microlithiasis and testicular microlithiasis, AR
SLC34A3: solute carrier family 34 (sodium phosphate cotransporter), member 3 9q34 609826	Encodes NPT2c: sodium/phosphate cotransporter expressed on the apical membranes of epithelial cells of the proximal renal tubule	Loss-of-function mutation results in hereditary hypophosphatemic rickets with hypercalciuria, AR
SLC9A3R1: solute carrier family 9, member 3, regulator 1 17q25.1 604990	Encodes NHERF1: a renal tubular sodium/hydrogen exchange regulatory factor that binds NPT2a anchoring it to the luminal membrane of the proximal renal tubule; phosphorylation by PTH leads to its dissociation from and endocytosis of NPT2a	Loss-of-function mutations result in hypophosphatemic rickets with nephrolithiasis, type 2, AD
CLCN5: chloride channel 5 Xp11.23-p11.22 300008	Encodes a proximal renal tubular exchanger of chloride and hydrogen ions	Loss-of-function mutations result in X-linked recessive hypophosphatemic rickets, hypercalciuria, nephrocalcinosis, XLR

TABLE 18-9 **Disorders of Mineralization: Rickets and Osteomalacia—cont'd**

Gene Chromosome MIM	Pathophysiology	Mutation: Clinical Manifestations
PHEX: phosphate-regulating endopeptidase homologue, X-linked Xp22.1 300550	Ectoenzyme expressed on the cell membrane of osteoblasts; its physiologic substrate may be MEPE and pASARM, MEPE's phosphorylated product that coats hydroxyapatite and hinders mineral deposition	Loss-of-function mutation leads to X-linked hypophosphatemic rickets; associated with increased expression of FGF23; X-linked dominant
DMP1: dentin matrix acidic phosphoprotein 1 4q22.1 600980	Noncollagenous, serine-rich, bone matrix protein; a small integrin-binding ligand, N-linked glycoprotein (SIBLING) expressed in osteocytes	Loss-of-function mutations lead to increased osteocyte synthesis of FGF23, hyperphosphaturia, and autosomal recessive hypophosphatemic rickets, AR
ENPP1: ectonucleotide pyrophosphatase/phosphodiesterase 1 6q23.2 173335	Ectoenzyme expressed by chondrocytes, bone, and plasma cells that hydrolyzes ATP to pyrophosphate, an inhibitor of bone mineralization	Loss-of-function mutations result in autosomal recessive hypophosphatemic rickets with increased expression of FGF23, AR
ANKH: ANK, mouse, homologue of 5p15.2 605145	Transmembrane-spanning cell surface protein that regulates pyrophosphate secretion	Inactivating mutations result in mild hypophosphatemia and joint ankylosis, developmental delay, deafness, and dentinogenesis imperfecta; AR
FGF23: fibroblast growth factor 23 12p13.3 605380	Product of osteoblast and osteocyte that depresses renal tubular reabsorption of phosphate and inhibits synthesis of calcitriol	Gain-of-function mutation that decreases the rate of degradation of FGF23 results in autosomal dominant hypophosphatemic rickets, AD; excessive ectopic synthesis by neoplasms leads to hypophosphatemic rickets; loss-of-function mutation leading to decreased FGF23 synthesis results in autosomal recessive hyperphosphatemic familial tumoral calcinosis, AR
GALNT3: UDP-N-Acetyl-alpha-D-Galactosamine: polypeptide N-acetylglactosaminyl transferase 3 2q24.3 601756	Encodes an enzyme that is essential for O-glycosylation of Thr178 of FGF23 during posttranslational processing; failure of this step leads to degradation of FGF23 prior to its secretion	Loss-of-function mutation leads to autosomal recessive hyperphosphatemic familial tumoral calcinosis, AR
KL: α-Klotho 13q13.1 604824	Coreceptor with FGFR1(IIIc) for FGF23 that converts FGFR1(IIIc) into the specific FGF23 receptor enabling signal transduction	Loss-of-function mutation leads to autosomal recessive hyperphosphatemic familial tumoral calcinosis, AR; translocation t(9;13(q21.13;q13.1) results in excessive klotho formation leading to hypophosphatemic rickets and hyperparathyroidism
Hypophosphatasia		
ALPL: alkaline phosphatase, liver 1p36.12 171760	Tissue nonspecific alkaline phosphatase: ectoenzyme expressed on the cell membrane of osteoblasts, removes organically bound phosphate; major substrates are pyrophosphate, phosphoethanolamine, pyridoxal-5′-phosphate	Loss-of-function mutations lead to hypophosphatasia and rickets of variable severity and onset: perinatal, infancy, transitional, childhood, adult, odontohypophosphatasia, pseudohypophosphatasia; AR, AD

Adapted from Farrow, E. G., & White, K. E. (2010). Recent advances in renal phosphate handling. Nat Rev Nephrol*,* 6*, 207–217.*

processes of modeling and remodeling of trabecular bone and the periosteal and endosteal surfaces of cortical bone, osteoid is formed by osteoblasts; failure to mineralize bone matrix in these regions results in osteomalacia. During intervals of calcium or phosphate deprivation the actively growing, weight-bearing child with open cartilage growth plates develops rickets and osteomalacia, whereas adults develop only osteomalacia during remodeling as unmineralized bone matrix accumulates. Thus, rickets is the expression of defective endochondral mineralization at the growth plate and osteomalacia is the failure of mineralization of bone cortex and trabeculae.

Clinically, rickets is manifested by skeletal deformities such as delayed closure of the fontanelles, craniotabes (reversible compression of the skull's outer table), frontal bossing (expansion of cranial bones), and occasional craniosynostosis in infants; bowing of the forearms in the preambulatory infant and genu varum or valgum in the weight-bearing infant and child; delayed tooth eruption with poor enamel formation and propensity to caries; pectus carinatum, prominence of the costochondral junctions, flaring of the lower rib cage, scoliosis, and kyphosis; flaring of the metaphyses of the long bones; and tibial or femoral torsion (Figure 18-8).[204] Radiographically,

FIGURE 18-8 ■ Clinical and radiographic manifestations of vitamin D–deficient rickets. Note flaring of the distal metaphyses of the long bones and radiographic response to treatment with vitamin D. (From Girgis, C. M., Clifton-Bligh, R. J., Hamrick, M. W., et al. (2013). The roles of vitamin D in skeletal muscle: form, function, and metabolism. *Endocr Rev*, *34*, 33–83. rickets is characterized initially by epiphyseal widening and loss of the defined zone of provisional calcification followed by cupping, splaying, and fraying of the metaphyses of long bones (particularly the distal ulna, distal femur, and proximal tibia), demineralization, deformation of the long bones, and fractures.[203,204] Looser zones are radiolucent lines with dense borders that are pseudofractures located at the femoral neck and shaft. Histologically, as a consequence of impaired calcification within the cartilage growth plate, the pattern of chondrocyte differentiation and maturation is disrupted and disorganized, whereas osteoid seams widen at other sites of bone formation.[205] In subjects deprived of phosphate, it is the trabeculae that are primarily undermineralized.

Impaired mineralization of osteoid may be due to dietary deficiencies or depressed intestinal absorption of calcium, phosphate, or vitamin D; inadequate amounts of these nutrients in fluids utilized in total parenteral nutrition; inborn errors in the metabolism or action of vitamin D; defects in renal tubular conservation of phosphate or calcium; or abnormalities of alkaline phosphatase generation and function (see Table 18-8). Broadly, rickets may be considered to be *calciopenic* (usually related to nutritional deprivation of vitamin D or, rarely, to a defect in its metabolism to the active metabolite—calcitriol—or in its cellular action or to a decreased intake of calcium or its excessive loss in urine) or *phosphopenic* (related to renal phosphate wasting due to primary renal tubular defects in phosphate reabsorption or to the generation of excessive amounts of phosphatonins, compounds that inhibit renal tubular reabsorption of phosphate). Thus, nutritional rickets may be due to decreased intake of vitamin D (or inadequate exposure to sunlight) or calcium or to marginal intakes of both nutrients.[206] Dietary deficiency of phosphate is unusual given its wide availability, but this nutrient may be deficient in parenteral fluids. Bone mineralization may also be directly impaired by abnormalities of alkaline phosphatase generation or by agents such as aluminum or fluoride.[205]

Calciopenic Rickets. Calciopenic rickets is most often due to deficiency of vitamin D that depresses intestinal

absorption of dietary calcium and renal reabsorption of filtered calcium. As determined by the measurement of serum concentrations of calcidiol (25OHD), vitamin D deficiency is present when values are below 12 to 15 ng/mL.[207,208] Calcidiol concentrations between 15 and 19.5 ng/mL indicate vitamin D "insufficiency," whereas those ≥ 20 ng/mL are adequate or "sufficient."[208] However, these guidelines, based on the recommendations of the Institute of Medicine report, are not accepted by all authorities and remain the subject of ongoing investigation.[209] Alternate guidelines state that a normal 25OHD concentration be defined as greater than 30 ng/mL (> 75 nmol/L) with values of 20 to 30 ng/mL (50 to 75 nmol/L) used to define "insufficiency" and values of less than 20 ng/ml (50 nmol/L) considered to identify vitamin D "deficiency." Neonates born to severely vitamin D–deficient mothers may display signs of rickets at birth, including fractures and hypocalcemic seizures. Clinical manifestations of rickets in preambulatory infants include bowing of the forearms, craniotabes, frontal bossing, and delayed closure of the cranial fontanelles. In older infants and children, genu varum or valgum (bowed legs or "knock knees") or a "windswept" deformity involving both legs, flaring (widening) of the metaphyses of the long bones with markedly enlarged wrists, prominence of the costochondral junctions (rachitic rosary), and indentation of the lower anterior thoracic wall (Harrison's groove) are noted. Tooth eruption may be delayed and the enamel hypoplastic predisposing to dental caries. Short stature and suboptimal weight are also present frequently. Because vitamin D has many extraskeletal sites of action, a number of nonosseous, systemic symptoms are observed in children with vitamin D–deficiency rickets; these include muscular weakness manifested by hypotonia and delay in walking, anorexia, and increased susceptibility to infection particularly pneumonia (due both to the lack of the stimulatory effect of vitamin D on the immune system and weakness of the thoracic wall).[203] Hypocalcemia, tetany, and seizures may occur in a severely vitamin D–deficient infant without gross clinical or radiographic signs of rickets. Rarely, vitamin D deficiency in an adolescent may be associated with hypocalcemic seizures and fractures.[210] Deficiency of vitamin D is frequently observed in darkly skinned children and adolescents with limited exposure to sunlight, particularly during and at the end of the winter months, or in those ingesting vegetarian diets or who are being treated with anticonvulsant or antiretroviral drugs.[208] Radiographically, osteopenia with cortical thinning and thin stress fracture lines as well as cupping, widening, and irregularity (fraying) of the distal metaphyses of the long bones are observed in the rachitic subject.[9,10,202] Areas of osteitis fibrosa cystica associated with secondary hyperparathyroidism may sometimes develop.

After the introduction of cod liver oil as a dietary supplement in 1918 (and the later fortification of infant formulas and milk and other foods with irradiated ergosterol) and the discovery in 1919 that exposure to sunlight prevented development of rickets, nutritional deficiency of vitamin D became relatively unusual in North America only to reemerge several decades later. Because the fetus is supplied with vitamin D by the transplacental transfer of maternal calcidiol, deficiency of vitamin D occurs predominantly in neonates who are born to mothers with low stores of vitamin D (women of color or those who are vegetarian, poorly nourished, or have limited exposure to sunlight).[211] Rickets develops in infants and young children who ingest a diet low in vitamin D (little or no milk, meat, eggs, or fish) without supplemental vitamin D who have limited exposure to sunlight because they are confined indoors due to illness, the climate, or parental choice or because they wear clothing that protects the entire body from sunlight. Vitamin D deficiency is more common in breastfed black infants than in white infants due in large part to increased maternal skin pigmentation resulting in decreased endogenous synthesis of cholecalciferol that coupled with socioeconomic circumstances leads to lower levels of calcidiol in maternal serum and of vitamin D in breast milk.[205] Because normal human breast milk contains only 25 IU/L of vitamin D, it is recommended that all breastfed infants receive supplemental vitamin D 400 IU/day.[212] Inasmuch as most commercial infant formulas contain 400 IU/liter of vitamin D, it is also recommended that formula-fed infants who consume less than 1 liter of formula daily also receive a supplement of 400 IU/day of vitamin D. Infants older than 2 year of age, children, and adolescents should receive supplemental vitamin D 600 IU daily.

Although definitions of hypovitaminosis D vary between individual studies, subtle forms of vitamin D deficiency or "insufficiency" are likely prevalent throughout the North American population, particularly in the winter months when there is little sunlight exposure and the ultraviolet light requisite for endogenous synthesis of vitamin D is limited.[9,10,208,213] In a group of 307 healthy urban male and female adolescents 11 to 18 years of age in the northeastern United States, 42% had serum concentrations of 25OHD less than 20 ng/mL.[214] The prevalence of very low 25OHD values (< 15 ng/mL) was most common in black (36%) and Hispanic subjects (22%), whereas 6% of white students had such levels. There was an inverse relationship between serum levels of 25OHD and PTH with secondary hyperparathyroidism present in many subjects with low 25OHD concentrations, implying the possibility of incipient metabolic bone disease. Although clinically apparent vitamin D deficiency is unusual in U.S. youth, vitamin D insufficiency may be relatively frequent.[213,215] In addition to skin pigmentation and northern latitude, low serum calcidiol values have been attributed to meager consumption of milk and multivitamins, large intake of phosphate-containing soft drinks, and increase in fat mass into which vitamin D is deposited and thus not bioavailable. Similar findings have been recorded in apparently healthy children and adolescents in the United Kingdom and attributed to lower socioeconomic status, nonwhite ethnicity, decreased outdoor activities, older age, advanced pubertal development, and female gender.[216,217] Indeed, serum concentrations of calcidiol below 13 ng/mL have been recorded in up to 40% to 50% of both southern and northern European children and adolescents.[218] Assuming a reliable assay such as those employing liquid chromatography-tandem mass spectrometry that measure both $25OHD_2$ and $25OHD_3$, calcidiol concentrations

below 12 to 15 ng/mL in children clearly indicate vitamin D deficiency, whereas values between 12 to 20 ng/mL are consistent with vitamin D insufficiency.[207,208] Serum levels of 25OHD that exceed 60 to 100 ng/mL are indicative of vitamin D excess. Dietary deficiency of calcium may accentuate the adverse effects of borderline vitamin D stores.[206,219]

Vitamin D deficiency may also be the consequence of intestinal malabsorptive disorders such as celiac or inflammatory bowel diseases, biliary obstruction, gastric and intestinal resection, or pancreatic exocrine insufficiency (e.g., cystic fibrosis), or ingestion of calcium binding agents such as cholestyramine, or by increased hydroxylation of vitamin D to water soluble forms that increase its urinary loss by anticonvulsant drugs such as phenytoin.[10] Use of a therapeutic glucocorticoid is also associated with lowered serum levels of calcidiol.[220] In the majority of infants and children with rickets due to vitamin D deficiency, serum concentrations of total calcium are borderline-normal or low, phosphate levels low, and alkaline phosphatase activity and PTH concentrations increased (Table 18-10). Secondary hyperparathyroidism develops as the intestinal absorption of calcium is reduced and its serum levels reduced; PTH increases urinary phosphate loss and lowers serum phosphate concentrations while enhancing the rates of bone resorption and turnover. PTH also increases synthesis of calcitriol, which may increase the rate of calcidiol catabolism and further deplete the body's store of vitamin D.[205] Typically, in vitamin D deficiency serum concentrations of calcidiol are low, whereas calcitriol values may be normal, high, or low depending on whether vitamin D deficiency is modest, moderate, or severe. Serum concentrations of osteocalcin are low; serum levels of PICP (a marker of bone formation) and ICTP and urinary excretion of NTx (markers of bone resorption) are substantially increased in infants with vitamin D–deficiency rickets, indicating increased collagen turnover in this disorder.[221] With treatment these values increase transiently and then fall to age-appropriate norms before radiographic healing of the rachitic lesions is complete.

Prevention of vitamin D deficiency is its most effective management. Because the amount of vitamin D in human breast milk is approximately 20 to 25 IU/L and vitamin D supplementation of the breastfeeding mother may be inadequate to ensure normal calcidiol levels in her infant (unless she is receiving approximately 2000 IU/day), it is important that all breastfed infants receive a supplement of vitamin D daily (400 IU/day); by extension this recommendation is also appropriate for infants who are not receiving adequate amounts of vitamin D in their prepared formulas or diet or have suboptimal exposure to sunlight. In the active, lightly dressed white child with skin that normally tans with exposure to sunlight and who plays outdoors 30 minutes thrice weekly or 10 to 15 minutes daily between 1000 to 1500 hours during spring, summer, and fall, endogenous vitamin D synthesis is usually sufficient to achieve satisfactory serum levels of calcidiol.[205,208] A yellow- or brown-skinned child requires 30 to 45 minutes of outdoor play, whereas a black-skinned child requires 60 to 150 minutes of sunlight exposure to achieve serum calcidiol concentrations comparable to those of the white-skinned child. The latitude in which the child lives, season of the year, time of day, local environmental pollutants, amount of clothing, and use of sunscreen affect the time required for sunlight exposure to evoke adequate vitamin D synthesis in the individual child. Between November and February, little or no vitamin D can be synthesized in areas that are above 35 degrees latitude (such as Atlanta, Georgia), but vitamin D insufficiency is also prevalent in lower latitudes.[10,222] (It is somewhat ironic that an increase in the incidence of vitamin D deficiency in infants and children coincides with well-intentioned recommendations that exposure to sunlight be limited by sunscreen and protective clothing.) Obesity is another risk factor for hypovitaminosis D and decreased bone mineralization.[223,224] In obese adolescents, serum concentrations of calcidiol

are inversely and PTH values are directly related to fat mass.[223] After diet and exercise-induced weight loss, abnormalities in serum levels of calcidiol and PTH are reversed, indicating that the aberrations seen in obese children are the consequence and not the cause of obesity.[224] In a study of 236 adolescent candidates for bariatric surgery, more than 50% were vitamin D deficient as defined by low serum concentrations of calcidiol.[225] Although 43% of these subjects were Caucasian and 15% African American, 82% of the vitamin D–deficient patients were African American compared to 37% of the Caucasian adolescents.

Vitamin D deficiency in the infant may be managed by administration of vitamin D 1000 to 5000 IU/day for infants > 1 to 12 months of age.[177] For the child who is 1 year of age or older or an adolescent, vitamin-deficient rickets may be treated with 5000 to 10000 IU/day of vitamin D. At the beginning of treatment, elemental calcium (30 to 75 mg/kg/day in three divided doses per day) must also be administered to the vitamin D–deficient child receiving vitamin D in order to avoid the hypocalcemia that accompanies rapid remineralization of bone matrix (the "hungry bone syndrome").[177] When there is radiographic evidence of healing, the vitamin D dose is lowered to 400 to 600 IU/day. Alternative therapeutic regimens for treatment of rickets include 50,000 IU orally weekly for 8 weeks or the administration of a single oral (or intramuscular) dose of 150,000 to 600,000 units of vitamin D_3, depending on patient age and other individual circumstances.[10,205] Serial measurement of total or bone-specific alkaline phosphatase values is an effective tool for monitoring the efficacy of treatment as levels decline progressively in tandem with the roentgenographic healing of the rachitic lesions. To avoid hypocalcemia or hypercalcemia, hypercalciuria, and nephrocalcinosis, serial determinations of serum values of calcium, phosphate, alkaline phosphatase, and creatinine and urinary excretion of calcium and creatinine should be determined. Sequential radiographs document reversal of rachitic changes (see Figure 18-8).

Rickets due primarily to a low dietary intake of calcium has been observed in infants who ingest low-calcium containing formulas and in children from developing countries whose diets contain 200 mg (or less) of elemental calcium per day despite a normal intake of phosphate and adequate endogenous stores of vitamin D as determined by serum calcidiol levels.[205] Calcium intake in these infants and children is well below that recommended (400 to 600 mg/day in infants; 700 mg/day in children below 4 years of age; 1000 to 1300 mg/day in older children and adolescents). Histologically, bone biopsies from children with calcium-deficiency rickets reveal widened seams of unmineralized osteoid and low bone turnover rates, findings compatible with rickets. In Nigerian infants, rickets due to vitamin D deficiency is most prevalent between 4 to 12 months of age. In 123 older Nigerian children (34 to 63 months of age) with rickets, low serum concentrations of calcium, normal phosphate levels, normal to low calcidiol and elevated calcitriol concentrations, administration of calcium alone (1000 mg daily in divided doses orally over 24 weeks) resulted in more rapid decline in serum levels of alkaline phosphatase and in radiographic healing of rickets than did administration of vitamin D (600,000 IU intramuscularly at inception of the study and again 12 weeks later), data supportive of the concept that calcium deficiency alone was the cause of the rickets in this population.[226] Interestingly, calcidiol values rose and calcitriol levels declined with calcium supplementation alone, suggesting that a low-calcium diet and attendant calcium deficiency led to increased secretion of PTH and accelerated conversion of calcidiol to calcitriol. Calcium-deficiency rickets also occurs in the United States when infants and children are weaned to low-calcium–containing foods after completion of breastfeeding.[219] Calcium deficiency rickets may also develop as a consequence of impaired intestinal absorption of dietary calcium that has been bound by ingestion of high-fiber and phytate-containing cereals. In a study of 67 Indian children with nutritional rickets, the ingestion of a diet high in phytate was larger and the intake of calcium was 50% of that of an age- and gender-matched, clinically well control population.[206] There was an inverse correlation between dietary calcium intake and radiologic severity of rickets. However, in both populations serum concentrations of calcidiol were below 20 ng/mL and not significantly different from one another. These data led to the conclusion that clinical and radiologic manifestations of rickets in this population of Indian children were dependent on the co-occurrence of both calcium and vitamin D deficiencies. Calcium deficiency is best addressed by its prevention, ensuring adequate intake of this element according to established guidelines for growing children and adolescents. When present, calcium-deficiency rickets may be effectively treated by ensuring an intake of 1000 to 1500 mg of elemental calcium daily for 6 months with provision of normal amounts of vitamin D by sunlight exposure or supplementation.[227]

Dietary phosphate deficiency is unusual because phosphate is present in large amounts in most foods. Phosphate deficiency occurs in patients with depressed renal tubular reabsorption of phosphate (Tables 18-9 and 18-11A), in subjects with decreased intestinal phosphate absorption, in those receiving parenteral nutrition with fluids low in phosphate, in subjects ingesting large amounts of aluminum-containing antacids as aluminum and phosphate coprecipitate in the intestinal tract, and in premature infants drinking human breast milk without supplemental phosphate.[227,228] In very premature infants receiving long-term parenteral nutrition, development of metabolic bone disease is frequent and related not only to deficiencies of calcium, phosphate, and vitamin D but also to excess aluminum in the infusates. Infants receiving large amounts of aluminum containing antacids over prolonged periods for treatment of gastroesophageal reflux may also have substantially low bone mass. Aluminum lowers the rate of bone formation by several mechanisms: administered orally aluminum binds intestinal phosphate, thereby impeding its absorption leading to phosphate depletion; administered intravenously during total parenteral nutrition or during hemodialysis, aluminum inhibits osteoblastic function and prevents mineralization of osteoid; it also impairs the secretion of PTH and decreases 25OHD-1α hydroxylase activity.[227]

TABLE 18-11A **Disorders of Phosphate Homeostasis in Children**

I Hypophosphatemia

A Decreased Intestinal Absorption

1 Decreased intake/absorption: parenteral hyperalimentation, antacid abuse, starvation (anorexia nervosa), alcoholism
2 Malabsorption: vitamin D deficiency, metabolism, function

B Increased Urinary Excretion

1 Hypophosphatemic rickets: X-linked (*PHEX*), autosomal dominant (*FGF23*), autosomal recessive (*DMP1, ENPP1*), hereditary autosomal recessive with hypercalciuria (*SLC34A3*), X-linked recessive (*CLCN5*), tumor-induced osteomalacia, linear sebaceous nevus syndrome, fibrous dysplasia (*GNAS*)
2 Renal tubular defects: Dent and Fanconi syndromes, postrenal transplantation, hypomagnesemia, fructose intolerance, macrophage activation syndrome
3 Hyperparathyroidism, acidosis, respiratory alkalosis
4 Drugs: diuretics (thiazides, acetazolamide, loop diuretics), iron polymaltose infusions, bicarbonate, glucocorticoids, calcitonin, antineoplastic agents (ifosfamide, cisplatin), antiretroviral agents (tenofovir, adefovir), mannitol, bisphosphonates
5 Expansion of extracellular fluid volume

C Transcellular Shifts from Extracellular to Intracellular Space

1 Recovery from diabetic ketoacidosis/insulin administration, sepsis, salicylate intoxication
2 Administration of glucose, catecholamines; nutritional repletion, "hungry" bone syndrome
3 Respiratory alkalosis

II Hyperphosphatemia

A Increased Intake

1 Intravenous, oral, rectal

B Decreased Urinary Excretion

1 Renal insufficiency
2 Hypoparathyroidism, acromegaly
3 Pseudohypoparathyroidism (*GNAS*)
4 Familial tumoral calcinosis (*FGF23, GALNT3*)
a Hyperostosis hyperphosphatemia syndrome (*FGF23, GALNT3*)
5 Drugs: growth hormone, bisphosphonates

C Excess Bone Resorption

1 Severe illness: acidosis (metabolic or respiratory), hemolytic anemia, diabetic ketoacidosis, hepatitis, catabolic states, rhabdomyolysis, hyperthermia
2 Drugs: cytotoxic therapy

Modified from Ward, L. M. (2005). Renal phosphate-wasting disorders in childhood. Pediatr Endocrinol Rev, 2, *342–350; Imel, E. A., & Econs, M. J. (2012). Approach to the hypophosphatemic patient.* J Clin Endocrinol Metab, 97, *696-706.*

Patients requiring total parenteral nutrition should receive as much calcium and phosphate as can be administered safely as well as supplemental vitamin D 400 IU/day. Periodic measurements of serum levels of calcium, phosphate, alkaline phosphatase, PTH, and calcidiol, and serial skeletal radiographs and estimations of skeletal mineralization are recommended in patients receiving total parenteral nutrition; if metabolic bone disease develops in spite of these efforts, serum aluminum levels should be measured and if elevated (> 100 μg/L) a search for the source of the aluminum should be initiated and that product eliminated from the infusate if possible. Cadmium, fluoride, and saccharated ferric oxide are also able to impede normal bone mineralization.[227]

Metabolic and functional defects of vitamin D lead to rare forms of rickets.[208,229] Rickets due to a deficit in 25-hydroxylation (vitamin D hydroxylation-deficient rickets, type 1B [VDDR1B], MIM 600081) has been described in two brothers of Nigerian origin in whom a homozygous loss-of-function mutation (Leu99Pro) in *CYP2R1* eliminated hydroxylase activity of this 501 amino acid protein.[230] Hypocalcemia, hypophosphatemia, skeletal abnormalities of rickets, low plasma levels of calcidiol, and normal values of calcitriol were present in these siblings. 25-Hydroxylase deficiency transmitted as a dominant disorder not due to a mutation in the coding exons or intronic regions of *CYP2R1* has also been described.[231] Vitamin D hydroxylation-deficient rickets, type 1A (VDDR1A) (MIM 264700), or pseudovitamin D deficiency rickets (PDDR) type 1 is due to loss-of-function mutations in *CYP27B1*, the enzyme in the renal proximal tubule that catalyzes 1α-hydroxylation of 25OHD (calcidiol) to 1,25$(OH)_2$D (calcitriol), the biologically active metabolite of vitamin D.[232] VDDR1A is an autosomal recessive disease whose clinical manifestations—including bone deformities (bowing of the forearms), growth retardation, muscle weakness, delayed motor milestones (walking), or hypocalcemic seizures—appear between 6 and 30 months of age; hypoplasia of dental enamel may also occur; biochemically, hypocalcemia, hypophosphatemia, hyperphosphatasemia, and markedly elevated serum levels of PTH are typical; radiographs reveal rachitic deformities of the long bones.[233] The diagnosis of VDDR1A is established by finding normal serum concentrations of calcidiol while calcitriol values are extremely low and do not increase after administration of vitamin D or calcidiol, and the diagnosis is confirmed by identification of the mutation in *CYP27B1* (see Table 18-10).

The clinical, biochemical, and radiographic manifestations of VDDR1A resolve completely and reasonably rapidly following treatment with physiologic amounts of calcitriol (10 to 20 ng/kg/day). Treatment goals are restoration of eucalcemia without hypercalciuria, resulting in increased muscular strength and healing of the rachitic lesions permitting normal growth.[233] Lifelong therapy is necessary, but effective and compliant treatment leads to normalization of all biochemical parameters, normal linear growth and adult height, and normal bone mineralization. The dose of calcitriol often needs to be increased during pregnancy; however, gestation is uncomplicated and the offspring of affected mothers are normal.[233] VDDR1A is found with high frequency in a Quebec French-Canadian population but

HR, hypophosphatemic rickets.

Adapted from Gattineni, J., & Baum, M. (2012). Genetic disorders of phosphate regulation. Pediatr Nephrol, 27, *1477–1487; Hori, M., Shimizu, Y., & Fukumoto, S. (2011). Minireview: fibroblast growth factor 23 in phosphate homeostasis and bone metabolism.* Endocrinology, 152, *4–10.*

occurs in all races and in diverse geographic regions. *CYP27B1* encodes a 508-amino-acid mitochondrial cytochrome P450 hydroxylase with conserved sites that bind ferredoxin and heme and utilizes electrons from reduced nicotinamide adenine dinucleotide phosphate and oxygen to convert 25OHD to $1,25(OH)_2D$.[229] Many loss-of-function missense, nonsense, splicing, and duplication or deletion/frameshift mutations in *CYP27B1* lead to inactive or truncated protein products that are unable to bind either substrate (calcidiol) or heme, the latter defect preventing electron transfer and inhibiting catalysis.[229] The most common mutation in *CYP27B1* in the Quebec French-Canadian population at-risk for VDDR1A is deletion of guanine at nucleotide 958 (codon 88, exon 2) (958delG) that changes the reading frame resulting in premature termination of translation and an inactive product (the Charlevoix mutation). A second common mutation in this population is duplication of a 7-base pair sequence in exon 8; however, this mutation is also found in patients of other ethnicities (Asian, Hispanic).

Homozygous or compound heterozygous inactivating mutations of *VDR*, the gene encoding the vitamin D receptor, lead to resistance to the biologic effects of calcitriol (autosomal recessive vitamin D–dependent rickets, type 2A [VDDR2A] or hereditary vitamin D–resistant rickets [MIM 277440]).[229,232] Clinical and biochemical manifestations of resistance to calcitriol include severe infantile-onset bony deformities characteristic of rickets, growth retardation, varying degrees of alopecia, hypocalcemia, hypophosphatemia, hyperalkaline phosphatasia, and extraordinarily high serum concentrations of calcitriol (300 to 1000 pg/mL) and PTH; serum levels of 25-hydroxyvitamin D are normal, whereas those of 24,25-dihydroxyvitamin D are often low (see Table 18-10). Radiographic examination of the skeleton reveals rachitic

changes. The high calcitriol values reflect the combined stimulatory effects of hypocalcemia, hypophosphatemia, and secondary hyperparathyroidism on the activity of $25OHD_3$ 1α-hydroxylase together with a decrease in its rate of catabolism due to depressed activity of calcitriol-dependent 1,25α-dihydroxyvitamin D_3 24-hydroxylase. Alopecia is the result of impaired vitamin D function in epithelial nuclei and those of the outer root-sheath cells of the hair follicle. Loss-of-function mutations (particularly in the DNA-binding region) of *VDR* result in a phenocopy of the generalized alopecia associated with loss of *HR* function (hairless; MIM 602302, chromosome 8p21.2); interestingly, the role of the VDR in the maintenance of normal hair growth is not dependent on its binding to ligand.[232,234]

Although VDDR2A is primarily manifested during infancy and early childhood, clinical manifestations of this disorder may vary and patients with milder defects in *VDR* may not be identified until adolescence or adulthood. Spontaneous remission of the rachitic process may occur, most often between ages 7 and 15 or when the patient enters puberty.[235] Indeed, after puberty in many patients with VDDR2A, serum levels of calcium, phosphate, and alkaline phosphatase normalize and calcium supplementation is no longer needed.[235,236] Apparently, the skeletal requirement for calcium declines after completion of bone growth, and vitamin D–independent mechanisms of intestinal calcium absorption develop. In a study of 17 patients with VDDR2A between 1.5 and 37 years of age, biochemical parameters improved, the need for supplemental calcium declined, and BMD by DEXA normalized in the latter half of the second decade of life, whereas serum calcitriol values remained elevated.[236] Examination of intestinal calcium absorption revealed that the fractional absorption of calcium for patients who ingested a low-calcium diet was substantially lower than that for control subjects in young patients; in patients 18 to 26 years of age, the fractional absorption of calcium was significantly higher than control values; in adult patients, the fractional absorption of calcium was similar to control data. Nevertheless, the growth impairing effects of severe childhood rickets persisted into adulthood in the majority of patients.[236]

The diagnosis of VDDR2A is established by the presence of elevated serum concentrations of calcitriol in the rachitic patient (in the absence of administration of exogenous calcitriol) and confirmed by identification of the loss-of-function mutation in *VDR*. The VDR is composed of DNA-, ligand-, and retinoic X receptor-binding domains and a transactivation domain to which many comodulators of VDR function are recruited. The VDR and RXR bind as a heterodimeric transcription-activating complex. Loss-of-function mutations have been found in each VDR domain: thus, the mutated VDR may be unable to bind calcitriol because of decreased receptor number or affinity for ligand, incapable of forming heterodimers with the retinoic X receptor or of translocating to the targeted gene in the nucleus, or unable to bind to the vitamin D response element (VDRE) or to initiate gene transcription once bound to the VDRE (Figure 18-9). More than 30 distinct heterozygous mutations in *VDR* have been identified scattered throughout the VDR protein but with a large number of variants in the ligand binding domain.[229] In general, patients with vitamin D–resistant rickets without alopecia may be more responsive to treatment. Administration of high doses of calcitriol (1 to 6 μg/kg/day) and supplemental calcium (1 to 3 g of elemental calcium daily) has been effective in increasing serum calcium concentrations and healing rickets in patients with nonsense and missense mutations in *VDR* that lead to decreased affinity for ligand or alter nuclear targeting; it is appropriate to provide a trial of high-dose calcitriol/calcium therapy to each patient with vitamin D–resistant rickets regardless of the *VDR* mutation.[232] During treatment, serum values of calcium, phosphate, alkaline phosphatase, creatinine, and PTH, urinary calcium and creatinine excretion, skeletal radiographs, and renal ultrasounds for development of nephrocalcinosis are monitored serially. In patients refractory to oral therapy, continuous intravenous or intracaval administration of large amounts of calcium (0.4 to 1.4 grams of elemental calcium/m^2/day) normalizes calcium, phosphate, alkaline phosphatase, and PTH values; heals rickets; and increases the growth rate in selected children. If this mode of therapy is employed, careful monitoring for catheter sepsis and cardiac arrhythmia as well as hypercalcemia, hypercalciuria, and nephrocalcinosis is mandatory. After healing of the rickets by parenteral calcium, maintenance therapy with large doses of oral calcium (3.5 to 9 grams of elemental calcium/m^2/day) is appropriate. In younger infants with vitamin D–resistant rickets prior to the development of florid rickets, high doses of oral calcium may ameliorate the rachitic process. These clinical observations indicate that the major defect in patients with vitamin D–resistant rickets is lack of calcium. With treatment, growth may normalize in patients with vitamin D resistance, but alopecia, if present, is unlikely to resolve.[235] As already noted, spontaneous improvement may occur in some patients with VDDR2A during and after puberty.[236]

Vitamin D–dependent rickets, type 2B (VDDR2B, MIM 600785) is a second form of resistance to vitamin D with a phenotype similar to that of VDDR2A (except that alopecia is unusual) but with an intact vitamin D nuclear receptor; VDDR2B is due to inhibition of binding of the liganded VDR-retinoic X receptor heterodimer to the VDRE by members of a family of heterogeneous nuclear ribonucleoproteins.[237,238] *HNRNPC* encodes heterogeneous nuclear ribonucleoprotein C, an RNA binding protein; it is one of several ribonucleoproteins that are able to bind the VDRE and thereby to inhibit its transactivation by the VDR-retinoic X receptor heterodimer.[238] The mechanism by which overexpression of these otherwise normal ribonucleoproteins occurs and the relationship of this observation to VDDR2B are unknown at present.

Phosphopenic Rickets. Hypophosphatemia in childhood may be due to hereditary or acquired disorders (Tables 18-8, 18-9, 18-11A, and 18-11B). Acute hypophosphatemia is accompanied by irritability, paresthesias, confusion, muscle weakness, and ileus.[239] Chronic hypophosphatemia in children is often manifested by rickets. Hypophosphatemia may be the consequence of the movement of extracellular phosphate into cells (during treatment of diabetic ketoacidosis with insulin as the intracellular phosphorylation of carbohydrates increases, acute respiratory alkalosis due to

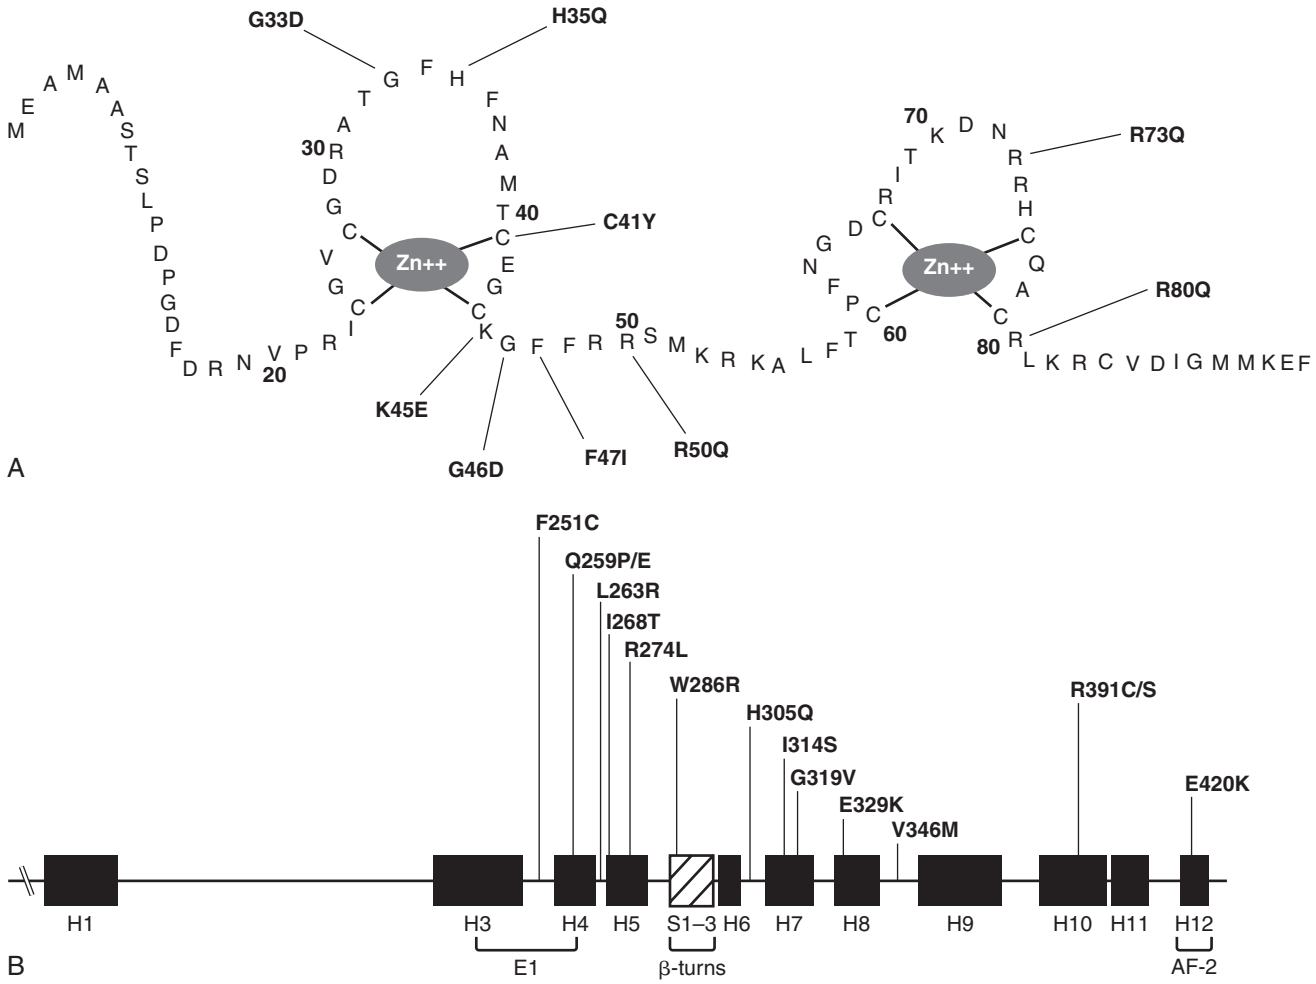

FIGURE 18-9 ■ Mutations in the vitamin D receptor (VDR) in patients with end-organ insensitivity to vitamin D. (From Malloy, P. J., & Feldman, D. (2010). Genetic disorders and defects in vitamin D actions. *Endocrinol Metab Clin North Am, 39,* 333–346.)

hyperventilation, sepsis), impaired intestinal absorption of phosphate (vitamin D deficiency, chronic ingestion of magnesium or aluminum containing antacids, chronic diarrhea or steatorrhea), or increased renal phosphate wasting (secondary to increased secretion of PTH or primary due to intrinsic abnormalities in the mechanisms that control renal tubular reabsorption of this anion). Hypophosphatemia is observed in nutritionally deprived subjects such as the LBW neonate or older patient who is dependent on parenteral alimentation, those with severe anorexia, or those who are addicted to alcohol. Hypophosphatemia occurs in many critically ill patients, especially those with sepsis. Rapid remineralization of osteopenic bone is accompanied by hypophosphatemia and hypocalcemia (the "hungry bone syndrome"). Most frequently, chronic hypophosphatemia is the result of hyperphosphaturia, due to either a primary or a secondary defect in the regulation of renal tubular phosphate reabsorption in the proximal (where 60% to 70% of the filtered load is reabsorbed) or distal (where 10% to 15% of filtered phosphate is reabsorbed) renal tubule.[228,239] Thus, increased secretion of PTH due to primary hyperparathyroidism or secondary to vitamin D deficiency or some other cause can lead to hyperphosphaturia and hypophosphatemia. The Fanconi syndromes are characterized by multiple functional renal tubular defects including phosphate reabsorption. Renal tubular defects that specifically impede the processes through which phosphate is reabsorbed by the renal tubules include abnormalities of transcellular transport of phosphate and excessive production of phosphaturic substances other than PTH such as fibroblast growth factor 23 (FGF23) and other phosphatonins (minhibins) and their cofactors.

In developed countries where severe vitamin D–deficiency rickets is not a common problem, X-linked dominant hypophosphatemic rickets (XLHR) is the most frequent form of rickets encountered (1:20,000 births). XLHR is due to loss-of-function mutations in *PHEX* (PHosphate-regulating Endopeptidase homologue, X-linked) encoding a zinc metallopeptidase expressed by bone cells (discussed later).[240] XLHR is manifested in both affected hemizygous males and heterozygous females, albeit with substantial inter- and intrafamilial variability in its clinical expression. Physical findings in children with XLHR include short stature; genu varum or valgum that develops when the infant begins to walk;

flaring of the metaphyses; rachitic rosary; frontal bossing; increased frequency of dental decay or periradicular abscesses in teeth free of caries; and bone, muscle, and joint aching and stiffness. Craniotabes, tetany, and muscular weakness are not found in patients with XLHR as they are in those with vitamin D deficiency. Because they are no longer growing, adults with XLHR have osteomalacia, bone pain, an increased fracture rate, and frequent dental abscesses; they may also develop stenosis of the spinal canal and progressive ankylosis of the vertebrae and large joints. Enthesopathy—the calcification of tendons, ligaments, and joint capsules—is common in adults with XLHR and may also occur in children with XLHR. Although completely penetrant, the clinical expression of XLHR may vary widely among affected families and among affected children in the same family.[241] Although serum levels of total calcium and Ca^{2+} are normal, hypophosphatemia is marked due to its urinary wastage because of substantially decreased renal tubular reabsorption of filtered phosphate and limited intestinal absorption of this anion. Serum concentrations of PTH and calcidiol are normal, but calcitriol values are inappropriately low for the degree of hypophosphatemia; serum alkaline phosphatase activity is increased.[242] Many of these biochemical abnormalities are present in the affected patient within the first several months after birth. Because the serum Ca^{2+} concentration is normal, secondary hyperparathyroidism does not occur unless the patient with XLHR receives excessive amounts of supplemental phosphate (discussed later). Normally, phosphate induces differentiation and death of hypertrophic chondrocytes in the cartilage growth plate by activating the mitochondrial apoptotic pathway that is caspase 9 dependent.[232,243] Thus, hypophosphatemia leads to a delayed loss and increased numbers of hypertrophic chondrocytes and expansion of the growth plate characteristic of rickets. Histomorphometrically in XLHR, unmineralized osteoid accumulates along the trabeculae within cancellous bone.

Classical XLHR is caused by loss-of-function mutations in *PHEX*, a 22 exon gene that encodes a 749-amino-acid integral membrane protein with very long extracellular (702 amino acids), transmembrane (27 amino acids), and short intracellular (20 amino acids) domains that structurally resembles several neutral endopeptidases (e.g., endothelin-converting enzyme-1, Kell antigen). The extracellular domain has 10 conserved cysteine residues and a pentapeptide motif (His-Glu-Phe-Thr-His) characteristic of zinc metallopeptidases that may either convert propeptides to active forms or degrade and inactivate their substrates. *PHEX* is expressed on the surface of osteoblasts and osteocytes as well as by teeth, muscle, lung, liver, testis, and ovary; *PHEX* transcription by osteoblasts is down-regulated by calcitriol.[241,244] In most patients with XLHR, inactivating mutations of *PHEX* have been found primarily in the extracellular domain and include frameshift deletions (16%), duplications, insertions (8%), deletional-insertional, splice site (15%), nonsense (27%), and missense (34%) mutations, many in exons 15 and 17; a mutation has also been identified in the 5′-untranslated region (A ⇒ G transversion 429 bp upstream of the ATG initiation site) (Figures 18-10A, 10B).[240,245] Because PHEX is a glycosylated protein, failure of glycosylation leads to its sequestration within the endoplasmic reticulum, thus impeding its movement (trafficking) to the cell membrane; other mutations interfere with the catalytic function of the protein or its three-dimensional conformation. Mutations in *PHEX* arise spontaneously in more than 20% of patients with XLHR. There is no correlation between the location or type of mutation in *PHEX* and the clinical manifestations or severity of the disease.[241,245,246]

Fibroblast growth factor (FGF)-23 is a substance synthesized by osteoblasts and osteocytes that inhibits phosphate reabsorption by the renal tubule and when secreted in excess leads to hyperphosphaturia and consequent hypophosphatemia.[247] Serum concentrations of FGF23 are high in patients with XLHR and are inversely correlated with serum phosphate values. FGF23 is synthesized as a 251-amino-acid protein; after removal of the 24-amino-acid signal sequence, mature FGF23 circulates as both 227- and 154-amino-acid glycosylated peptides, the latter isoform lacking the 73-amino-acid carboxyl terminal sequence.[247] Acting through its receptor (FGFR1) and coreceptor (α-klotho), FGF23 inhibits sodium-dependent phosphate uptake by renal proximal tubular cells and depresses 25OHD-1α hydroxylase activity and thus synthesis of calcitriol. These two bioactivities define a "phosphatonin," a family of phosphaturic agents that includes, in addition to FGF23, matrix extracellular phosphoglycoprotein (MEPE) and serum frizzled related protein-4 (sFRP4).[239,248] FGF23 inhibits phosphate reabsorption by down-regulating expression of *SLC34A1* and *SLC34A3*, respectively, encoding type II (a and c) sodium-phosphate cotransporters (NPT2a, NPT2c) in the apical membranes of the proximal renal tubule by facilitating their internalization and removal from the renal tubule brush border and thereby depressing reabsorption of filtered phosphate.[239] FGF23 also down-regulates expression of *CYP27B1* encoding 25-hydroxyvitamin D-1α hydroxylase, thus decreasing the synthesis of calcitriol. FGF23 is expressed and secreted primarily by osteoblasts and osteocytes; FGF23 is coexpressed with PHEX in these cells. Although FGF23 is inactivated by cleavage between amino acids Arg179 and Ser180, it is not a biologic substrate for PHEX.[249] Rather, FGF23 is cleaved by subtilisin-like proprotein and furin-like convertases. Disruption of the regulatory mechanism(s) that result in increased FGF23 synthesis in patients with XLHR is unknown but may involve products of *PHEX*, *DMP1*, and *ENPP1*.[247,250]

Although FGF23 is not a physiologic substrate of PHEX, a phosphorylated peptide derived from another phosphatonin (MEPE) may well be the primary PHEX substrate.[250-253] MEPE, a 525-amino-acid noncollagenous protein secreted by osteoblasts, is found in extracellular bone matrix, teeth, and brain. Because MEPE inhibits renal tubular uptake of phosphate and depresses synthesis of calcitriol, it is a phosphatonin. MEPE is also one of the SIBLING (short integrin-binding ligand-interacting glycoprotein) group of noncollagenous matrix proteins whose members include, in addition to MEPE, osteopontin, bone sialoprotein, dentin matrix protein 1, and dentin sialophosphoprotein 1. MEPE contains an acidic serine aspartate-rich MEPE-associated motif

FIGURE 18-10 ■ Missense (**A**) and frameshift (**B**) mutations in PHEX resulting in X-linked recessive hypophosphatemic rickets. (From PHEXdb, McGill University, Montreal, Quebec, www.phexdb.mcgill.ca/Missense.html and www.phexdb.mcgill.ca/Frameshift.html.)

(ASARM) in its carboxyl terminal region that can be released by cathepsin B; phosphorylated (p)ASARM binds avidly to hydroxyapatite. A noncatalytic property of PHEX is its ability to bind to MEPE, thereby preventing proteolytic degradation of MEPE by cathepsin B and thus preventing the release of ASARM. In the absence of normal PHEX-MEPE binding, ASARM is released from MEPE by cathepsin B, and then its serine residue is phosphorylated. In patients with XLHR, serum ASARM levels are increased. Serine-phosphorylated pASARM coats the surface of hydroxyapatite by interacting with its calcium atoms; it thus impairs further deposition of calcium and phosphate and thereby inhibits mineralization. pASARM is also a substrate for the enzymatic activity of PHEX, which proteolytically cleaves the peptide between serine-glutamate and serine-aspartate residues; by doing so, PHEX destroys pASARM and prevents pASARM-mediated inhibition of bone mineralization. Although nonphosphorylated ASARM also binds (weakly) to hydroxyapatite, inhibits mineralization, and can be enzymatically cleaved by PHEX, the role of nonphosphorylated ASARM in the mineralization process is as yet incompletely understood. Accordingly, in XLHR the primary pathophysiologic abnormalities appear to be the failure of mutated, bioinactivated PHEX (1) to bind to MEPE and thereby to inhibit the cathepsin B–mediated proteolytic cleavage of MEPE and release of ASARM and (2) to destroy enzymatically the pASARM derived from MEPE and thereby permit pASARM to coat hydroxyapatite and inhibit mineralization. In addition to the role of PHEX-pASARM in the pathogenesis of XLHR, the two phosphatonins—FGF23 and MEPE—present in excess exacerbate the mineralization defect by impairing renal tubular reabsorption of phosphate thus increasing renal phosphate excretion and decreasing the supply of phosphate ions necessary for the construction of hydroxyapatite and by decreasing the synthesis of calcitriol, thus depressing the intestinal absorption of calcium. There is a feedback relationship between pASARM and FGF23 as pASARM increases expression of *FGF23* in bone cells.[253] Inasmuch as ASARM motifs are present in all SIBLING proteins, pASARM is also derived from osteopontin, providing another source of a peptide that is able to bind to and inhibit mineralization of hydroxyapatite; osteopontin-derived pASARM is also a PHEX substrate.[250,252] The pathophysiologic roles of osteopontin and its pASARM moiety in XLHR are uncertain at present.

Normally, FGF23 values are highest in young infants and decline during child and adolescence to adult values (approximately 30 pg/mL utilizing an immunometric assay that detects intact FGF23). FGF23 levels increase with phosphate loading and decline in response to phosphate deprivation.[254] Elevated levels of FGF23 are present in patients with many forms of hypophosphatemic rickets including XLHR, autosomal dominant and recessive hypophosphatemic rickets, the disorders of McCune-Albright, osteoglophonic dysplasia, and Jansen-type metaphyseal chondrodysplasia, the linear nevus sebaceous syndrome, and tumor induced rickets/osteomalacia.[255] Serum PTH concentrations are normal in subjects with primary hypophosphatemia due to an abnormality in renal tubular resorption of phosphate—either intrinsic to the renal cell or mediated by a circulating phosphatonin.[240] Secondary hyperparathyroidism as a cause of hypophosphatemia may be suspected by the presence of elevated serum concentrations of PTH (e.g., vitamin D deficiency).

The diagnosis of XLHR is established when the typical family history (if the patient does not carry a de novo mutation), clinical findings (deformities of the lower extremities, flaring of the metaphyses), roentgenographic (rachitic changes) and laboratory data (hypophosphatemia, hyperphosphaturia, inappropriately low serum level of calcitriol, normal serum concentration of PTH, calcium, creatinine, and 25OHD) are present and when other causes of hypophosphatemia and hyperphosphaturia have been excluded (see Tables 18-8, 18-9, 18-10, and 18-11). The diagnosis of XLHR may be further confirmed by identification of the *PHEX* mutation, although no mutation in *PHEX* is detected by current methods in perhaps half of patients with XLHR.[246] Rarely, somatic and germline mosaicism for a mutation in *PHEX* may mimic autosomal dominant transmission of hypophosphatemic rickets.[256] The primary therapeutic agents employed in the treatment of XLHR are calcitriol (25 to 70 ng/kg/day) administered in two daily doses with the larger dose given at night when PTH secretion tends to increase and elemental phosphorus 0.25 to 3 grams daily (beginning at a dose of 30 mg/kg/day and increasing to 70 mg/kg/day administered in four to six divided daily doses to a maximum of 3500 mg/day) depending on age, size, compliance, and response to therapy.[240,241] Table 18-3 lists the preparations of oral phosphate; infants and young children may tolerate a phospha-soda solution more readily than other preparations; when able, most older children prefer a chewable phosphate tablet to the powder form that is dissolved in water or juice. Acidic potassium phosphate products are preferred, as they do not increase intravascular volume and phosphate excretion and do acidify the urine, thereby increasing the solubility of calcium phosphate. Calcitriol (Rocaltrol; Roche Pharmaceuticals) is available as an oral solution at a concentration of 1 μg/mL and as either 0.25- or 0.5-μg capsules. If hypercalcemia or hypercalciuria (urine calcium excretion more than 4 mg/kg/day) occurs during treatment, the dose of calcitriol should be lowered; if that exacerbates the rachitic process, an agent (e.g., amiloride) that increases renal tubular resorption of calcium may be added cautiously to the therapeutic program. Frequent (every 3 months) clinical evaluation and measurement of serum and urine calcium, phosphate, alkaline phosphatase, creatinine levels, and serum intact PTH values are essential to avoid hypercalcemia, hypercalciuria and nephrocalcinosis, and secondary hyperparathyroidism, as high doses of phosphate may lead to counterproductive secondary (and sometimes tertiary) hyperparathyroidism. Two goals of therapy of XLHR are to maintain serum phosphate concentrations determined before a daytime dose of phosphate in the low normal range and alkaline phosphatase values within the high normal range. Renal sonograms prior to treatment and at 12-month intervals during therapy to identify an early

stage of nephrocalcinosis and yearly skeletal radiographs to assess the degree of healing of the rickets are recommended. Complete radiologic healing of XLHR is often difficult to attain. Development of nephrocalcinosis (and compromise of renal function in some patients) is directly related to the amount of phosphate the patient receives; hyperoxaluria has also been implicated in the pathogenesis of nephrocalcinosis. Co-management with an experienced orthopedist is important, as the orthopedist may prescribe braces or, in patients with extreme and progressive deformities, perform corrective surgery. Femoral and tibial hemiepiphysiodeses are surgical procedures for the correction of limb deformities in children with XLHR who are younger than 10 years of age.[257] Osteotomies may be required by older subjects.

The development of drugs that suppress FGF23 secretion or interfere with its function would address one of the fundamental pathogenic mechanisms of XLHR. Calcitonin decreases serum FGF23 concentrations in patients with XLHR.[258] In one study, after a single injection of 200 IU of salmon calcitonin to seven patients with XLHR, serum levels of FGF23 declined 23% in 4 hours and remained 12% below baseline values 16 hours after calcitonin administration. Serum levels of phosphate and calcitriol increased after calcitonin administration, whereas urinary phosphate excretion was not altered.[258] Whether calcitonin will prove to be an agent that can improve treatment of patients with XLHR remains to be explored. Very short-term administration of the calcimimetic cinacalcet to children with XLHR led to a suppression of phosphate-induced secretion of PTH, suggesting that this drug might be useful for preventing the secondary hyperparathyroidism that often develops when XLHR patients are treated with phosphate and calcitriol, but further data on the efficacy and safety of this agent in children with XLHR are required.

Although the birth length of children with XLHR is normal, growth rate is slow during the first several years of life, leading to progressive shortening of height. Many children with XLHR are significantly short by 5 years of age, although some patients (particularly girls) with minimal involvement may grow normally. Treatment of the older child with XLHR with calcitriol and phosphate may improve growth rate, in part due to correction of the deformities of the lower extremities. During puberty, gain in height is normal in boys (+28.2 cm) and girls (+24.2 cm) with XLHR; thus, the compromised adult stature in XLHR is related to impaired early childhood and preadolescent growth. In a series of 19 closely monitored children with XLHR, initiation of treatment with calcitriol and phosphate at a mean chronologic age of 4.2 months (range 7 weeks to 6 months, N = 8) resulted in greater adult stature (−0.2 versus −1.2 SDS) than when treatment began at a mean age of 2.1 years (range 1.3 to 8 years, N = 11) with no difference in complication rate (secondary hyperparathyroidism, nephrocalcinosis, craniosynostosis) between the two groups.[259] The enhanced growth response to early treatment was likely related to the normal length and mild skeletal and biochemical signs of rickets in early infancy and the prevention of more clinically significant bone disease as the child aged. Despite close adherence to treatment, many children with XLHR remain stunted in height due primarily to short lower limbs and retain mild to moderate radiographic signs of rickets and mildly elevated serum alkaline phosphatase activities, although the extent of lower limb deformities is partially ameliorated by good compliance.[260] Human growth hormone increases glomerular filtration rate, renal tubular resorption and serum concentrations of phosphate, and the rate of accrual of bone mineral; it accelerates height velocity and the rate of increase in limb length of children with XLHR and may modestly increase adult stature in some but not very many subjects.[261-263]

Many untreated adults with XLHR are hypophosphatemic; serum alkaline phosphatase activity is increased and osteomalacia is present on bone biopsy; nevertheless, these patients are often clinically asymptomatic except for frequent dental abscesses, degenerative hip disease due to deformities of the lower limbs, and hearing impairment.[240] Occasionally, a female with XLHR may be clinically well despite isolated hypophosphatemia. Roentgenographic manifestations of XLHR in adults include thickening of the spinous processes and fusion of the vertebrae and stenosis of the spinal canal. BMD determined by single and dual photon absorptiometry tends to be normal in adults with XLHR (despite the histomorphologic abnormalities), suggesting that most of these subjects are not at increased risk for osteoporotic fractures. However, in approximately 25% of adults with XLHR there is clinical evidence of osteomalacia such as progressive lower limb deformities, bone pain, fractures, and pseudofractures. Treatment of selected adult XLHR patients with calcitriol and phosphate may be beneficial.[241]

Inactivating mutations in *CLCN5* encoding a voltage-gated proximal renal tubular chloride channel lead to X-linked recessive hypophosphatemic rickets with hypercalciuria, nephrocalcinosis, and renal failure (XLRH, MIM 300554) as well as X-linked nephrocalcinosis, nephrolithiasis, and renal failure (MIM 310468), and Dent disease (aminoaciduria, proteinuria, glycosuria, hypercalciuria, nephrocalcinosis, nephrolithiasis; MIM 300009).[264] Mutations in different domains of this 12 exon, 746-amino-acid transmembrane chloride channel result in varying clinical and biochemical manifestations; the Ser244Leu mutation in *CLCN5* has been associated with X-linked recessive hypophosphatemic rickets.

Autosomal dominant hypophosphatemic rickets (ADHR, MIM 193100) is a partial phenocopy of XLHR with hyperphosphaturia and inappropriately normal or low serum levels of calcitriol that is due to mutations (Arg176Gln, Arg179Trp) in *FGF23* that render the product less susceptible to cleavage between amino acid residues 179 and 180 by subtilisin-like proteases and thus extend the biologic life and effects of this peptide.[239,242,255] ADHR may be incompletely penetrant, variable in age of onset (childhood to adult), and rarely self-limiting. The clinical, biochemical, and radiographic findings in ADHR are similar to those of XLHR except that ADHR subjects manifest muscle weakness as a consequence of hypophosphatemia. ADHR may be identified by its pattern of transmission and detection of a mutation in *FGF23*. Treatment involves administration of calcitriol and

phosphate with close serial monitoring both for safety and because hyperphosphaturia may occasionally resolve spontaneously.

Hypophosphatemic rickets with hyperparathyroidism (MIM 612089) is a disorder characterized by the onset of hypophosphatemia and diffuse parathyroid hyperplasia in infancy.[265] Pathogenetically, it is considered to be the result of excessive production of α-klotho, the coreceptor with FGFR1(IIIc) for FGF23 that converts FGFR1(IIIc) into the specific FGF23 receptor that transduces the FGF23 intracellular signaling pathway and its bioactivity. α-Klotho excess appears to enhance the production and bioactivity of FGF23 resulting in hyperphosphaturia and hypophosphatemia and also to mediate parathyroid gland hyperplasia leading to excessive synthesis of PTH.[247] In one patient with this disorder, excessive production of α-klotho was attributed to a spontaneously occurring balanced translocation between the long arms of chromosomes 9 and 13 [−t(9;13)(q21.13;q13.1)] (near the site of *KL*) possibly involving a promoter region that permitted excessive expression of *KL* and synthesis of α-klotho.[265]

Autosomal dominant hypophosphatemia with urolithiasis type 1 (MIM 612286) is due to *monoallelic* inactivating mutations in *SLC34A1* encoding the sodium-phosphate cotransporter NPT2a (also designated NaPi-IIa). Haploinsufficiency of NPT2a in the brush border membrane of proximal renal tubular cells leads to diminished phosphate reabsorption, hyperphosphaturia, hypophosphatemia, increased synthesis of calcitriol with augmented absorption of intestinal calcium, hypercalciuria, formation of renal calculi, and osteopenia. Autosomal recessive Fanconi syndrome with hypophosphatemic rickets (MIM 613388) (also designated Fanconi renotubular syndrome 2) is due to *biallelic* inactivating mutations in *SLC34A1* encoding the sodium-phosphate cotransporter NPT2a.[266,267]

Autosomal dominant hypophosphatemia with urolithiasis type 2 (MIM 612287) is attributable to heterozygous loss-of-function mutations in *SLC9A3R1* encoding the sodium hydrogen exchanger regulatory factor 1 (NHERF1).[242,268,269] NHERF1 is an adaptor protein; one of its several functions is to anchor the sodium-phosphate cotransporter NPT2a to the brush border of the renal proximal tubule; another is to modulate PTH1R signaling in response to PTH. Loss of NHERF1 function results in decreased expression of NPT2a at the apex of proximal renal tubular cells and thus in diminished renal tubular reabsorption of filtered phosphate, hyperphosphaturia, and hypophosphatemia. Hypophosphatemia leads to increased renal tubular synthesis of calcitriol and intestinal absorption of calcium resulting in mild hypercalcemia, hypercalciuria, and nephrolithiasis.[270] Patients with mutations in *SCL9A3R1* are also osteopenic. In these subjects, serum levels of PTH and FGF23 are normal.[268]

Hereditary hypophosphatemic rickets with hypercalciuria (MIM 241530) is due to biallelic inactivating mutations in *SLC34A3* encoding the sodium-phosphate cotransporter NPT2c.[266] This 599-amino-acid protein with eight transmembrane domains is located in the brush border of juxtamedullary proximal renal tubular cells. Loss of activity of NPT2c leads to hyperphosphaturia, hypophosphatemia, increased synthesis of calcitriol with augmented absorption of intestinal calcium, hypercalciuria, the formation of renal calculi, and rickets. Inasmuch as the regulation of calcitriol synthesis is normal in these subjects, its production is substantially elevated in response to hypophosphatemia; thus, intestinal absorption of calcium and its urinary excretion are increased. Heterozygotic carriers of inactivating mutations in *SLC34A3* also have moderately increased serum concentrations of calcitriol, hyperphosphaturia, and hypercalciuria but do not have identified metabolic bone disease. Loss-of-function missense and nonsense mutations have been found throughout the coding region of *SLC34A3* as well as deletions in introns 9 and 10. This disorder may be treated with phosphate salts in conjunction with hydration and avoidance of a high-sodium diet; supplemental vitamin D is not needed and may even be detrimental.

Excessive production of FGF23 with hypophosphatemic rickets and inappropriately low calcitriol values has also been documented in patients with autosomal recessive hypophosphatemic rickets (discussed later), the McCune-Albright syndrome of fibrous dysplasia (MIM 1740800) due to a gain-of-function mutations in *GNAS*; the linear nevus sebaceous syndrome (MIM 163200) related to postzygotic somatic gain-of-function mutations in *HRAS* or *KRAS*; osteoglophonic dysplasia (MIM 166250; craniosynostosis, rhizomelic shortening of the limbs, noncalcifying bone lesions) associated with activating mutations in *FGFR1*, opsismodysplasia (MIM 258480), a spondylo(epi)metaphyseal dysplasia with delayed ossification, micromelia, platyspondyly, vertebral hypoplasia) attributed to biallelic inactivating mutations in *INPPL1* encoding an inositol-1,4,5-trisphosphatase that hydrolyzes inositol-1,4,5-trisphosphate to inositol-4,5-bisphosphate, an important transducer of intracellular signaling; Jansen type metaphyseal chrondrodysplasia (MIM 156400) due to constitutively activating mutations in *PTH1R*.[248,255,271-273] In most of these disorders, there is excessive skeletal production of FGF23 of unknown pathogenesis, although it has been suggested that in situations in which the rate of bone remodeling is high, the production of FGF23 is also increased.[247] Tumor-induced osteomalacia/rickets is an acquired disorder due to excessive synthesis of one of several phosphatonins by a tumor of mesodermal origin. The majority of such tumors have secreted FGF23, but these neoplasms have also synthesized produced frizzled related protein-4, matrix extracellular phosphoglycoprotein, and FGF7 all of which increase urinary phosphate excretion and suppress renal synthesis of calcitriol, albeit perhaps not to the same extent as FGF23.[248,274] The identification of an FGF23 secreting tumor is dependent on the sensitivity of the FGF23 assay employed.[275] Although unusual in children, tumor-induced osteomalacia/rickets has been described in this age group. For example, an 11-year-old girl had significant bone pain and functional limitation associated with biopsy-proven hypophosphatemic osteomalacia/rickets and markedly elevated serum levels of FGF23.[276] Following removal of a benign fibro-osseous tumor from a small exostosis on a distal ulnar metaphysis, serum FGF23 concentrations normalized within 7 hours

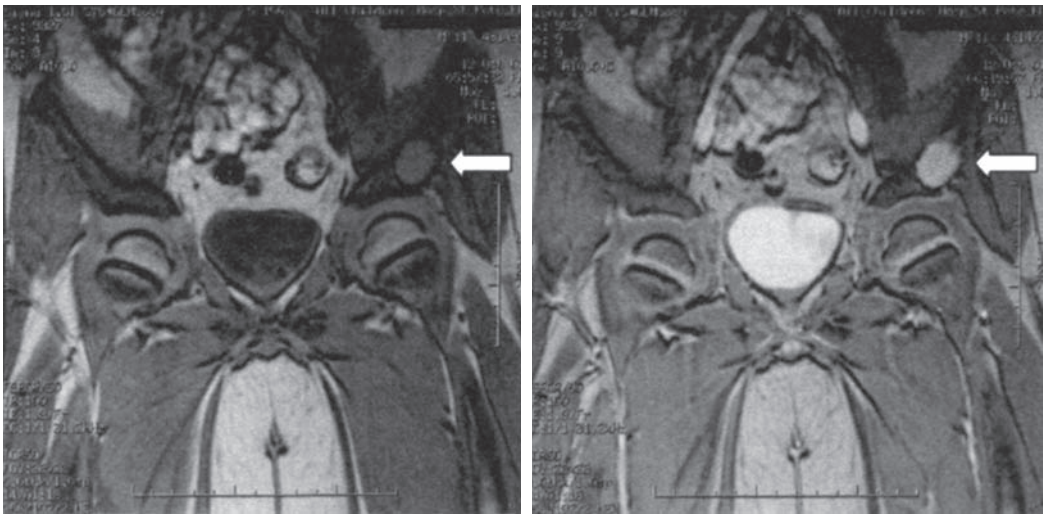

FIGURE 18-11 ■ Demonstration by gradient recall echo magnetic resonance imaging of a FGF23 producing hemangiopericytoma in the left iliac wing of an 11-year-old boy with tumor-induced rickets. (From Shulman, D. I., Hahn, G., Benator, R., et al. (2004). Tumor-induced rickets: usefulness of MR gradient echo recall imaging for tumor localization. *J Pediatr, 144*, 381–385.)

postoperatively and phosphate levels were normal 2 weeks later. Clinical symptoms abated and radiographic and histomorphometric abnormalities resolved within 1 year after surgery. In an 11-year-old boy with severe bone pain, weakness progressing to confinement to a wheelchair, hyperphosphaturia and hypophosphatemia, elevated levels of FGF23 (1874 RU/mL) declined to normal values (43 RU/mL) within 48 hours after removal of a FGF23-containing hemangiopericytoma from his left iliac wing.[277] This lesion had not been identified by routine roentgenograms, computed tomographic or magnetic resonance imaging, or technetium bone scan; the tumor was demonstrated only by gradient recall echo magnetic resonance imaging (Figure 18-11). Within 2 weeks after surgery the lad was walking without assistance, and several weeks thereafter he resumed normal activity.

Mutations in two genes result in autosomal recessive hypophosphatemic rickets (ARHR) that is clinically, biochemically, pathogenetically, and histomorphometrically similar to XLHR and ADHR but distinguished by its mode of transmission and development of osteosclerosis at the base of the skull and in calvarial bones. ARHR type 1 (ARHR1, MIM 241520) is due to biallelic loss-of-function mutations in the gene encoding dentin matrix acidic phosphoprotein 1 (*DMP1*).[255,278,279] DMP1 is a noncollagenous, serine-rich, bone matrix calcium-binding protein that is a secreted small integrin-binding ligand, N-linked glycoprotein (SIBLING) expressed by osteocytes; DMP1 is important for bone mineralization and may also play a role in the regulation of FGF23 synthesis.[250] ARHR type 2 (ARHR2, MIM 613312) is due to biallelic loss-of-function mutations in the gene encoding ectonucleotide pyrophosphatase/phosphodiesterase (*ENPP1*), a pyrophosphohydrolase expressed by chondrocytes and bone and plasma cells that hydrolyzes ATP to pyrophosphate, an inhibitor of bone mineralization.[242,255] The pathophysiology of bone disease due to ENPP1 deficiency resembles that of hypophosphatasia due to a deficiency of alkaline phosphatase (discussed later). Mutations in ENPP1 have also been associated with generalized arterial calcification of infancy; indeed, the same genetic mutation in *ENPP1* may be clinically expressed as either disease in the same family.[280,281,282] Serum concentrations of FGF23 are elevated in these subjects, and calcitriol values are inappropriately normal; urinary calcium excretion is normal. The mechanism or mechanisms by which loss of ENPP1 activity increases FGF23 synthesis are unclear.

Increased urinary phosphate excretion due to acquired and heritable disorders of the proximal renal tubule is characteristic of the metabolic bone disease that accompanies various forms of the Fanconi syndrome of renal tubular acidosis, glucosuria, and amino aciduria (heritable: cystinosis, tyrosinemia, galactosemia, oculo-cerebral-renal syndrome, fructose intolerance, Wilson disease; acquired: renal transplantation, nephrotic syndrome, renal vein thrombosis, mercury, lead and copper poisoning, outdated tetracycline).[283] In addition to hypophosphatemia, acidosis contributes to the pathogenesis of bone disease in Fanconi syndrome by increasing the solubility of the mineral phase of bone and increasing urinary loss of calcium and by impairing conversion of calcidiol to calcitriol.

Hyperphosphatemia may be due to intrinsic gene variants or to exogenous causes such as excessive parenteral administration of phosphate or to the administration of phosphate containing enemas, an acutely increased rate of cellular destruction (crush injuries, rhabdomyolysis, during chemotherapy for malignancy), a decreased rate of renal phosphate excretion (renal failure), impaired secretion or action of PTH, and during administration of some bisphosphonates (see Tables 18-11A and B).[239] Hyperphosphatemic familial tumoral calcinosis (MIM 211900) is an autosomal recessive disorder characterized by progressive deposition of calcium phosphate in soft

tissues and in periarticular regions of the long bones, manifested clinically by periarticular masses of ectopically deposited calcium and at times by complaints of bone pain.[284] Cortical bone hyperostosis and periosteal elevation are common radiologic findings. The disorder is due to the decreased availability of biofunctional FGF23 due to loss-of-function mutations in *FGF23* itself, the rapid degradation of FGF23 because it has not been glycosylated due to an inactivating mutation in *GALNT3* encoding UDP-N-acetyl-alpha-D-galactosamine: polypeptide N-acetylglactosaminyl transferase 3, or tissue nonresponsiveness to FGF23 because of an inactivating mutation in KL, encoding its coreceptor α-klotho. Surgical excision of tumoral masses that impair function, administration of intestinal phosphate binders, agents that increase renal phosphate excretion (acetazolamide), and diets low in calcium and phosphate have been the major therapeutic strategies employed in the treatment of these patients.[239]

Disorders of Alkaline Phosphatase Activity. In its most severe forms, hypophosphatasia (MIM 241500) is an autosomal recessive disorder due to loss-of-function mutations in *ALPL*, the gene encoding tissue nonspecific (bone/liver/kidney) alkaline phosphatase (TNSALP); less damaging forms of this disease are transmitted as autosomal dominant traits (MIM 241510, 146300).[108-110] Alkaline phosphatases are zinc and magnesium-dependent alkaline optimum orthophosphoric monoester phosphohydrolases. Bone, liver, and kidney alkaline phosphatase isoforms differ not by their amino acid structure but by their patterns of posttranslational glycosylation.[109] Homotetrameric bone TNSALP is anchored through its carboxyl terminal to the exterior cell membrane of hypertrophic chondrocytes and osteoblasts (i.e., it is an ectophosphatase) by a phosphatidylinositol-glycan moiety. Pathophysiologically, decreased TNSALP activity leads to accumulation of its endogenous substrates: inorganic pyrophosphate, pyridoxal 5′-phosphate, and phosphoethanolamine. Pyrophosphate is an inhibitor of osteoid mineralization and when present in excess leads to the inadequate formation of hydroxyapatite resulting in rickets or osteomalacia. Calcification of bone matrix is impaired by pyrophosphate coating of the surface of hydroxyapatite crystals and restricting their growth; in addition, the inability to raise bone matrix inorganic phosphate levels to values sufficient to permit the deposition of hydroxyapatite may contribute to decreased bone mineralization in this disorder. Thus, the pathophysiology of bone disease due to TNSALP deficiency resembles that due to the deficiency of ENPP1 in which disorder pyrophosphate also accumulates but by a distinctively different mechanism (as discussed previously). Decreased pyridoxal 5′-phosphate, the major circulating form of vitamin B_6, leads to pyridoxine-responsive seizures.

The incidence of severe hypophosphatasia ranges from 1/2500 newborns in Canadian Mennonite families to 1/300,000 in European populations.[109] Clinical manifestations of inactivating mutations of *ALPL* reflect primarily the extent of loss-of-function of mutant *ALPL*; the younger the age of onset, the more severe is the disease likely to be. Currently, there are seven recognized forms or types of hypophosphatasia: six classical forms (numbers 1 to 6) and one transitional type (here designated type 2A):

1. The *perinatal* form is evident in utero and is most often lethal (at times even before birth) due to marked osteopenia leading to malformation of the skull, intracranial hemorrhage, pyridoxine-dependent seizures, fractures of the ribs, and deformities of the chest wall resulting in postnatal respiratory insufficiency and apnea; the extremities are short, bowed, and fractured; radiologic findings include absent or extremely poor bone mineralization with rachitic deformities, irregular radiolucent extensions into metaphyses, apparently "missing" vertebrae, and protruding midshaft fibular and ulnar bone spurs.
2. The *infantile* form (MIM 241500) becomes clinically apparent in the first 6 months of life and is characterized by anorexia, impaired linear growth and weight gain, deformities of the long bones and rib cage, and widely "open" fontanelles and sutures (calvarial hypomineralization) with functional craniosynostosis with increased intracranial pressure manifested by prominence of the anterior fontanelle, proptosis, and papilledema, weakness, developmental delay, pyridoxine-dependent seizures, hypotonia, constipation, hypercalcemia, hypercalciuria, nephrocalcinosis, early shedding of deciduous teeth, and radiographic evidence of rickets with marked skeletal hypomineralization; the neonatal and infantile forms of hypophosphatasia are transmitted as autosomal recessive disorders; until recently, the majority of patients with perinatal hypophosphatasia and 50% of those with infantile hypophosphatasia died of respiratory failure before their first birthday (discussed later).

2A. In the *benign prenatal* or *transitional* form of hypophosphatasia, the fetus and neonate manifest skeletal deformities but not radiographic signs of rickets; shortly after birth there is spontaneous and substantial improvement; findings that distinguish this less severe type of hypophosphatasia are fetal crowding, normal fetal bone mineralization, and appropriate chest volume; this form of hypophosphatasia may be associated with either monoallelic or biallelic mutations in *TNSALP*.[285,286]

3. In the *childhood* form of hypophosphatasia (MIM 241510), clinical findings of hypophosphatasia develop after 6 months of age and range from isolated premature shedding of deciduous teeth to physical and radiographic evidence of low bone mass and rickets and musculoskeletal and joint pain; radiography may demonstrate radiolucent projections from the growth plate into metaphyses; spontaneous clinical improvement may occur during puberty and this form may evolve into type 4.
4. The *adult* form (MIM 146300) may be subclinical and identified only during study of a family with an offspring with a more significant form of hypophosphatasia; the parent may have a history of premature loss of teeth, increased susceptibility to recurrent fractures predominantly of the metatarsal bones, pseudofractures of the proximal femur,

chondrocalcinosis, or pseudogout due to articular deposition of calcium pyrophosphate dihydrate crystals; subtrochanteric femoral pseudofractures may be demonstrated radiographically.

5. *Odontohypophosphatasia* (MIM 146300) is manifested only by premature shedding of primary teeth without radiologic abnormalities; periodontitis may also develop; the childhood and adult forms of hypophosphatasia and odontohypophosphatasia are usually (but not invariably) transmitted as monoallelic, autosomal dominant disorders.
6. *Pseudohypophosphatasia* is phenotypically and biochemically similar to classic infantile hypophosphatasia, but serum alkaline phosphatase activity in vitro is normal, indicating that in this disorder enzyme activity toward artificial substrates in high pH solutions is preserved but alkaline phosphatase activity toward endogenous substrates at pH 7.4 is abnormal.[109]

In addition to the site(s) of mutation of *ALPL*, the clinical severity of hypophosphatasia is related inversely to the age at which skeletal disease is evident and to individual biologic (possibly epigenetic) factors that affect the expression of the disease with wide individual variability even in family members with the identical *ALPL* mutation(s). In the lethal perinatal form of hypophosphatasia, missense, nonsense, and donor splice site mutations and frameshift deletions in *TNSALP* cluster in crucial segments of the protein within (Ala94Thr, Arg167Trp) or near (Gly103Arg, Gly317Asp) its catalytically active enzymatically functional site or at the dimeric interface (Ala23Val, Arg374Cys) or they may impair movement of TNSALP to its active transmembrane site.[109] Mutations may interrupt binding of TNSALP to the phosphorylated ligand or destabilize attachment of necessary cofactors such as zinc or magnesium. *ALPL* mutations associated with the childhood form of hypophosphatasia (Arg119His, Asp361Val) tend to cluster on the three-dimensional surface of the enzyme molecule at sites that relate to its tethering to the cell surface or its formation of tetramers; such variants may retain substantial residual bioactivity. In some patients with moderately severe hypophosphatasia, heterozygotic mutations in *ALPL* (Gly46Val, Arg167Trp, Asn461Ile) exert a dominant-negative effect on the intact TNSALP dimer; these mutations have been clustered at the enzyme active site or at the domain(s) involved with dimerization, tetramerization, or membrane anchoring.[287] Odontohypophosphatasia has been associated with heterozygotic mutations in *ALPL* (Pro91Leu, Ala99Thr).

Diagnostically, in addition to the clinical findings and radiographic features of rickets, patients with hypophosphatasia have low serum levels of total and bone-specific alkaline phosphatase activity in contrast to other forms of rickets in which alkaline phosphatase values are increased (see Table 18-10). Additionally, there are increased serum concentrations of pyrophosphate (controls < 200 μmol/g of creatinine) and pyridoxal-5′-phosphate (~5000 nM) and elevated urinary excretion of phosphoethanolamine (controls < 15 years of age 83 to 222 μmol/g of creatinine). Serum concentrations of calcium and phosphate are often elevated in patients with the perinatal and infantile forms of the disease, because intestinal absorption of calcium and renal tubular reabsorption of phosphate are at least normal, whereas the bone formation rate is depressed; calcium values are usually normal in the childhood form of hypophosphatasia.[108,109] Serum levels of PTH are normal or low; there is no evidence of secondary hyperparathyroidism. Although serum alkaline phosphatase activity in vitro is normal in patients with pseudohypophosphatasia, it is functionally inadequate in vivo—perhaps because the TNSALP protein is sequestered within the cell due to a defect in its transport to the cell surface or because the protein is active with artificial substrate but not with natural substrates at physiologic pH. The prenatal diagnosis of hypophosphatasia may be considered in a fetus in whom ultrasonography has demonstrated short ribs and long bones, cupping of the metaphyses, osseous spurs, patchy ossification, and demineralization of the skull and thoracic spine.[288] To be included in the differential diagnosis of a fetal sonogram with these findings are achondrogenesis and osteogenesis imperfecta type II. Other causes of hypophosphatasemia include hypothyroidism; vitamin C deficiency; starvation; magnesium, zinc, or copper deficiency; celiac disease; profound anemia; and massive transfusion.[109]

Until recently, treatment of the perinatal and infantile forms of hypophosphatasia has been unsatisfactory. Attempts to administer alkaline phosphatase by infusion of serum from patients with Paget disease and high alkaline phosphatase activity have been of only occasional and limited benefit. Bone marrow transplantation has been beneficial in some subjects, whereas transplantation of bone fragments and osteoblasts has effectively restored alkaline phosphatase activity in a few patients with infantile hypophosphatasia.[108,289] A biosynthetic human recombinant ectodomain of tissue nonspecific alkaline phosphatase fused to the human IgG1 Fc domain and a terminal deca-aspartate motif targeting bone (asfotase alfa; Enobia Pharma) has been developed that has proven extraordinarily effective in the treatment of patients with the perinatal and infantile forms of hypophosphatasia.[111] Administration of this compound to nine such patients was followed by radiographic healing of rickets after 24 weeks of treatment; in addition motor development and pulmonary function improved. No serious adverse effects were recorded in this study. A clinical trial (NCT00739505) of the efficacy and safety of biosynthetic human recombinant tissue nonspecific alkaline phosphatase fusion protein in patients with the adult form of hypophosphatasia has been completed as well; data analysis of this cohort is anticipated.[290] Administration of even small doses of vitamin D or its metabolites should be avoided, as these patients easily develop hypercalcemia. Hypercalcemia in infants with hypophosphatasia responds to bisphosphonates and transiently to calcitonin. Seizures may be responsive to pyridoxine administration. Milder adult forms of hypophosphatasia may be responsive to teriparatide (rhPTH$^{1\text{-}34}$).[291]

Serum bone-specific alkaline phosphatase activity is normally increased during puberty and in response to skeletal injuries and reflects increased osteoblastic activity. Transient increase in serum alkaline phosphatase activity may also be observed in children with viral infections (including human immunodeficiency virus), after liver or kidney transplantation, or during treatment of

leukemia/lymphoma.[292] Transient hyperphosphatasemia of infancy and early childhood is encountered in clinically well infants and children younger than 5 years of age (median age: 16 months); serum activities of both bone and liver alkaline phosphatase isoforms are increased (despite absence of liver or bone disease); it is a self-limited process with alkaline phosphatase values returning to normal within several months.[292] Transient hyperphosphatasemia (alkaline phosphatase values > 1000 U/L) has been reported to occur in approximately 2% to 3% of children younger than 2 years of age.[293] It has been suggested that benign and transient hyperphosphatasemia are the consequence of excessive sialylation of alkaline phosphatase that delays its degradation and extends its half-life, but the reason for the excessive sialic acid content of the molecule is uncertain.[292] Rarely, hyperphosphatasemia may be familial and transmitted as a benign autosomal dominant trait or associated with mental retardation (MIM 239300). Occasionally, an adolescent with persistent, nonfamilial, benign hyperphosphatasemia may be encountered. Hyperphosphatasemia is also present in patients with juvenile Paget disease/hyperostosis corticalis deformans juvenilis (MIM 239000), familial expansile osteolysis (MIM 174810), and osteosclerotic hyperostosis corticalis generalisata/van Buchem disease (MIM 239100) (discussed later).

Chronic Kidney Disease-Mineral and Bone Disorder

Chronic kidney disease-mineral and bone disorder (CKD-MBD) is the term presently employed to characterize the aberrations in calcium and phosphate metabolism, PTH and vitamin D synthesis and secretion, skeletal homeostasis, and ectopic vascular, extravascular, and cardiac calcifications that are encountered in patients with impaired renal function.[293a,294] CKD-MBD replaces the designation of renal osteodystrophy that pertains solely to the pathologic changes present in the bones of patients with chronic renal failure. Renal osteodystrophy is most commonly associated with rapid bone remodeling and increased rates of both bone resorption and formation that are due to secondary hyperparathyroidism ("high-turnover" lesions of osteitis fibrosa). Adynamic ("low-turnover") bone disease with relatively low PTH secretion and osteomalacia due to accumulation of aluminum may also occur. Generally, areas of both low and high bone turnover, termed *mixed renal osteodystrophy*, are detected by histomorphometry.[157,295]

As renal function declines, the secretion of both FGF23 and PTH increases. It is likely that FGF23 secretion increases relatively early in patients with CKD when phosphate retention first occurs and even when the glomerular filtration rate exceeds 80 mL/min/1.73 m^2.[296] The secretion of PTH increases when the glomerular filtration rate declines to values less than 70 mL/min/1.73 m^2.[294] Inasmuch as serum concentrations of FGF23 rise before renal function declines in patients with CKD-MBD, urinary phosphate excretion increases—initially maintaining normal serum phosphate values; thus, FGF23 levels increase before serum levels of phosphate rise.[296] Furthermore, increasing production of FGF23 as renal failure progresses contributes to declining renal tubular synthesis of calcitriol and lower intestinal calcium absorption. As the glomerular filtration rate progressively declines, urinary phosphate excretion is impaired, leading to its intracellular and extracellular accumulation, hyperphosphatemia (when the glomerular filtration rate falls below 20 mL/min/1.73 m^2), and modest hypocalcemia.[294] Increasing serum concentrations of phosphate, falling levels of calcium (due both to decreased intestinal absorption of this cation attributable to calcitriol deficiency and the need to maintain a constant calcium x phosphate product), and rising levels of FGF23 that exert a direct stimulatory effect on *PTH* expression lead to a secondary increase in PTH generation and when uncontrolled to tertiary hyperparathyroidism. Other factors that contribute to the development of parathyroid chief cell hyperplasia and secondary hyperparathyroidism in CKD-MBD include down-regulation of the expression of *CASR* in uremic parathyroid glands (raising of the set point concentration at which calcium depresses *PTH* expression) and skeletal insensitivity to PTH. Phosphate may also slow the rate of degradation of PTH mRNA within the parathyroid gland and exert a direct enhancing effect on the growth of parathyroid glands as well. Because calcitriol inhibits parathyroid gland growth and function, a decrease in its synthesis also results in increased proliferation of parathyroid chief cells and synthesis of PTH. In the presence of elevated PTH secretion and various cytokines (IL-1, -6, -11, TNF, macrophage-colony stimulating factor [M-CSF]), osteoclastogenesis, and the rates of bone resorption and formation are increased. Acidosis contributes to the dissolution of the mineral phase of bone directly and by impairing osteoprotegerin-mediated inhibition of osteoclast generation.

Chronic renal disease and osteodystrophy in children may be clinically silent except for the failure of linear growth; as the disease progresses deformities of the extremities, slipped epiphyses, fractures, bone and joint pain, muscular weakness, and lassitude develop. In patients in whom the rate of bone formation is diminished and the volume of unmineralized bone (i.e., osteomalacia) increased, the process has been due to an accumulation of aluminum at the mineralization front, but with discontinuation of aluminum-containing phosphate binders osteomalacia in renal failure is now unusual.[157] In the absence of osteomalacia, adynamic bone disease in chronic renal failure is the result of decreased PTH generation due to improved control of serum phosphate levels, increased calcium stores, higher levels of PTH$^{7\text{-}84}$ and other carboxyl terminal fragments of PTH that inhibit bone resorption, and other factors that affect tissue response to PTH. The cardiovascular complications (hypertension, ectopic vascular calcifications, uremic vasculopathy, cardiomyopathy) that develop in children with CKD-MBD begin prior to the need for and progress during dialysis and are the primary cause of death in children and adolescents with CKD.[293a] Hyperphosphatemia, secondary hyperparathyroidism, and elevated levels of FGF23 adversely affect the cardiovascular system.

Biochemically, CKD-MBD is marked primarily by hyperphosphatemia, low-normal serum calcium levels, and increased serum PTH and FGF23 concentrations and alkaline phosphatase activity. Radiographic signs of rickets, low bone mass, and pseudofractures are often

present in children with renal osteodystrophy. Therapeutically, the goals in treating a child with chronic renal failure in an effort to minimize the adverse systemic effects of CKD-MBD are to maintain (near) normal serum calcium, phosphate, and alkaline phosphatase values and to prevent the development or progression of secondary hyperparathyroidism. To do so, minimal amounts of supplemental vitamin D and calcium may be needed and dietary phosphate restriction imposed. Calcitriol is able to decrease the rate of bone formation in patients with chronic renal insufficiency by inhibiting osteoblast differentiation or function, decreasing PTH synthesis, altering degradation of PTH within the parathyroid glands, and decreasing expression of *PTH1R*. Calcium-containing oral phosphate binders may also be useful. Dialysis fluids must be prepared with aluminum-free water. When indicated, suppression of PTH secretion may be further achieved with the use of calcitriol analogs such as paricalcitol or of a synthetic ligand of the CaSR—cinacalcet hydrochloride (with caveats previously mentioned).[157,294] Experimentally, although immunoneutralization of FGF23 in a rat model of CKD-MBD led to a decrease in PTH secretion, increased calcitriol and calcium concentrations, and improved bone formation, there was an increase in aortic calcification and mortality rate in the anti-FGF23 treated animals.[297] Thus, "control" of FGF23 activity may have paradoxically unwanted consequences. Even after successful renal transplantation, secondary hyperparathyroidism may persist for months or years—its extent and intensity reflecting the severity and duration of chronic renal failure before renal transplantation, development of nodular or monoclonal hyperplasia of the parathyroid glands, and the 20-year life span of the parathyroid chief cell.[298] Five years after renal transplantation during childhood, serum concentrations of PICP, osteocalcin, and ICTP remain significantly increased, indicating an accelerated bone turnover rate, whereas areal and volumetric bone mineral densities at the distal third of the nondominant radius are normal for height but subnormal for age.[299] Hypercalcemia and persistent secondary or tertiary hyperparathyroidism requiring parathyroidectomy may become apparent in children after renal transplantation. The osteopenic effects of glucocorticoids and immune suppressive agents such as cyclosporin are observed in postrenal transplantation patients as well.

Disorders of Bone Mineralization

Bone mineralization may be depressed or exaggerated by dysfunction of either osteoblasts or osteoclasts. Abnormalities of osteoblast function result in either impaired (e.g., osteogenesis imperfecta) or exaggerated bone mineralization (e.g., osteosclerosis). Thus, in patients with the osteosclerotic disorder hyperostosis corticalis generalisata/van Buchem disease type 1 (MIM 239100), decreased expression of *SOST* encoding sclerostin, an inhibitor of WNT signaling by its interaction with the WNT coreceptors low-density lipoprotein receptor-related proteins (LRP) 5 and 6, is associated with enhanced osteoblast function and increased bone mineralization. Although derived from a common hematopoietic stem cell, there are a number of osteoclast subtypes with unique physiologic profiles that reflect the site at which they act (intramembranous or endochondral bone, cartilage); the remodeling process in which they participate (targeted—to sites of bone replacement, stochastic—hormonally [PTH, calcitonin, calcitriol] mediated for maintenance of eucalcemia); the type of bone (cortical, trabecular) upon which they act; and the time of day (diurnal variation) at which the osteoclast is most active.[300] Decreased osteoclast formation or function results in increased bone mass and various forms of osteopetrosis, whereas augmented osteoclast activity leads to decreased bone mass due to osteolysis. In a number of bone disorders, skeletal areas of both increased and decreased bone mineralization may be present. Juvenile Paget disease/hyperostosis corticalis deformans juvenilis (MIM 239000) is a hyperphosphatasemic disorder that often begins in early childhood and is characterized clinically by expanded and bowed extremities, nontraumatic fractures of the long bones, kyphosis, macrocephaly, and muscular weakness; this disorder may progress to wheelchair dependence.[301] Serum levels of alkaline phosphatase are markedly increased, a coupled response to increased osteoclastic action. Radiographic skeletal abnormalities include cortical thickening, both osteosclerosis and osteopenia, coarse trabeculations, and progressive skeletal deformities. The disorder is due to biallelic loss-of-function mutations of *TNFRSF11B* (MIM 602643) encoding osteoprotegerin, a member of the tumor necrosis factor (TNF) receptor superfamily that functions as a decoy acceptor for and consequently an inhibitor of *R*eceptor *A*ctivator of *N*uclear factor κB-*L*igand (RANKL), the stromal cell-osteoblast derived osteoclastogenic factor. Normally, osteoprotegerin inhibits osteoclastogenesis; hence, inactivating mutations of *TNFRSF11B* are associated with enhanced osteoclastic activity. The severity of juvenile Paget disease depends on the site of mutation in *TNFRSF11B*—those that result in deletion of the entire gene or those in the ligand binding domain that involve loss of cysteine residues result in marked clinical disease.[302] Treatment with recombinant osteoprotegerin has resulted in clinical and radiologic improvement as has the administration of bisphosphonates, but the latter agents are associated with the risk of substantial hypocalcemia.[303,304] Familial expansile osteolysis (MIM 174810), early onset familial Paget disease of bone, and expansile skeletal hyperplasia are autosomal dominant disorders that are pathophysiologically similar to juvenile Paget disease although clinically and etiologically distinct. These three disorders are due to monoallelic gain-of-function mutations of the gene (*TNFRSF11A*, MIM 603499) encoding RANK that result in an increase in NFκB signaling as a consequence of which there is augmented osteoclastogenesis.[305] In adolescents with familial expansile osteolysis, focal areas of increased bone turnover in the appendicular skeleton appear in the second decade of life followed by medullary expansion, pathologic fractures, and skeletal deformities; deafness and premature loss of dentition may occur in these subjects. Patients with either expansile skeletal hyperplasia or early onset Paget disease of bone demonstrate focal areas of osteolytic and hyperostotic bone, premature loss

of teeth, and deafness. Increased activity of mutant RANK is thought due to tandem duplications of 18 or 27 bases in the signal peptide region of exon 1 of *TNFRSF11A*. However, because the mutant forms of RANK are trapped in the endoplasmic reticulum and unable to interact with RANKL directly, the mechanisms through which these heterozygous mutations increase NFκB-mediated osteoclastogenesis are uncertain.[305,306] It has been hypothesized that mutant RANK may be able to interact with residual intact RANK and either slow its rate of degradation or prolong its interaction with RANKL.[305] Conversely, loss-of-function mutations of *TNFRSF11A* are associated with autosomal recessive, osteoclast-poor osteopetrosis type 7, and hypogammaglobulinemia (discussed later).[305,307] Inactivating mutations in *TNFSF11* encoding RANKL are associated with osteoclast-poor osteopetrosis type 2 (discussed later).

Low Bone Mass

Low bone mass is often associated with increased fracture risk, although in some disorders with high bone mass the fracture rate is increased because abnormal bone microarchitecture leads to decreased bone strength (e.g., osteopetrosis, picnodysostosis, discussed later).[308] Fifty percent of boys and 40% of girls will sustain a traumatic fracture during childhood or adolescence (peak incidence between 11 and 12 years in girls and 13 and 14 years in boys), most often at the distal radius because of a transient decline in cortical strength at this site.[308,309] It is important to distinguish a high-impact traumatic fracture from one that is the result of increased bone fragility such as compression vertebral fractures and "spontaneous" femoral fractures due to a primary or secondary disorder of bone mineralization (Table 18-12A and B).

TABLE 18-12A Disorders of Bone Mineralization: Low Bone Mass

I Primary/Genetic

A Osteogenesis Imperfecta (types I - >XIII; see Table 18-12B)
B Osteoporosis-Pseudoglioma Syndrome (LRP5)
C Idiopathic Juvenile Osteoporosis (LRP5)
D Marfan Syndrome (FBN1)
E Ehlers-Danlos Syndrome (COL1A1)
F Homocystinuria (CBS)
G Fibrous Dysplasia (GNAS)
H Glycogen Storage Disease Type I (G6PC)
I Galactosemia (GALT)
J Menkes: Kinky Hair Syndrome (ATP7A)
K Hypophosphatasia (ALPL)
L Rickets (genetic forms; see Tables 18-9 and 18-11)

II Secondary

A Suboptimal Nutrition
1 Socioeconomic
2 Cultural
3 Excessive exercise (athletic amenorrhea)
4 Anorexia nervosa
5 Vitamin D deficiency
6 Malabsorption: cystic fibrosis, celiac disease, biliary atresia, "short gut" syndrome, post gastric bypass surgery
7 Idiopathic hypercalciuria

B Endocrinopathies/Metabolic Diseases
1 Constitutional delay in growth and sexual development
2 Hypogonadism
  a Hypergonadotropic: gonadal dysgenesis (Turner, Klinefelter syndromes), aromatase deficiency, estrogen receptor deficiency
  b Hypogonadotropic: Kallmann syndrome, excessive physical activity, hyperprolactinemia
3 Diabetes mellitus
4 Hyperglucocorticoidism
5 Hyperthyroidism, excessive exogenous thyroxine
6 Hyperparathyroidism
7 Panhypopituitarism
8 Inborn errors of metabolism: homocystinuria, lysinuric protein intolerance, propionic aciduria, methylmalonic aciduria, glycogen storage disease, galactosemia

C Disuse/Immobilization
1 Fracture
2 Cerebral palsy
3 Duchenne muscular dystrophy
4 Quadriplegia/paraplegia
5 Spina bifida
6 Weightlessness

D Inflammatory Diseases
1 Juvenile arthritis
2 Systemic lupus erythematosus
3 Dermatomyositis
4 Inflammatory bowel disease

E Drugs
1 Glucocorticoids, immune suppressants, anticonvulsant drugs, antiretroviral therapy, warfarin, lithium, methotrexate, cyclosporine
2 Alcohol, tobacco
3 Aromatase inhibitors, medroxyprogesterone
4 Protein pump inhibitors

F Chronic Illness
1 Hemoglobinopathies: thalassemia, sickle cell disease
2 Hemophilia
3 Cranial radiation
4 Renal failure, postrenal transplantation, nephrotic syndrome
5 Malignancy: leukemia, lymphoma, cytotoxic chemotherapy
6 Human immunodeficiency virus infection, highly active antiretroviral therapy
7 Severe burns

TABLE 18-12B **Disorders of Mineralization: Osteogenesis Imperfecta**

Type: MIM Gene Chromosome	Severity	Clinical Features	Growth Impairment	Blue Sclera	Inheritance	Functional Defect
I: 166200: *COL1A1*: collagen type I, alpha-1 17q21.33 1120150 or *COL1A2*: collagen type I, alpha-2 7q22.13 120160	Mild	Few (often vertebral) fractures, little deformity, hearing loss in 50%; rarely dentinogenesis imperfecta	Minimal	Present: intense	AD	Nonsense and frameshift mutations result in haploinsufficiency and decreased production of collagen type I
II: 166210: *COL1A1* or *COL1A2*	Perinatal lethal: congenital (see also types VII, VIII, IX, X)	Many rib and long bone fractures in utero and at birth, severe long bone deformities, "beaded" ribs, unmineralized calvarium	Severe	Present	AD, parental mosaicism	
III: 259420: *COL1A1* or *COL1A2*	Severe, progressive, deforming	Moderate to severe bowing, multiple long bone and vertebral fractures, dentinogenesis imperfecta, hearing loss	Severe	Present but lighten with age	AD	Glycine substitutions in *COL1A1* or *COL1A2* result in structurally abnormal collagen type I
IV: 166220: *COL1A2* or *COL1A1*	Moderately deforming	Mild to moderate bowing, fractures, dentinogenesis imperfecta	Moderate, variable	Grayish or absent	AD	Glycine substitutions in *COL1A1* or *COL1A2* result in structurally abnormal collagen type I
V: 610967: *IFITM5*: interferon-induced transmembrane protein-5 11p15.5 614757	Moderately deforming, clinically similar to type IV	Mild to moderate bone fragility, ossification of interosseous membranes of forearm, hyperplastic callus formation at fracture sites; "meshlike" bone lamellation pattern	Mild to moderate	Absent	AD	Osteoblast specific membrane protein essential for osteoblast differentiation; functional consequence of the constant mutation in *IFITM5* is uncertain
VI: 613982: *SERPINF1*: serpin peptidase inhibitor, clade F, member 1 17p13.3 172860	Moderately to severely deforming, clinically similar to type IV	Onset of fractures of long bones and vertebrae in infancy, increased alkaline phosphatase activity and osteoid, "fish-scale" pattern of lamellation	Moderate to severe	Grayish	AR	Loss-of-function mutations in pigment epithelium-derived factor (PEDF): regulator of bone mineralization and osteoclast differentiation
VII: 610682 **CRTAP*: cartilage associated protein 3p22.3 605497	Moderately deforming to severely deforming or lethal (see type II)	Fractures may be present at birth, rhizomelia, limb deformities	Moderate	Absent or faint	AR	Inactivating mutations (duplication) of *CRTAP* impair 3-hydroxylation of prolyl-986 of procollagen α1(I)
VIII: 610915 1p34.2 610339	Severely deforming to lethal, overlaps types II and III	Markedly decreased bone mineralization, scoliosis, platyspondyly, prominent metaphyses, long phalanges	Severe	Absent	AR	Inactivating mutations of *LEPRE* encoding prolyl-3-hydroxylase (leprecan) impair 3-hydroxylation of prolyl-986 of procollagen α1(I)

IX: 259440: *_PPIB_: peptidyl-prolyl isomerase B 15q22.31 123841	Lethal to severely deforming (see type II)	Shortened, bowed, and fractured long bones in midgestation	Severe	Gray	AR	Inactivating mutations of *PPIB* encoding peptidyl-prolyl isomerase B impair 3-hydroxylation of prolyl-986 of procollagen α1(I)
X: 613848: *SERPINH1*: serpin peptidase inhibitor, clade H, member 1 11q13.5 600943	Severe	Short bowed femora in utero, multiple fractures in first month of life, dentinogenesis imperfecta	Severe	Present	AR	Loss-of-function mutations in CBP2 (HSP47): chaperone, essential for maintenance of integrity of the triple helical structure of collagen type 1 and its resistance to proteolytic degradation
XI: 610968 17q21.2 607063	Severe and progressive deformities, overlaps type III	Limbs are short and bowed, joint contractures; dentinogenesis imperfecta; "fish-scale" pattern of bone lamellation (see type VI)	Moderate	Gray	AR	Loss-of-function mutations in a chaperone protein, FKBP65: essential for posttranslational processing of procollagen type I; also mutated in Bruck syndrome type 1
XII: 613849: *SP7*: transcription factor specificity factor (Sp)7 12q13.13 606633	Moderate to severe, resembles OI type IV	Multiple fractures in early infancy; short, bowed long bones, highly arched palate	Severe	Absent	AR	Inactivating mutations in Osterix, a transcription factor essential for osteoblast differentiation and bone mineralization
XIII: 614856: *BMP1*: bone morphogenetic protein 1 8p21.3 112264	Moderate to severe; resembles type III	Generalized deformities of all bones, multiple fractures despite *increased* bone mineral density	Severe	Faint blue	AR	Inactivating mutations of procollagen type I C-terminal propeptide endoproteinase impair collagen formation
XIV: 615066: *TMEM38B*: transmembrane protein 38B 9q31.1 611236	Moderate, similar to type IV	Variable severity; fractures occur in utero or during early childhood; moderate bowing of the lower limbs	Moderate	Absent	AR	Inactivating mutations of a component of an intracellular monovalent cation channel necessary for Ca^{2+} release from storage sites
Undesignated						
PLOD2: procollagen-lysine, 2-oxoglutarate 5-dioxygenase 2 3q24 601865	Severe; osseous fragility with congenital joint contractures	Fractures in infancy, pterygia, scoliosis	Severe	Absent	AR	Encodes a procollagen lysyl hydroxylase necessary for formation of collagen type 1 telopeptide; Bruck syndrome 2

*Form a complex essential for hydroxylation of carbon 3 of proline at position 986 of procollagen type α1(I).

In adults, *osteopenia* and *osteoporosis* ("porous bone") are terms that designate states of reduced bone mass and matrix, abnormal bone microarchitecture, and decreased bone strength that increase the risk for fracture; osteomalacia refers to a decrease in the mineral phase of bone.[310,311,312] Osteoporosis in older adults (primarily postmenopausal women) is defined by the World Health Organization (WHO) as an areal bone mineral density (aBMD) at a specific bone site that is −2.5 or more standard deviations (SD) below the mean peak young adult value for gender (T score). Postmenopausal osteoporosis is usually the consequence of an increase in the rate of bone resorption relative to that of bone formation and is due to estrogen deficiency. In older adults, osteopenia is present when the aBMD lies between −1.1 and −2.4 SD below the mean peak young adult value for gender (a T score of −1.1 to −2.4), and a normal aBMD is one that is not more than one SD below or above the mean peak young adult value (a T score of −1.0 to +1.0). When the aBMD is more than +2 SD above the mean for age and gender (a T score of +2), bone mass is considered high. Because in premenopausal women aBMD alone is not a good assessor of fracture risk, the International Society for Clinical Densitometry (ISCD) recommends that use of the term *osteoporosis* be restricted to those patients with both low aBMD (as defined by a BMD Z score of −2—i.e., one that is below −2 SDs for age- and gender-matched control subjects) and history of low-impact (fragility) fractures.[313] Women with aBMDs that are below −2 SDs but have no history of fracture are designated as having an aBMD that is "below expected range for age"; the use of the term *osteopenia* is eschewed in this population. The International Osteoporosis Foundation (IOF) has defined osteoporosis in young adults as a vertebral or hip aBMD T score that is below −2.5 and is associated with a disorder that adversely affects bone mineralization.[312] Both groups agree that in young adults, the presence of osteoporosis is not defined by low BMD alone. Many of the diseases that lead to osteoporosis in young adults begin during childhood and adolescence (see Table 18-12A).

The WHO and IOF-designated criteria for low or high bone mass do not apply to children and adolescents in whom variability in height, weight, and stage of sexual maturation as well as gender affect bone mineralization. Use of the terms *osteopenia* and *osteoporosis* had been discouraged when describing decreased bone mass in children and adolescents in favor of the designation of increased bone fragility as evidenced by fractures caused by low impact trauma in association with low bone mass (−2 SD) for chronologic age, height, or stage of sexual maturation for gender.[314] However, the term *osteoporosis* has been reintroduced and by definition is applied to a child/adolescent with both low bone mass for gender, age, height, and sexual maturation *and* one who has sustained a low impact fracture.[314,315,316] A fracture due to bone fragility/decreased bone strength is defined as one that has occurred from a vertical distance that is equal to or less than standing height.[315] *Osteopenia* is a term that is not employed in the pediatric population. In children and adolescents, bone mass may be quantitated by DEXA determination of aBMD of "whole body" or "whole body minus head."[315,317,318] However, inasmuch as the skull does not respond directly to environmental factors such as exercise, aBMD of whole body minus head/skull is generally considered a more appropriate method of measurement of bone mineral content or density.[316] Regional (lumbar spine, hip, distal one-third radius) aBMD standard data are also available.[317] (DEXA analyses of hip bone mass are variable in children and adolescents and not usually employed for analysis of BMC or BMD.) DEXA measurements of the nondominant forearm may be employed to determine aBMD of the radius and ulna in the ultra distal, middistal, and one-third distal regions.[319] A portable DEXA-like x-ray device that measures aBMD in the one-third distal region of the nondominant forearm provides data comparable to those recorded by a fixed DEXA unit and thus may enable expanded use of this technology.[319] The method employed to determine bone mineralization (DEXA, quantitative computed tomography [QCT], peripheral QCT [pQCT], quantitative ultrasonography [QUS]) and the specific instrument, the software version utilized for analysis, and the ethic mix of the reference population should be stated in the report of bone mineralization.[317,318,320] Low bone mass is defined as a BMC or BMD that is −2 SD (a Z score of −2) for gender, age, height, and stage of sexual maturation by the method employed for its measurement.[317,318] Despite its limitations (provision of areal rather than volumetric BMD data and failure to distinguish between trabecular and cortical bone), DEXA is the most widely employed bone densitometric method in children at this time, although pQCT may become the method of choice in the future because it quantitates bone volume and mass as well as other dimensions of cortical and trabecular bone. Relative to bone strength determined by calculation of the stress-strain index of a long bone with data garnered by pQCT, DEXA whole body aBMC (minus the skull) for height also appears to afford a reliable measurement for determining cortical bone strength and hence fracture risk.[321] Relative to healthy prepubertal and pubertal boys without a history of fractures, those in whom a traumatic fracture has occurred tend to have as a group lower (although still within the broad range of normal) regional BMDs, aberrant microstructure, and decreased bone strength, abnormalities present even in the prepubertal state that may reflect an intrinsic bone defect.[309]

Although heritable factors account for 60% to 80% of optimal bone mineralization, modifiable factors that contribute to the development of osteopenia and osteoporosis in adulthood (weight-bearing exercise, nutrition, body mass, hormonal milieu) have their genesis in utero, infancy, childhood, and adolescence.[310,311,322] In children as in adults, bone mass, composition, microarchitecture, and size determine bone strength. Because many youths consume excessive amounts of carbonated beverages and diluted fruit juices, thus limiting their intake of milk, children and adolescents ingest only 55% to 70% of the recommended daily calcium allowance (1300 mg/day), although late pubertal males tend to consume more than do pubertal females.[323] In adolescent and adult females, an excessive intake of cola drinks with high phosphoric acid levels lowers body calcium content by sequestering dietary calcium in the intestinal tract and increasing

dissolution of bone mineral to neutralize acid with the consequent development of mild secondary hyperparathyroidism.[324] Sedentary, non-weight-bearing activities encouraged by television, videogames, and computer games also impair bone mineralization.[325] Although body weight and fat mass often correlate with bone mass, overall fat has a negative effect on the accrual of bone mass.[325,326] In a study of 300 male and female adolescents and young adults (13 to 21 years of age) employing both the DEXA assessment of body composition and the QCT measurement of the axial and appendicular skeletons, a positive correlation between lean mass and all bone measurements has been demonstrated in both genders, whereas fat mass has had either an inverse or no relationship to bone mass. These observations indicate that bone mass and strength are determined by dynamic muscular force and not by static load.[326] Further evidence of the adverse effects of increased fat mass on bone strength during childhood is the observation that the odds ratios for fractures of the foot, ankle, leg, and knee increase as the body mass index rises, particularly in 6- to 11-year-old children.[327] An obesity-induced decrease in bone mass may be due, in part, to marginal stores of vitamin D, because at similar intakes of vitamin D obese subjects have lower serum levels of 25-hydroxyvitamin D than do normal-weight subjects, to the diversion of progenitor cells from the pathway of osteoblastogenesis to that of adipogenesis, and to products of white fat cells (leptin, adiponectin) that may exert either inhibitory and stimulatory effects on bone mass.

In children and adolescents, the longer and more intense the weekly sporting activity is (soccer, basketball, gymnastics, tennis), the greater are the vertebral and femoral aBMDs independently of calcium intake.[328] In pre- and peripubertal children, simple school physical education programs utilizing jumping, hopping, and skipping exercises two to three times weekly significantly increase areal BMD at the femoral trochanter in as little as 8 months relative to children engaged in a standard physical education curriculum.[329] Thus, suboptimal nutrition and sedentary activities during childhood and adolescence, as well as the consumption of colas and alcohol and the smoking of cigarettes, prevent optimal bone mineralization and increase the likelihood of later development of osteoporosis and its complications.[323] Because the risk of developing an osteoporotic fracture as an adult declines by 40% for every 5% increase in peak bone mineral mass, the foundation for the prevention of osteoporosis in the adult must be constructed in the child and adolescent by maintaining adequate calcium intake, vitamin D stores (serum concentrations of 250HD $>$ 20 ng/mL), and complementary weight-bearing activity during these formative years. Although calcium and vitamin D supplementation for 1 year can increase bone mass in premenarchal girls, combined quantitative analyses of multiple trials of calcium supplementation in children have revealed little effect on BMD or reduction of the risk of fracture.[330,331] Nevertheless, the effects of sustained calcium supplementation over the many years of childhood and adolescence on future fracture risk merits systematic examination. Other nutrients (e.g., magnesium, vitamins C and K, and copper) must also be consumed for optimal bone matrix synthesis.[332] It may be possible to identify the child or early pubertal subject at (genetic) risk for the accrual of low peak bone mass and thus for later development of osteopenia/osteoporosis (e.g., offspring of a mother with osteopenia or osteoporosis, survey of children utilizing portable DEXA devices). Axial and appendicular BMD and bone size determined by central or peripheral QCT in the normal early pubertal boy and girl may accurately predict these measurements at sexual maturity.[333] If so, children at risk for low peak bone mass might benefit from a targeted diet and exercise program during puberty that increases these values.

Nutritional deprivation depresses the rate of bone accrual, a process observed most dramatically in subjects with anorexia nervosa. The majority of postmenarchal, late adolescent females with anorexia nervosa have significantly decreased total body, vertebral, and femoral neck aBMDs, although volumetric BMDs may be normal for their small bone size.[334] In adolescent females with anorexia nervosa, decreased bone mineralization is associated with a slow rate of bone turnover as demonstrated by lower serum concentrations of osteocalcin, estradiol, free testosterone, IGF-I, leptin, and bone-specific alkaline phosphatase and depressed urinary excretion of deoxypyridinoline relative to normal-weight subjects. In these patients, serum levels of osteoprotegerin correlate negatively with fat mass and leptin values and with lumbar spine areal (by DEXA) and apparent BMDs.[335] The decline in bone mass in adolescents with anorexia nervosa may be attributed to nutritional deprivation, chronic acidemia, and functional hypogonadism. Pathophysiologically, the osteopenia encountered in patients with anorexia nervosa is the result of generalized nutritional deprivation with a suboptimal intake of protein, calcium, and vitamin D, hypercortisolemia, and lowered IGF-I generation leading to decreased osteoblast-mediated bone formation coupled with hypoestrogenically mediated enhanced osteoclast-stimulated bone resorption.[336] The bone loss of the patient with anorexia nervosa does not fully recover even after a return to normal weight, resulting in a several-fold increase in fracture risk for these women. In adolescents with anorexia nervosa, the administration of estrogen/progestin does not increase bone mass or prevent its loss. Bisphosphonates, IGF-I, and dehydroepiandrosterone have been reported to increase or maintain BMD in small series of patients with anorexia nervosa, but their use should be limited.[336] The "athletic triad" of suboptimal body fat mass, amenorrhea in women, and decreased bone mass attributed to low sex hormone production is encountered in the highly trained female athlete and in elite male long-distance runners. Additionally, the adolescent amenorrheic athlete has an abnormality of bone microarchitecture.[337] There is a population of children, adolescents, and young adults with "constitutional thinness" that is characterized by long-standing underweight for height, normal growth, sexual maturation and fertility, and the absence of systemic disease or psychologic dysfunction in whom aBMD is low but fracture risk is apparently not increased.[338] Young adults who experienced delay in onset and

completion of sexual development as adolescents may also have low bone mass.[312]

Acute immobilization of the healthy, active child and adolescent leads to a sudden reduction in weight bearing and a consequent decrease in the mechanical load on bones and thus a lowered rate of bone formation; in the presence of continued bone resorption, hypercalciuria and later hypercalcemia and lowered bone mass develop.[339] In the chronically partially or fully immobilized child or adolescent (due to cerebral palsy, spastic quadriplegia, muscular dystrophy), the fracture rate (primarily of the femur) is high during such simple maneuvers as turning, dressing, or feeding. In this group of subjects, not only lack of weight bearing but also the severity of the primary illness, body size and pubertal status, state of general nutrition, vitamin D and calcium intake, coexisting inflammatory states, and medications (e.g., anticonvulsants, glucocorticoids) as well as indoor confinement adversely impact bone mass and fracture risk. In a study group of 117 patients (2 to 19 years of age) with moderate to severe cerebral palsy, distal femoral aBMD Z scores were below −2.0 in 77%, and the incidence of low femoral and vertebral aBMDs as well as fractures increased with advancing age.[340] Distal femoral and lumbar vertebral aBMDs increase at slower than normal rates as the child with spastic cerebral palsy ages resulting in diminution of aBMD Z score in the older subject.[341] Both intravenous administration of pamidronate and subcutaneous injections of recombinant human GH have increased aBMD in small selected groups of children with quadriplegic and spastic cerebral palsy.[342,343] Areal BMD increased substantially in 26 immobile patients with quadriplegic cerebral palsy (3 to 17 years of age) during the administration of the bisphosphonate alendronate (1 mg/kg/week orally), calcium (600 mg/day), and vitamin D (400 IU/day) over 1 year of treatment.[344] Assisted standing by itself increases BMD in children with severe cerebral palsy.[345]

The fundamental importance of normal gonadal sex steroid secretion during age-appropriate sexual maturation is emphasized by the observation that in adult males with delayed sexual development, radial, vertebral, and femoral areal BMDs are lower than in males with normal timing of pubertal maturation.[312] Volumetric BMD may be either normal or subnormal in young adult men with a history of delayed adolescence. Reduced bone mass and abnormal microarchitecture result in decreased skeletal strength and an increased risk of fracture; histomorphometrically, in adult sex-steroid deprived osteoporotic bone there is decrease in cortical width, trabecular number, osteoid, and mineralization activity.[346] As a consequence of estrogen (and androgen) deficiency, there is an increase in the production but a decline in the life span of osteoblasts and osteocytes, whereas osteoclastogenesis is stimulated and the life span of osteoclasts prolonged; these events reflect the sum of the activities of multiple pro-osteoclastogenic cytokines whose synthesis is regulated by estrogen including M-CSF, IL-1, IL-6, TNFα, RANKL, and osteoprotegerin. Although osteopenia responsive to estrogen has been recorded in adult males with aromatase deficiency, mature women with complete androgen insensitivity are also osteopenic despite normal to increased estrogen production, clearly indicating that androgens, too, are important for normal bone mineralization.[346]

There is an increased risk of fractures in prepubertal and adolescent girls and adult women with Turner syndrome that is attributable to both intrinsically abnormal bones (as manifested by Madelung deformity of the wrist, scoliosis, cubitus valgus and shortened metacarpal and metatarsal bones) and osteopenia related to chronic estrogen deprivation.[347] Although decreased relative to chronologic age, areal and volumetric BMDs may be normal relative to height or bone age in girls with Turner syndrome. In patients with Turner syndrome, there is selective deficiency of cortical bone, whereas trabecular bone density is normal. The frequency of wrist fractures is increased during childhood, as may be the general risk for fractures in adults with Turner syndrome. Estrogens, growth hormone, and particularly the administration of both agents increase bone calcium deposition and aBMD in adolescents with Turner syndrome.[348] If estrogen replacement therapy is begun in the early adolescent years, cortical and trabecular bone mass increase substantially, but if estrogen replacement is delayed decreased cortical bone mass persists into adulthood, although trabecular bone mass normalizes.[347] Although recombinant human growth hormone increases growth rate and adult stature in many patients with Turner syndrome, its effects on bone density and fracture risk in these subjects is uncertain. As with all individuals, an appropriate intake of calcium and vitamin D and weight-bearing exercises should be strongly endorsed. However, the use of bisphosphonates is not recommended in patients with Turner syndrome, because these drugs act primarily upon trabecular bone that responds well to estrogens alone.[347]

Pubertal subjects with primary (Klinefelter syndrome, galactosemia, post radiation or chemotherapy) or secondary hypogonadism (anorexia nervosa, excessive physical training, hypogonadotropism) also have decreased bone mineralization. By decreasing estrogen production, even short-term (6 months) use of the intramuscular contraceptive depot medroxyprogesterone acetate (MPA) results in significant loss in bone mass in adolescent females and young women (18 to 21 years of age) when BMD would ordinarily be increasing; however, bone mass increases over time after this agent is discontinued.[336] The adverse impact of depot MPA on BMD may be prevented by concomitant administration of estrogen. After treatment of the child with central precocious puberty for 1 to 2 years with a gonadotropin releasing hormone analog that suppresses pituitary-gonadal function, there may be arrest or even decline in bone mineral accumulation in the peripheral and axial skeletons, a process that can be prevented or reversed by the co-provision of 1 gram of calcium per day during analogue therapy.[349]

The low bone mass of glucocorticoid excess is the result of (1) inhibition of osteoblastogenesis; (2) an increase in the rate of apoptosis of the osteoblast and osteocyte, leading to decrease in the rate of bone matrix formation and microfracture repair; (3) enhanced osteoclastogenesis; and (4) a decrease in the rate of apoptosis of the osteoclast—permitting prolonged and excessive bone resorption.[350,351]

Because of decreased osteocyte regulation of bone remodeling, during each remodeling cycle the amount of bone replaced is far less than the amount removed and skeletal microarchitecture degraded, resulting in declining bone mass and strength. At the molecular level, glucocorticoids suppress expression and synthesis of RUNX2 and BMP-2, factors essential for prenatal and postnatal osteoblast differentiation, respectively, and increase osteoblast expression of RANKL and decrease expression of osteoprotegerin, changes that favor osteoclastogenesis.[350,352] Glucocorticoids interfere with WNT/β-catenin signaling and consequently inhibit synthesis of collagen type I as well as increase its rate of degradation; they impair IGF-I formation and function. These compounds direct the mesenchymal osteoblast precursor into the pathway of adipocyte differentiation. To a limited extent, glucocorticoids inhibit normal vitamin D metabolism and thereby vitamin D–dependent intestinal absorption of calcium. They increase renal loss of calcium by a direct effect on the renal tubule leading to secondary hyperparathyroidism.[350,352] Glucocorticoids also reduce production of sex hormones in the adolescent and adult. The muscle weakness of chronic glucocorticoid exposure reduces the impact of mechanical forces on bone formation. Finally, the disease (e.g., asthma, nephrotic syndrome, chronic inflammatory disorders such as juvenile arthritis) for which pharmacologic doses of glucocorticoids have been prescribed may contribute to decreased bone mass by impairing mobility and by elaboration of osteoclastogenic cytokines. Glucocorticoids adversely affect trabecular bone formation initially and later impair cortical bone accumulation.[351] Although glucocorticoid-reduced bone mass accumulation is greater with frequent intermittent bursts of oral glucocorticoids than with inhaled glucocorticoids in boys with asthma, in high doses over prolonged periods inhaled glucocorticoids can also lead to decreased bone mass.[353-355] In young adults with asthma there is an inverse relationship between vertebral and femoral aBMDs and the cumulative dose of inhaled glucocorticoid with increasing fracture risk as the dose and duration of glucocorticoid administration increases; a cumulative dose of 5000 mg leads to a 1 SD decline in vertebral BMD.[356] In adult women with 21-hydroxylase–deficient congenital adrenal hyperplasia treated with glucocorticoids, bone mineralization is modestly reduced, in part related to the extent to which adrenal androgen production is suppressed.[357] It is suggested that when children begin to receive either oral or inhaled glucocorticoids that they also be instructed to ingest age-appropriate amounts of calcium and vitamin D and to engage in weight-bearing exercises. In children experiencing adverse effects of glucocorticoids on growth and bone mineralization, it is important to lower their steroid dose to the greatest extent possible and to withdraw them if at all feasible. In 7 of 10 children with juvenile rheumatoid arthritis and other rheumatic disorders and glucocorticoid/illness-mediated low bone mass, pamidronate at a dose of 2 to 4 mg/kg per infusion administered at 6-month intervals was followed by decline in bone pain, improved ambulation, and a progressive increase in BMD of the lumbar spine.[358] Although generally recommended for adults being treated with glucocorticoids, routine administration of a bisphosphonate to children receiving these agents is not recommended unless there is steady decline in bone mass or the patient has had a low-impact or fragility fracture attributable to low bone mass.[351] Teriparatide ($PTH^{1\text{-}34}$) increases bone mass in adults with glucocorticoid-induced osteoporosis, but its efficacy and safety in children with this problem have not yet been evaluated. Denosumab, a human monoclonal, neutralizing antibody against RANKL (thus mimicking the antiosteoclastogenic effects of osteoprotegerin) may also prove useful in the treatment of glucocorticoid-mediated deficits in bone mass.[351]

Growth hormone (GH) exerts direct and indirect actions on bone formation. In growth plate cartilage, GH stimulates proliferation of resting chondrocytes and promotes local generation of IGF-I; in bone, it enhances osteoblast differentiation, proliferation, and function resulting in increased osteoblast synthesis of IGF-I, IGFBP-3, osteocalcin, bone-specific alkaline phosphatase, and procollagen type I; it also stimulates osteoclastogenesis and bone resorption.[359,360] IGF-I regulates differentiation of chondrocytes and maintains their rate of proliferation.[360] Osteoblast and osteocyte-synthesized IGF-I affects osteoblast maturation and the rates of matrix mineralization and bone turnover and mediates the response of bone to a mechanical load and to parathyroid hormone.[360] Administration of GH to GH-deficient children and adults increases the rates of both bone formation and destruction, the latter predominating initially; over long periods of treatment (12 to 18 months) GH increases aBMD in these patients; to achieve peak bone mass, however, GH therapy must be continued into adulthood. Nevertheless, in many untreated adults with congenital GH deficiency due to an inactivating mutation in hypothalamic *GHRH*, volumetric BMD is often normal despite low aBMD values reflecting the smaller size of their bones.[361] Thus, although lack of GH has long been considered a cause of low bone mass in patients with GH deficiency of either childhood- or adult-onset, critical analysis of data concerning bone mass and fracture risk in children and adults with GH deficiency has questioned the validity of this relationship.[362] GH primarily affects formation of cortical bone (an observation consistent with the known clinical effects of GH on exuberant growth of membrane bone). In part, low bone mass in the GH-deficient child may be attributed to the small bone size of the short child compared to age peers when examined as aBMD by DEXA. However, measurement of bone mass by either size-corrected aBMD or volumetric methods (e.g., pQCT) indicates that volumetric BMD is normal in the majority of GH-deficient subjects. Thus, neither isolated GH deficiency or resistance to the effects of GH due to loss-of-function mutations of the GH receptor is associated with increase in fracture risk in children or adults.[362] In patients with hypopituitarism of adult onset associated with multiple pituitary hormone deficiencies, fracture risk is increased, but this may be attributable to a loss of gonadotropin stimulated sex hormone secretion and to the decreased mechanostat effects of reduced muscle mass on bone accretion in these fully grown subjects.

Thyroid hormone, through direct action on the osteoblast, increases synthesis of osteocalcin, alkaline

phosphatase, and IGF-I; it also enhances osteoclastogenesis and, thus, the rate of bone resorption, the latter effect predominating in patients with excess thyroid hormone in whom there is increase in the rate of bone turnover but decrease in the length of the bone remodeling cycle (primarily due to shortening of the bone formation phase) resulting in a net loss of mineralized bone.[363] As in adults with thyrotoxicosis, whole body, vertebral, and femoral BMDs are low in children and adolescents with hyperthyroidism, but they substantially increase within the first 12 to 24 months after restoration of the euthyroid state. Administration of physiologic replacement doses of thyroxine to children with acquired or congenital hypothyroidism does not adversely affect bone mineralization during childhood, although adults with congenital hypothyroidism have a 10% reduction in radial bone mass. In adolescents with type 1 diabetes mellitus, whole body, axial, and appendicular bone mass assessed by DEXA is decreased relative to control subjects and inversely related to hemoglobin A1c values reflecting the adverse effects of chronic hyperglycemia and insulin deficiency upon bone formation.[364,365] Utilizing pQCT in young, prepubertal subjects with type 1 diabetes mellitus, cortical bone cross-sectional area and BMD were found to be decreased, implying an increased risk for fracture.[366]

Bone mass is decreased in 80% of children with acute lymphoblastic leukemia, and 40% sustain a fracture within the first 2 years of treatment. Pathogenetic factors involved in the suppression of bone remodeling and the development of low bone mass in these subjects include adverse effects of the disease itself directly on bone; radiation injury of bone; inhibitory effects of glucocorticoid, chemotherapeutic, antibiotic, and immunosuppressive agents on bone formation; diminished physical activity; decreased caloric, protein, and vitamin D intake; sex hormone deficiency due to delayed or arrested adolescent development; and GH deficiency in children who have received cranial radiation.[367] Cyclosporine A induces bone loss in organ transplant recipients by increasing osteoblast expression of RANKL and decreasing production of osteoprotegerin thereby augmenting osteoclastogenesis. Methotrexate and intrathecal chemotherapy exert significant inhibitory effects on bone mineralization in children with malignancies who should receive appropriate calcium and vitamin D supplements and weight-bearing exercises to the extent possible.[367] Those who develop GH deficiency following cranial radiation may be treated with rhGH if they remain GH deficient after the primary illness has been in prolonged remission. Decreased bone mineralization is common in the post bone marrow or solid organ transplant subject; its diverse pathogenesis includes the primary disease itself and the chronic illness that may accompany it, the use of high-dose glucocorticoids and antirejection medications, as well as altered intestinal, renal, hepatic, and gonadal function.[368] In addition to the provision of adequate nutrition, calcium, and vitamin D, in adults the effects of transplantation may be partially ameliorated by the administration of bisphosphonates.

In severely burned patients and children with hemophilia, sickle cell disease, central diabetes insipidus, Marfan syndrome, homocystinuria, lysinuric protein intolerance, and propionic and methylmalonic aciduria, aBMD is also decreased and fracture risk increased. Children with cystic fibrosis may have low vertebral and femoral neck aBMD Z scores as a consequence of suboptimal nutrition, vitamin D deficiency, chronic inflammation, concomitant diabetes mellitus, pubertal delay, and drug therapy. However, approximately one third of optimally managed cystic fibrosis patients with good clinical control may nevertheless have subnormal BMDs (a Z score below −1 but seldom below −2.5), although this is not necessarily translated into increased fracture risk.[369] Low bone mass and vertebral collapse may be early manifestations of chronic inflammatory bowel disease. Vitamin D deficiency and secondary hyperparathyroidism as well as the chronic inflammatory state and therapeutic agents such as glucocorticoids likely contribute to decreased bone formation and increased bone resorption in this illness. That whole body aBMC in children, adolescents, and young adults with chronic inflammatory bowel disease may be normal relative to lean body mass (although reduced relative to racial, age, and height norms) does not necessarily imply that bone strength in these patients is normal as evidenced by the increased fracture risk of adults with this disorder.[370] Low bone mass is common in children and adults with celiac disease.[371] Pathogenetic factors associated with low bone mass in children with celiac disease include malabsorption of vitamin D, calcium, protein, and other nutrients, synthesis of osteoclast activating and proinflammatory cytokines such as interferon γ and interleukins −15, −18, and −21, and secondary hyperparathyroidism. In children and adolescents infected with the human immunodeficiency virus, whole body BMD is decreased as a consequence of the infective agent itself, the chronic inflammatory state it induces, suboptimal nutrition, and the administration of highly active antiretroviral therapy that may have direct effects on osteoblast and osteoclast generation and function.[372,373] Despite clinical well-being and normal linear growth, the rate of accrual of bone mass is decreased in these subjects, whereas the rate of bone resorption is increased. Bone mass is reduced in children with a variety of connective tissue diseases (juvenile idiopathic arthritis, systemic lupus erythematosus, juvenile dermatomyositis) due to the chronic inflammatory state and production of pro-osteoclastic cytokines and to therapy with glucocorticoids.[374]

Idiopathic juvenile osteoporosis (MIM 259750) is an unusual disorder of generalized low bone mass of unknown pathogenesis that appears in both boys and girls between 8 and 12 years of age and often resolves as sexual maturity is achieved.[375] In affected subjects, roentgenograms obtained for evaluation of joint, muscle, or back pain, difficulty walking, foreshortening of the trunk, or the presence of kyphosis reveal biconcave vertebrae or vertebral compression fractures, radiolucent areas in long bones, and metaphyseal fractures. DEXA and QCT analyses demonstrate decreased bone mineralization. Chemical studies are normal. Dynamic histomorphometric studies reveal low rates of bone formation and turnover with a reduction in cancellous bone volume and trabecular thickness due primarily to decreased osteoblast activity on the endosteal but not the periosteal bone

surface; there is no evidence of increased bone resorption. Idiopathic juvenile osteoporosis is quite likely to be genetically heterogenous in origin. Mutation analyses of *COL1A1* and *COL1A2* have been normal in these subjects. In 15% of patients with juvenile osteoporosis, a familial heterozygous loss-of-function mutation in the gene encoding LDL receptor-related protein 5 (*LRP5*) has been detected.[376] Homozygous loss of *LRP5* results in the osteoporosis-pseudoglioma syndrome (discussed later). One of the most difficult diagnostic challenges is the clinical distinction between idiopathic juvenile osteoporosis and osteogenesis imperfecta type I (discussed later). The latter disease is characterized clinically by a positive family history, onset in early infancy, lifelong persistence, diaphyseal fractures, wormian bones, lax ligaments and decreased muscular strength, blue sclerae, abnormal dentition, hearing loss, and a high rate of bone turnover.[196,375] Additionally, there are some children with low bone mass and recurrent fractures whose clinical picture is not as severe as those with idiopathic juvenile osteoporosis, suggesting that there is a wide spectrum of clinical findings in children and adolescents with marginal bone mineralization.[375] In children with classical idiopathic juvenile osteoporosis, symptomatic treatment is offered; in some patients calcitriol or supplemental sodium fluoride has been of benefit. Although the disorder ameliorates and even disappears at puberty, treatment of the prepubertal patient with sex steroids does not seem to accelerate the healing process. Administration of the bisphosphonate pamidronate has been helpful in reducing bone pain and increasing vertebral BMD in small groups of children with idiopathic juvenile osteoporosis.[375]

Low density lipoprotein receptor-related protein 5 (*LRP5*, MIM 603506) is a cell membrane protein expressed by osteoblasts that serves as coreceptor for signal transduction through the WNT-frizzled-β-catenin pathway leading to differentiation and function of osteoblasts. WNT signaling enhances differentiation of pluripotential mesenchymal precursor cells into the pathway of chondrogenesis and osteogenesis and impedes its differentiation into the pathway of adipogenesis.[377] By stimulating RUNX2, β-catenin further directs the osteochondroprogenitor cell into the osteoblastic track, and in the mature osteoblast, β-catenin enhances expression of osteoprotegerin and thus depresses osteoclastogenesis.[378] Sclerostin (encoded by *SOST*, MIM 605740) binds to the extracellular domain of LRP5 and thereby inhibits WNT signaling.[379] Intrinsic abnormalities of *LRP5* expression have been associated clinically with disorders of both impaired and excessive bone mineralization. The osteoporosis-pseudoglioma syndrome (MIM 259770) is characterized clinically by congenital or early infantile onset of severe visual impairment due to micro-ophthalmia and hyperplasia of the vitreous (pseudoglioma that may be erroneously identified as retinoblastoma) leading to retinal detachment, glaucoma, and blindness; marked osseous fragility with craniotabes and fractures during late infancy, childhood, or adolescence; and variable cognitive impairment, ligamentous laxity, and hypotonia.[380] The disorder is transmitted as an autosomal recessive trait and is due to biallelic (homozygous or compound heterozygous) inactivating (missense [Val336Met, Arg494Gln], nonsense [Arg428Ter, Arg1002Ter], frameshift, splice-site) mutations in *LRP5*, primarily located in the extracellular domain of LRP5.[381,382] Missense mutations likely prevent normal binding of LRP5 to the product of the mesoderm development gene (MIM 607783, chromosome 15), a chaperone protein that directs LRP5 to the cell membrane. Although often asymptomatic, heterozygous carriers are usually osteopenic; however, vision is not impaired. Intravenous administration of pamidronate over several years can increase bone mass in children with this disorder.[382] Loss-of-function mutations in *LRP5* have also been associated with familial exudative vitreoretinopathy (MIM 133780), a developmental disorder of retinal vasculature that may be transmitted as either an autosomal dominant (Leu145Phe) or an autosomal recessive (Arg570Gly, Arg752Gly) trait; these patients also have reduced bone mass. LRP5 transduces not only the WNT signal but also that of Norrin (MIM 310600, chromosome Xp11.4). Norrin signaling modulates ocular vitreoretinal formation. Gain-of-function mutations in *LRP5* are associated with increased bone mass (discussed later).

Evaluation and Management of Low Bone Mass

Evaluation of the child or adolescent with a possible low-impact fracture due to decreased bone strength (previously defined as a fracture sustained by a fall from a distance that is less than the standing height of the patient) begins with historical review and physical examination directed to the identification of factors that might adversely affect skeletal formation and bone mineralization.[308,315] In addition to genetic and hormonal influences, the most important elements necessary for the accrual and maintenance of bone mass that need be inquired about are those that relate to diet (sufficient intake of calcium and protein, absence of anorexia nervosa), sustained normal vitamin D stores either by exposure to sunlight or ingestion of supplements, consistent but not excessive weight-bearing exercise, and the presence or absence of diseases (e.g., asthma) or therapeutic agents (e.g., glucocorticoids) that might impair bone development. It is important to examine the patient's growth pattern to determine whether statural growth has been normal and normal weight for stature and gender has been attained and maintained; an assessment by physical examination of stages of primary and secondary sexual maturation is also essential. Determination of skeletal maturation (bone age) is useful to establish if the child is growing in accord with his or her genetic potential. If pertinent, systemic illnesses such as chronic renal disease, celiac disease, inflammatory bowel disease, and endocrinopathies should be eliminated. Assessment of areal bone mineralization is most often accomplished by DEXA in children with referral to age and gender-specific reference data.[315,318] Interpretation of a DEXA BMD relative to height and to bone age is often useful.[383] In a series of 304 children and adolescents undergoing DEXA bone mineralization studies at a children's hospital, 36% were doing so because of a history of fractures, 27% because of hypogonadism, and 22% because of

gastrointestinal (celiac, inflammatory bowel) disease.[384] Low body mass index and low vitamin D stores were the most significant predictors of subnormal BMD (below −2 SDs for age and gender). Interestingly, for subjects with a history of fractures, there was no difference in the number of fractures in those with a BMD below or above −2 SDs for age and gender. Depending on the individual patient, measurements of serum calcium, phosphate, alkaline phosphatase, creatinine, iPTH, 25OHD, and reproductive hormones, as well as disease-specific analytes (e.g., for inflammatory bowel or celiac diseases), may be indicated. Bone turnover markers are of marginal diagnostic utility in children, although they are perhaps useful as indices of therapeutic response.[385,386] After assessment and when necessary and appropriate, intervention may include elimination of or reduction in glucocorticoid dose in an asthmatic child or treatment of an accompanying underlying systemic disease or endocrinopathy that may be of pathogenetic significance in the development of low bone mass. When attempting to prevent bone loss or restore lost bone, initial efforts are directed to the assurance that these basic approaches are being utilized to the fullest extent possible for the specific patient.

Therapeutic agents increase skeletal mass either by inhibiting bone resorption (antiresorptive or anti-remodeling drugs) or by stimulating bone formation (anabolic agents).[387,388] The most widely employed antiresorptive medications are sex hormones, selective estrogen receptor modulators, teriparatide ($PTH^{1\text{-}34}$), denosumab, and bisphosphonates. Selective estrogen receptor modulators (SERMS) are triphenylethylene, benzothiophene, or naphthalene-related compounds (e.g., raloxifene) that bind with high affinity to estrogen receptor α in specific tissues where they alter the three-dimensional configuration of the receptor and recruit tissue-selective cohorts of various cofactors, thus either reducing (breast, brain) or inducing (bone) receptor function in targeted sites.[389] SERMs decrease osteoclast formation primarily at trabecular bone sites, but their efficacy in increasing BMD is less than that of estrogens themselves.[390]

Denosumab is a human monoclonal antibody to RANKL that binds tightly to its ligand and prevents its interaction with RANK, thereby inhibiting osteoclastogenesis; denosumab thus acts as a "pseudo-osteoprotegerin." In postmenopausal women with decreased bone mineralization, denosumab decreases bone resorption and increases lumbar spine BMD.[391] Experience with its use in children is limited. Strontium renalate is an agent that has been considered for treatment of low bone mass in adults, because it is incorporated into the structure of bone mineral.[352] Although nasal salmon calcitonin inhibits osteoclast function directly and has modest bone restorative effects, it is seldom utilized for the treatment of osteoporosis in adults or children.[392]

Bisphosphonates are analogs of pyrophosphate with carbon substituted for the oxygen bridge between two phosphate groups; also attached to the carbon atom are two side chains: R1 is usually a hydroxyl group or chloride atom that together with phosphate residues binds tightly to hydroxyapatite and coats bone surface; the R2 side chain may be "simple" and contain chloride or sulfur atoms, or it may be more complex and heavier with nitrogen atoms and ring structures composed of carbon and oxygen (Figure 18-12). Bisphosphonates that contain nitrogen as a constituent in one of the side chains are substantially more potent than are the "simple" bisphosphonates.[393] Bisphosphonates chelate the calcium ions of hydroxyapatite and thus are targeted to bone; within the resorption lacuna beneath an osteoclast, bisphosphonates dissociate from hydroxyapatite as the pH is lowered by osteoclast secretion of H^+ and are then endocytosed into the interior of the osteoclast. Once within the osteoclast, bisphosphonates impede osteoclast function by hastening their death by two distinct mechanisms: (1) "simple" bisphosphonates such as medronate, etidronate, and clodronate are metabolized into analogs of adenosine triphosphate (ATP) that interfere with release of phosphate and hence with energy generation; additionally, "simple" bisphosphonates prevent movement of ATP into the osteoclast's mitochondria as a consequence of which mitochondria disintegrate and osteoclast apoptosis is initiated—thereby further interfering with bone resorption; (2) large, nitrogen-containing bisphosphonates (pamidronate, zoledronate) act by impairing cholesterol synthesis by inhibiting farnesyl pyrophosphate synthase activity in osteoclasts. This enzyme is essential for synthesis of cholesterol through the mevalonate pathway; its inhibition prevents prenylation of proteins, a posttranslational modification that enables prenylated proteins to interact with proteins and to bind to cell membranes.[393] Inhibition of this pathway in osteoclasts impairs formation of the ruffled border and actin rings, movement of osteoclast products into the resorption lacuna, and resorption of degraded bone products—all metabolic functions of osteoclasts essential for bone resorption. The biologic activity of a bisphosphonate on osteoclast

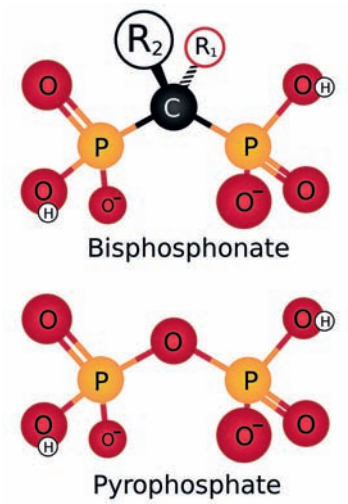

FIGURE 18-12 ■ Bisphosphonates are analogues of pyrophosphate in which carbon has been substituted for the oxygen bridge between two phosphate groups; two side chains (R1, R2) are attached to the carbon atom: R1 may be a hydroxyl group or chloride atom that together with phosphate residues binds tightly to hydroxyapatite and coats bone surface; R2 may contain chloride or sulfur atoms or it may be composed of ring structures containing carbon, oxygen, and nitrogen. function is observed immediately after its administration as serum calcium concentrations decline rapidly; indeed, this rapid effect has been utilized in the treatment of hypercalcemic infants and children. In adults, the effects of bisphosphonates on bone mass last long after the agent has been discontinued (the "residence time"), enabling some compounds to be given as infrequently as once yearly (zoledronate). Indeed, the bisphosphonates remain in bone for extremely long intervals and their long-term effects are cumulative. Histomorphometric analysis has revealed that bisphosphonate-mediated inhibition of osteoclast stimulated bone resorption increase bone mineralization by decreasing the number of resorption cavities and thus the remodeling space, preserving cancellous (trabecular) bone architecture, and decreasing porosity of cortical bone. Bisphosphonates have been useful in improving mineralization in children with osteogenesis imperfecta (discussed later) as well as in those with glucocorticoid induced osteoporosis, osteoporosis-pseudoglioma syndrome, Menkes disease, and cerebral palsy (as discussed previously). In most infants and children, intravenous pamidronate (0.5 to 1 mg/kg/dose on 3 consecutive days every 2 to 4 months up to 2 to 15 mg/kg/yr administered once every 3 to 6 months) has been utilized, although a number of different regimens have been employed with reasonably similar increases in BMD, decline in fracture incidence, and improved well being.[308] Limited data indicate that oral bisphosphonates (pamidronate, alendronate, olpadronate) administered daily also increase BMD in children with osteogenesis imperfecta but with lower efficacy than intravenous administration and, therefore, are not generally utilized in these patients. At present, the Food and Drug Administration has not approved bisphosphonates for use in children.

Side effects of bisphosphonates have been both acute (fever, myalgia, abdominal pain, vomiting, hypocalcemia) and chronic (inflammatory disorders of the eye, osteonecrosis of the jaw in the elderly, and induced "osteopetrosis") (discussed later).[394] Experimentally and in adults receiving long-term therapy, bisphosphonates can suppress bone turnover and contribute to hypermineralization, the latter leading paradoxically to reduced mechanical strength and increased fracture risk.[395] Therefore, when considering a child for treatment with bisphosphonates one must carefully evaluate the primary diagnosis and whether the patient's low bone mass and fracture frequency merit therapy in view of the potential side effects of bisphosphonates. In addition, there are many unanswered questions concerning which bisphosphonate to use, its route of administration, the dose of the drug, the duration of therapy, and the method of outcome analysis. The use of bisphosphonates should be confined to centers with experience in the care and management of children with bone disease.[308] Treatment with bisphosphonates several years prior to conception does not appear to have an adverse effect on fetal outcome, but treatment during pregnancy is contraindicated because of possible toxicity.[396]

$PTH^{1\text{-}34}$ (teriparatide) is the most widely employed bone anabolic agent. Administered continuously, $PTH^{1\text{-}84}$ and its analog $PTH^{1\text{-}34}$ increase osteoclast-mediated dissolution of bone, but when administered intermittently these agents exert anabolic effects on osteoblast function and bone formation. This property is employed clinically through the use of $PTH^{1\text{-}34}$ in the treatment of postmenopausal women with osteoporosis. When administered intermittently in small amounts, $PTH^{1\text{-}34}$ preferentially accelerates the rates of bone remodeling and of bone formation relative to that of bone resorption by direct effects on osteoblast differentiation, maturation, and longevity.[388] $PTH^{1\text{-}34}$ also acts on the osteocyte to decrease the production of sclerostin, an inhibitor of bone synthesis that acts by repressing WNT- and BMP-mediated bone formation (discussed later).[397] The quantity of bone formed in each remodeling unit is increased with consequent augmentation of trabecular thickness and interconnectivity and periosteal new bone formation and cortical thickness resulting in increased bone size, mass, and strength. Side effects of $PTH^{1\text{-}34}$ administration include transient hypercalcemia, hypercalciuria, and the development of antibodies to the peptide—all rather unusual events. Although osteosarcoma has been observed in mice receiving very high doses of PTH and $PTH^{1\text{-}34}$, no malignant disorders have been recorded in adults receiving either agent. The pediatric use of $PTH^{1\text{-}34}$ has been primarily limited to children with hypocalcemia due to a gain-of-function mutation in *CASR* and consequent hypercalciuric hypocalcemia, which is one form of familial isolated hypoparathyroidism.[24] An analog of PTHrP ($PTHrP^{1\text{-}36}$) that increases lumbar spine BMD in postmenopausal women with osteoporosis has been described but not further explored.[388,398] Future potential therapeutic agents for the management of low bone mass are those that would enhance the WNT/β-catenin signaling pathway of osteoblast differentiation and function such as substances that increase LRP5 activity, inhibit sclerostin or Dickkopf function, or enhance BMP, TGFβ, or vascular endothelial growth factor A (VEGF) signaling within mesenchymal stem cells directing their differentiation into osteoblasts.[388,399]

Osteogenesis Imperfecta

Osteogenesis imperfecta or "brittle bone disease" is a disorder of increased bone fragility due to low bone mass that varies in clinical severity from lethality in utero or perinatally to mildly increased susceptibility to fractures in later life and that may be transmitted as either autosomal dominant or autosomal recessive traits.[196,199] The original Sillence classification of four types of osteogenesis imperfecta based on clinical characteristics and disease course has been expanded to include at least 10 additional numbered types of this disorder and the identification of additional mutant genes to which the illnesses can be attributed (see Table 18-12B).[193,196,199,400,401] (The types of osteogenesis imperfecta are numbered in the order of their clinical description.) The hallmark of each type is increased bone fragility, but severity varies with type II being lethal in the perinatal period due to respiratory insufficiency as a consequence of multiple rib fractures that reduce chest volume and type I being a relatively benign form (discussed later); in decreasing order of severity, the categories are type II > type VIII ≥ type III > types IV, V, VI, VII > type I. In osteogenesis

imperfecta types I through IV, heterozygous loss-of-function mutations have been identified in one or the other of the two genes (*COL1A1*, *COL1A2*) encoding procollagen subunits α1(I) and α2(I), respectively, that intertwine to form collagen type I in bone, skin, ligaments, tendons, sclerae, and teeth.[193,196] (The triple helical structure of type I collagen is comprised of two collagen α1[I] [COL1A1] peptide and one collagen α2[I] [COL1A2] peptide, each of which is composed of triple repeats of glycine and two additional amino acids—often proline, hydroxyproline, or lysine.) Transmitted as an autosomal dominant trait, insertions, duplications, frameshift or point mutations within *COL1A1* or *COL1A2* reduce the amount of collagen synthesized or alter its structure and properties interfering with the development of a normal three-dimensional configuration, thus leading to decreased bone formation, low bone mass, and increased fracture risk (Figure 18-13). To a limited extent, the site of the mutations identified within *COL1A1* or *COL1A2* is related to the clinical phenotype of osteogenesis imperfecta types I through IV. Mutations that lead to a stop codon result in a truncated procollagen product that is rapidly degraded; thus, only normal collagen type I is produced but in reduced amounts. Lethal mutations in *COL1A1* are those that alter an amino acid with a branched or charged side chain and those within the binding sites of the collagen monomer for integrins, matrix metalloproteins, fibronectin, and cartilage oligomeric matrix protein and those that result in binding to and degradation of intact procollagen subunits.[193] Lethal mutations in *COL1A2* are those that interfere with its binding to proteoglycans. Mutations (Arg134Cys) in *COL1A1* may also be found in patients with classical Ehlers-Danlos syndrome (MIM 130000) of hyperextensible skin and laxity of ligaments of the spine and large and small joints. Children with clinical features of both osteogenesis imperfecta (osseous fragility) and Ehlers-Danlos syndrome have been described.[402] In these patients, the mutations have been concentrated within the first 90 amino acids of the helical region of collagen-α1(I) and prevent normal posttranslational removal of the procollagen amino-propeptide; although the mutant protein can be incorporated into collagen, the structural integrity of the product is impaired, as its fibrils are thin and weak.[403] Osteogenesis imperfecta types I-IV describe clinical forms of this disease associated with loss-of-function mutations in *COL1A1* or *COL1A2* that are transmitted in an autosomal dominant manner.

Osteogenesis imperfecta type I (MIM 166200) is an autosomal dominant disorder (new mutation in 33% of patients) due primarily to "functional null alleles"—the result of splicing defects or point mutations leading to insertion errors or truncation (*COL1A1*: Gly178Cys, Arg963Ter, IVS26DS), mutations that result in decreased transport of procollagen-α1(I) into the cytoplasm or its release into matrix—thereby modestly decreasing production of intact procollagen type I. Its clinical manifestations are relatively benign: intensely blue sclerae that are present at birth and persist throughout adulthood, modestly low bone mass, infrequent fractures with little deformity (however, 15% of affected children develop deformities and 24% kyphoscoliosis before 10 years of age), low normal adult stature, hearing loss in 50%, mitral valve prolapse in 18%, and rarely dentinogenesis imperfecta (osteogenesis imperfecta type IB). (Paradoxically, patients with mild osteogenesis imperfecta type I due to mutations in the procollagen type I carboxyl terminal propeptide cleavage sites [*COL1A1*, p.Asp1219Asn; *COL1A2*, p.Ala1119Thr] may have normal or increased lumbar spine BMD by both DEXA and QCT examinations

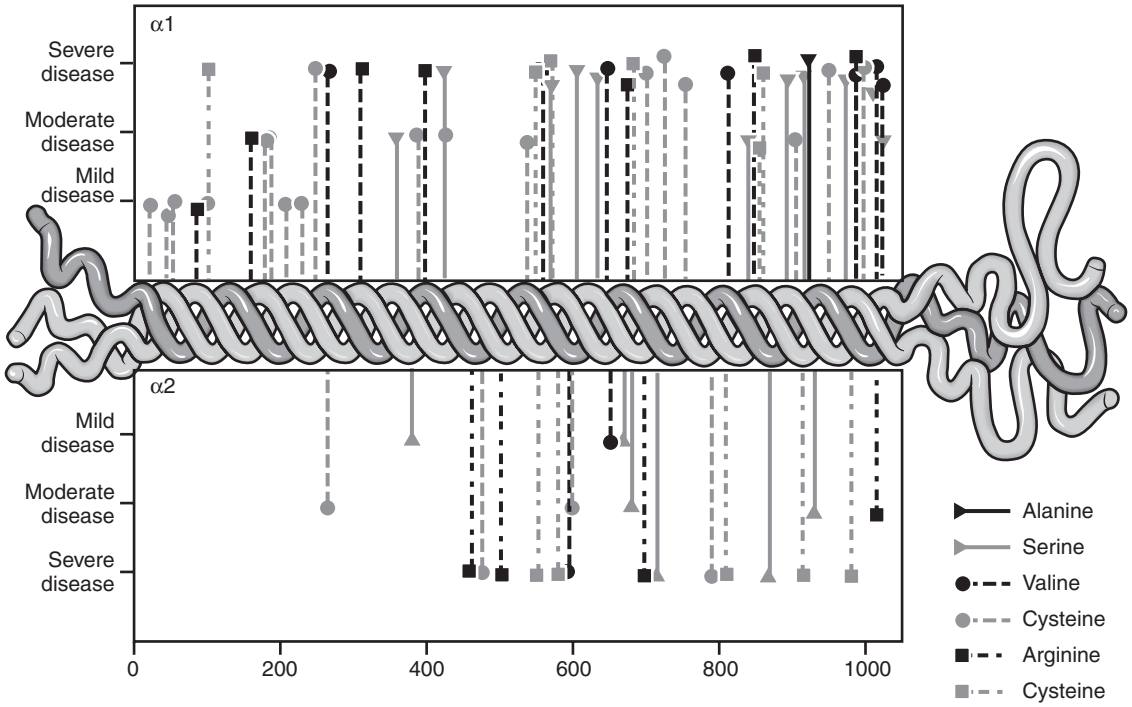

FIGURE 18-13 ■ Mutations in *COL1A1* and *COL2A1* that result in glycine substitutions associated with osteogenesis imperfecta of variable clinical severity. (From Prockop, D. J. (2005). Type II collagen and avascular necrosis of the femoral head. *N Engl J Med, 352,* 2268–2270.)

despite increased bone fragility.[404] Please see the discussion of osteogenesis imperfecta type XIII, presented later.) Mutations in *COL1A2* less frequently lead to the phenotype of osteogenesis imperfecta type I. Subjects with mutations in *COL1A1* more often have blue sclerae and taller stature than those with mutations in *COL1A2*. Osteogenesis imperfecta type II (MIM 166210) is a disorder that is lethal in the perinatal period or in early infancy. It is usually the result of de novo heterozygous mutations in *COL1A1* or *COL1A2* with alternative amino acid being substituted for glycine in the triple helical domains of the procollagen α1(I)/α2(I) chains (*COL1A1*: Gly94Cys, Gly391Arg, Gly1003Ser; *COL1A2*: Gly547Asp, Gly865Ser, Gly976Asp); these mutations lead to the synthesis of abnormal procollagen chains that bind to and thereby inactivate intact procollagen peptides in a dominant-negative manner severely curtailing the synthesis of intact collagen type I. Clinically, it is manifested by in utero fractures, long bone deformities, very little calvarial mineralization, and death due to respiratory insufficiency. Lethal phenotypes of osteogenesis imperfecta are also associated with homozygous loss-of-function mutations in *LEPRE*, the gene encoding prolyl 3-hydroxylase 1, *CRTAP*, encoding cartilage-associated protein, *PPIB*, encoding peptidyl-prolyl isomerase B, and *SERPINH1*, encoding serpin peptidase inhibitor (discussed later) (see Table 18-12B).[194] Osteogenesis imperfecta type III (MIM 259420) is an autosomal dominant trait due to point or frameshift mutations in *COL1A1* (Gly154Arg, Gly844Ser) or *COL1A2* (Gly526Cys). It is characterized by recurrent fractures leading to progressive bone deformities that are often apparent at birth, kyphoscoliosis, extreme short stature, blue sclerae that lighten with age, abnormal dentition (in 80% of children younger than 10 years of age), and hearing loss. Osteogenesis imperfecta type IV (MIM 166220) is an autosomal dominant disease usually associated with point mutations or small deletions in *COL1A2* (Gly586Val, Gly646Cys, Gly1012Arg) and occasionally in *COL1A1* (Gly175Cys, Gly832Ser). It is of variable severity with prolonged survival, mild to moderate bone deformities, short stature, normal sclerae, dentinogenesis imperfecta, and hearing loss.

Among the most important posttranslational modification of type I procollagen (a triple helix comprised of two pro-COL1A1 and one pro-COL1A2 chains) is hydroxylation of proline and lysine residues by prolyl and lysyl hydroxylases. Hydroxylation of proline residues at carbon 4 affords thermal stability, whereas hydroxylation of lysyl residues permits binding of carbohydrates (galactose or glucosyl-galactose) and the formation of cross-links within or between procollagen chains.[199] Hydroxylation of proline at carbon 3 in position 986 of COL1A1 and at position 707 of COL1A2 are especially critical for stability of the three-dimensional configuration of type I procollagen and its subsequent maturation to collagen type I.[199] Prolyl 3-hydroxylase 1 (P3H1, also termed *leprecan* and encoded by *LEPRE1*, MIM 610339) specifically hydroxylates carbon 3 of the proline residue at codon 986 in COL1A1 and at codon 707 in COL1A2, reactions that require interaction of P3H1 with cartilage-associated protein (CRTAP; MIM 605497) and peptidyl-proline (cis-trans) isomerase B (PPIB also termed cyclophilin B, MIM 123841); these proteins that also serve as chaperones for the movement of collagen from the endoplasmic reticulum.[199] *CRTAP* is expressed in the proliferative zone of developing cartilage and at the chondro-osseous junction. *Crtap* "knockout" mice develop an osteochondrodysplasia (kyphoscoliosis, rhizomelic shortening of the proximal segment of the limbs) and severe osteopenia, the latter due to reduced production and alteration in the quality of osteoid and consequent decreased rate of mineral deposition.[405] Mice deficient in *Crtap* are unable to 3-hydroxylate the proline residue near the carboxyl terminus of bone COL1A1 leading to increased hydroxylation of lysine residues and resultant abnormal structure of the collagen fibril—changes that result in defective mineralization of bone collagen type I. Nonhydroxylated proline at codon 986 in bone COL1A1 was demonstrated in 3 of 11 patients with a recessively transmitted lethal or severe osteogenesis imperfecta characterized by multiple fractures of the long bones resulting in rhizomelic shortening of the limbs with externally rotated and abducted legs, poorly mineralized calvaria and ribs, proptotic eyes, and white or light blue sclerae.[406] This proved due to homozygous or compound heterozygous loss-of-function mutations in *CRTAP*—frameshift (c.879delT), 16 bp duplication in exon 1, nonsense (Gly276Ter), missense (Met1Ile), splice donor site of exon 1 at the first intronic nucleotide (IVS1+1G ⇒ C)—that interfered with effective hydroxylation of the proline residue at codon 986 of bone procollagen α1(I). This disorder has been designated osteogenesis imperfecta type VII (MIM 610682). In other patients with osteogenesis imperfecta type VII, a homozygous mutation in *CRTAP* has been identified in which alteration of one nucleotide (c.472 - 1021C ⇒ G) generates a cryptic splice donor site that leads to inclusion of 73 bp of intron 1 into the genome of *CRTAP*, thus extending exon 2.[405] This mutation results in more rapid degradation of CRTAP and consequently leads to decreased 3-hydroxylation of proline 986 in bone COL1A1. Osteogenesis imperfecta type VII has been identified in a Native American population in northern Quebec. Clinically, it is an autosomal recessive disorder in which fractures are present at birth; often the frequency of fractures declines with advancing age, particularly after adolescence; the sclerae are slightly bluish; there is progressive skeletal deformation, which leads to rhizomelic shortening of the limbs and restricted ambulation.[407] Inactivating mutations in *CRTAP* can also result in a lethal form of osteogenesis imperfecta resembling that of type II.

The phenotype of osteogenesis imperfecta type VIII (MIM 610915) overlaps with those of types II/III; in addition to osseous fragility, it is associated with substantial growth retardation, white sclerae, and bulbous metaphyses. It is due to loss-of-function mutations in *LEPRE1* encoding P3H1.[408] Osteogenesis imperfecta type VIII occurs primarily in African-American and Middle Eastern subjects.[408-410] CRTAP and P3H1 mutually stabilize one another in the collagen prolyl 3-hydroxylation complex.[411] Loss-of-function mutations in *PPIB*, the gene encoding cyclophilin B, has been designated osteogenesis imperfecta type IX, an often lethal disorder in which osseous fragility is evident in utero (see Table 18-12B).[412-414]

Heterozygous mutations in *IFITM5* (encoding interferon-induced transmembrane protein-5 or bone-restricted ITIFM5-like protein, MIM 614757) result in osteogenesis imperfecta type V (MIM 610967), a fragile bone syndrome that is phenotypically similar to osteogenesis imperfecta type IV but whose phenotype is markedly variable (see Table 18-12B).[415-417] Distinguishing features of osteogenesis imperfecta type V are calcification of the interosseous membranes between radius and ulna and exuberant callous formation at fracture sites. Other clinical characteristics of type V osteogenesis imperfecta are autosomal dominant transmission, moderate to severe bone fragility (lumbar spine areal BMD Z scores range between −7.7 and −0.7), moderate to mild growth retardation (adult height Z scores vary from −8.7 to −0.1), dislocation of the radial head, white sclerae, and normal dental development. Histologically, there is irregular arrangement of lamellae. After excluding mutations in *COL1A1* and *COL1A2* in patients with autosomal dominantly transmitted osteogenesis imperfecta, several groups of investigators identified the common mutation in *IFITM5* by whole exome sequencing—a heterozygous c.-14C > T transition within its 5′ untranslated region.[415-417] This mutation is 14 bp upstream of the reference initiation codon and creates a new initiation signal that adds 5 amino acids (Met-Ala-Leu-Glu-Pro) to the amino terminus of IFITM5 increasing its length from 132 to 137 amino acids. IFITM5 is a protein that is abundantly expressed within osteoblast membranes during embryonic and postnatal development of the skeleton; it has amino and carboxyl extracellular termini, two transmembrane domains, and an intracellular helical domain. IFITM5 is an osteoblast differentiation factor that is involved in protein trafficking and folding; experimentally, loss of *IFITM5* results in decreased bone formation, particularly in utero.[418] The functional consequence (whether it is activating or inactivating) of the identified consistent mutation in *IFITM5* is uncertain at present.

Osteogenesis imperfecta type VI (MIM 610968) is also phenotypically similar to type IV. It is an autosomal recessive disorder due to loss-of-function mutations in *SERPINF1* (serpin peptidase inhibitor, clade F, member 1; MIM 172860) that is characterized clinically by severe bone fragility that first manifests after 6 months of age, excess unmineralized osteoid, and a "fish-scale" pattern of lamellation of bone matrix on microscopic examination consistent with a defect in bone mineralization.[199,419-421] Serpins are a family of serine protease inhibitors (first identified in retinal pigment epithelial cells). *SERPINF1* encodes pigment epithelium derived factor (PEDF), a peptide synthesized by chondrocytes, osteoblasts and osteoclasts that interferes with function of vascular endothelial growth factor (VEGF), a protein that enhances migration of osteoblasts and osteoclasts into cartilage; PEDF may regulate bone mineralization and increase synthesis of osteoprotegerin. Thus, loss-of-function mutations in *SERPINF1* may interfere with bone formation while increasing osteoclast generation and bone dissolution. Serum concentrations of PEDF are undetectable in patients with osteogenesis imperfecta type VI, providing a diagnostic tool for this illness.[422] Interestingly, patients with osteogenesis imperfecta type VI do not respond to treatment with bisphosphonates as well as do patients with other forms of this heterogeneous disease.

Osteogenesis imperfecta type X is an autosomal recessive disorder due to biallelic inactivating mutations in *SERPINH1* (serpin peptidase inhibitor, clade H, member 1; MIM 600943) encoding a multifunctional 418-amino-acid peptide designated collagen type 1 binding protein (CBP) 2 that is also termed heat shock protein (HSP) 47. Type X osteogenesis imperfecta is a severe disorder with fractures occurring throughout the skeleton that begins in utero.[199,423] CBP2/HSP47 is essential for cartilage organization, the formation of endochondral bone, and the fabrication and maintenance of the integrity of the triple helical structure of procollagen type I, its transcellular movement and secretion, and its resistance to proteolytic degradation.[423-425] Type XI osteogenesis imperfecta is transmitted as a severe autosomal recessive disorder that begins in infancy; affected patients have repeated long bone fractures and progress to wheelchair dependency in early childhood; they may or may not develop joint contractures but do not display dentinogenesis imperfecta.[426-428] It is due to inactivating mutations in *FKBP10* (FK506-binding protein 10; MIM 607063) encoding an endoplasmic reticular protein (FKBP65) that is also a chaperone for procollagen type I —one that is essential for hydroxylation of lysine in its telopeptide, a modification necessary for cross-linking, as well as its transcellular movement and secretion.[429] In the absence of functional FKBP65, procollagen type I accumulates in the endoplasmic reticulum of the osteoblast. Mutations in *FKB506* have also been recorded in patients with Bruck syndrome 1 (MIM 259450; pterygia, congenital contractures, fractures in infancy resulting in limb deformities, growth retardation, scoliosis), suggesting that osteogenesis imperfecta type XI and Bruck syndrome 1 are likely allelic disorders whose clinical manifestations depend on the mutation site and other modifying factors.[426,430] Osteogenesis imperfecta type XII is a moderately severe form of this disease characterized by multiple fractures in early infancy with short, bowed long bones and highly arched palate but normal teeth, hearing, and sclerae.[431] It is transmitted as an autosomal recessive disorder and is due to inactivating mutations in *SP7* (transcription factor specificity factor 7 or Osterix; MIM 606633). Osterix is a 431-amino-acid essential transcription factor for osteoblast differentiation and function and hence for both endochondral and intramembranous bone development; its expression is regulated by *RUNX2*.[432] Type XIII osteogenesis imperfecta is a disorder of moderate severity with multiple fractures annually, either borderline low or *elevated* bone mass by DEXA, substantial growth retardation, faintly blue sclerae, and normal teeth.[433,434] It is the result of biallelic inactivating mutations (Phe249Leu; c.34G>C) in *BMP1* (bone morphogenetic protein 1; MIM 112264). BMP1 is a multifunctional protein; one of its most important activities is as a procollagen type I C-terminal propeptide endoproteinase. Inactivation of *BMP1* impairs proteolytic removal of the carboxyl terminal propeptide from procollagen type I and the normal assembly of mature collagen type I fibrils. Interestingly,

this form of osteogenesis imperfecta is associated with either borderline low or even increased lumbar spine aBMD by DEXA despite which treatment with bisphosphonates has been clinically and radiographically useful.[433] In this regard, it should be noted that in patients with mild osteogenesis imperfecta type I due to mutations in the procollagen type I carboxyl terminal propeptide cleavage sites also have normal or increased lumbar spine BMD by both DEXA and pQCT examinations.[404] Type XIV osteogenesis imperfecta is a disorder of variable severity with fractures occurring in utero or during early childhood but with normal dentition, hearing, and sclerae that has been identified in Middle Eastern families.[435,436] It is an autosomal recessive disorder due to a homozygous inactivating mutation (deletion of exon 4) in *TMEM38B* (transmembrane protein 38B; MIM 611236) encoding the 291-amino-acid trimeric intracellular cation channel type B (TRICB). TRICB is one component of TRIC, a monovalent cation channel that is critical for the release of Ca^{2+} from intracellular storage sites such as the sarcolemma and endoplasmic reticulum and thus maintenance of cytosolic Ca^{2+} concentrations, a process necessary for normal cell differentiation, division, and function (including the osteoblast). Bruck syndromes type 1 (MIM 259450) and 2 (MIM 609220) are skeletal disorders marked by increased bone fragility and congenital joint contractures, the latter due to restricted fetal movements. Bruck syndrome type 2 is due to biallelic loss-of-function mutations in *PLOD2* (procollagen-lysine, 2-oxoglutarate 5-dioxygenase 2; MIM 601865), a lysyl hydroxylase.[437] Hydroxylation of collagen type I lysine residues is essential for the integrity of cross-linked collagen telopeptides and for the posttranslational attachment of galactose or glucosyl-galactose to collagen. A pathophysiologic classification of the various types of osteogenesis imperfecta is presented in Table 18-12C.

The clinical manifestations of osteogenesis imperfecta vary from mild (e.g., type I) to moderate (e.g., types IV, V, VI, VII, XIII, XIV), severe (e.g., types III, VII, VIII, IX, X, XI, XII), or lethal (e.g., types II, VII, VIII, IX, X).[199,438] Radiographic findings in subjects with osteogenesis imperfecta include, in addition to diffusely low bone mass, thin cortices, metaphyseal flaring, fractures and bone deformities resulting there from, wormian skull bones (frequent but not pathognomonic of osteogenesis imperfecta), platybasia that may compress overlying hindbrain, vertebral compression, and a triradiate pelvis.[193] Bone densitometry reveals decreased mineralization, the extent of which correlates to a degree with clinical manifestations. The diagnosis of osteogenesis imperfecta is established by clinical criteria and confirmed by genotyping of *COL1A1* or *COL1A2* or other pertinent gene(s), although failure to detect a genetic mutation does not necessarily rule out this disorder. Undetectable serum levels of PEDF are indicative of osteogenesis imperfecta due to inactivation of *SERPINF1*.[422] Occasionally, biopsy of the iliac crest and histologic examination of the bone may be necessary for subclassification of the disorder. Determination of the rate of synthesis and forms of procollagen secreted by dermal fibroblasts in vitro permits identification of the forms and relative amounts of collagen subunits and intact proteins being synthesized, but in general gene analyses have superceded this procedure.[439,440] Osteogenesis imperfecta type II can be identified prenatally by fetal ultrasonography; types I, III, and IV can be determined prenatally by analysis of collagen synthesized by cells cultured from chorionic villus biopsies and by analysis of the *COLA1A*, *COLA12*, *CRTAP*, or other genes. Included in the differential diagnosis of recurrent fractures in children are child abuse, various forms of rickets including hypophosphatasia, the McCune-Albright syndrome of fibrous dysplasia (MIM 174800), juvenile Paget disease, and juvenile osteoporosis.

TABLE 18-12C **Pathophysiologic Classification of Disorders of Collagen Formation Associated with Osteogenesis Imperfecta**

Site	Gene(s)	OI Types
Osteoblast and bone formation	*IFITM5*	V, IV
	SERPINF1	VI, IV
	SP7	XII, IV
Synthesis of collagen type I subunits	*COL1A1*	I, II, III, IV
	COL1A2	
Post-translational processing of collagen type I		
Chaperoned movement	*SERPINH1*	X, III
	FKBP10	XI, III, Bruck syndrome 1
Prolyl-3 hydroxylation	*LEPRE1*	VIII, II
	CRTAP	VII, II
	PPIB	IX, II
Lysyl hydroxylation	*PLOD2*	Bruck syndrome 2
Procollagen type I C-terminal propeptide endoproteinase	*BMP1*	XIII, III
Uncertain	*TMEM38B*	XIV

Modified from Rohrbach M, Giunta, C. (2012). Recessive osteogenesis imperfecta: clinical, radiological, and molecular findings. Am J Med Genet Part C 160C:175-189.

The basic management of patients with osteogenesis imperfecta is directed to prevention of fractures to the extent possible and to the treatment of fractures that do occur by sound orthopedic procedures and by orthopedists familiar with this disorder. Expert orthopedic management is essential for the child with osteogenesis imperfecta, as the use of intramedullary rods for correction of long bone deformities and for their linear growth and the proper correction of scoliosis require substantial experience.[439] Rehabilitative services and physical therapy to improve muscle strength and mobility within the constraints of bone fragility are to be encouraged as are protected ambulation and exercises such as swimming.[193] The use of bisphosphonates for the management of infants, children and adolescents with osteogenesis imperfecta types I, III, and IV has been of substantial benefit. Patients with these disorders have often responded symptomatically (decreased musculoskeletal pain, increased mobility) to the intermittent intravenous administration of a bisphosphonate (e.g., pamidronate) and bone mass has increased, but the effect of bisphosphonates on the fracture rate is uncertain.[439,441] It has been recommended that bisphosphonates be employed in infants with osteogenesis imperfecta with congenital and recurrent fractures, deformities of the long bones, and decreased bone mass. Infants as young as 2 months of age have safely tolerated 4-hour intravenous infusions of pamidronate (0.5 mg/kg/day for 3 consecutive days every 6 to 8 weeks) realizing clinical improvement such as decline in bone pain (perhaps a placebo effect), an increase in lumbar vertebral BMD of 86% to 227%, and a decrease in fracture rate after 1 year of therapy.[193] Bisphosphonate administration is also recommended for children with OI and recurrent fractures of the extremities or vertebral collapse that is symptomatic in concert with demonstrated decreased bone mineralization.[442] In children (3 to 16 years of age), pamidronate administered as a 4-hour infusion (1.5 to 3 mg/kg/day) for 3 consecutive days every 4 months resulted in increases in lumbar spine BMD of 42% per year, metacarpal cortical width of 27% per year, and vertebral size as well as a decline in fracture rate, and symptomatic improvement. During 2 to 4 years of intravenous pamidronate administration, increase in vertebral (trabecular) bone mass and size are accompanied by a decline in the extent of vertebral compression and fewer compressed vertebrae than in untreated patients.[443] In the iliac crest, bisphosphonates increase cortical bone thickness and trabecular number but not trabecular thickness; in metacarpals bisphosphonates enhance cortical thickness. However, in treated subjects the relative risk of long bone fracture after treatment with bisphosphonates is modest at best.[193] In older children and adolescents with osteogenesis imperfecta, bisphosphonates are employed if the patient has more than two fractures in 1 year and bone mass is low.[439] Among the complications of bisphosphonate therapy are transient hypocalcemia and a "flulike" reaction of fever, vomiting, and rash after the first exposure managed symptomatically. Administration of bisphosphonates is also accompanied by transient hypocalcemia, increased levels of PTH and calcitriol, and decreased levels of markers of bone turnover.[441] Near maximal benefits of bisphosphonates on lumbar vertebral aBMD (DEXA) and on mean cortical width, cancellous bone volume, and trabecular bone formation rate by histomorphometric analysis of iliac crest bone biopsies are achieved within the first 2 to 4 years of treatment with little further change with more prolonged therapy.[444] Because of the accumulation and persistence of bisphosphonates in bone and their long-term effects, it is recommended that these agents be administered to patients with osteogenesis imperfecta for no more than 2 to 4 years.[445] In addition to pamidronate, children with osteogenesis imperfecta have been treated with intravenous infusions of zolendronate every 4 to 6 months or with oral residronate or alendronate.[441] Transplantation of mesenchymal stem cells or bone marrow stromal cells have been undertaken in patients with osteogenesis imperfecta, but this is an experimental therapy, as are specific-gene replacement and mutation silencing strategies.[446]

Fibrous Dysplasia

Fibrous dysplasia is a usually benign fibro-osseous lesion that involves long bones, ribs, and skull; it may be monostotic, polyostotic, or panostotic.[447,448] It may be an isolated abnormality but characteristically occurs in patients with the McCune-Albright syndrome (MIM 174800) in association with very large, irregularly edged café-au-lait pigmentations and various endocrinopathies including isosexual precocious puberty, hypersomatotropism, thyrotoxicosis, and hyperadrenocorticism, as well as dysfunction in many other tissues (heart, liver, pancreas). Bone and skin lesions are often on the same side of the body.[448] Fibrous dysplasia is due to mosaicism for postzygotic, early embryonic, somatic, gain-of-function missense mutations (Arg201 to Cys, His, Ser, Gly; Gln227Leu) in *GNAS*, the gene encoding the α subunit of the Gs-protein that render Gsα constitutively active by prolonging its biologic life.[449] The extent and severity of disease are determined by the point in fetal development at which the mutation occurs and its tissue distribution. The mutations result in loss of intrinsic guanosine triphosphatase activity within the Gsα subunit; thus, the stimulatory effect of Gsα on adenylyl cyclase is extended thereby increasing the generation of cyclic AMP. Among the targeted signaling pathways of cyclic AMP is that involving WNT/β-catenin in osteoblast progenitor cells.[448] In response to excess cyclic AMP, clones of mutated mesenchymal preosteoblasts proliferate, but their differentiation to mature osteoblasts is incomplete and their secreted matrix is abnormal; continued expansion of osteoprogenitor cells in bone marrow leads to local fibrosis. As the osteogenic cells increase in number, they steadily erode contiguous bone. These lesions can also synthesize FGF23 and thus lead to hyperphosphaturia, hypophosphatemia, and excess unmineralized osteoid and a rickets-like clinical state. Fibrodysplastic lesions are initially silent, whereas osteoclasts at the periphery of the lesions actively compress and thin bone cortices, ultimately resulting in bone pain and pathologic fractures of the long bones, particularly the proximal femoral metaphyses. Children between 6 and 10 years of age have the highest fracture rate (0.4 fractures per year). Within the skull base and facial bones, expansion of fibrous dysplastic lesions leads to disfiguration and compression of cranial

nerves. Radiographically, the fibrodysplastic lesion is viewed as a "cystlike" medullary structure with a "ground-glass" consistency without a trabecular pattern.[448] Histologically, there are abundant immature bone marrow stromal cells, incompletely differentiated osteoblasts, irregularly formed bone trabeculae that may resemble Chinese characters, many undermineralized osteoid seams characteristic of osteomalacia, and islands of cartilage. The clinical manifestations of fibrous dysplasia depend on the sites and extent of bone involvement and associated endocrinopathies. Diagnosis of fibrous dysplasia is based on clinical characteristics and confirmation of the genetic mutation in *GNAS*. In addition to managing the multiple endocrinopathies and organ defects, attention must be paid to the osseous lesions. Fractures are repaired by standard techniques including intramedullary nailing when indicated; occasionally it may be feasible to evacuate a fibrodysplastic lesion surgically and to fill the cavity with bone grafts. In children with fibrous dysplasia, the bisphosphonate pamidronate has been useful in ameliorating bone pain but not the skeletal lesions. In a 9-year-old boy with a rapidly growing femoral mass due to fibrous dysplasia (and a somatic mutation in *GNAS*), treatment with denosumab led to a rapid decline in the rate of tumor growth and lowered the levels of bone turnover markers.[450] However, the child developed hypocalcemia and secondary hyperparathyroidism, requiring supplemental calcium, phosphate, and calcitriol. Cessation of denosumab was marked by a rebound increase in values of bone turnover markers and hypercalcemia.

High Bone Mass

Abnormally increased bone mass is the consequence of disruption of the normal equilibrium between the processes of bone formation and resorption. Thus, it may be due to a decrease in the rate of bone resorption as a result of a paucity or abnormal function of osteoclasts or to an increase in the rate of bone formation due to excessive osteoblast activity. An increase in cortical bone width is termed *hyperostosis*; thickening of trabecular bone is termed *osteosclerosis*.[8] Tables 18-13A and B list selected dysplastic, metabolic, and other diseases associated with increased bone mass and ectopic bone formation in children and adolescents. Failure of osteoclast-mediated bone resorption leads to osteopetrosis that may be associated with a large number of poorly functioning osteoclasts ("osteoclast-rich" osteopetrosis) or with a normal number or paucity of osteoclasts ("osteoclast-poor" osteopetrosis).[300] Impaired development of osteoclasts results in "osteoclast-poor" osteopetrosis and is attributable to mutations in genes encoding RANKL (*TNFSF11*) and RANK (*TNFRSF11A*). *IKBKG* is an X-linked gene that encodes a subunit of the inhibitor of kappa B (IκB)

TABLE 18-13A **Disorders of Bone Mineralization: High Bone Mass**

I Decreased Bone Resorption

A Osteopetrosis

1 Autosomal recessive (infantile/intermediate)
  a Osteoclast-rich/normal (*TCIRG1, CLCN7, OSTM1, CA2, PLEKHM1, SNX10*)
  b Osteoclast poor (*TNFSF11, TNFRSF11A*)
2 Autosomal dominant (adult) (*LRP5, CLCN7*)
3 X-linked (*IKBKG*)
4 Pycnodysostosis (*CTSK*)
5 Osteopetrosis with neuroaxonal dystrophy
6 Drug-induced: bisphosphonates

II Increased Bone Formation

A Activating Mutations of LRP

1 Autosomal dominant high bone mass (*LRP5*)
2 Endosteal osteosclerosis (van Buchem disease type 2) (*LRP5*)
3 Sclerosteosis type 2 (*LRP4*)

B Inactivating Mutations of SOST

1 Sclerosteosis type 1
2 Van Buchem disease type 1

C Dysplasias

1 Dysosteosclerosis
2 Infantile cortical hyperostosis (Caffey disease) (*COL1A1*)
3 Juvenile Paget disease (*TNFRSF11B*)
4 Metaphyseal dysplasia (Pyle disease)
5 Osteopoikilosis (*LEMD3*)
6 Progressive diaphyseal dysplasia (Camurati-Engelmann disease) (*TGFB1*)
7 Tubular stenosis, type 1 (Kenny-Caffey syndrome) (*TBCE*)

D Metabolic Disorders

1 Fluorosis
2 Heavy metal poisoning
3 Hypervitaminosis A, D
4 Hypoparathyroidism, pseudohypoparathyroidism
5 Milk-alkali syndrome
6 Renal osteodystrophy

E Ectopic Calcification/Bone Formation

1 Tumoral calcinosis, normophosphatemic, familial (*SAMD3*)
2 Tumoral calcinosis, hyperphosphatemic, familial (*GALNT3, FGF23, KL*)
3 Fibrodysplasia ossificans progressiva (*ACVR1*)
4 Progressive osseous heteroplasia (*GNAS*)

F Other

1 Hepatitis C–associated osteosclerosis
2 Ionizing radiation
3 Sarcoidosis
4 Sickle cell disease (*HBB*)
5 Tuberous sclerosis (*TSC1*)
6 Sickle cell disease
7 Leukemia

Modified from Whyte, M. P. (2008). Sclerosing bone disorders. In C. J. Rosen (Ed.), Primer on the metabolic bone diseases and disorders of mineral metabolism *(7th ed.) (pp. 412–423). Washington, DC: American Society of Bone and Mineral Metabolism.*

TABLE 18-13B **Gene Mutations Associated with Osteopetrosis and Increased Bone Mass**

Disease Type MIM	Gene Chromosome	Clinical Manifestations	Pathophysiology
Osteoblast Mediated			
Autosomal dominant osteopetrosis type I 607634	*LRP5*: Low-density lipoprotein receptor-related protein 5 11q13.2 603506	Endosteal hyperostosis, osteosclerosis, van Buchem disease type 2; not associated with increased fracture risk	Monoallelic gain-of-function mutations in a transmembrane WNT coreceptor expressed on plasma membrane of osteoblasts and osteocytes enhance WNT/β-catenin mediated osteoblast proliferation and function
Osteoclast Mediated			
Autosomal dominant osteopetrosis type II 166600	*CLCN7*: Chloride channel 7 16p13.3 602727	Osteopetrosis: intermediate severity: sclerosis of skull, "rugger jersey" spine, pelvis; fractures; dental abscesses	Monoallelic inactivating mutations of the α3 subunit of a channel protein that transports Cl^- into subosteoclastic lacunae impede hydroxyapatite dissolution (see autosomal recessive osteopetrosis types IV,V,VIII)
Autosomal recessive osteopetrosis type I 259700	*TCIRG1*: T cell immune regulator 1 11q13.2 604592	Osteopetrosis: severe infantile malignant form; hepatosplenomegaly, hydrocephalus, hypocalcemia	Inactivating mutations of a subunit of vacuolar proton pump that transports H^+ into the subosteoclastic lacunae disrupt dissolution of hydroxyapatite
Autosomal recessive osteopetrosis type II 259710	*TNFSF11*: Tumor necrosis factor ligand superfamily, member 11 13q14.11 602642	Osteopetrosis: moderate severity	Loss-of-function mutations in RANKL decrease RANK-mediated osteoclastogenesis
Autosomal recessive osteopetrosis type III 259730	*CA2*: Carbonic anhydrase II 8q21.2 611492	Osteopetrosis: moderate severity; renal tubular acidosis, intracranial calcification	Loss-of-function mutations of an osteoclast enzyme that generates protons (H^+) from carbonic acid that are secreted into subosteoclast lacunae impair dissolution of hydroxyapatite
Autosomal recessive type IV 611490	*CLCN7*: Chloride channel 7 16p13.3 602727	Osteopetrosis: severe, infantile malignant form; neurodegeneration and retinal atrophy	Biallelic inactivating mutations in the α3 subunit of a channel protein that transports Cl^- into the subosteoclastic lacunae severely impair dissolution of hydroxyapatite (see autosomal dominant type II and autosomal recessive type V)
Autosomal recessive osteopetrosis type V 259720	*OSTM1*: Osteopetrosis-associated transmembrane protein 1 6q21 607649	Osteopetrosis: severe infantile malignant form; retinal and neural dysplasia	Inactivating mutations in OSTM1, a cofactor with CLCN7 in a molecular complex that cooperatively enables transport of Cl^- from the osteoclast into the subosteoclastic lacuna, impair dissolution of hydroxyapatite (see autosomal recessive type IV)
Autosomal recessive osteopetrosis type VI 611497	*PLEKHM1*: Pleckstrin homology domain-containing protein, family M, member 1 17q21.3 611466	Osteopetrosis: intermediate severity; Erlenmeyer flask deformities of long bones	Inactivating mutations of a protein that may affect vesicular transport within the osteoclast and the attachment of osteoclast to bone
Autosomal recessive osteopetrosis type VII 612301	*TNFRSF11A*: Tumor necrosis factor receptor superfamily, member 11A 18q21.33 603499	Osteopetrosis: severe; with hypogammaglobulinemia in some patients	Inactivating mutations of RANK decrease NFκB-mediated osteoclastogenesis and osteoclast function

Autosomal recessive osteopetrosis type VIII 615085	*SNX10*: Sorting nexin 10 7p15.2 614780	Osteopetrosis: severe; with macrocranium, optic atrophy	Inactivating mutations may impair movement of TCIRG1 to the osteoclast's ruffled border and secretion of H^+ into the subosteoclastic lacuna
X-linked osteopetrosis 300301	*IKBKG*: Inhibitor of kappa light polypeptide gene enhancer in B cells, kinase of, gamma Xq28 300248	Osteopetrosis: with immunodeficiency, lymphedema, anhidrotic ectodermal dysplasia	Also termed NEMO (NFκB essential modulator): inactivating mutations of this component of IκB kinase complex decrease NFκB-mediated osteoclastogenesis and osteoclast function
Pycnodysostosis 265800	*CTSK*: Cathepsin K 1q21.3 601105	Osteosclerosis: skull, maxilla, phalanges, bone fragility	Biallelic loss-of-function mutations in an osteoclast lysosomal cysteine proteinase secreted into subosteoclast lacunae impair degradation of bone matrix
Osteoblast Mediated			
van Buchem disease 239100	*SOST*: Sclerostin 17q21.31 605740	Osteosclerosis: increased thickness of skull, mandible, ribs, long bones; leads to cranial nerve insults: impaired vision, hearing, facial movement	Biallelic loss of a specific downstream 3′ regulatory element of *SOST* transcription decreases inhibition of WNT/β-catenin mediated osteoblast differentiation and function
Sclerosteosis 1 269500	*SOST:* Sclerostin 17q21.31 605740	Severe, progressive generalized skeletal osteosclerosis and hyperostosis; increased intracranial pressure; loss of vision, hearing, facial movement; syndactyly of second and third fingers	Biallelic loss-of-function mutations in *SOST* decrease inhibition of WNT/β-catenin mediated osteoblast differentiation and function
Sclerosteosis 2 614305	*LRP4*: Low density lipoprotein receptor-related protein 4 11p11.2 604270	Osteosclerosis and hyperostosis of skull and long bones; impaired hearing, facial movement; syndactyly, dysplastic nails	Mono- or biallelic loss-of-function mutations decrease sclerostin-mediated inhibition of WNT/β-catenin stimulated osteoblast differentiation and function
Progressive diaphyseal dysplasia (Camurati-Engelmann disease) 131300	*TGFB1*: Transforming growth factor, beta-1 19q13.2 190180	Osteosclerosis of diaphyses of long bones; limb pain; disturbed gait	Monoallelic mutations lead to constitutive activation of TGFβ1, stimulation of bone formation, and repression of bone resorption
Osteopoikilosis 166700	*LEMD3*: LEM domain-containing protein 3 12q14.3 607844	Osteosclerotic foci in metaphyses and epiphyses of long bones, pelvis, scapula that are symmetrical but unequal; subcutaneous collagen containing nodules	Monoallelic loss-of-function mutations in a nuclear membrane protein that modulates signal transduction by both BMPs and TGFβ
Osteopathia striata 300373	*AMER1/FAM123B*: Family with sequence similarity 123, member B Xq11.2 300647	Dense linear striations that course vertically within the long bones, fan-shaped striations in the iliac bones, sclerosis of skull with compromise of cranial nerve function	Inactivation of an X-linked protein that enhances degradation of β-catenin, its loss extends WNT/β-catenin stimulated osteoblast maturation and function,

Modified in part from Stark, Z., & Savarirayan, R. (2009). Osteopetrosis. Orphanet J Rare Dis, *4, 4, doi: 10.1186/1750-1172-4-5; Ihde, L. L., Forrester, D. M., Gottsegen, C. J., et al. (2011). Sclerosing bone dysplasias: review and differentiation from other causes of osteosclerosis.* RadioGraphics, 31, *1865–1882.*

kinase complex that is also essential for activation of NFκB and osteoclastogenesis. Despite being present in normal number or in abundance ("osteoclast-rich" osteopetrosis), osteoclast activity may be reduced because of decreased synthesis of acid (due to loss-of-function mutations in *CA*, the gene encoding carbonic anhydrase), impaired production of ion channels that transport H^+ and Cl^- into the subosteocytic lacunae (channel proteins encoded by *TCIRG1* or its cofactor *OSTM1* and *CLCN7*, respectively), or subnormal generation of proteinases such as cathepsin K (due to inactivating mutations in *CTSK*). Excessive deposition of bone mineral due to increased osteoblast function may be a consequence of decreased inhibition of the WNT/β-catenin signal transduction pathway due to loss-of-function mutations in *LRP4* or *LRP5* (encoding low-density lipoprotein receptor-related proteins 4 and 5, respectively) or *SOST* (encoding sclerostin). Interestingly, in patients with inactivating mutations in *LRP5* and autosomal dominant osteopetrosis type I (see Table 18-13B), there is also a paucity of osteoclasts.[300]

Osteopetrosis or "marble bone disease" is a group of dominant or recessive heritable disorders manifested by increased bone mineralization with heterogeneous clinical manifestations including increase osseous fragility that vary in severity from lethality to radiographic skeletal changes primarily.[8,451] Histopathologically, bone in the majority of forms of osteopetrosis is characterized by quiescent osteoclasts—either increased, normal, or few in number—and retained "islands" of calcified cartilage formed during endochondral ossification (primary spongiosa) due to failure of reabsorption of immature bone.[8] Although densely packed with mineral, osteopetrotic bone is actually quite fragile because the abnormality in bone remodeling due to decreased osteoclastic bone resorption leads to the incorporation of weak calcified growth plate cartilage into bone and delays the repair of microfractures. Radiographically, osteopetrosis is characterized by a diffuse increase in bone mass involving both cortical and trabecular bone, diaphyseal/metaphyseal widening with an "Erlenmeyer flask" appearance, alternating bands of sclerotic and lucent bone at the ends of the long bones, iliac crest, and vertebrae, sclerotic changes at the base of the skull, narrow medullary cavities, and pathologic fractures.[8] Cranial computed tomography often reveals narrowing of the bony canals through which cranial nerves (II, III, IV, VII, VIII) pass. Although, classically, three clinical forms of osteopetrosis were identified—infantile malignant, intermediate, and adult—as knowledge of the genetic mutations responsible for the disease have been delineated this classification has been replaced by one that identifies its mode of transmission (autosomal dominant or recessive) and in accord with the responsible mutated gene (see Tables 18-13A and B). Thus, the infantile/malignant form of osteopetrosis (MIM 259700) may be due to biallelic mutations in *TCIRG1*, *CLCN7*, or *OSTM1*—genes encoding osteoclast H^+ and Cl^- transport channel proteins that enable the osteoclast to secrete acid into the lacunae to dissolve hydroxyapatite, the mineral phase of bone. A severe form of osteopetrosis associated with hypogammaglobulinemia is attributable to deleterious variations in *TNFRSF11A*. Forms of osteopetrosis of intermediate severity are the result of mutations in *TNFSF11*, *CA*, *PLEKHM1*—genes encoding RANKL, carbonic anhydrase, and a protein that is involved with vesicular transport within the osteoclast and the attachment of osteoclast to bone, respectively. Activating mutations in *LRP5* and heterozygous inactivating variations in *CLCN7* are associated with osteopetrosis of mild to intermediate severity that are transmitted as autosomal dominant characteristics.

The infantile/malignant form of osteopetrosis is an autosomal recessive disorder (Albers-Schonberg disease) with attenuated growth particularly of the limbs, delayed development, increased fracture rate, and failure of tooth eruption. Bony overgrowth leads to macrocephaly, maldevelopment of the paranasal sinuses, and symptomatic nasal "stuffiness." Narrowing of cranial foramina compromises cranial nerve function (II, III, VII, VIII) with consequent blindness and deafness. Decrease in bone marrow volume leads to depressed intramedullary hematopoiesis, anemia, and leukopenia partially compensated by extramedullary hematopoiesis and ensuing hepatosplenomegaly with consequent increased susceptibility to infection and hemorrhage. Retention of teeth within the sclerotic jaw leads to recurrent and persistent mandibular and maxillary osteomyelitis. Physical examination reveals short stature, macrocephaly, frontal bossing, and small facial features. Osteopetrotic neonates and infants are often hypocalcemic (because of inability to reabsorb calcium deposited in bone) with secondary hyperparathyroidism and elevated calcitriol values; levels of serum acid phosphatase and the brain isoenzyme of creatine kinase are also increased.[7,8] Death usually occurs, often within the first decade of life, due to sepsis, anemia, or hemorrhage. Autosomal recessive osteopetrosis may be due to biallelic mutations in the α3 subunit of the osteoclast's vacuolar proton pump (*TCIRG1*), its chloride channel (*CLCN7*), the osteopetrosis-associated transmembrane protein-1 (*OSTM1*), or a protein that guides TCIRG1 to the osteoclast's ruffled membrane (*SNX10*) (discussed later). Biallelic mutations in *TNFRSF11A* encoding RANK give rise to a severe form of osteopetrosis often in association with hypogammaglobulinemia.[452]

The intermediate clinical form of osteopetrosis is also transmitted as an autosomal recessive trait and is associated with short stature, macrocephaly, recurrent fractures, variable compromise of cranial nerve function, abnormal dental development predisposing to osteomyelitis of the mandible or maxilla, and anemia. Pathogenetically, it represents the variable penetrance of one of the genetic mutations that may be associated with the infantile form of osteopetrosis, predominantly of *CLCN7*, but also of *CA*, *TNFSF11*, and *PLEKHM1*. Mutations in *TNFSF11* encoding RANKL also result in an osteopetrosis of moderate severity. There are two clinical and radiographic forms of autosomal dominant osteopetrosis: type I (MIM 607634) is characterized by an enlarged and dense cranial vault and diffuse vertebral sclerosis and is related to activating mutations of *LRP5*; it is not associated with an increase in fracture rate as bone strength is actually increased; type II (MIM 166600) is typified by thickening of the vertebral end plates resembling "bone within bone" and resulting in a "rugger jersey spine" and sclerotic

bands of bone in the pelvis and base of the skull. It is a variant of Albers-Schonberg disease that results from heterozygotic loss-of-function mutations in *CLCN7*.[8] Affected subjects manifest cranial nerve compromise (16%), mandibular and nonmandibular osteomyelitis (19%), osteoarthritis of the hip (27%), and fractures (78%). Clinical evidence of the disease tends to worsen over time. However, the expression of the trait is variable. Thus, one third of carriers of an inactivating mutation in *CLCN7* have no radiographic or clinical manifestations, although they do have significantly higher BMD than do subjects with the wild-type gene.[453] In one quarter of clinically apparent patients with a heterozygous loss-of-function mutation in *CLCN7*, the expression of illness (fractures, osteomyelitis, compromised vision) is identifiable at birth or early in infancy or childhood. Patients with radiologic/clinical manifestations of this disorder have elevated serum concentrations of tartrate-resistant acid phosphatase and the BB isoform of creatine kinase elaborated by osteoclasts; these values are normal in unaffected carriers.[8]

Genetic mutations that impede resorption of bone in osteopetrotic subjects are related to abnormalities in osteoclastogenesis or osteoclast function—particularly the efficiency of acidification of the resorption lacuna beneath the osteoclast's ruffled membrane and mineral dissolution or enzymatic degradation of organic bone matrix. *TNFSF11* encodes RANK-ligand (RANKL), a 317-amino-acid transmembrane protein expressed on the surface of stromal cells and osteoblasts that interacts as a trimer with its receptor (RANK encoded by *TNFRSF11A*), a plasma membrane protein expressed by osteoclast precursor cells to form a heterohexameric complex that stimulates NFκB and thereby induces osteoclastogenesis.[454] Inactivating mutations in *TNFSF11* and *TNFRSF11A* result in impaired osteoclast formation and thus "osteoclast-poor" osteopetrosis. Loss-of-function variations in the structure of RANKL associated with osteopetrosis include a missense mutation (Met199Lys) and 2-bp (828delCG) and 5-bp (intron 7 -532+4_532+8) deletions of *TNFSF11* (Figures 18-14A, 14B).[455] Patients with osteopetrosis due to inactivating mutations in *TNFSF11* do not respond to hematopoietic stem cell transplantation because the abnormality in osteoclastogenesis is extrinsic to the osteoclast cell line; because recombinant RANKL protein can transform the monocytes of affected patients into functioning osteoclasts in vitro, a potentially alternative therapeutic avenue may be available.[455] Biallelic missense (Gly53Arg, Arg 170Cys), nonsense (Trp244Stop, Gly280Stop), and insertion loss-of-function mutations in the extracellular domain of RANK also impair binding to RANKL and consequent stimulation of NFκB and osteoclastogenesis.[305,452] Many patients with inactivating mutations in TNFRSF11A also develop impaired B lymphocyte function and hypogammaglobulinemia.[307] Hematopoietic stem cell transplantation is curative in osteopetrotic subjects with deleterious mutations in *TNFRSF11A*; as anticipated, monocytes from these subjects are functionally unresponsive to recombinant RANKL and to macrophage-colony stimulating (M-CSF) proteins in vitro.[452] Inactivating mutations in *IKBKG*, encoding the inhibitor of the kinase of kappa light polypeptide gene enhancer in B cells (gamma subunit), alternatively termed NFκB essential modulator (NEMO), also impair NFκB generation and osteoclastogenesis resulting in the syndrome of osteopetrosis, lymphedema, anhidrotic ectodermal dysplasia, and immunodeficiency (OL-EDA-ID, MIM 300301).[456] *IKBKG* is located on the long arm of the X chromosome, and thus its loss is transmitted as an X-linked trait. IKBKG is a 419-amino-acid component of the IκB kinase complex that activates NFκB. The co-association of osteopetrosis and juvenile xanthogranuloma has also been recorded in a neonate with a mutation in *PLEKHM1*.[457]

Carbonic anhydrase II (one of several zinc metalloisoenzymes) is a protein that is expressed in osteoclasts, erythrocytes, brain, and kidney; it regulates the formation of carbonic acid from water and carbon dioxide ($CO_2 + H_2O \Rightarrow H_2CO_3$) that then dissociates to form proton/hydrogen (H^+) and bicarbonate (HCO_3^-) ions. Loss-of function homozygous or compound heterozygous (Lys17Glu, Tyr40Ter, His107Tyr, Asn252Asp) mutations in *CA2* lead to autosomal recessive osteopetrosis that presents in childhood with failure to thrive, short stature, visual impairment, and developmental delay in association with mild proximal and severe distal renal tubular acidosis, cerebral calcifications within the cortex and basal ganglia, and osteopetrosis with increased fracture risk.[8] Osteopetrosis is of modest severity and usually nonprogressive; it may even improve at puberty. Bicarbonate may be employed to normalize acid-base balance. After generation by carbonic anhydrase II, H^+ is extruded from the osteoclast into the subobsteoclastic resorption lacuna through transporters and proton pumps. *TCIRG1* (T cell immune regulator 1) encodes an 822-amino-acid, 116 kDa protein that is a subunit of the osteoclast's vacuolar proton pump (H^+-ATPase). (By alternative splicing, this gene also encodes a 614 amino acid protein—TIRC7 —that is essential for activation of T lymphocytes.) Biallelic inactivating (missense, nonsense, deletion, insertion, splice site) mutations in *TCIRG1* whose loss impairs transport of H^+ and thus decreases bone mineral resorption have been found in 50% of subjects with the neonatal/infantile form of lethal osteopetrosis (MIM 259700).[458,459] TCIRG1 may be guided to the osteoclast's ruffled membrane above the subosteoclastic lacuna by the product of *SNX10*; a biallelic mutation (Arg51Gln) of *SNX10* also results in infantile malignant osteopetrosis.[460] Osteoclasts in this disorder are distinguished by the large number of cytoplasmic vesicles they contain. Loss-of-function mutations in *CLCN7*, a chloride channel expressed in the ruffled membrane of the activated osteoclast and its lysosomes, also impair acidification of the subosteoclastic resorption space and hence mineral dissolution.[461] Heterozygotic inactivating mutations (Arg767Trp; 2 bp deletion, 1423AG) of *CLCN7* lead to an autosomal dominant form of osteopetrosis (MIM 166600), whereas biallelic loss-of-function mutations (Ile261Phe, Arg762Gln, Leu766Pro) are found in infants with the lethal, autosomal recessive, and intermediate forms of this disease (MIM 611490).[462,463] Mutations in *CLCN7* account for 15% of subjects with severe

FIGURE 18-14 ■ Biochemical defects in osteoclasts (**A**) and osteoblasts (**B**) associated with osteopetrosis (see text for details). (From Ihde, L. L., Forrester, D. M., Gottsegen, C. J., et al. (2011). Sclerosing bone dysplasias: review and differentiation from other causes of osteosclerosis. *RadioGraphics, 31*, 1865–1882.) *This image can be viewed in full color online at ExpertConsult.*

and 40% of patients with intermediate autosomal recessive osteopetrosis and 75% of adults with autosomal dominant osteopetrosis type II.[462] *CLCN7* is coexpressed with and complexed to *OS*teopetrosis-associated *Trans**m**embrane protein 1 (*OSTM1*) in endosomes and lysosomes and in the ruffled membrane of activated osteoclasts.[464] By decreasing posttranslational stability of CLCN7, homozygous loss-of-function (nonsense, deletion) mutations in *OSTM1* have been pathogenetically related to autosomal recessive lethal osteopetrosis in a subset of patients.[465,466] The product of *PLEKHM1* is a protein that may be essential for vesicular transport within the osteoclast and for formation of its supralacunar ruffled borders; biallelic inactivating mutations of *PLEKHM1* result in osteopetrosis of intermediate severity.[467,468] Monoallelic gain-of-function mutations (Gly171Arg/Val, Ala242Thr, del Gly171/Glu172) in *LRP5* augment WNT/β-catenin signal transduction leading to increased osteoblast differentiation and function and asymptomatic high bone mass or autosomal dominant osteopetrosis type I, a disorder characterized by extremely dense skulls (with endosteal hyperostosis), vertebrae, and long bones, large mandible, and torus palatinus.[469]

Related to the long-acting inhibitory effects of bisphosphonate on bone modeling and remodeling, the administration of high doses of intravenous pamidronate (2800 mg) over a 3-year period resulted in an acquired "osteopetrosis-like" disorder in a 12-year-old boy with unexplained hyperalkaline phosphatasemia that persisted for at least several years after this agent was discontinued.[394] The metaphyses were extremely dense and club shaped, the base of the skull sclerotic, and the vertebral endplates thickened. Histologically, iliac crest biopsy revealed bars of calcified cartilage and quiescent osteoclasts. Despite the severity of the radiographic and microscopic findings, the patient was clinically well with normal growth and without evidence of bone marrow suppression or extramedullary hematopoiesis, although the risk for future fractures may have been increased.

A multidisciplinary team skilled in the management of patients with osteopetrosis is essential for the optimal care of infants and children with this disorder. Hypocalcemia and rickets occurring in neonates and infants with osteopetrosis may be managed with supplemental calcium and vitamin D.[8,470] In addition to appropriate orthopedic, neurosurgical, and anesthesiology input, medical therapy of osteopetrotic patients may at times be helpful. Nonspecific treatment with interferon-γ and high doses of calcitriol (with limited calcium intake) has arrested progression of the disease and even led to its regression in some osteopetrotic children.[8] In this setting, calcitriol acts as an osteoclast activating factor, whereas interferon γ indirectly stimulates osteoclast formation and increases the generation of superoxide in osteoclasts, an important factor for osteoclast-mediated bone resorption.[471] Depending on the cause of osteopetrosis, most patients (but not those with abnormalities of RANKL) improve after bone marrow or hematopoietic stem cell transplantation from human leukocyte antigen-identical donors with replacement of defective osteoclasts by normal osteoclast progenitor cells.[8,472,473] Hypercalcemia often complicates the posttransplantation period as osteoclast function resumes, particularly in patients with inactivating mutations in *TNFRSF11A*.[452] Hypercalcemia has been managed with dietary restriction, calcitonin, and bisphosphonate administration or by use of an inhibitor of RANKL such as denosumab, a monoclonal antibody raised against RANKL that binds to and depresses RANKL activity, that has been employed successfully to manage posttransplant hypercalcemia in children with this cause of osteopetrosis.[474] With improved treatment, there has been increased life span and improved developmental progress. Osteopetrosis due to deficiency of carbonic anhydrase II is not corrected by restoration of normal systemic acid-base balance, but bone marrow transplantation may be useful.[8] Identification and correction of the specific underlying gene defect may ultimately be feasible in patients with osteopetrosis.[475,476]

Pycnodysostosis (MIM 265800) is clinically manifested by disproportionate short stature during infancy and childhood with macrocranium and open cranial sutures, high forehead, small facial features, proptosis, bluish sclerae, beaked and pointed nose, micrognathia, highly arched palate, retained primary teeth, short fingers with hypoplastic nails, narrow thorax, pectus excavatum, and kyphoscoliosis with lumbar lordosis.[8] Radiologically, there is increased bone density that becomes progressively worse with age despite which susceptibility to fractures is increased; other characteristics include open fontanelles, impaction of permanent and supernumerary teeth, clavicles that are slim and hypoplastic laterally, partial or total absence of the ribs and hyoid bone, and acro-osteolysis of the distal phalanges (a pathognomic characteristic of pycnodysostosis).[477] Laboratory data and bone histology are basically normal, although there is biochemical evidence of decreased osteoblastic and osteoclastic activity. The microscopic observation that an abundance of osteoclasts with ruffled borders surrounded by enlarged clear zones suggested that dissolution of bone mineral was normal but that degradation of matrix was abnormal in these patients. Indeed, there are large amounts of decalcified matrix within both the subosteoclastic lacunae and the osteoclasts.[300] Pycnodysostosis is due to biallelic loss-of-function mutations in *CTSK* encoding cathepsin K, the osteoclast's lysosomal cysteine protease that degrades organic matrix after the mineral phase of bone has been reabsorbed. Among the variations in *CTSK* identified in patients with pycnodysostosis have been unipaternal isodisomy for chromosome 1 with paternal *CTSK* harboring an inactivating Ala277Val mutation, Leu9Pro substitution in the signal peptide of the precursor form of the enzyme protein preventing completion of its posttranslational processing, and Ter330Trp substitution permitting the addition of 19 amino acids to the carboxyl terminus of this enzymatic protein.

In contrast to diseases that increase bone mass by decreasing bone resorption are those disorders that primarily increase bone formation (see Figure 18-14B). An example of the latter is the familial, relatively benign form of autosomal dominant high bone mass (MIM 601884) that is associated with a heterozygous gain-of-function mutation (Gly171Val) in *LRP5*.[478] Loss-of-function mutations in the same gene are associated with idiopathic juvenile osteoporosis, the osteoporosis-pseudoglioma syndrome, and familial exudative vitreoretinopathy. LRP5 (and LRP6) is a coreceptor for WNT proteins whose primary receptor is Frizzled. After binding to LRP5 and Frizzled, WNT glycoprotein activates a canonical pathway that involves repression of glycogen synthase kinase 3 and leads to dephosphorylation of β-catenin permitting its translocation to the nucleus where it interacts with T-cell factor/lymphoid enhancing factor to control target genes that divert the mesenchymal stem cell into the track leading to osteoblastogenesis. In the mature osteoblast, WNT/β-catenin stimulates expression of osteoprotegerin, thus impairing osteoclastogenesis. Dickkopf and sclerostin (discussed later) are proteins that bind to the extracellular domain of LRP5 and internalize the receptor complex thereby blocking WNT signaling.[379] Mutations in LRP5 associated with high bone mass are clustered near the amino terminal of its extracellular domain at the sites of binding to Dickkopf and sclerostin.[381] The Gly171Val mutation in *LRP5* interferes with the binding of LRP5 to Dickkopf and thus prolongs the interaction of LRP5 with Frizzled, thereby augmenting the WNT/β-catenin signal and increasing bone formation.[479] Although generally benign, activating mutations of *LRP5* may also be associated with neurologic complications such as hearing loss, headaches, and pain in the extremities.[381] In some families, heterozygous activating mutations (Ala242Thr) of *LRP5* and exuberant bone formation have been associated with autosomal dominant generalized endosteal osteosclerosis (van Buchem disease, type 2—MIM 607636) or autosomal dominant osteopetrosis type I (Gly171Arg, Thr253Ile) (as discussed previously). However, the dense bones encountered in these subjects are not prone to fracture as in classic forms of osteopetrosis.

Sclerosteosis type 1 is an autosomal recessive disorder that is first manifested in childhood and is characterized

by very thick peripheral and cranial bones with calvarial overgrowth leading to facial disfigurement; entrapment of cranial nerves II, VII, and VIII; increased intracranial pressure; and brainstem compression.[8,379,480] Affected patients also have variable asymmetric cutaneous or bony syndactyly of the index and middle fingers and excessive somatic growth; they are extraordinarily resistant to fractures. Serum levels of alkaline phosphatase and procollagen type 1 N-terminal propeptide (P1NP) are elevated in these subjects, whereas concentrations of sclerostin are low or unmeasurable.[480] Sclerosteosis type 1 is due to biallelic loss-of-function mutations in *SOST* encoding sclerostin, a 213-amino-acid peptide secreted primarily by osteocytes embedded within bone. Physiologically, sclerostin inhibits WNT-mediated bone formation by binding to and internalizing LRP5, the coreceptor for WNT.[379,480] When sclerostin activity is decreased, increased bone formation ensues. Sclerostin also increases osteoclastogenesis by increasing osteocytic synthesis of RANKL.[480] In heterozygous carriers of inactivating mutations in *SOST*, bone mass is increased but not to pathologic levels.[481] Hyperostosis corticalis generalisata/van Buchem disease type 1 is an autosomal recessive disorder characterized by thickening and enlargement of the bones of the skull, mandible, ribs, and diaphyses of the long bones that result in increased bone density and encroachment upon cranial nerve passageways resulting in abnormalities of vision, hearing, and facial movement.[8,480] However, patients with van Buchem disease type 1 do not have syndactyly or tall stature, thus distinguishing it from sclerosteosis type 1. This disorder is also due to biallelic loss of expression of *SOST* but as a result of deletion of a regulatory element that is 35 kb downstream (5′) of *SOST* rather than by a mutation within the exonic/intronic structure of *SOST* itself.[482] Thus, this disease is allelic to sclerosteosis; it differs clinically in that gigantism and hand abnormalities are present in patients with sclerosteosis but not in those with van Buchem disease type 1. The clinical manifestations of sclerosteosis type 2 are similar to those of type 1 but are pathogenetically related to biallelic loss-of-function mutations in *LRP4*.[483] The inhibitory effect on bone formation of the interaction of sclerostin and LRP5/LRP6 is facilitated by the binding of sclerostin to LRP4. Thus, inactivating mutations (Arg1170Trp, Trp1186Ser) in *LRP4* impede the interaction of sclerostin with LRP5/6 and thus the inhibitory effect of sclerostin on osteogenesis. Treatment of these disorders is primarily symptomatic.

Progressive diaphyseal dysplasia (Camurati-Engelmann disease) is an autosomal dominant, cranial-peripheral hyperostotic disorder with variable expressivity that presents in children with problems such as limping, waddling gait, or leg pain, fatigue, and nonprogressive muscular weakness. Radiographically, there is symmetrical cortical thickening (hyperostosis) due to increased periosteal and endosteal bone formation in the diaphyses of the long bones, axial skeletons, and skull.[484,485] Pathogenetically, this disorder is primarily due to missense mutations within the "latency associated peptide" domain of the precursor propeptide of TGFβ1 (*TGFB1*). Normally, after posttranslational processing, two latency associated peptides are noncovalently linked to two mature TGFβ1 peptides to form a "latency complex." Mutations within the latency associated peptide domain of *TGFB1* (particularly at codon 218, a mutational "hot spot") impair this association, resulting in premature activation of TGFβ1 and consequent stimulation of bone formation and repression of bone resorption.[486] TGFβ1 also inhibits myogenesis and adipogenesis. Because of the inhibitory effects of glucocorticoids on bone formation and its stimulatory effects on bone resorption, short courses of these agents have been useful in alleviating many of the clinical symptoms and radiologic abnormalities in patients with progressive diaphyseal dysplasia.[484] Other hereditary sclerosing bone dysplasias include osteopoikilosis (MIM 166700) due to heterozygous inactivating mutations in *LEMD3* encoding a nuclear membrane protein that modulates signal transduction by BMPs and TGFβ, osteopathia striata (MIM 300373) the result of loss-of-function mutations in *AMER1/FAM123B* encoding a protein that promotes the proteasomal degradation of β-catenin (its loss thus extending the biologic activity of the WNT/β-catenin signal transduction system that promotes osteoblast maturation and function), and several forms of endosteal hyperostosis.[485] The hereditary and nonhereditary (e.g., intramedullary osteosclerosis) sclerosing bone dysplasias must be differentiated from acquired sclerosing diseases such as sickle cell anemia and myelofibrosis.[485]

Heterotopic Bone Formation/Ectopic Calcification

Disorders of heterotopic ossification are those in which bone develops outside of the skeleton and within soft tissues (Table 18-13C).[53] Dysregulation of the processes of differentiation and maturation enable precursor cells to develop as osteoblasts that then produce normal endochondral or membrane bone but in abnormal, extraskeletal sites. Sporadic heterotopic bone formation occurs in sites of severe wounds and burns, after spinal cord injuries, and in areas of pressure ulcers. Fibrodysplasia ossificans progressiva (FOP, MIM 135100) is a disabling disorder of ectopic bone formation that may develop spontaneously or at sites of injury and leads to ankylosis of all major joints that severely limits mobility.[53,487] It is characterized by progressive ectopic ossification of skeletal muscle and connective tissue (fascia, tendons, ligaments) leading to immobility and fusion of the mandible, neck, spine, hips, and other joints and the development of a "second skeleton" that encases and imprisons the body. The disorder may be present at birth and is often manifest by 5 years of age. FOP is also associated with congenital abnormalities of the great toes (hallux valgus, malformed first metatarsal bones, monophalangism), characteristic facial features (long narrow face, small mandible, low set ears), deafness, scalp baldness, and mild developmental delay.[488] Microscopically, there is normal but ectopic endochondral osteogenesis that occurs after a preceding inflammatory phase that develops either in the absence of trauma or following minor injury such as an immunization; the pathologic course proceeds through the phases of monocytic infiltration, muscle fiber degeneration, fibrous proliferation, angiogenesis, chondrogenesis, and osteogenesis.[53] Although usually sporadic because affected subjects rarely

TABLE 18-13C **Genetic Causes of Heterotopic Bone Formation and Ectopic Calcification**

Disease Type MIM	Gene Chromosome	Clinical Manifestations	Pathophysiology
Heterotopic Bone Formation			
Fibrodysplasia ossificans progressiva 135100	*ACVR1*: Activin A receptor, type I 2q24.1 102576	Progressive ossification of skeletal muscles, fascia, tendons, and ligaments	Specific monoallelic activating mutation (Arg206His) in the cytoplasmic domain of a type 1 BMP receptor increases extraskeletal chondrogenesis and osteogenesis
Progressive osseous heteroplasia 166350	*GNAS*: GNAS complex locus 20q13.32 139320	Ossification of dermis beginning in infancy followed by membranous bone formation within deep muscle and fascia in childhood	Monoallelic inactivating mutations in the paternally encoded $G_s\alpha$ subunit of G-protein enable subcutaneous bone formation; related to pseudopseudohypoparathyroidism
Ectopic Calcification			
Tumoral calcinosis, hyperphosphatemic, familial 211900	*GALNT3*: UDP-N-acetyl-alpha-D-galactosamine: polypeptide N-acetylgalactosaminyl-transferase 3 2q24.3 601756	Progressive deposition of calcium phosphate crystals in periarticular region, soft tissue, and bone	Biallelic mutations in a cofactor required for synthesis of bioactive FGF23 and renal tubular excretion of phosphate
Tumoral calcinosis, hyperphosphatemic, familial 211900	*FGF23*: Fibroblast growth factor 23 12p13.32 605380	Progressive deposition of calcium phosphate crystals in periarticular region, soft tissue, and bone	Biallelic inactivating mutations in a factor that inhibits renal tubular resorption of phosphate
Tumoral calcinosis, hyperphosphatemic, familial 211900	*KL*: Klotho 13q13.1 604824	Progressive deposition of calcium phosphate crystals in periarticular region, soft tissue, and bone	Biallelic inactivating mutation in a cofactor enabling FGF23 to inhibit renal tubular resorption of phosphate
Tumoral calcinosis, normophosphatemic, familial 610455	*SAMD9*: Sterile alpha motif domain-containing protein 9 7q21.2 610456	Postinflammatory periarticular and peripheral calcified masses	Biallelic inactivating mutations in a protein that regulates cell division, motility, longevity, and inflammation

reproduce, FOP can be transmitted as an autosomal dominant trait. This disease is primarily due to a highly specific (c.617G > A transition leading to Arg206His) mutation in *ACVR1* (encoding activin A receptor, type-1); another described *ACVR1* mutation in patients with classical FOP is c.744G > C transversion leading to Arg258Ser.[53,489] Activins are members of the TGFβ superfamily that includes the bone morphogenetic proteins (BMPs) together with the inhibins and Mullerian duct inhibiting factor. *ACVR1* encodes a type I BMP receptor that is expressed in chondrocytes and osteoblasts.[53] The Arg206His mutation in *ACVR1* resides at the junction of the receptor's cytoplasmic glycine-serine activation and tyrosine kinase domains and results in a constitutively active BMP type I receptor product that signals through the SMAD and mitogen-activated protein kinase transduction pathways to direct the pluripotent mesenchymal stem into the chondrogenic pathway leading to (ectopic) endochondral new bone formation. BMPs alone are able to stimulate complete endochondral osteogenesis in ectopic sites.[490] Patients with clinical variants of FOP and *ACVR1* mutations other than Arg206His and Arg258Ser have been described; they have been classified as those with FOP plus abnormalities of the brain, eye, or bone marrow, or those with FOP variants—either without abnormalities of the great toes or with less severe heterotopic osteogenesis; patients with mutations in codon 328 have varied in severity from classical to late-onset FOP; patients with an Arg201Ile mutation in *ACVR1* have adult onset of extraskeletal ossification and normal toes.[53,491] Management of these patients is primarily symptomatic and palliative to the extent possible, although immunosuppression may diminish the intensity of extraskeletal ossification.[53,492]

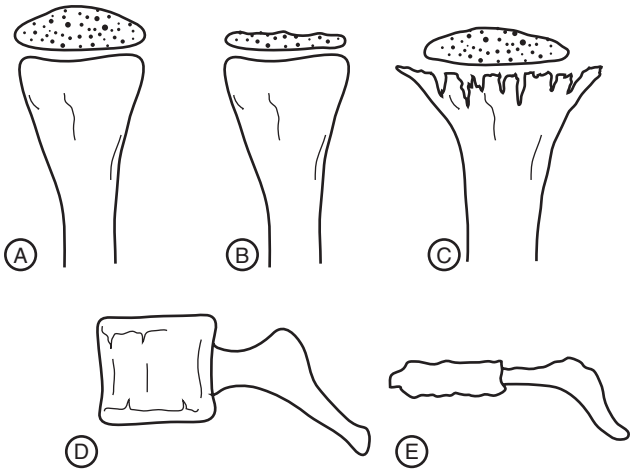
Progressive osseous heteroplasia (POH, MIM 166350) is characterized by multiple foci (trunk, extremities, or digits) of adipose tissue-associated dermal intramembranous bone formation (osteoma cutis) beginning in infancy in the absence of any local injury or inflammatory insult.[53] Lesions may be asymptomatic or painful. Over time, heterotopic ossification progresses into skeletal muscle and deep connective tissue and may be incorporated into skeletal bone. POH is transmitted as an autosomal dominant trait and occurs in both boys and girls; it is due to inactivating mutations of the *GNAS* allele usually inherited from the father.[493,494] Paternal transmission of mutated *GNAS* is associated with significant intrauterine growth restriction and more severe clinical manifestations of POH than when the *GNAS* mutation is transmitted by the mother.[494] Identical mutations in *GNAS* may be clinically manifested as either POH, pseudohypoparathyroidism (PHP), or pseudopseudohypoparathyroidism (PPHP) in different members of the same family (e.g., 1 bp del, 725C); all of these disorders

are associated with subcutaneous (dermal) ossification (as discussed previously). However, patients with POH do not have physical features of Albright's hereditary osteodystrophy nor are they hormone resistant. Only symptomatic treatment of patients with POH is currently available.

Extraskeletal calcification/ossification may occur sporadically in a number of hypercalcemic, hyperphosphatemic, or dystrophic states (renal failure, hypo- and hyperparathyroidism, sarcoidosis, after cell lysis induced by cancer chemotherapy, subcutaneous fat necrosis, dermatomyositis, atherosclerosis) as well as in specific diseases (e.g., pseudohypoparathyroidism type IA, McCune-Albright syndrome).[495] Familial tumoral calcinosis is a disorder characterized by deposition of crystals of basic calcium phosphate in soft tissues, periarticular spaces, and at times bone. Hyperphosphatemic and normophosphatemic forms of familial tumoral calcinosis have been described. Hyperphosphatemic familial tumoral calcinosis presents in childhood with recurrent bone pain, extensive and large cutaneous, periarticular, and vascular deposits of calcium phosphate; in some patients the ectopic calcifications may be confined to the eyelids; it is characterized radiographically by cortical hyperostosis, periosteal reaction, and mineral deposits around large joints, particularly the hips and shoulders.[496,497] Microscopically, there is a histiocytic response with formation of calcified bursa-like structures.[498] Laboratory studies reveal marked hyperphosphatemia and relative hypophosphaturia due to increased renal tubular reabsorption of phosphate and inappropriately normal or elevated serum calcitriol levels, because, despite hyperphosphatemia, PTH secretion is not increased and synthesis of calcitriol and intestinal calcium absorption persist. The disorder is due to a functional loss of FGF23 action and consequently unhindered renal tubular reabsorption of phosphate. The pathophysiology of this disorder is, thus, the mirror image of that associated with X-linked and autosomal dominant forms of hypophosphatemic rickets and tumor-induced osteomalacia in which there is exaggerated FGF23 production and activity leading to hyperphosphaturia and consequent hypophosphatemia, rickets, and osteomalacia. Hyperphosphatemic familial tumoral calcinosis is genetically heterogeneous. Homozygous inactivating mutations (Ser71Gly; Met96Thr, Ser129Phe) in *FGF23* have been identified in patients with this disorder; in the absence of FGF23, renal tubular resorption of filtered phosphate is unopposed.[496] More commonly detected in patients with hyperphosphatemic familial tumor calcinosis are biallelic loss-of-function microdeletions, splice site, and missense or nonsense mutations (Arg162Stop, Thr272Lys, Cys574Gly, Gln592Stop) in *GALNT3* (UDP-*N*-acetyl-alpha-D-galactosamine: polypeptide *N*-acetylgalactosaminyltransferase 3).[499] The product of *GALNT3* is a glycosyl transferase that initiates *O*-glycosylation in which *N*-acetylgalactosamine is the first sugar in the side chain, a step that is essential for secretion of intact and functional FGF23. Failure to *O*-glycosylate FGF23 at Thr178 in the Golgi apparatus permits its rapid intracellular cleavage between Arg179 and Ser180 to biologically inactive amino and carboxyl terminal fragments.[500] Serum concentrations of intact FGF23 are low or nondetectable, whereas carboxyl terminal FGF23 levels are elevated in patients with familial tumoral calcinosis due to either gene mutation. Therapy with an oral phosphate binder and the carbonic anhydrase inhibitor acetazolamide has resulted in hyperphosphaturia and reabsorption of ectopic calcifications without change in serum phosphate or calcium concentrations.[501] The hyperostosis hyperphosphatemia syndrome (MIM 610233) is a clinical variant of familial tumoral calcinosis and is also due to mutations in either *FGF23* or *GALNT3*; symptoms and signs may precede development of the more typical phenotype of familial tumoral calcinosis.[499,500] Hyperphosphatemic familial tumoral calcinosis has also been attributed to a homozygous loss-of-function mutation (His193Arg) in *KL* encoding α-klotho, a cofactor necessary for the interaction of FGF23 with its receptor in the renal tubule.[502] Normophosphatemic familial tumor calcinosis is a form of dystrophic calcification, as inflammatory lesions always precede ectopic calcification, that is due to inactivating mutations (Arg344Stop, Lys1495Glu) in *SAMD9* (encoding sterile alpha motif domain-containing protein 9), a 1589-amino-acid protein that regulates cell division, motility, and longevity.[503] SAMD9 generation is responsive to tumor necrosis factor-alpha (TNFα) and interferon-gamma (IFNγ) and regulates expression of EGR1 (MIM 128990), a transcription factor that controls expression of *TGFB1* and is involved with cell migration, inflammation, and tissue calcification.[504]

OSTEOCHONDRODYSPLASIAS

The osteochondrodysplasias are composed of a heterogeneous group of malformations of cartilage and bone that initially were grouped according to clinical and radiologic characteristics into those involving long bone growth alone (epiphyseal, metaphyseal, or diaphyseal dysplasias) or those involving the long bones and vertebrae (spondyloepiphyseal or spondyloepimetaphyseal dysplasias) and variants thereof (Figure 18-15).[505] More recently, disorders of skeletal morphology or bone cell function have been classified according to known genetic variations (e.g., *FGF23*, *COLA1A*) that adversely influence bone development or mineralization and within which mutations in one gene may give rise to several clinically defined disorders together with disorders characterized by clinical and radiographic findings that may be attributable to variations in many different genes (e.g., acromesomelic dysplasias). Thus, abnormal skeletal phenotypes have been classified into 40 groups based on the underlying genetic mutations or clinical and radiographic manifestations of the disorders.[322,506] Groups 1 through 8 are multiple disorders attributed to variations in a single gene (e.g., group 1 *FGFR3*, group 2 *COL1A1*, group 3 *COL11A1*, group 4 *DTDST*, group 5 *PLC*, group 6 *AGC1*, group 7 *FLNA*, group 8 *TRPV4*). Groups 9 through 40 rely on clinical and radiographic findings for classification; within each group, variations in different genes may give rise to the same observed abnormality(ies) (e.g., group 10 multiple epiphyseal dysplasias: *COMP*, *COL9A2*, *MATN3*; group



Involvement	Disease Category
A+D	Normal
B+D	Epiphyseal dysplasia
C+D	Metaphyseal dysplasia
B+E	Spondyloepiphyseal dysplasia
C+E	Spondylometaphyseal dysplasia
B+C+E	Spondyloepimetaphyseal dysplasia

Rosen (Ed.), *Primer on the metabolic bone diseases and disorders of mineral metabolism* (7th ed.) (pp. 428-429). Washington, DC: American Society of Bone and Mineral Metabolism.)

13 spondylo-epi-[meta]-physeal dysplasias: *MATN3*, *SEDL*, *DYM*; group 17 mesomelic/rhizo-mesomelic dysplasias: *SHOX*, *GPC6*, *RDR2*). Group 23 encompasses variants of osteopetrosis, group 25 variants of osteogenesis imperfecta, group 27 the lysosomal disorders, and group 30 the overgrowth syndromes.[506] Disorders of skeletal development and function are of interest not only because of the diagnostic and therapeutic clinical challenges they present but also because they have identified many basic physiologic factors that normally regulate cartilage and bone development and function. The application of genome wide association studies (GWAS) to the classification of skeletal disorders has added significant insight into the plethora of genes and intracellular signaling pathways that influence skeletal differentiation, morphology, and function.[322]

Table 18-14 describes some of the more commonly encountered genetic variations associated with the osteochondrodystrophies. Achondroplasia (MIM 100800), the most common of the human chondrodystrophies (1/15,000 to 1/40,000 live births), and its related osteochondrodystrophies (hypochondroplasia, thanatophoric dwarfism, SADDAN syndrome) are due to gain-of-function mutations in *FGFR3*, the gene encoding fibroblast growth receptor 3. FGFR3 is a transmembrane protein with three immunoglobulin domains in the extracellular region of the receptor and two tyrosine kinase domains in its intracellular portion (Figure 18-16). The four disorders are transmitted as autosomal dominant traits but with a high rate of spontaneous mutations (primarily of the paternal *FGFR3* allele). Clinically, achondroplasia is manifested by short limbs but normal trunk length, large head, frontal bossing, and depressed nasal bridge, and complicated by increased risk for cervical cord compression and spinal stenosis.[507] Thanatophoric dysplasia is characterized by severe bony malformations, particularly of the skull, long bones, and ribs, the latter leading to respiratory insufficiency and early death; there are two radiographic forms of this disorder (I and II). The syndrome of severe achondroplasia-developmental delay-acanthosis nigricans (SADDAN syndrome) is a clinical phenotype intermediate in severity between those of thanatophoric dysplasia and achondroplasia. It is associated with significant rhizomelic short stature, acanthosis nigricans, and mild developmental challenges; acanthosis nigricans may also develop in patients with classical achondroplasia and in those with mutations in FGFR2.[508] Hypochondroplasia is a clinically less severe manifestation of mild short limbed (rhizomelic) short stature that presents in mid-childhood. Mutations in *FGFR3* correlate with the clinical phenotype. Although achondroplasia is most often (98%) associated with a monoallelic missense mutation (Gly380Arg) in the transmembrane domain of FGFR3, Gly375Cys and other variants in *FGFR3* have been recorded in patients with achondroplasia. The birth to normal parents of a second child with achondroplasia may reflect paternal germinal mosaicism for the Gly380Arg mutation in *FGFR3*.[509] Thanatophoric dysplasia type I is related to mutations (Arg248Cys, Gly370Cys) in the extracellular ligand-binding region next to the transmembrane domain of the receptor and to substitutions at the normally terminal codon 807—Ter807Gly, Ter807Cys, and Ter807Arg—all of which lead to the addition of 141 amino acids to the carboxyl terminus of the FGFR3 protein. Thanatophoric dysplasia type II is associated with a mutation (Lys650Glu) in the distal tyrosine kinase domain. Dual mutations in the same *FGFR3* allele have also been associated with thanatophoric dysplasia.[510] SADDAN syndrome is also the result of a Lys650Met mutation. Hypochondroplasia has been associated with mutations within the proximal (Asn540Lys in 60%) and distal (Lys650Gln) tyrosine kinase domains, respectively, as well in the immunoglobulin domains of the extracellular region (Ser84Leu, Arg200Cys) and transmembrane domain (Val381Glu) of *FGFR3*.[507,511] It is noteworthy that different mutations at Lys650 result in three distinct phenotypes: hypochondroplasia, thanatophoric dysplasia type II, and SADDAN syndrome. *FGFR3* activating mutations have also been encountered in patients with Muenke nonsyndromic coronal craniosynostosis and Crouzon syndrome—evidence of the genetic heterogeneity of these clinical syndromes. A loss-of-function mutation (Arg621His within the distal tyrosine kinase domain) in *FGFR3* has been identified in a family whose members display the phenotype of tall stature, camptodactyly, and hearing loss.[512]

The Gly380Arg variant of *FGFR3* alters the conformation of the gene product enabling ligand-independent autophosphorylation of tyrosine residues 647 and 648 within its cytoplasmic tyrosine domain that then is able to propagate signals through the MAPK and signal the transducer and activator of transcription (STAT) pathways resulting in inhibition of mitosis, matrix synthesis, and terminal (hypertrophic) differentiation.[513] Experimentally, in

TABLE 18-14 **Genetic Variants Associated with Osteochondrodystrophies (Selected)**

Gene Chromosome MIM	Pathophysiology	Clinical Disorder (MIM)
TRIP11: Thyroid hormone interactor 11 14q31-q32 604505	Coactivator of the nuclear triiodothyronine receptor; interacts with microtubules and Golgi apparatus	Achondrogenesis, type IA (200600), AR
Collagenopathies		
COL2A1: Collagen, type II, alpha 1 12q13.11 120140	Subunit of collagen type II, the major collagen of cartilage comprised of three 3-alpha 1(II) chains	Achondrogenesis, type II/ Hypochondrogenesis (200610), AD Spondyloepiphyseal dysplasia congenita (183900), AD Spondyloepimetaphyseal dysplasia (184250), AD
COL9A1: Collagen, type IX, alpha 1 6q13 120210	Encodes a collagen that is a component of hyaline cartilage	Multiple epiphyseal dysplasia, type 6 (614135), AD Stickler syndrome type 4 (614134), AR
COL10A1: Collagen, type X, alpha 1 6p22.1 120110	Component of cartilage expressed at late stages of endochondral bone formation	Metaphyseal chondrodysplasia, Schmid type (156500), AD
COL11A1: Collagen, type XI, alpha 1 1p21.1 120280	Subunit of collage type XI composed of two alpha 1 subunits and a modified COL2A1 subunit; important for fibrillogenesis	Stickler syndrome type 2 (604841), AD Marshall syndrome (154780), AD
FLNB: Filamin B 3p14.3 603381	Cytoplasmic actin-binding protein enabling formation of and communication with the cytoskeleton; influences vertebral segmentation, endochondral ossification, joint formation	Atelosteogenesis I (108720), AD Atelosteogenesis III (108721), AD
Fibroblast Growth Factor Receptors		
FGFR1: Fibroblast growth factor receptor 1 8p11.22 136350	Transmembrane tyrosine kinase receptor for FGFs	Pfeiffer (101600), AD
FGFR2: Fibroblast growth factor receptor 2 10q26.13 176943	Transmembrane tyrosine kinase receptor for FGFs	Apert (101200), AD Crouzon (123500), AD Jackson-Weiss (123150), AD Antley-Bixler with normal steroidogenesis (207410), AD
FGFR3: Fibroblast growth factor receptor 3 4p16.3 134934	Transmembrane tyrosine kinase receptor for FGFs	Achondroplasia (100800), AD Hypochondroplasia (146100), AD Thanatophoric dysplasia types I (187600) and II (187601), AD
Sulfation Disorders		
SLC26A2- Solute carrier family 26 (sulfate transporter) 5q32 606718	Also termed DTDST; encodes sulfate transporter essential for normal collagen synthesis	Achondrogenesis, type IB (600972), AR; Atelosteogenesis II (256050), AR Diastrophic dysplasia (222600), AR Multiple epiphyseal dysplasia, type 4 (226900), AR
HSPG2: Heparan sulfate proteoglycan of basement membrane 1p36.12 142461	Also termed perlecan, a heparan sulfate proteoglycan; coreceptor for FGFR2; stabilizes basement membranes and regulates their permeability	Schwartz-Jampel type 1 myotonic chondrodystrophy (255800), AR
PAPSS2: 3-Prime-phosphoadenosine 5-prime-phosphosulfate synthase 2 10q23.2-23.3 603005	Enzyme that synthesizes the sulfate donor (3′-phosphoadenosine 5′-phosphosulfate) from ATP and sulfate; cofactor for adrenocortical sulfotransferase	Spondyloepimetaphyseal dysplasia (Brachyolmia type 4) (612847), AR
ARSE: Aryl sulfatase E Xp22.33 300180	Enzyme that removes a sulfate group from its protein	Chondrodysplasia punctata type 1 (302950), X-linked recessive
PTPN11: Protein tyrosine phosphatase, nonreceptor, type 11 12q24.1 176876	Encodes SHP2: a nonreceptor protein tyrosine phosphatase that acts upstream of RAS	Monoallelic loss-of-function mutations lead to metachondromatosis (156250), AD Noonan syndrome with multiple lentigenes: monoallelic gain-of-function mutations result in Noonan syndrome (163950), AD

TABLE 18-14 **Genetic Variants Associated with Osteochondrodystrophies (Selected)—cont'd**

Gene Chromosome MIM	Pathophysiology	Clinical Disorder (MIM)
Others		
COMP: Cartilage oligomeric matrix protein 19p13.1 600310	Chondrocyte protein that binds calcium and collagen types I, II, and IX	Pseudoachondroplasia (177170), AD Multiple epiphyseal dysplasia (132400), AD
TRPV4: Transient receptor potential cation channel, subfamily V, member 4 12q24.11 605427	Cation channel that mediates calcium influx	Metatropic dysplasia (156530), AD Spondyloepimetaphyseal dysplasia: Maroteaux (184095), AD
SHOX: Short stature homeobox Xp22.33 312865	Homeobox gene transcription factor located also on the pseudoautosomal region of Yp	Leri-Weill dyschondrosteosis (127300), X-linked dominant Langer dysplasia (249700), biallelic/X and Y
SOX9: SRY-box 9 17q24.3 608160	Transcription factor essential for chondrogenesis and testicular differentiation	Campomelic dysplasia (114290), Monoallelic due to haploinsufficiency
RUNX2: Runt-related transcription factor 2 6p21 600211	Osteoblast specific transcription factor	Cleidocranial dysostosis (119600), AD
PTH1R: PTH receptor 1 Xp22.33 168468	GPCR recognizing PTH and PTHrP with equal affinity	Inactivating mutations lead to hypocalcemia and Blomstrand osteochondrodysplasia (215045), AR; Eiken syndrome (600002), AR; activating mutations result in hypercalcemia and Murk-Jansen metaphyseal chondrodysplasia (156400), AD
PRKAR1A: Protein kinase, cAMP-dependent regulatory, type 1, alpha 17q24.2 188830	Component of PKA response to cyclic AMP that leads to cascade of intracellular signal transduction signals in response to Gαs that regulate cell division, differentiation, metabolism, apoptosis	Gain-of-function mutation leads to acrodysostosis (101800) and peripheral resistance to the biologic effects of PTHrP, PTH, and TSH; (de novo)
POR: Cytochrome P450 oxidoreductase 7q11.2 124015	Flavoprotein cofactor that donates electrons to microsomal 17α-hydroxylase, 21-hydroxylase, and aromatase	Inactivating mutations lead to congenital adrenal hyperplasia usually with genital ambiguity in both 46XX and 46XY subjects (613571), AR; at times in association with skeletal abnormalities (Antley-Bixler syndrome: craniosynostosis, midface hypoplasia, choanal stenosis, femoral bowing, radioulnar synostosis, 201750, AR)
RMRP: Mitochondrial RNA-processing endoribonuclease, RNA component of 9p13.3 157660	Untranslated RNA subunit of the mitochondrial RNA-processing endoribonuclease: RNase MRP	Dependent on the severity of the biallelic loss-of-function mutation(s) the spectrum of anauxetic dysplasia (607095), cartilage hair hypoplasia (250250) emerges
INPPL1: Inositol polyphosphate phosphatase like-1 11q13.4 600829	Enzyme that hydrolyzes inositol-1,4,5-trisphosphate to inositol-4,5-bisphosphate: transducer of intracellular signaling	Inactivating mutations result in opsismodysplasia (258480); associated with increased skeletal synthesis of FGF23, AR

Adapted from Warman, M. L., Cormier-Daire, V., Hall, C., et al. (2011). Nosology and classification of genetic skeletal disorders: 2010 revision. Am J Med Genet *(Part A),* 155A, *943–968.*

mice expressing the gain-of-function mutation in *Fgfr3* associated with achondroplasia, there is enhanced bone development but decreased bone mass and increased osteoclastic activity.[514] Thus, FGFR3 normally functions as a negative regulator of cartilage and bone formation. As a single gene disorder, it is possible to identify a mutation in *FGFR3* in an affected fetus by analysis of fetal cell-free DNA in maternal plasma, if the mother is unaffected.[515] Activating mutations in *FGFR1* and *FGFR2* have been associated with chondrodysplasias complicated by premature craniosynostosis (Pfeiffer, Apert, Crouzon, Jackson-White, Antley-Bixler, and Beare-Stevenson cutis gyrata syndrome). Interestingly, loss-of-function mutation in *FGFR1* have also been associated with hypogonadotropic hypogonadism (MIM 147950), as FGFR1 is an essential neuronal migration factor.[516] Mutations in *FGFR4* have not been associated with osteochondrodysplasias to date.

Defective formation of several types of collagen due to mutations in *COL2A1*, *COL9A1*, *COL9A2*, *COL10A1*, *COL11A1*, and *COL11A2* result in a large number of skeletal malformations depending on the site and developmental timing of the synthetic error (see Table 18-14). Mutations in several different collagen-encoding genes (*COL2A1*, *COL9A1*, *COL9A2*, *COL11A1*, *COL11A2*)

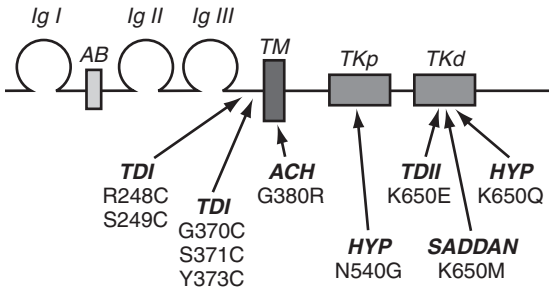


FIGURE 18-16 ■ Mutations in fibroblast growth factor receptor-3 leading to achondroplasia (ACH), hypochondroplasia (HYP), thanatophoric dysplasia (TD) types I and II, and severe achondroplasia-developmental delay-acanthosis nigricans (SADDAN). (From Horton, W. A. (2006). Molecular pathogenesis of achondroplasia. *Growth Genet Horm, 22,* 49–54.)

result in variants of Stickler syndrome characterized by abnormalities of the skeleton (epiphyseal dysplasia), face (micrognathia, cleft palate), and vision (myopia, retinal detachment), as well as impaired hearing that may be transmitted as autosomal dominant or recessive traits. Atelosteogenesis is a skeletal disorder characterized by absent, short, or distally tapered femora and humeri, short bowed tibiae and ulnae, absent fibulae, vertebral hypoplasia, and subnormal metacarpal ossification; this disorder has several variants; it is the result of monoallelic loss-of-function mutations in *FLNB* encoding a cytoplasmic protein that binds actin, thereby enabling actin to form the cytoskeleton, and it also facilitates intracellular communication between the cell membrane and its cytoskeleton. Abnormalities of sulfate transport, collagen matrix protein sulfation, and sulfatase activity result in several chondrodysplasias. *SLC26A2* encodes a sulfate transporter that is mutated in patients with diastrophic dysplasia (DTD) and achondrogenesis type IB. Spondylepimetaphyseal dysplasia/brachyolmia type 4 is due to biallelic loss-of-function mutations (Thr48Arg, Ser438Ter) in the gene (*PAPSS2*) encoding 3′-phosphoadenosine-5′-phosphosulfate synthase 2, an enzyme with dual activities; it catalyzes both the synthesis of adenosine 5′-phosphosulfate and its phosphorylation to 3′-phosphoadenosine 5′-phosphosulfate, the universal sulfate donor necessary for sulfation of cartilage and bone matrix proteins. Clinical manifestations of this disorder include short limbs, kyphoscoliosis, brachydactyly, and enlarged knee joints. Inactivating mutations in *ARSE*, encoding a member of the sulfatase enzyme family, lead to X-linked recessive brachytelephalangic chondrodysplasia punctata type 1.[517] This disorder is marked clinically by compromised stature attributable to rhizomelic shortening of the limbs, stippling of the epiphyses, craniofacial defects, atrophic and pigmented ichthyosiform skin lesions, alopecia, cataracts, and developmental delay. Loss-of-function mutations (insertions, missense, nonsense) in *SOX9*—a transcription factor that is expressed in both developing chondrocytes where it is coexpressed with *COL2A1* and in the genital ridges during gonadal differentiation—cause both campomelic dysplasia (MIM 114290) and male-to-female sex reversal in 75% of affected 46XY subjects. Inasmuch as SOX9 is essential for normal expression and function of *COL2A1* during chondrogenesis, its absence leads to impaired cartilage formation and malformation of bones embryologically derived from endochondral bone. In the developing bipotential gonad of the 46XY fetus, the expression of *SOX9* is governed by SRY; *SOX9* expression is essential for normal differentiation and development of Sertoli cells and other components of the testis. Clinically, campomelic dysplasia is characterized by prenatal onset of bowing of tubular bones, hypoplastic scapulae, 11 ribs, cleft palate, and micrognathia leading often to neonatal death as well as failure of masculinization of the 46XY conceptus.

The X- and Y-linked pseudoautosomal gene *SHOX* (*S*hort stature *HO*meobo*X*-containing gene) encodes two nuclear proteins: SHOXa with 292 amino acids and SHOXb with 225 amino acids. SHOX is a transcription factor expressed in late proliferative, prehypertrophic, and hypertrophic chondrocytes one of whose target genes is *NPPB* encoding natriuretic peptide precursor B.[518] Absence of one *SHOX* functional gene is the proximate cause of the short stature of girls with Turner syndrome and some children with "idiopathic" short stature. Heterozygous microdeletions and intragenic inactivating mutations (Leu 132Val, Ala170Pro, Arg195Stop) of *SHOX* resulting in haploinsufficiency are present in patients with Leri-Weill dyschondrosteosis typified by mesomelic limb shortening and growth retardation, Madelung deformity of the wrist, bowing of the radius, and ulnar dislocation. The Leri-Weill phenotype has been recorded in patients with intact *SHOX* but with microdeletions of downstream segments of the X chromosome pseudoautosomal region, implying the presence of modifying genes in this region.[519] Biallelic loss (X and Y chromosomes) of *SHOX* leads to Langer mesomelic dysplasia typified by severe hypoplasia of the ulna and fibula and a thickened, curved radius and tibia.

Both gain- and loss-of-function mutations of *PTH1R* lead to abnormalities of bone formation and growth. Blomstrand chondrodysplasia is an autosomal recessive disorder lethal in utero that may be identified in the fetus with short, extremely dense long bones and markedly advanced skeletal maturation as well as somatic anomalies such as aortic coarctation and facial anomalies. Pathologically, epiphyseal cartilage is reduced, and there are irregular columns and erratic distribution of chondrocytes within matrix. The abnormality is the result of inactivating mutations (deletions, missense mutations—Pro132Leu, Arg383Gln) of the gene encoding the PTH/PTHrP receptor. The Eiken syndrome of severely delayed ossification of the epiphyses and pelvis is also due to a biallelic loss-of-function mutation (Arg485Stop) in *PTH1R*. Patients with Murk-Jansen metaphyseal chondrodysplasia have short limbs and fingers, micrognathia, and deformities of the spine and pelvis, but they survive to adulthood where the average adult height is 125 cm and childbearing is possible. Characteristically, these patients have hypercalcemia, hypophosphatemia, and low or undetectable serum levels of both PTH or PTHrP. The disorder is due to monoallelic activating mutations (His223Arg, Thr410Pro) of *PTH1R* and is associated with extraordinary delay in chondrocyte differentiation and decreased mineralization due to excessive bone resorption. Both disorders reflect the altered functional effects of PTHrP acting through PTH1R in developing cartilage where it normally acts to slow differentiation and decrease

the rate of chondrocyte apoptosis, thus prolonging chondrocyte proliferation and enhancing long bone growth.

Anauxetic dysplasia (MIM 607095) is a spondylometaepiphyseal dysplasia transmitted as an autosomal recessive disorder characterized by intrauterine growth retardation (birth length < 40 cm), severely compromised adult height (< 85 cm), hypodontia, and mild mental retardation. All bones are malformed; there are few chondrocytes in the cartilage growth plates. It is due to loss-of-function mutations (insertions) in *RMRP* (*R*NA component of *M*itochondrial *R*NA-*P*rocessing endoribonuclease), a gene that encodes the untranslated RNA subunit of the mitochondrial RNA-processing endoribonuclease, RNase MRP.[520,521] This enzyme is involved in (1) the assembly of ribosomes (the structural units in which translation and protein synthesis take place), (2) the generation of RNA primers for replication of mitochondrial DNA, and (3) the regulation of the cyclin-dependent cell cycle. The mutations that result in anauxetic dysplasia impair ribosome assembly and protein synthesis exclusively. Inactivating mutations (duplications, insertions) in *RMRP* that modestly impair both ribosomal assembly and regulation of the cell cycle are present in patients with cartilage hair hypoplasia (MIM 250250) and metaphyseal dysplasia without hypotrichosis (MIM 250460). Thus, cartilage hair hypoplasia and anauxetic dysplasia represent different manifestations and the functional severity of inactivating mutations of *RMRP*.

Errors in the biosynthesis of cholesterol have been associated with a number of disorders that adversely affect bone development as well as many other systems (Table 18-15) (Figure 18-17).[522] Cholesterol is a constituent of the cell's plasma membrane as well as the membranes of intracellular organelles; it covalently binds to the amino terminal and is essential for the function of Indian hedgehog, Sonic hedgehog, and Desert hedgehog, inductive factors necessary for the normal development of cartilage and bone, brain, and testes, respectively. It is a precursor of steroids and bile acids. It is likely that lack of cholesterol exerts its teratologic effects through many pathways—by impairing membrane function or the intracellular signaling response(s) to normal stimuli. Additionally, accumulation of precursors of cholesterol may be toxic to the developing fetus. In patients with the Smith-Lemli-Opitz syndrome, inactivating mutations of the microsomal enzyme Δ^7-dehydrocholesterol reductase (*DHCR7*) impair the final step in the synthetic pathway of cholesterol from 7-dehydrocholesterol and lead to intrauterine and postnatal growth retardation, short limbs, syndactyly and polydactyly, characteristic facial features (blepharoptosis, anteverted nares, broad alveolar ridges, cleft palate), congenital malformations of the heart and central nervous system, microcephaly, incomplete virilization of male external genitalia, hypoplastic thumbs, developmental delay, autism, and compromised adrenocortical function, a malformation syndrome with an incidence of 1/15,000 to 1/40,000 births.[523]

TABLE 18-15 **Osteochondrodystrophies Attributable to Genetic Variants of Proteins Essential for Cholesterol Synthesis**

Gene Chromosome MIM	Pathophysiology	Clinical Disorder (MIM)
DHCR7: 7-Dehydrocholesterol reductase 11q12-q13 602858	3β-Hydroxysteroid Δ^7 reductase converts 7-dehydrocholesterol to cholesterol	Smith-Lemli-Opitz syndrome (270400), AR
DHCR24: 24-Dehydrocholesterol reductase 1p32.3 606418	3β-Hydroxysterol Δ^{24} reductase converts desmosterol to cholesterol	Desmosterolosis (602398), AR
SC5DL: Sterol C5-desaturase-like 11q23.3 602286	Microsomal enzyme (3β-hydroxysteroid-Δ5-desaturase) that converts lathosterol to 7-dehydrocholesterol, precursor of cholesterol and cholecalciferol (vitamin D)	Lathosterolosis (607330), AR
EBP: Emopamil-binding protein Xp11.23 300205	Dual function protein: binding protein; 3β-Hydroxysteroid Δ^7,Δ^8 isomerase converts cholest-8(9)-en-3β-ol to lathosterol	Chondrodysplasia punctata type 2 (302960), X-linked dominant
NSDHL: NAD(P)H steroid dehydrogenase-like protein Xq28 300275	3β-Hydroxysteroid C4 demethylase complex converts 4,4-dimethylcholest-8(9)-en-3β-ol to cholest 8(9)-en-3β-ol; other members of complex are *SC4MOL* (607545) and *HSD17B7* (606756)	CHILD (congenital hemidysplasia, ichthyosiform erythroderma, limbs defects) syndrome (308050), X-linked dominant
LBR: Lamin B receptor 1q42.12 600024	Dual function protein: promotes heterochromatin binding to inner nuclear membrane; 3β-Hydroxysteroid Δ^{14} reductase important for synthesis of cholesterol	HEM (hydrops-ectopic calcification-"moth-eaten" or Greenberg) dysplasia (215140), AR
POR: Cytochrome P450 oxidoreductase 1q11.2 124015	Flavoprotein electron donor to all P450 enzymes including P450c17, P450c21, P450arom	Antley-Bixler syndrome with genital anomalies and disordered steroidogenesis, (201750), AR (ABS with exclusively skeletal anomalies [207410] due to mutation in *FGFR2*, AD)

Adapted from Forbes, F. D., & Herman, G. E. (2011). Malformation syndromes caused by disorders of cholesterol synthesis. J Lipid Res, 52, *6–34.*

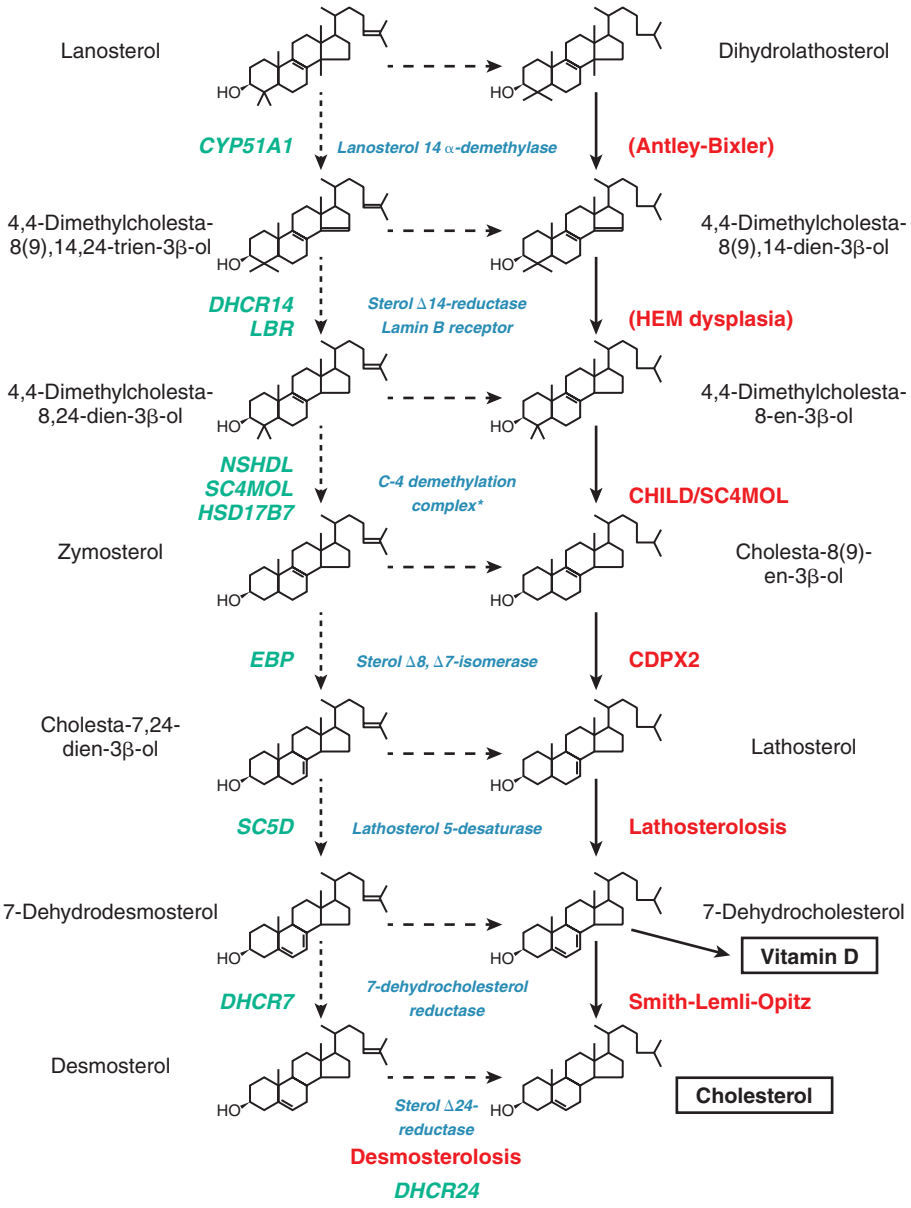

FIGURE 18-17 ■ Biosynthesis of cholesterol depicting the sites of enzyme activity lost by inactivating mutations that lead to skeletal, genital, and systemic malformations. The conversion of lanosterol to cholesterol may proceed through two pathways as depicted (see text for details). (From Forbes, F. D., & Herman, G. E. (2011). Malformation syndromes caused by disorders of cholesterol synthesis. *J Lipid Res, 52*, 6–34.) *This image can be viewed in full color online at ExpertConsult.*

Stippled epiphyses are detected by radiologic examination. Serum concentrations of cholesterol are depressed, whereas those of 7-dehydrocholesterol are elevated. The 7-dehydrocholesterol/cholesterol ratio is related to the clinical severity of the Smith-Lemli-Opitz phenotype under usual circumstances.[524] Anecdotal reports suggest that cholesterol supplementation may improve the health, behavior, and growth of children with the Smith-Lemli-Opitz syndrome.

Desmosterolosis is an autosomal recessive disorder with diverse clinical manifestations that include impaired growth, osteosclerosis, shortened limbs, macro- or microcephaly, cleft palate, micrognathia, thick alveolar ridges, developmental delay, and spasticity. Cranial magnetic resonance imaging reveals little white matter and a thinned to almost complete agenesis of the corpus callosum. Desmosterolosis is due to biallelic inactivating mutations of the gene (*DHCR24*) encoding 3β-hydroxysterol-Δ^{24} reductase, an enzyme that converts desmosterol to cholesterol.[522,525,526] Lathosterolosis is characterized by microcephaly, bitemporal narrowing of the skull, cataracts, anteverted nostrils, and other physical anomalies recorded in patients with the Smith-Lemi-Opitz syndrome.[522] It is the result of loss-of-function mutations in the gene (*SC5DL*) encoding 3β-hydroxysteroid-Δ5-desaturase, an enzyme that converts lathosterol to 7-dehydrocholesterol. Chondrodysplasia punctata 2 is an X-linked dominant disorder (Conradi-Hünermann-Happle syndrome) that is ordinarily (but not always) lethal in the affected male. It is characterized clinically

in the affected female by short stature with asymmetric short proximal limbs (rhizomelic dwarfism), frontal bossing, scaly and erythematous skin lesions that resemble ichthyosis in children and atrophic pigmentary lesions in adults, coarse hair with alopecia, and cataracts; reflecting functional X-chromosomal mosaicism in females, the phenotype may vary from stillborn to mildly affected.[522] Radiographic examination reveals generalized osteosclerosis, irregular punctate calcification (stippling) of epiphyses of the long bones, vertebrae, and tracheal cartilage in children. This disorder is due to loss-of-function mutations in *EBP* (*E*mopamil-*B*inding *P*rotein), the gene encoding 3β-hydroxysteroid-Δ^8,Δ^7isomerase, an enzyme that converts cholesta-8(9)-en-3β-ol to lathosterol; in the serum of subjects with chondrodysplasia punctata 2 plasma concentrations of 8-dehydrocholesterol cholest-8(9)-en-3β-ol are elevated. This protein also binds many unrelated molecules; its genetic designation derives from its ability to bind emopamil (i.e., EBP), a calcium ion antagonist. X-linked recessive and autosomal recessive forms of the Conradi-Hünermann-Happle syndrome have also been reported, suggesting genetic heterogeneity for this phenotype. The CHILD syndrome of congenital hemidysplasia with ichthyosiform erythroderma or nevus and limb defects is remarkable for its unilateral distribution of anomalies that are confined to half of the body.[522] It is an X-linked disorder due to loss-of-function mutations in *NSDHL* (*N*ADPH *s*teroid *deh*ydrogenase-*l*ike) encoding a sterol dehydrogenase or decarboxylase that is part of the 3β-hydroxysteroid C-4 sterol demethylase complex that also includes the products of *SC4MOL* and *HSD17B7*. This complex converts 4,4-dimethylcholesta-8-en-3β.ol to cholesta-8(9)-en-3β-ol.

The often-lethal Greenberg dysplasia of hydrops-ectopic calcification-moth-eaten (HEM) skeletal dysplasia is transmitted as an autosomal recessive trait associated with short-limbed dwarfism, polydactyly, and irregularly decreased calcification of the long bones together with calcification of the larynx and trachea. It is due to a loss-of-function mutation in the gene (*LBR*) encoding the lamin B receptor, a nuclear envelope inner membrane protein that not only binds lamin B but also has 3β-hydroxysteroid-Δ^{14} reductase activity, an enzyme that converts 4,4-dimethylcholesta-8(9)-dien-3β-ol to 4,4-dimethylcholesta-8-en-3β-ol, a necessary step for normal cholesterol biosynthesis. 3β-hydroxysteroid-Δ^{14} reductase activity is also encoded by *DHCR14*, an endoplasmic reticular enzyme that too catalyzes reduction of unsaturated C14-C15 intermediate sterols.[522,527] The HEM dysplasia is considered to be a laminopathy rather than an inborn error in cholesterol biosynthesis. The Antley-Bixler syndrome (MIM 207410) of craniosynostosis, humeroradial synostosis, femoral bowing midface hypoplasia, choanal stenosis/atresia, and joint contractures has been associated with heterozygous mutations in *FGFR2* (MIM 176943). When these skeletal anomalies coexist with genital malformations and defects in steroidogenesis (MIM 201750), biallelic loss-of-function mutations have been identified in *POR* (MIM 124015), encoding P450 oxidoreductase, a donor of electrons for the P450 enzymes required for synthesis of adrenocortical and gonadal steroids. Thus, when POR activity is decreased, function of the enzyme encoded by *CYP51A1* MIM601637)) that converts dihydrolathosterol to 4, 4-dimethylcholesta-8(9).14-dien-3β-ol is depressed.

CONCLUDING REMARKS

Deciphering of the complex mechanisms that underlie the pathophysiology of illnesses that adversely affect the regulation of calcium, phosphate, and magnesium metabolism; chondrocyte differentiation and growth, and bone formation, mineralization, and strength has been further informed by the insights that advances in genetics, epigenetics, and proteomics have brought to these clinical problems. It may be anticipated that further clarification of the basic mechanisms that underlie these disorders will enable translation of these findings into the care of many disorders that affect young patients.

ADDENDUM

Loss-of-function mutations in *GNA11* encoding guanine nucleotide-binding protein alpha 11 (chromosome 19p13.3, MIM 139313) have been identified in patients with autosomal dominant familial hypocalciuric hypercalcemia type 2 (MIM 145981).[534] Gain-of-function mutations in GNA11 have been found in patients with autosomal dominant hypoparathyroidism.[534,535]

Inactivating mutations in *AP2S1* encoding adaptor protein-2α subunit (chromosome 19q13, MIM 602242) involving solely the Arg15 residue of AP2S1 have been identified in patients with autosomal dominant familial hypocalciuric hypercalcemia type 3 (MIM 600740) clinically associated with hypophosphatemia, elevated serum levels of PTH, and decreased bone mineralization.[536] AP2S1 is one subunit of a heterotetrameric protein critical for clathrin-related endocytosis of G protein-coupled receptors. Inactivating variants of AP2S1 decrease sensitivity of CASR to Ca^{2+}_0, reduce its rate of endocytosis, and decrease intracellular signal transduction.

Kenny-Cafey syndrome 2 (MIM 127000) has been attributed to monoallelic loss-of-function mutations in *FAM111A* (MIM 615292, chromosome 11q12.1), a protein with sequences common to trypsin like proteinases. [537,538]

Osteogenesis imperfecta type XV (MIM 615220) has been assigned to mutations in *WNT1*[539,540]. *WNT1* encodes the ligand of the osteoblast membrane receptor Frizzled; binding of *WNT1* to Frizzled and its co-receptors LRP 5/6 regulates intracellular signaling through the β-Catenin, $G_{\alpha q}$-protein, and PLC signal transduction pathways resulting in both osteoblastogenesis and osteoblast function. Biallelic loss-of-function in *WNT1* have been identified in several families whose members have had fractures at a young age, bone deformities, decreased bone mineralization, growth retardation, and occasionally blue sclerae. Dental development and hearing have been normal in these patients but some affected subjects have had developmental delay and brain malformations.[541]

ADHR	Autosomal dominant hypophosphatemic rickets
AHO	Albright hereditary osteodystrophy
AMP	Adenosine monophosphate
APECED	Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy
APS	Autoimmune polyendocrine syndrome
ARHR	Autosomal recessive hypophosphatemic rickets
ASARM	Acidic serine aspartate-rich MEPE-associated motif
ATP	Adenosine triphosphate
BCE	Bovine cartilage equivalent
BMC	Bone mineral content
BMD	Bone mineral density
BMP	Bone morphogenetic protein
Ca^{2+}_e	Calcium-ionized, extracellular
CaSR	Calcium sensing receptor
CBP	Collagen binding protein (HSP)
CKD-MBD	Chronic kidney disease-mineral and bone disorder
COL1A1	Bone collagen subunit α1 (I)
CRTAP	Cartilage-associated protein
CTx	Carboxyl terminal cross-link telopeptide of collagen type I
DEXA	Dual-energy x-ray absorptiometry
DGCR	DiGeorge syndrome critical region
DGS	DiGeorge syndrome
DMR	Differentially methylated region
Dpd	Deoxypyridinoline
FGF	Fibroblast growth factor
FGFR	FGF receptor
FIHP	Familial isolated primary hyperparathyroidism
FISH	Fluorescent in situ hybridization
FOP	Fibrodysplasia ossificans progressiva
GDNF	Glial-derived neurotrophic factor
GDP	Guanosine diphosphate
GH	Growth hormone
GLP-2	Glucagon-like peptide 2
GPCR	G-protein coupled receptor
$G_s\alpha$	α Subunit of stimulatory G-protein (Gsα)
GTP	Guanosine triphosphate
H^+	Hydrogen ion
HDR	Hypoparathyroidism, deafness, renal disease syndrome (Barakat disease)
HHC	Hereditary hypocalciuric hypercalcemia
HRD	Hypoparathyroidism, retardation, dysmorphism syndrome
HSP	Heat shock protein (CBP)
ICTP	Carboxyl telopeptide of collagen type I
IFITM5	Interferon-induced transmembrane protein-5 or bone-restricted ITIFM5-like protein
IGF	Insulin-like growth factor
IL	Interleukin
IOF	International Osteoporosis Foundation
ISCD	International Society for Clinical Densitometry
KCS	Kenny-Caffey syndrome
LBW	Low birth weight
MAPK	Mitogen-activated protein kinase
M-CSF	Macrophage-colony stimulating factor
MCT	Medullary carcinoma of thyroid
MEN	Multiple endocrine neoplasia
MEPE	Matrix extracellular phosphoglycoprotein
Mg^{2+}	Magnesium
MIM	Mendelian Inheritance in Man*
MPA	Medroxyprogesterone acetate
NFκB	Nuclear factor κB
NHERF1	Sodium hydrogen exchanger regulatory factor 1
NSHPT	Neonatal severe hyperparathyroidism
NTx	Amino terminal telopeptide of collagen type I
OIC	Osteogenesis imperfecta congenita
OSTM1	Osteopetrosis-associated transmembrane protein-1
P3H1	Prolyl 3-hydroxylase 1
PDDR	Pseudovitamin D–deficiency rickets
PEDF	Pigment epithelium derived factor
PHEX	Phosphate-regulating endopeptidase homologue, X-linked
PHP	Pseudohypoparathyroidism
PICP	Carboxyl terminal propeptide of collagen type I
PIIINP	Amino terminal propeptide of collagen type III
POH	Progressive osseous heteroplasia
PPHP	Pseudopseudohypoparathyroidism
PTG	Parathyroid gland
PTH	Parathyroid hormone
PTHrP	PTH related protein
PTHR1	PTH/PTHrP receptor 1
Pyr	Pyridinoline
QCT	Quantitative computed tomography
QUS	Quantitative ultrasound
RANK	Receptor activator of nuclear factor κB
RANKL	RANK-ligand
SDS	Standard deviation score
SERM	Selective estrogen receptor modulator
sFRP4	Serum frizzled related protein-4
SIBLING	Short integrin-binding ligand-interacting glycoprotein
SOS	Speed of sound
TALH	Thick ascending limb of the loop of Henle
TGFβ	Transforming growth factor β
TNF	Tumor necrosis factor
TNSALP	Tissue nonspecific alkaline phosphatase
TRAP	Tartrate resistant acid phosphatase
TSH	Thyroid-stimulating hormone
VDDR1A	Vitamin D–dependent rickets type 1A
VDR	Vitamin D receptor
VDRE	Vitamin D response element
VEGF	Vascular endothelial growth factor
VLBW	Very low birth weight
WBS	Williams-Beuren syndrome
WINAC	WSTF including nucleotide assembly complex
WHO	World Health Organization
WSTF	Williams syndrome transcription factor
XLHR	X-linked dominant hypophosphatemic rickets
XLRH	X-linked recessive hypophosphatemic rickets
$1,25(OH)_2D_3$	1,25-Dihydroxyvitamin D_3 (calcitriol)
$25OHD_3$	25-Hydroxyvitamin D_3 (calcidiol)

QUESTIONS

1. Pathophysiologically, what causes hypocalcemia?
   a. Abnormalities in the packaging of parathyroid hormone (PTH) within the Golgi apparatus of the parathyroid chief cell
   b. A subnormal rate of transit of parathyroid hormone (PTH) through the endoplasmic reticulum to the plasma membrane
   c. Inhibition of *PTH* transcription
   d. Increased sensitivity of the calcitonin receptor to its endogenous ligand
   e. Impaired release of PTH from the parathyroid chief cell

Answer: e

2. Pseudohypoparathyroidism type IA is the result of monoallelic variations in which of the following?
   a. Paternal transcript of *PTH1R* (PTH/PTHrP receptor)
   b. Maternal genes encoding both adenylyl cyclase (*ADC1*) and protein kinase B (*AKT1*)
   c. Product of paternal *MAP2K1* (encoding mitogen-activated protein kinase kinase 1)
   d. Maternal Gαs transcript of *GNAS* (guanine nucleotide-binding protein, alpha-stimulating activity polypeptide)
   e. Maternal transcript of *TBCE* (encoding tubulin specific chaperone E)

Answer: d

3. In the majority of patients, neonatal severe hyperparathyroidism is the result of which genetic variation?
   a. Biallelic insertion of the amino acid glycine at codon 73 of paternal *CASR* (encoding the calcium sensing receptor)
   b. Monoallelic paternal activating mutation in *CASR*
   c. Biallelic loss-of-function mutations in *CASR*
   d. Monoallelic deletion of the entire maternal *CASR* gene
   e. Mutations in the 5′ regulatory region of *CASR*

Answer: c

4. What results from a loss of renal 24-hydroxylase activity?
   a. Hypophosphatemia
   b. Hypercalcemia
   c. Osteopenia
   d. Rickets
   e. Osteosclerosis

Answer: b

5. Which of the following describes the Williams-Beuren syndrome of infantile hypercalcemia?
   a. It is characterized by mitral valve prolapse, extremely fine facial features, and overgrowth.
   b. It is related to loss-of function of *BAZ1B* (encoding the Williams syndrome transcription factor).
   c. It is the result of increased functional activity of WINAC (WSTF including nucleoside assembly complex).
   d. It is dependent on increased activity of hepatic 25-hydroxylase.
   e. It is transmitted as a sex-linked recessive trait.

Answer: b

6. Which of the following is true about phosphopenic rickets due to loss-of-function mutations in *PHEX* (encoding phosphate-regulating endopeptidase homologue, X linked)?
   a. It is manifested radiographically by extremely fragile long bone with decreased cortical width.
   b. It is pathogenetically related to a functional abnormality of the vitamin D nuclear receptor.
   c. It is associated with decreased production of fibroblast growth factor-23 (FGF23).
   d. It adversely affects membrane bone formation primarily.
   e. It is due to failure to prevent the release and degradation of phosphorylated acidic serine aspartate-rich MEPE-associated motif (ASARM).

Answer: e

7. What causes the metabolic bone disease that develops in children with chronic renal insufficiency?
   a. Decreased secretion of FGF23
   b. Excessive osteoblast synthesis of collagen type I
   c. Impaired renal excretion of phosphate
   d. Increased renal tubular calcium reabsorption in response to α-klotho
   e. Subnormal activity of the parathyroid chief cells

Answer: c

8. Which of the following is true about bisphosphonates?
   a. In excess, they paradoxically decrease bone density.
   b. They are administered by deep intramuscular injection.
   c. They act by incorporating into bone marrow precursor cells, thus prolonging their life span.
   d. They augment bone mineralization by increasing osteoblastogenesis.
   e. They are retained in bone for many years.

Answer: e

CHAPTER 19

Diabetes Mellitus

CHAPTER OUTLINE

INTRODUCTION

Diabetes mellitus (DM) is best defined as a syndrome characterized by inappropriate fasting or postprandial hyperglycemia, caused by absolute or relative insulin deficiency and its metabolic consequences, which include disturbed metabolism of protein and fat. This syndrome results from a combination of deficiency of insulin secretion and its action. Diabetes mellitus occurs when the normal constant of the product of insulin secretion times insulin sensitivity, a parabolic function termed the "disposition index" (Figure 19-1), is inadequate to prevent hyperglycemia and its clinical consequences of polyuria, polydipsia, and weight loss. At high degrees

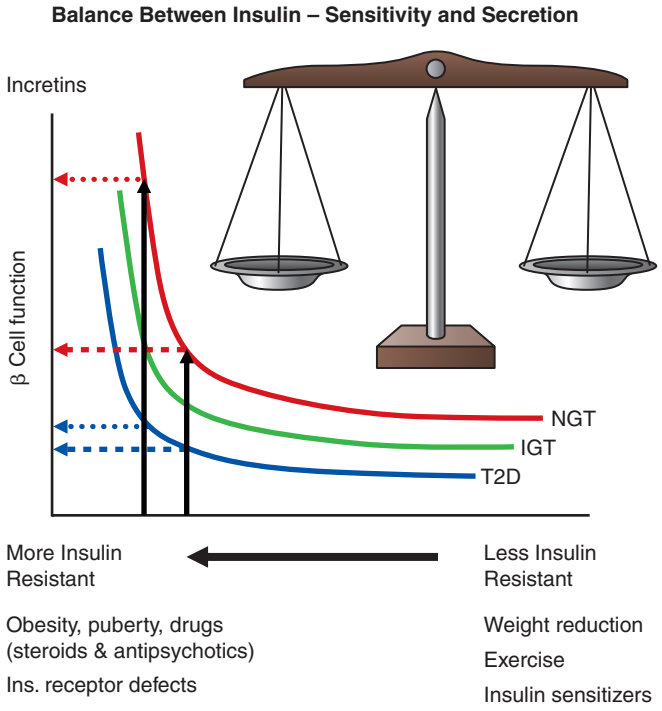

FIGURE 19-1 ■ **This figure shows the hyperbolic relationship of insulin resistance and beta cell function. On the y-axis is beta cell function as reflected in the first-phase insulin response during intravenous (IV) glucose infusion; on the x-axis is insulin sensitivity and its mirror image resistance. In a subject with normal glucose tolerance (NGT) and beta-cell reserve, an increase in insulin resistance results in increased insulin release and normal glucose tolerance. In an individual for whom the capacity to increase insulin release is compromised, increasing insulin resistance with partial or no beta-cell compensation results in progression from normal glucose tolerance, to impaired glucose tolerance (IGT), and finally to diabetes (T2D). Differences between these categories are small at high insulin sensitivity, which may be maintained by weight reduction, exercise, and certain drugs. At a critical degree of insulin resistance, due to obesity or other listed factors, only a further small increment in resistance requires a large increase in insulin output. Those that can increase insulin secretion to this extent retain normal glucose tolerance; those who cannot achieve this degree of insulin secretion (e.g., due to a mild defect in genes regulating insulin synthesis, insulin secretion, insulin action, or an ongoing immune destruction of beta cells) now unmask varying degrees of carbohydrate intolerance. The product of insulin sensitivity (the reciprocal of insulin resistance) and acute insulin response (a measurement beta-cell function) has been called the "disposition index." This index remains constant in an individual with normal beta cell compensation in response to changes in insulin resistance. IGT, impaired glucose tolerance; NGT, normal glucose tolerance; T2D, type 2 diabetes.** (From Ize-Ludlow, D., & Sperling, M. A. (2005). The classification of diabetes mellitus: a conceptual framework. *Pediatr Clin North Am, 52*, 1533–1552.)

of insulin sensitivity, small declines in the ability to secrete insulin cause only mild, clinically imperceptible defects in glucose metabolism. However, irrespective of insulin sensitivity, a minimum amount of insulin is necessary for normal metabolism. Thus, near absolute deficiency of insulin must result in severe metabolic disturbance as occurs in type 1 diabetes mellitus (T1DM). By contrast, with decreasing sensitivity to its action, higher amounts of insulin secretion are required for a normal disposition index. At a critical point in the disposition index curve (see Figure 19-1), a further small decrement in insulin sensitivity requires a large increase in insulin secretion; those who can mount these higher rates of insulin secretion retain normal glucose metabolism, whereas those who cannot increase their insulin secretion because of genetic or acquired defects now manifest clinical diabetes as occurs in type 2 diabetes (T2DM).

By simultaneously considering insulin secretion and insulin action in any given individual, it becomes possible to account for the natural history of diabetes in that person (e.g., remission in a patient with T1 diabetes or ketoacidosis in a person with T2DM). Thus, diabetes mellitus may be the result of absolute insulin deficiency, or of absolute insulin resistance, or a combination of milder defects in both insulin secretion and insulin action.[1] Collectively, the syndromes of diabetes mellitus are the most common endocrine/metabolic disorders of childhood and adolescence. The application of molecular biologic tools continues to provide remarkable insights into the etiology, pathophysiology, and genetics of the various forms of diabetes mellitus that result from deficient secretion of insulin or its action at the cellular level.

Morbidity and mortality stem from the metabolic derangements and from the long-term complications that affect small and large vessels, resulting in retinopathy, nephropathy, neuropathy, ischemic heart disease, and arterial obstruction with gangrene of extremities.[2] The acute clinical manifestations can be fully understood in the context of current knowledge of the secretion and action of insulin.[3] Genetic and other etiologic considerations implicate autoimmune mechanisms in the evolution of the most common form of childhood diabetes, known as type 1a diabetes.[4,5] Genetic defects in insulin secretion are increasingly recognized and understood as defining the causes of monogenic forms of diabetes such as maturity-onset diabetes of youth (MODY) and neonatal DM and contributing to the spectrum of T2DM.[6]

There is strong evidence that the long-term complications are related to the degree and duration of metabolic disturbances.[2] These considerations form the basis of standard and innovative therapeutic approaches to this disease that include newer pharmacologic formulations of insulin, delivery by traditional and more physiologic means, and evolving methods to continuously monitor blood glucose to maintain it within desired limits by linking these features to algorithm-driven insulin delivery pumps for an "artificial pancreas."

CLASSIFICATION

Diabetes mellitus is not a single entity but a heterogeneous group of disorders in which there are distinct genetic patterns as well as other etiologic and pathophysiologic mechanisms that lead to impairment of glucose tolerance.[1,7] Box 19-1 outlines an etiologic classification of diabetes mellitus in children, based on the "Report of the Expert Committee on the Classification and Diagnosis of Diabetes Mellitus," published by the American Diabetes Association in January of 2013.[7]

BOX 19-1 Etiologic Classification of Diabetes Mellitus

I. Type 1 Diabetes (Beta-Cell Destruction Ultimately Leading to Complete Insulin Deficiency)
- A. Immune mediated
- B. Idiopathic

II. Type 2 Diabetes (Variable Combinations of Insulin Resistance and Insulin Deficiency)
- A. Typical
- B. Atypical

III. Genetic Defects of Beta-Cell Function
- A. MODY syndromes
  1. MODY 1 chromosome 20, HNF-4α
  2. MODY 2 chromosome 7, glucokinase
  3. MODY 3 chromosome 12, HNF-1α, TCF-1
  4. MODY 4 chromosome 13, IPF-1
  5. MODY 5 chromosome 17, HNF-1β, TCF-2
  6. MODY 6 chromosome 2q32, neuro-D1/beta-2
- B. Mitochondrial DNA mutations (includes one form of Wolfram syndrome, Pearson syndrome, Kearns-Sayre, diabetes mellitus, deafness)
- C. Wolfram syndrome—DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, deafness): WFS1-Wolframin—chromosome 4p
  1. Wolfram locus 2—chromosome 4q22-24
  2. Wolfram mitochondrial
- D. Thiamine responsive megaloblastic anemia and diabetes

IV. Drug or Chemical Induced
- A. Antirejection—cyclosporine, sirolimus
- B. Glucocorticoids (with impaired insulin secretion; e.g., cystic fibrosis)
- C. L-Asparaginase
- D. β-Adrenergic blockers
- E. Vacor (rodenticide)
- F. Phenytoin (dilantin)
- G. Alfa-interferon
- H. Diazoxide
- I. Nicotinic acid
- J. Others

V. Diseases of Exocrine Pancreas
- A. Cystic fibrosis–related diabetes
- B. Trauma—pancreatectomy
- C. Pancreatitis—ionizing radiation
- D. Others

VI. Infections
- A. Congenital rubella
- B. Cytomegalovirus
- C. Hemolytic-uremic syndrome

VII. Variants of Type 2 Diabetes
- A. Genetic defects of insulin action
  1. Rabson-Mendenhall syndrome
  2. Leprechaunism
  3. Lipoatrophic diabetes syndromes
  4. Type A insulin resistance—acanthosis
- B. Acquired defects of insulin action
  1. Endocrine tumors—rare in childhood
- C. Pheochromocytoma
- D. Cushing
- E. Others
  1. Anti-insulin receptor antibodies

VIII. Genetic Syndromes with Diabetes and Insulin Resistance/Insulin Deficiency
- A. Prader-Willi syndrome, chromosome 15
- B. Down syndrome, chromosome 21
- C. Turner syndrome
- D. Klinefelter syndrome
- E. Others
  1. Bardet-Biedel
  2. Alstrom
  3. Werner

IX. Gestational Diabetes

X. Neonatal Diabetes
- A. Transient—chromosome 6q24, KCNJ11, ABCC8, INS, HNF1β, others
- B. Permanent—agenesis of pancreas—glucokinase deficiency, homozygous, KCNJ11, ABCC8, others (see Table 9-1)

Our classification is modified to reflect more accurately the major categories in childhood, including the emergence of type 2 diabetes mellitus, cystic fibrosis-related diabetes, and drug-induced diabetes—largely from the antirejection agents cyclosporine, sirolimus, and tacrolimus (formerly FK-506). Table 19-1 presents a summary of the classification originally proposed in 1979 but incorporates the newer criteria for blood glucose values used to diagnose diabetes, impaired glucose tolerance, and gestational diabetes.

Among the insulin-dependent forms, severe lack of insulin secretion results most commonly from presumed autoimmune destruction of islets in genetically predisposed hosts. This form is synonymous with type 1a diabetes, formerly called juvenile-onset diabetes.[4,5,8,9] Severe insulin-dependent diabetes mellitus, clinically indistinguishable from the autoimmune form, may, however, not have any evidence of autoimmunity and can result from mitochondrial or other gene defects that interfere with normal insulin secretion or rarely from pancreatic agenesis.[10-13]

The more severe forms of the MODY syndromes, subsequently detailed, also may require insulin.[12,13] Clinically similar forms of diabetes may occur secondary to cystic fibrosis[14,15] from toxic drugs such as the immunosuppressive agents cyclosporine, sirolimus and tacrolimus,[16,17] the rodenticide Vacor,[18] or streptozotocin as used for certain pancreatic islet cell tumors[19]; with the hemolytic uremic syndrome[20]; or after pancreatectomy, such as for persistent hyperinsulinemic hypoglycemia in infancy.[21] Childhood insulin-dependent diabetes is generally type 1a diabetes mellitus.

TABLE 19-1 **Summary of Classification of Diabetes Mellitus in Children and Adolescents**

Category	Criteria
Diabetes Mellitus	
Type 1	Typical symptoms: glucosuria, ketonuria; random plasma glucose > 200 mg/dL
Type 2	Fasting plasma glucose > 126 mg/dL with 2-hour intervening value > 200 mg/dL on OGTT more than once and in the absence of precipitating factors
Other types	Type 1 or 2 criteria with genetic syndrome, drug therapy; pancreatic disease or other known causes or associations
Impaired fasting glucose	Glucose > 110 mg/dL but < 126 mg/dL
Impaired glucose tolerance	Fasting plasma glucose < 126 mg/dL with 2-hour > 140 mg/dL but < 200 mg/dL on OGTT
Gestational diabetes	Two or more abnormal fasting plasma glucose levels > 105 mg/dL, 1-hour > 180 mg/dL, 2-hour > 155 mg/dL, 3-hour > 140 mg/dL on OGTT
Statistical Risk Classes	
Previous abnormality of glucose tolerance	Normal OGTT with previously abnormal OGTT, spontaneous hyperglycemia, or gestational diabetes
Potential abnormality of glucose tolerance	Genetic propensity (e.g., identical twin with diabetes mellitus); islet cell antibodies

Type 1 Diabetes Mellitus

This condition is characterized by severe insulinopenia and dependence on exogenous insulin to prevent ketosis and to preserve life. Thus, it was termed insulin-dependent diabetes mellitus (IDDM). The natural history of this disease indicates that there are preketotic non–insulin-dependent phases before and after the initial diagnosis. Although the onset is predominantly in childhood, the disease may occur at any age.[1] Therefore, such names as "juvenile diabetes," "ketosis-prone diabetes," and "brittle diabetes" were abandoned in favor of the term *type 1 diabetes*.

Type 1a diabetes is generally distinct by virtue of its association with certain histocompatibility locus antigens (HLAs) and other genetic markers the majority of which determine the response to self (or exogenous) antigens; by the presence of circulating antibodies to cytoplasmic and cell-surface components of islet cells; of antibodies to insulin in the absence of previous exposure to exogenous injection of insulin, of antibodies to glutamic acid decarboxylase (GAD, the enzyme that converts glutamic acid to γ-aminobutyric acid found abundantly in the innervation of pancreatic islets), of antibodies to IA-2 (an islet cell-associated phosphatase and antibodies to the zinc transporter molecule ZnT8); by lymphocytic infiltration of islets early in the disease; and by coexistence with other autoimmune diseases.[4,5] Occasionally, markers of autoimmunity are not found and yet there is profound insulinopenia and dependence on insulin without evidence of a mitochondrial or other genetic defect. In these cases, type 1 diabetes is considered idiopathic (type 1b). With the exceptions noted, diabetes in children is usually insulin dependent and fits the type 1a category.[1]

Type 2 Diabetes

Persons with this subclass of diabetes (formerly known as "adult-onset diabetes," "maturity-onset diabetes" [MOD], or "stable diabetes") may not be permanently insulin dependent and only occasionally develop ketosis. Some may, however, need insulin to correct symptomatic hyperglycemia—and ketosis may develop in some during severe infections or other stress. Therefore, this was previously called non–insulin-dependent diabetes mellitus (NIDDM).[1] This form of diabetes is becoming an increasing problem in overweight adolescents, especially those from vulnerable groups such as Africans, Mexicans, Native Indians, and other susceptible ethnic groups.[22,23]

Type 2 diabetes (T2DM) is not a single entity.[1] T2DM may be a primary disorder, with inadequate insulin secretion caused by mutations in one of several genes encoding enzymes or transcription factors important to islet cell development and insulin secretion. Several of these defects are now part of the spectrum of the syndromes commonly associated with maturity onset diabetes of youth (MODY), which has a dominant mode of inheritance.[12,13,24] However, some patients with MODY defects, which we term *monogenic diabetes of youth*, may require insulin from

the outset or as they grow older and become insulin resistant, exceeding their ability to compensate by increasing insulin secretion (see Figure 19-1). A defect in the gene regulating glucose transport into the pancreatic beta cell, the GLUT2 transporter, may be responsible for another form of type 2 diabetes.[24]

Defects in glycogen synthase have also been implicated.[25,26,] A primary defect in insulin receptors—often associated with acanthosis nigricans,[27] postreceptor defects (including Rad [Ras associated with diabetes]),[28] and milder mitochondrial gene defects[10]—also may result in type 2 diabetes. Secondary causes of type 2 diabetes mellitus include excessive counterregulatory hormones, especially pharmacologic doses of glucocorticoids, antibodies to the insulin receptor, and obesity with impaired insulin secretion.[29-40]

In type 2 diabetes mellitus, the serum concentration of insulin may be increased, normal, or moderately depressed depending on whether the defect is one of insulin action or secretion.[27-40] The onset of type 2 diabetes mellitus occurs in children generally around the time of puberty or shortly thereafter, but it is recognized, that it may occur at any age and is becoming increasingly frequent in childhood and adolescence.[22,23] In some instances, there appears to be adequate secretion of insulin but resistance to its actions, and in some individuals it may represent slowly evolving type 1 diabetes mellitus.[38] As an initial approach, weight reduction is indicated in children who are obese. In type 2 diabetes, there is no association with specific HLA antigens, autoimmunity, or various islet cell antibodies (ICAs).[40] However, several genetic abnormalities regulating insulin secretion are increasingly implicated in T2DM.[40]

TYPE 1 DIABETES MELLITUS

Epidemiology

The prevalence of diabetes mellitus is highly correlated with increasing age. Available data indicate a range of 1 case per 1430 children at 5 years of age to 1 case in 360 children at 16 years.[41-45] Data on incidence in relation to racial or ethnic backgrounds indicate a range of more than 50 new cases annually per 100,000 population in Finland and Sardinia to about 1 per 100,000 in China and parts of South America[42-46] (Figure 19-2). In all examined areas there appears to be an increasing incidence of T1DM of about 2% to 3% per year. However, the incidence of T1DM in Finland was reported to have peaked and slightly decined.[41]

In the United States, the occurrence of type 1 in blacks had previously been reported to be only between one third and two thirds of that in whites.[46] More recent data suggest that the incidence of diabetes mellitus in African Americans is increasing.[46,47] It is not clear, however, whether this increase in incidence among African Americans is exclusively type 1 or includes cases of type 2 presenting in ketoacidosis and thus misclassified.[46] The annual incidence in the United States is 20 to 25 cases per 100,000 of the childhood population[44] (see www.cdc.gov/diabetes/projects/diabetes/children.htm and Figure 19-2).

Males and females appear to be almost equally affected. There is no apparent correlation with socioeconomic status. Peaks of presentation occur in two age groups: at 5 to 7 years of age and at the time of puberty. The first peak corresponds to the time of increased exposure to infectious agents coincident with the beginning of school. The latter corresponds to the pubertal growth spurt induced by increased pubertal growth hormone secretion that antagonizes insulin action. The incidence of type 1 diabetes is increasing worldwide, most prominently in certain populations (e.g., Finland) and in certain age groups (especially those younger than age 5 years).[44,45] As mentioned, there appears to be a plateau in incidence reported from Finland.[41] In younger patients, onset appears to be more abrupt and the extent of immune markers is less apparent than in older children.[48] Type 1b diabetes with abrupt onset, less evidence of autoimmunity, and indicators of viral infection (including evidence of pancreatitis) has been described in Japan.[49,50]

Seasonal and long-term cyclical variations have been noted in the incidence of type 1 diabetes. Newly recognized cases appear to occur with greater frequency in the autumn and winter in the northern and southern hemispheres.[51] Seasonal variations are most apparent in the adolescent years.[51] There is no consistent pattern linking long-term cyclicity with the incidence of viral infections; however, there is a definite increased incidence of diabetes in children with congenital rubella.[52,53] These changing patterns in incidence and associations with viral infections suggest a potential role for viruses or other microbial agents or their products as direct or indirect triggering mechanisms for inducing T1DM in a susceptible host.[52-57]

Etiology, Pathogenesis, and Genetics

The cause of the initial clinical findings in this predominant form of diabetes in childhood is the sharply diminished secretion of insulin.[58] Although basal insulin concentrations in plasma may be normal in newly diagnosed patients, insulin production in response to a variety of potent secretagogues is blunted and usually disappears over a period of months to years. In certain individuals considered at high risk for the development of type 1 diabetes, such as the nonaffected identical twin of a diabetic, a progressive decline in insulin-secreting capacity has been noted for months to years before the clinical appearance of symptomatic diabetes that usually manifests when insulin-secreting reserve is 20% or less than normal for that individual (Figure 19-3).[4,5,58]

The mechanisms that lead to failure of the function of pancreatic beta cells point to autoimmune destruction of pancreatic islets in predisposed individuals. Type 1 diabetes has long been known to have an increased prevalence among persons with such disorders as Addison disease and Hashimoto thyroiditis, in whom autoimmune mechanisms are known to be pathogenic.[58] These conditions, as well as type 1 diabetes mellitus, are known to be associated with an increased frequency of genes involved in the regulation of immunity including the autoimmune regulator gene AIRE, PTPN22, CTLA4, and INS gene itself as well as certain histocompatibility loci antigens

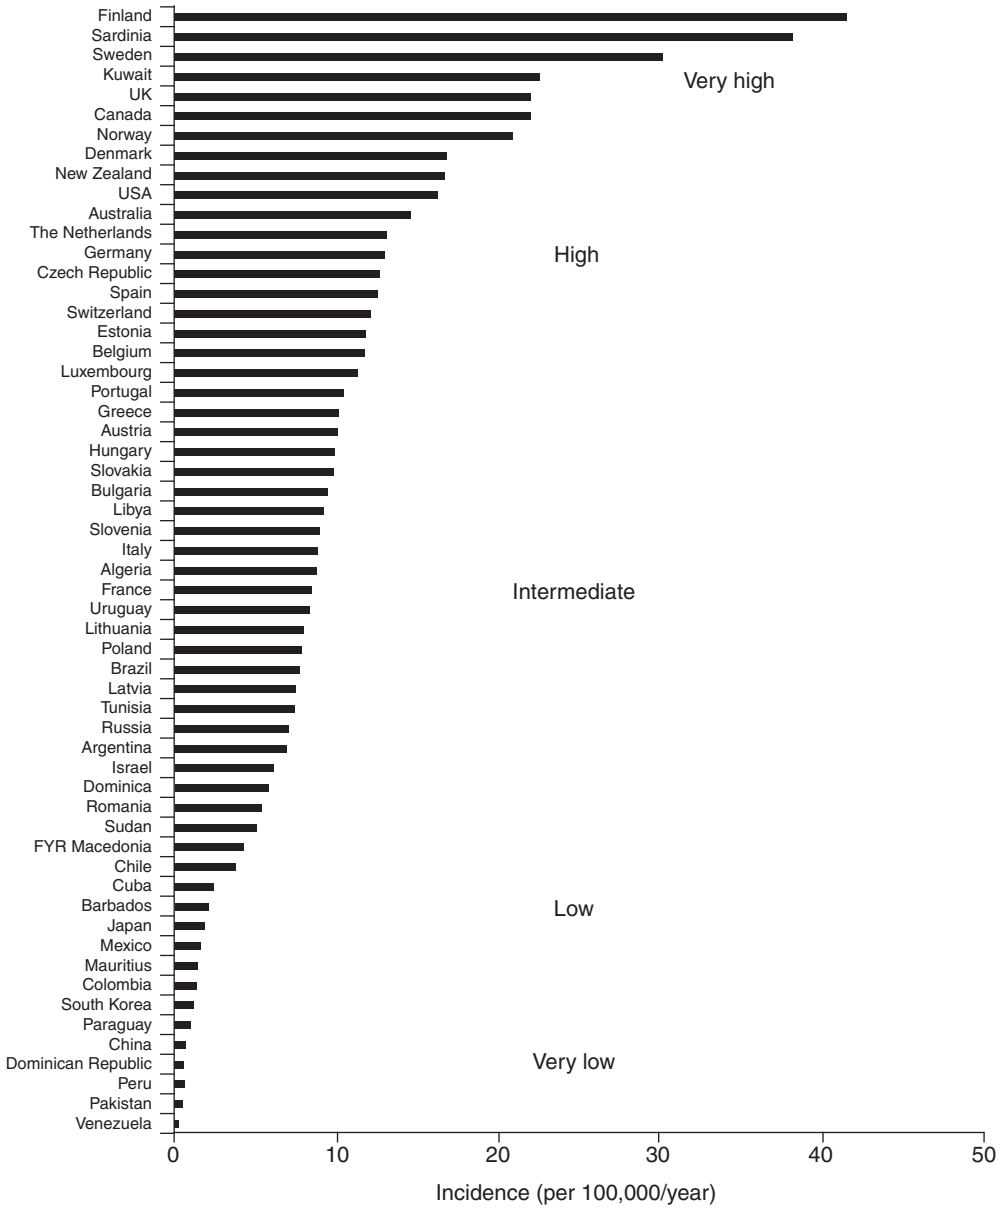

FIGURE 19-2 ■ Age-standardized incidence (per 100,000/year) of type 1 diabetes in children younger than 14 years of age in 100 populations. Data for boys and girls have been pooled. Countries are arranged in descending order according to the incidence. (Puerto Rico and the Virgin Islands are presented separately from other populations in the United States.) (From Diamond Project Group (2006). Incidence of trends of childhood type1 diabetes worldwide 1990-1999. *Diabet Med, 23,* 857–866.)

(HLAs)—in particular, DR3 and DR4.[58,59] Located on chromosome 6, the HLA system is the major histocompatibility complex—consisting of a cluster of genes that code transplantation antigens and play a central role in immune responses.[58-70]

Increased susceptibility to a number of diseases has been related to one or more of the identified HLA antigens. The inheritance of HLA DR3 or DR4 confers a twofold to threefold increased risk for developing type 1 diabetes. When both DR3 and DR4 are inherited, the relative risk for developing diabetes is increased sevenfold to tenfold. Application of newer molecular genetic techniques has revealed further heterogeneity in the HLA D region among individuals with and without diabetes despite possessing the DR3 or DR4 markers, suggesting the participation of other susceptibility loci within these markers.[58-70]

Extensive genome-wide scans of markers associated with type 1 diabetes mellitus have uncovered more than a 40 loci considered to confer susceptibility (Table 19-2). Some of these loci are confirmed and replicated by at least three different data sets. Others are suggestive but as yet not definitively linked. The strongest markers are those on chromosomes 6 and 11 (IDDM1 and IDDM2), respectively, linked to the HLA DQ β chain and the insulin gene itself.

In IDDM1, the homozygous absence of aspartic acid at position 57 of the HLA DQ *b* chain (non-Asp/non-Asp) confers an approximately 100-fold relative risk for developing type 1 diabetes. Those who are heterozygous

Adapted from Barrett, J. C., Clayton, D. G., Concannon, P., et al. for the Type 1 Diabetes Genetics Consortium (2009). Genome-wide association study and meta-analysis find that over 40 loci affect risk of type 1 diabetes. Nat Genet, 41, *703–707.*

with a single aspartic acid at position 57 (non-Asp/Asp) are less likely to develop diabetes and are no more susceptible than individuals who contain aspartic acid on both DQ *b* chains (i.e., homozygous Asp/Asp; Table 19-3). Some studies suggest that type 1 diabetes mellitus is proportional to the gene frequency of non-Asp alleles in that population.[69] In addition, arginine at position 52 of the DQ *a* chain confers marked susceptibility to type 1.[63] Position 57 of the DQ *b* and position 52 of the DQ *a* chains are at critical locations of the HLA molecule that permit or prevent antigen presentation to T-cell receptors and activate the autoimmune cascade (Figure 19-4).[60-63]

IDDM2 is a polymorphic marker near the transcription start site of the insulin gene, giving rise to variable numbers of tandem repeats (VNTR) at the promoter end of the insulin gene on chromosome 11. Each tandem repeat element consists of an approximately 14-bp DNA segment with a consensus nucleotide sequence. The number of repeats ranges from about 25 to about 200, and the three classes of alleles are based on overall size. Class I insulin VNTR consists of 26 to 63 repeats and confers susceptibility, whereas class III consists of 140 to 200 or more repeats and is protective of diabetes. Together, the gene markers on chromosomes 6 and 11 (i.e., IDDM1 and IDDM2) account for 50% to 60% of the heritability of type 1 diabetes. However, combinations of certain DQ alleles in association with certain DR alleles may confer susceptibility or protection to the development of type 1 diabetes (see Table 19-3).

In addition, other as yet undefined genetic factors play a role because the same high-risk genotypes are about sixfold more likely to develop diabetes in an individual with a positive family history than in one without a family history without type 1 diabetes (Table 19-4). Investigation of four genome-wide linkage scans in close to 1500 families with more than one affected member having

TABLE 19-3 **HLA DR and DQ Phenotype Frequencies in Patients with Type 1 Diabetes Mellitus and Healthy Control Subjects**

Phenotype	Diabetic (%)	Nondiabetic	Odds Ratio (%)
DR (Serology)			
DR3/DR4	33	6	8.3
DR3/DR3	7	1	9.8
DR3/DRX	7	14	0.05
DR4/DR4	26	0	—
DR4/DRX	22	16	1.5
DRX/DRX	4	63	0.02
DQ (Molecular Probes)			
Non-Asp/non-Asp	96	19	107.2
Non-Asp/Asp	4	46	0.04
Asp/Asp	0	34	0

Based on Morel, P. A., Dorman, J. S., Todd, J. A., et al. (1988). Aspartic acid at position 57 of the HLA-DQ beta chain protects against type 1 diabetes: a family study. Proc Natl Acad Sci USA, 85, *8111.*

T1DM identified several susceptibility loci. Of these, about 40% can still be attributed to allelic variation of HLA loci, and the influence of the VNTR in the insulin gene was confirmed.[59,64]

In addition, the cytotoxic T-lymphocyte antigen 4 (CTLA4) gene on chromosome 2 and the protein tyrosine phosphatase nonreceptor 22 (PTPN22) gene on chromosome 1p13 were found to contribute significantly to predisposition to T1DM. However, the genome scan identified other potential loci conferring susceptibility on chromosomes 2q31-q33, 10p14-q11, and 16q220q24 and a locus on the long arm of chromosome 6 (6q21) distinct from the HLA region on 6p21. The precise genes in these regions that may predispose to T1DM have not been identified as yet, although some have been excluded[59] and newer candidate genes—such as CBLB interacting with CTLA4,[66] the decay-accelerating factor gene (DAF, a complement inhibitor),[67] and the interleukin 2A receptor IL2RA—are under scrutiny.[63]

These considerations provide a rational framework for the long-recognized association of type 1 diabetes with genetic factors on the bases of the increased incidence in some families, of the concordance rates in monozygotic twins, and of ethnic and racial differences in prevalence.[59,63,70] From multiple family pedigrees and HLA typing data, it has been estimated that if a sibling shares both HLA D haplotypes with an index case the risk for that individual is 12% to 20%; for a sibling sharing only one haplotype, the risk for IDDM is 5% to 7%; and with no haplotypes in common, the risk is only 1% to 2%.[70] HLA typing is not recommended for routine practice, but for purposes of genetic counseling it can be safely assumed that in whites the overall recurrence risks to siblings is approximately 6% if the proband is younger than 10 years of age and 3% if older at the time of diagnosis. The risk to offspring is 2% to 5%, with the higher risk in the offspring of a diabetic father. [63,70]

Factors other than pure inheritance must also be involved in evoking clinical diabetes. For example, DR3 or DR4 is found in approximately 50% of the general population and non-Asp/non-Asp is found in approximately 20% of white nondiabetics in the United States. However, the risk for type 1 diabetes in these subjects is only one tenth that in an HLA-identical sibling of an index case with type 1 diabetes possessing these markers.[70] Even siblings sharing only one haplotype have a sixfold to tenfold greater risk of developing type 1 compared with the normal population (see Table 19-4).

Importantly, approximately 10% to 15% of patients with type 1 do not have HLA DR3 or DR4 (see Table 19-3).[58] Most compelling is the fact that the concordance rate among identical twins of whom one has insulin-dependent diabetes is only about 50%, suggesting the participation of environmental triggering factors or other genetic factor such as the postnatal selection of certain autoreactive T-cell clones that bear receptors recognizing "self." This postnatal process occurs within the thymus and implies that identical twins are not identical with respect to the T-cell receptor repertoire they possess.

Triggering factors might include viral infections.[54-57] In animals, a number of viruses can cause a diabetic syndrome, the appearance and severity of which depend on the genetic strain and immune competence of the species of animal tested. In humans, epidemics of mumps, rubella, and coxsackievirus infections have been associated with subsequent increases in the incidence of type1 diabetes. The acute onset of diabetes mellitus, presumably induced by coxsackievirus B4, has been described.[57] The viruses may act by directly destroying beta cells, by persisting in pancreatic beta cells as slow viral infections, or by triggering a widespread immune response to several endocrine tissues.[57]

A superantigen response may be involved in triggering T cells, bypassing the classic presentation by antigen-presenting cells (APCs) of the processed antigen in the context of restricted HLA molecules to T-cell receptors.[71] Some viruses and certain endotoxins or exotoxins are capable of inducing a superantigen response. In addition, the virus may induce initial beta cell damage—which

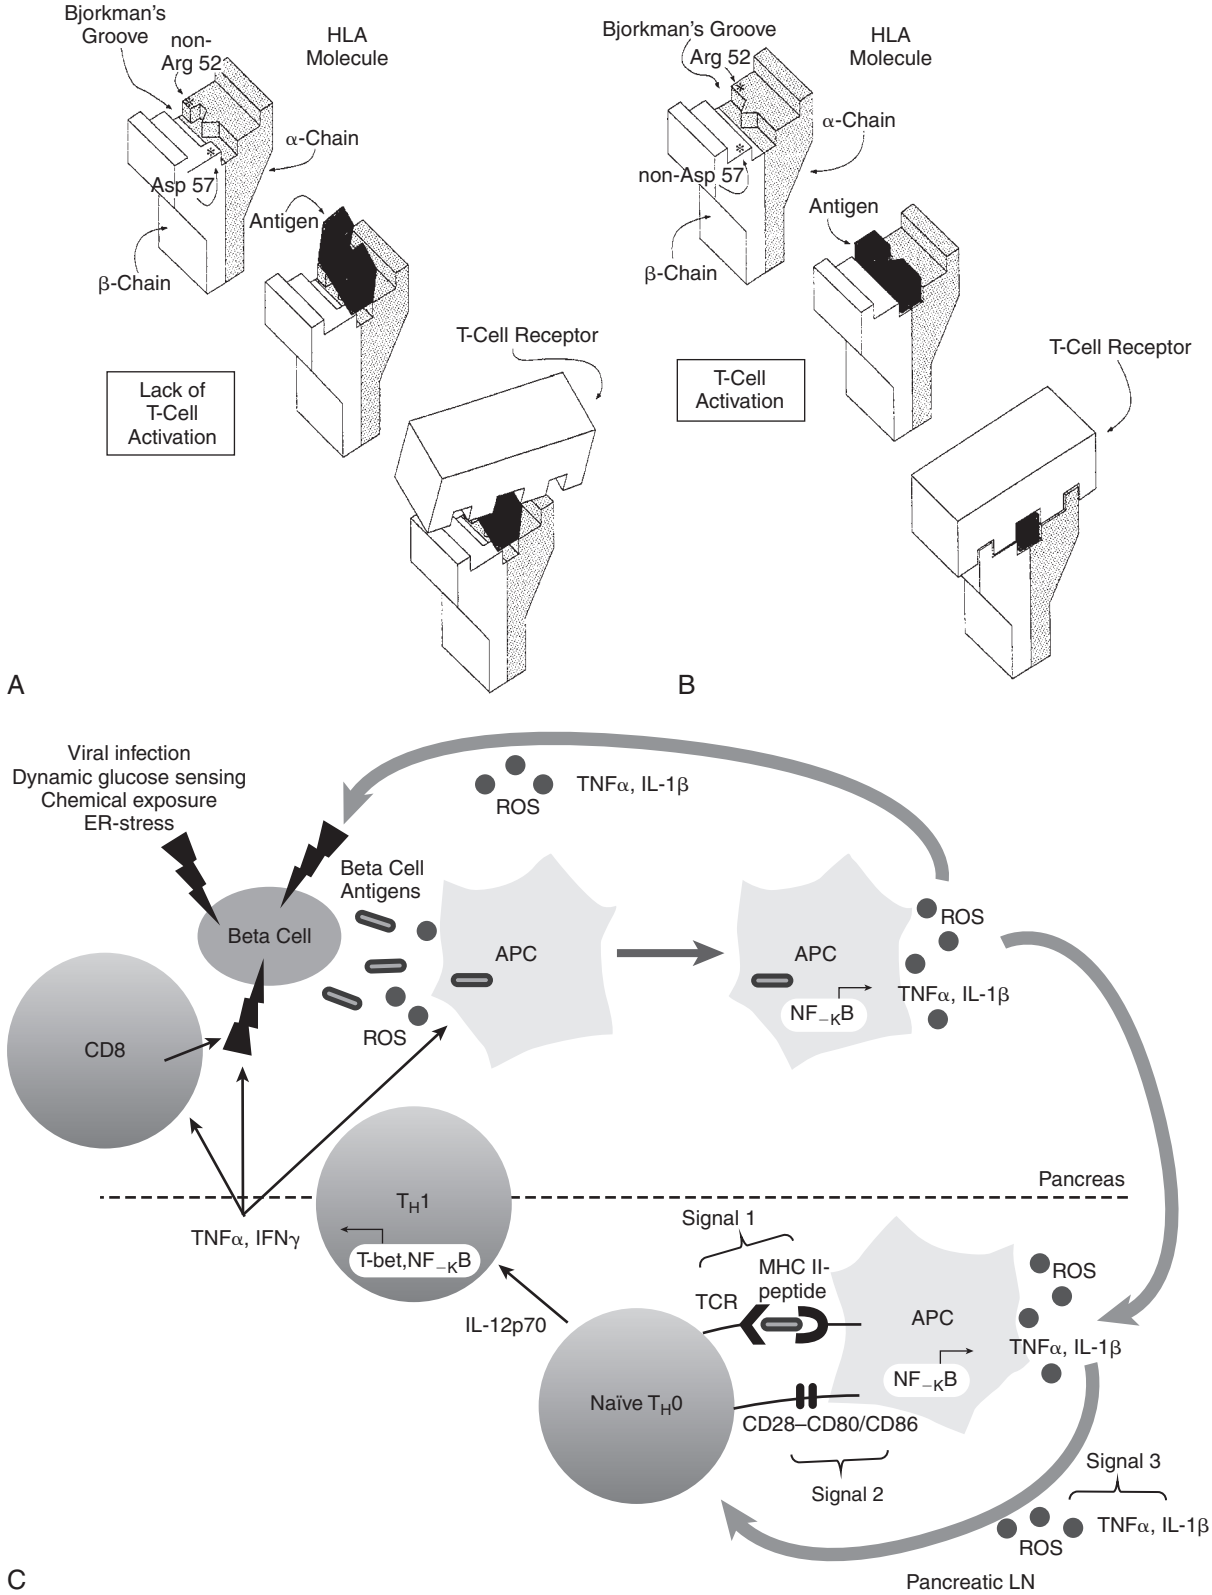

FIGURE 19-4 ■ Representation of the interaction between antigen presentation in the context of specific HLA-DQ subtypes and the T-cell receptor. **A,** Presence of aspartic acid at position 57 of the DQ *b* chain and an amino acid other than arginine at position 52 of the *a* chain prevents antigen lodging in the Bjorkman groove. Therefore, antigen presentation to the T-cell receptor is impaired—and in the absence of this "fit," T-cell activation is prevented. **B,** Lack of aspartic acid at position 57 of the DQ *b* chain and arginine at position 52 of the DQ *a* chain permits antigen to fit and be recognized by the T-cell receptor that is now activated. **C,** Role of redox in the immunopathology of type 1 diabetes. An initial genetic or environmental insult to the beta cell triggers the release of beta-cell antigens as well as the production of reactive oxygen species (ROS). Beta-cell antigens are phagocytosed, and ROS are able to stimulate redox-dependent transcription factors such as NF-κB, which leads to antigen presenting cell (APC) activation and cytokine secretion. ROS and proinflammatory cytokines secreted by APCs act as the third signal within the T-cell-APC immunologic synapse, which occurs in the pancreatic lymph node. ROS play a critical role in the progression of naïve TH0 cells to cytokine-secreting TH1 cells. Release of IFNγ by TH1 cells then works directly on the beta cells as well as activating more APCs and CD8 cells, all of which can impart deleterious effects on the islets. results in the presentation of previously masked or altered antigenic determinants. It is also possible that the virus shares some antigenic determinants with those present on or in beta cells, including GAD, such that antibodies formed in response to the virus may interact with these shared determinants of beta cells, resulting in their destruction, an example of molecular mimicry.[72-79]

Nitrosamines and early exposure to cow's milk have been suggested as factors that may trigger diabetes in those genetically at risk, thus explaining the reported lower incidence of diabetes among exclusively breastfed infants. This is the basis for one ongoing primary prevention study: the Trial to Reduce Insulin-dependent Diabetes in Those Genetically at Risk (TRIGR).[72-79] Antecedent stress and exposure to certain chemical toxins have been implicated in the development of type 1 diabetes. Although the rodenticide Vacor has been a cause of diabetes in individuals deliberately or inadvertently poisoned by this agent, some of these patients had islet cell antibodies (ICAs), suggesting that such antibodies are secondary to islet damage or that evolving type 1 disease preceded the drug ingestion. Nitrosamines in cured meat have also been implicated in type 1 diabetes, as have other environmental toxins.[72,80]

Evidence supports an autoimmune basis for the development of type 1 diabetes. but why the beta cell is the specific target remains a mystery.[43,81] Is the pancreatic beta cell the sole target of immune destruction (homicide) or a contributor to its own demise (suicide)? [43,81] Histologic examination of pancreas from patients with type 1 who die of incidental causes has revealed lymphocytic infiltration around the islets of Langerhans. Later the islets become progressively hyalinized and scarred, a process suggesting an ongoing inflammatory response that is possibly autoimmune.[82] However, these changes are often patchy in distribution, so that areas that appear to contain normal beta cells are interspersed with areas of beta-cell destruction, similar to the patchy distribution of depigmentation found in vitiligo.[58,83] Eighty percent to 90% of newly diagnosed patients with type 1 diabetes have ICA directed at cell surface or cytoplasmic determinants in their islet cells. The prevalence of these antibodies decreases with the duration of established disease. In contrast, after pancreatic transplantation ICA may reappear in patients whose sera had become negative for ICA before transplantation. Taken together, these findings suggest that ICA disappears as the antigens intrinsic to pancreatic islets are destroyed and reappear when fresh antigen (transplanted islets) is presented.

Studies in identical twins and in family pedigrees demonstrate that the existence of ICA may precede by months to years the appearance of symptomatic type 1 diabetes.[4] In vitro, ICA may impair insulin secretion in response to secretagogues and can be shown to be cytotoxic to islet cells—especially in the presence of complement or T cells from patients with type 1 diabetes. About 80% of patients may have antibodies to GAD, and 30% to 40% of newly diagnosed patients have spontaneous anti-insulin antibodies at initial diagnosis. These antibodies may be detected months to years before clinical diabetes becomes apparent.[4,60,75,81] A more recently described antibody, the zinc transporter, ZnT8, appears to be a major marker for progressive impairment of beta-cell function.[4] There is also evidence of abnormal T-cell function with an alteration in the ratio of suppressor (regulatory) to killer T cells at the onset of the disease.[4,5,8] Thus, the ability of Treg to modify the activity of T effector cells in causing beta-cell destruction is an area of investigation. These findings suggest that type 1 diabetes (akin to other autoimmune diseases such as Hashimoto thyroiditis) is a disease of "autoaggression" in which autoantibodies in cooperation with complement, T cells, cytokines, FAS, and FAS's ligand, and other factors, induce apoptosis or destruction of the insulin-producing islet cells.[5-8] Thus, the inheritance of certain genes (such as those associated with the HLA system on chromosome 6 or other immunoregulatory or immunomodulatory genes) appears to confer a predisposition for autoimmune disease—including diabetes—when triggered by an appropriate stimulus such as a virus.[4,5,9] Evidence of superantigen-triggered T-cell receptor activation was discussed earlier.[71]

Although it is understood that some insulin-dependent diabetic patients have none of the frequently associated HLA antigens, the evidence for an immune basis of islet cell destruction is sufficiently compelling to have fostered several studies of different immunosuppressive agents in the treatment of newly diagnosed diabetics (Table 19-5). None of these immunosuppressive or immunomodulatory agents has had long-term positive outcome, and some (e.g., cyclosporine) have proven toxic to beta cells.

TABLE 19-5 **Partial List of Past and Ongoing Trials in Type 1 Diabetes***

Intervention	Outcome	Study Status
Prevention Trials		
Cow's milk protein avoidance (TRIGR)	Pilot, promising	Fully powered trial enrolled, results pending
Gluten avoidance	Pilot, inconclusive	
Omega-3 fatty acid supplementation (NIP)	Pilot, did not reach primary outcome	
Vitamin D supplementation	Pilot, promising	
Parenteral insulin (DPT-1)	No effect	
Oral insulin (DPT-1)	Did not reach primary outcome; promising in subset of subjects	Enrolling confirmatory study
Intranasal insulin	Finnish study, no effect	Study enrolling in Australia (INIT II)
Nicotinamide (ENDIT)	No effect	
Anti-CD3 mAb		Currently enrolling
CTLA-4 Ig		Currently enrolling
Preservation Trials		
Anti-CD3 mAb	Series of phase 2 and 3 studies, promising	
CTLA-4 Ig	Phase 2, promising	
LFA-3 Ig	Phase 2, promising, under-enrolled and just missed primary endpoint	
ATG, cyclophosphamide, G-CSF	Three phase 1 studies, promising efficacy but safety concerns	
ATG	Phase 2, did not meet primary endpoint	
G-CSF	Small phase 2	Fully enrolled with results pending
ATG + G-CSF	Small phase 2	Fully enrolled with results pending
IL-2 + rapamycin	Phase 1, transient decrease in C-peptide	Study discontinued
IL-2, low dose		Fully enrolled with results pending
Polyclonal regulatory T cells	Two phase 1 studies, promising	North American study currently enrolling
Umbilical cord blood	Phase 1, no effect	
Anti-CD20 mAb	Phase 2, promising	
Anti-IL - 1 mAb	Phase 2, no effect	
Anti-IL - 1 receptor	Phase 2, no effect	
Alpha - 1 antitrypsin	Pilot, promising	Phase 2, fully enrolled with results pending
GAD-alum vaccine	Phase 2, 3 studies, no effect	
Diapep277 vaccine	Phase 2, 3 studies, mixed results	
Sitagliptin + lansoprazole	Phase 2	Fully enrolled with results pending
Intense metabolic control	Phase 2, no effect

Although newer approaches are being attempted, all must be considered as experimental and not be viewed as established or recommended therapy.[82-89] The Diabetes Prevention Trial for T1DM (DPT1) was a multicenter randomized but nonblinded study using daily subcutaneous insulin and an annual admission for intravenous insulin infusion in first-degree relatives with proven risk factors for developing T1DM. Whereas prediction was highly accurate in identifying those most likely to develop T1DM within 5 years of entering the study, insulin injections had no protective effect to prevent the appearance of T1DM.[82-89] Figures 19-3 and 19-4 summarize current concepts of the cause of type1 diabetes as an autoimmune disease, the tendency for which is inherited and in which autoimmune destruction of beta cells is triggered by an as yet unidentified agent (possibly a virus). The slope of decline in insulin varies, and there may be periods of partial recovery such that the course of decline in insulin secretion is bumpy rather than smooth. The point at which clinical features appear corresponds to approximately 80% destruction of insulin secretory reserve. This process may take months to years in adolescent and

older patients, and weeks in the very young patient in whom acute destruction by non-autoimmune mechanisms may play a significant role. Higher titers of spontaneous anti-insulin antibodies and ICA are characteristic of more active islet cell destruction, typically in the younger patient, and may prove useful in predicting evolving diabetes.[82-89]

Prediction and Prevention

Although no presently available single marker or test can accurately predict type 1 diabetes mellitus, evidence suggests that a combination of immune and genetic markers for type1 diabetes may provide predictability.[82-89] Some authorities suggest that type1 diabetes is a predictable disease, but other authorities have raised objections because predictability is not as robust in their studies. Definitive preventive therapy is not available, thereby raising ethical dilemmas, and the majority of new cases occur sporadically in the absence of a positive family history in a first-degree relative.

Most predictive studies have been performed in first-degree relatives of patients with new-onset type 1 diabetes.[74] Nevertheless, there is increasing evidence that the presence of high titers of islet cell, GAD, IA2, ZnT8, and insulin autoantibodies combined with a consistently diminished first-phase response of insulin to a pulse of intravenous glucose (corresponding to the fifth percentile or less for age in insulin response) can be used to reliably predict the onset of type 1 disease.[82-89]

Figure 19-5 demonstrates that in a set of first-degree relatives, conversion to type1 diabetes was highly dependent on the number of antibodies detected in their sera. Of those with three antibodies, about half developed clinical diabetes within 5 years of follow-up. First-phase insulin response and genetic (HLA) markers may be used to augment the predictability. For example, Table 19-6 demonstrates that the relative risk of developing clinical diabetes within 4 years of detecting ICA is almost 230 among those who possess all four heterodimers in HLA DQ β that predispose to diabetes (i.e., Asp57 2/2 and Arg52 1/1).

As technologic improvements continue, it is likely that population-wide screening for antibody markers (alone or combined with specific genetic markers) will be available to identify those at risk for developing type 1 diabetes.

TABLE 19-6 **Influence of Diabetic Heterodimers (ASP57neg Arg52pos) and Islet Cell Antibody (ICA) Status on Relative Risk for Developing Diabetes after 4 Years**

	ICA Negative				ICA Positive			
Diabetic heterodimers (dH)	0	1	2	4	0	1	2	4
Developed IDDM after 4 years	12	16	37	12	12	18	29	15
Relative risk	1.0	2.9	8.6	25.4	9.0	26.5	78.0	229.3

Such population-wide screening would be ethically justified if prevention could be proven effective. Presently, the data are sufficiently persuasive to have fostered national trials in Europe and the United States to predict and possibly prevent the clinical onset of type 1 diabetes through immune intervention strategies (see Table 19-5).

The European Nicotinamide Diabetes Intervention Trial (ENDIT) was a multicenter trial that screened approximately 22,000 first-degree relatives of patients with type 1 diabetes to identify 500 considered to be at high risk for developing this disease.[86-89] These at-risk individuals were treated with nicotinamide or a placebo in a double-blind fashion. The purported advantage of nicotinamide was that it was not known to be toxic or harmful in humans at the recommended doses; its major disadvantage was that the proposed protective effects in delaying diabetes were based on a small sample cohort. The results of ENDIT were disappointing, with positive protection not apparent.

The U.S. Diabetes Prevention Trial for T1DM (DPT1) was based on promising pilot data that suggested preservation of insulin secretion and prevention of progression to diabetes mellitus in at-risk individuals treated with insulin.[85] Daily subcutaneous insulin, coupled with intensive intravenous insulin every 9 months, prevented diabetes for at least 3 years in five subjects considered to be at risk because of genetic markers, islet cell and insulin autoantibodies, and diminished first-phase insulin response. Among seven similar at-risk subjects who chose not to be treated, six developed insulin-dependent diabetes within 3 years. DPT-1 was concluded in 2001, and there was no difference in the rates of developing diabetes among the placebo and insulin-treated groups. However, the ENDIT and DPT1 studies proved that large-scale multicenter studies could be successfully undertaken and that the prediction of progression to clinical diabetes was remarkably accurate. Thus, in those at highest risk (such as first-degree relatives of patients with T1DM) prediction is feasible and the discovery of a successful means of arresting or reversing progression to clinical diabetes is the subject of intense research.

Another study (TRIGR) involves 3000 families in whom half will avoid cow's milk for the first 9 months of life to test the hypothesis that the ingestion of breast milk and avoidance of cow's milk formula (with its bovine serum albumin [BSA]) may protect participants from the appearance of diabetes.[78] Several other studies are examining the utility of antibodies to the IL2 receptor, CD3 antibodies, immune suppressors such as mycophenolate mofetil, and immune modulators in preventing diabetes, including oral insulin. These studies are conducted by worldwide consortia of participating institutions (see www2.diabetestrialnet.org).

In animal models, oral insulin or oral GAD has been successfully used to prevent diabetes.[90] It is postulated that ingestion of T lymphocyte–dependent antigens can establish immunologic tolerance. Such oral strategies have been proposed and oral insulin is being tested in humans.[90] The subjects of primary prevention trials and secondary intervention trials to preserve residual insulin secretion at initial diagnosis are of major interest to investigators and clinicians alike. Progress is likely, but at present all of these strategies must be viewed as experimental and not currently in the domain of daily clinical practice.

Insulin Biosynthesis

Insulin is synthesized on the ribosomes of pancreatic islet beta cells and released into the circulation as a molecule composed of two separate straight polypeptide chains linked by disulfide bridges between and within these chains.[91-98] The two chains are not synthesized separately but are derived from a larger precursor, proinsulin, a single coiled chain in which the NH_2 terminus of the A chain is linked to the COOH terminus of the B chain by a connecting peptide, known as C-peptide (Figure 19-6). An even larger precursor (preproinsulin, containing an additional peptide chain on the NH_2 terminus of the A chain) is first synthesized, but this additional piece (important to the initiation of synthesis) is rapidly excised. Further processing of proinsulin within the beta cell cleaves the C-peptide, consisting of 31 amino acids, from the insulin molecule at the sites indicated in the figure.

Defects in these cleavage sites are inherited in an autosomal-dominant manner and result in insulin molecules with less-than-normal biologic activity that can give rise to two types of familial hyperproinsulinemia. One defect yields B-C proinsulin, cleaved at site 1 but not at site 2 (see Figure 19-6). This intermediate has 50% of the biologic activity of insulin, which is sufficient to prevent any abnormality in carbohydrate metabolism. The defect at site 1 yields A-C proinsulin, cleaved at site 2 but not at site 1, which has inadequate biologic activity to prevent carbohydrate intolerance. A structural mutation in the proinsulin molecule, between the C-peptide and insulin, has been confirmed.[90-96] In addition, a defect also occurs in the enzymatic conversion of a normal proinsulin molecule to insulin—yielding hyperproinsulinemia and mild carbohydrate intolerance.[91]

The proconvertases responsible for correct conversion of proinsulin to insulin are also involved in the processing of other hormones. Thus, impaired prohormone processing may lead to obesity and secondary hypocortisolism owing to defective processing of proopiomelanocortin (POMC) and to hypogonadotropic hypogonadism.[97-98] Native proinsulin has less than 5%, whereas C-peptide has none, of the biologic activity of insulin. During synthesis, the role of C-peptide appears to be the provision of the spatial arrangement necessary in the formation of the disulfide bonds. Other defects have been described in insulin biosynthesis involving substitution of amino acids in the B chain that lead to impaired glucose tolerance in the presence of hyperinsulinemia.[91-99]

The insulin gene has been cloned and localized to chromosome 11, and genetic defects in insulin synthesis may be associated with diabetes—especially the syndromes MODY1, -3, -5, and -6 with candidate genes for MODY7.[12,13] By some estimates, MODY syndromes may constitute 2% to 5% of all lean persons developing clinical diabetes between the ages of 10 and 30 years. The association of VNTRs in the insulin gene with genetic predisposition for diabetes was described earlier.

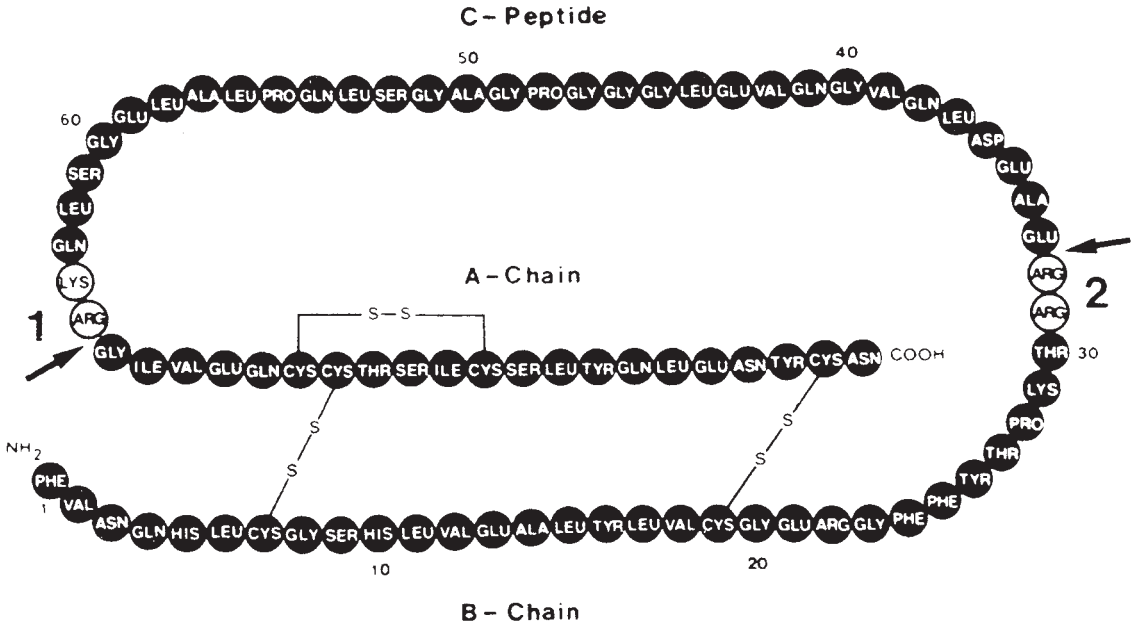

FIGURE 19-6 ■ Structure of proinsulin. Arrows 1 and 2 indicate the two sites of normal cleavage that yield insulin and C-peptide when the amino acid residues indicated in the open circles are removed. These cleavage points are known mutation sites, are inherited in an autosomal-dominant manner, and can yield two types of familial hyperproinsulinemia. During insulin secretion, equimolar amounts of insulin and C-peptide are released.

Under normal circumstances, only small quantities of proinsulin are released into the circulation—amounting to less than 15% of total insulin as measured by radioimmunoassay (RIA). Even smaller quantities of proinsulin intermediates are also released. However, during insulin secretion induced by all stimuli, one molecule of C-peptide is released with each molecule of insulin. Thus, the plasma of normal individuals contains small amounts of proinsulin, proinsulin intermediates, and almost equimolar amounts of insulin and C-peptide. The plasma metabolic half-life of C-peptide is, however, longer than that of insulin. Therefore, the molar ratio of C-peptide to insulin in peripheral plasma is always greater than 1 and the peak of C-peptide secretion or the nadir after suppression of release appears to occur later than that of insulin. Although standard RIA of insulin will also measure proinsulin, C-peptide will not be measured because it is immunologically distinct.

Separation of proinsulin from insulin can be achieved by chromatography to separate the larger proinsulin before assay. This is done with the use of an enzyme that degrades insulin but not proinsulin, or with the use of a C-peptide assay that will also measure proinsulin but not insulin. Because C-peptide is immunologically distinct, RIAs for this substance can be used to assess beta cell secretory reserve even in the presence of insulin antibodies formed in response to injections of bovine-porcine or human insulin.

Endogenous insulin secretion is accompanied by C-peptide release, whereas exogenous insulin administration suppresses endogenous insulin (and therefore C-peptide) secretion in all circumstances except insulinoma. Results of standard RIA with double-antibody precipitation are high in both circumstances. These attributes are important in distinguishing abuse of individuals by injection of exogenous insulin (high insulin, low C-peptide) from insulinomas or dysregulated insulin secretion (high insulin, high C-peptide) in cases of hypoglycemia. Measurements of C-peptide kinetics or of urinary excretion of C-peptide can be used as an index of endogenous insulin secretion.[29]

Insulin Secretion

Insulin secretion is governed by the interaction of nutrients, hormones, and the autonomic nervous system. Glucose, as well as certain other sugars metabolized by islets, stimulates insulin release. Basal and peak insulin levels are closely related to the glucose concentration, and prolonged fasting will further reduce glucose and insulin levels—which, however, remain in the measurable range at 2 to 5 mU/mL. There is evidence that a product or products of glucose metabolism may be involved in maintaining insulin secretion and that sugars not metabolized by islet cells do not promote insulin release.[100-102]

The initial steps of glucose-stimulated insulin release are depicted in Figure 19-7 and discussed in detail in Chapter 6 in connection with mutations in the sulfonylurea receptor (SUR)-Kir6 (inward-rectifying potassium channel) complex of the adenosine triphosphate-regulated potassium channel K_{ATP}, along with the subsequent steps that may cause activation of glucose or amino acid-stimulated insulin secretion.[103] This schema involves glucose transport into the beta cell through the GLUT2 glucose transporter and phosphorylation of glucose by means of glucokinase. Defects in the former are associated with type 2 diabetes, whereas heterozygous

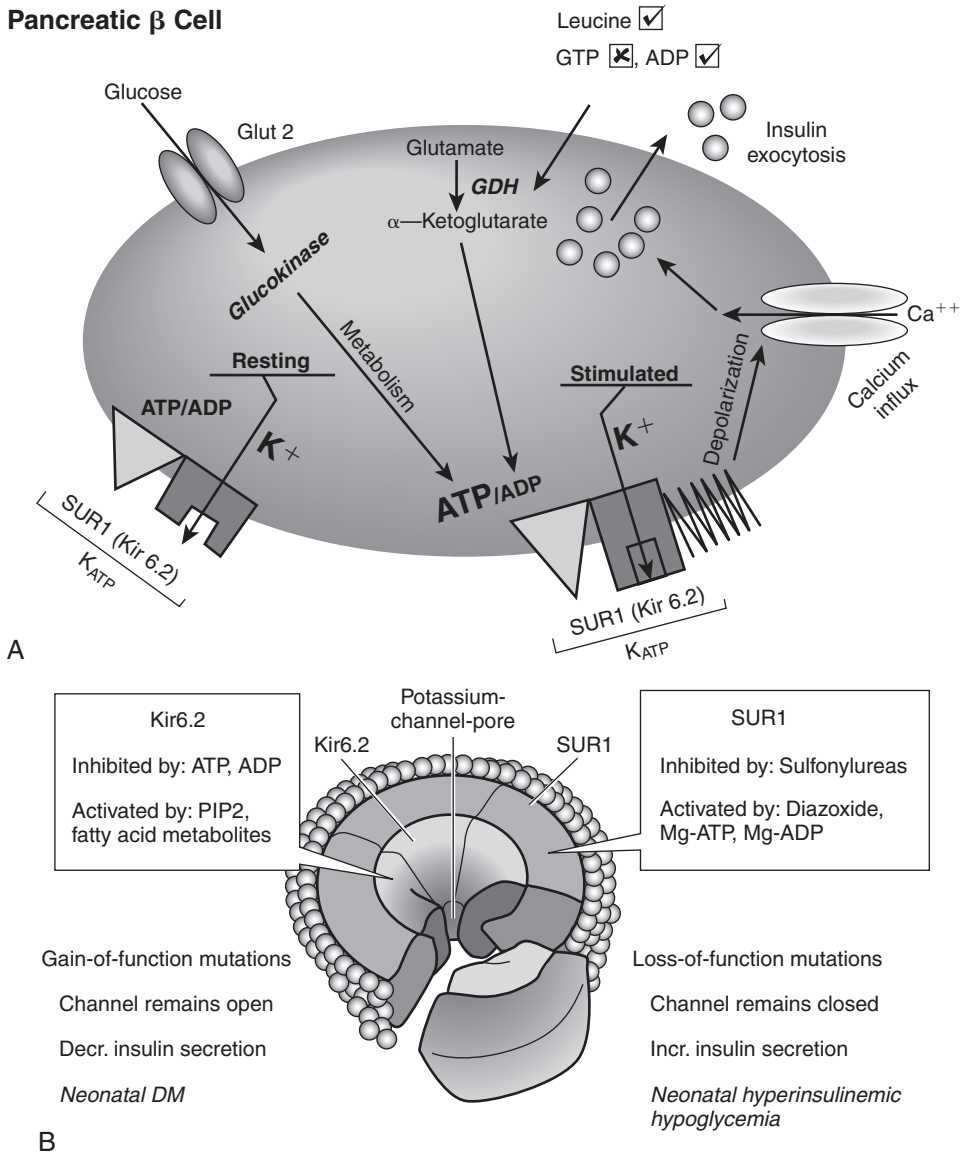

FIGURE 19-7 ■ **A,** Model of insulin secretion by pancreatic beta cell. Glucose transported into the beta cell by the insulin-independent glucose transporter (Glut 2) undergoes phosphorylation by glucokinase and is metabolized. This results in an increase in the ATP/ADP ratio with subsequent closure of the KATP channel and initiation of a cascade of events that is characterized by decreased flux of potassium across the membrane, membrane depolarization, calcium influx, and release of insulin from storage granules. Leucine stimulates insulin secretion by allosterically activating glutamate dehydrogenase (GDH) and by increasing the oxidation of glutamate; this increases the ATP/ADP ratio and closure of the KATP channel. The check mark sign (√) indicates stimulation of insulin secretion; the cross sign (x) indicates inhibition of insulin secretion. Diazoxide inhibits insulin secretion by interacting with the sulfonylurea receptor; somatostatin and calcium channel blockers interfere with calcium signaling. **B,** Regulation of insulin secretion. The Kir6.2–SUR1 complex and its regulation and genetic variability. The panel shows the detailed subunit structure of the KATP channel, which is composed of four small subunits, Kir6.2, that surround a central pore and four larger regulatory subunits constituting SUR1. In the normal resting state, the potassium channel is open, modulated by the ratio of ATP to ADP. PIP2 denotes phosphatidylinositol-4,5-bisphosphate. Kir6.2 denotes the inward rectifying potassium channel 6.2; SUR1 denotes the sulfonylurea receptor 1. ADP is adenosine diphosphate; ATP is adenosine triphosphate. As noted, in gain-of-function mutations, the channel remains open leading to decreased insulin secretion so that neonatal diabetes may result. With loss-of-function mutations, the channel remains closed, leading to persistent insulin secretion and hence is a cause of neonatal hyperinsulinemic hypoglycemia. (Redrawn from Sperling, M. A. (2006). ATP-sensitive potassium channels—neonatal diabetes mellitus and beyond. *New Engl J Med, 355,* 507–510.)

mutations in the latter are associated with MODY. Homozygous mutations in glucokinase result in permanent neonatal diabetes mellitus (as described in detail in Chapter 9). Glucokinase defects are generally associated with normal insulin release at higher glucose concentrations, and therefore with a milder type of diabetes.[12,13] After intravenous glucose infusion in normal persons, insulin secretion is biphasic—with an initial spike followed by a sustained plateau. It is proposed that the initial spike represents preformed insulin, whereas the sustained plateau represents newly synthesized insulin.

Cyclic adenosine monophosphate (AMP) is involved in stimulating insulin release. Therefore, agents that inhibit phosphodiesterase and reduce cyclic AMP destruction

(such as theophylline) augment insulin release. Translocation of calcium ions into the cytoplasm from the exterior, as well as from the intracellular organelles (see Figure 19-7) plays a key role in the contractile forces that propel insulin to the cell surface.[103] There, the membrane of the insulin vesicle fuses with the cell membrane—allowing extrusion of insulin granules into the surrounding vascular space, a process known as emiocytosis. Other ions, including potassium and magnesium, are involved in the insulin secretion.[103-106] The sulfonylurea receptor is closely linked to potassium channels in the beta cell.[103-106] Amino acids also stimulate insulin release, although the potency of individual amino acids varies.[107] A group of amino acids is more potent than any single one, and the insulin-secretory response is potentiated in the presence of glucose.[107] Free fatty acids and ketone bodies may also stimulate insulin release.[107] Insulin responses to oral glucose administration are always greater than responses to intravenous administration of glucose that result in the same blood glucose profile a finding that led to the concept that gut factors (incretins) modulate and increment insulin secretion.[108] Although a variety of gut hormones participate in promoting insulin release,[108] gastrointestinal polypeptide (GIP) pancreatic glucagon and the glucagon-like peptides (GLP) play a major role in stimulating insulin release.[108] These properties have found application as agents, collectively named incretins, in augmenting insulin secretion in persons with T2DM and in some persons with T1DM. Somatotropin release-inhibiting factor (somatostatin), produced in the delta cells of islets, inhibits insulin and glucagon release and reduces splanchnic blood flow. These properties have found application to reduce insulin secretion in neonates with hyperinsulinemic hypoglycemia of infancy (see Chapter 6). Together, these factors may finely regulate nutrient intake and its disposition and form an enteroinsular axis for metabolic homeostasis.[108] In addition to these gut hormones, several other hormones modulate insulin secretion. Growth hormone is involved in insulin synthesis and storage. Persons with congenital growth hormone deficiency have subnormal basal and stimulated insulin responses, whereas in acromegaly basal and stimulated insulin levels are increased. Human chorionic somatomammotropin (also known as human placental lactogen), structurally related to growth hormone, likewise affects insulin release. The stimulatory effect of each hormone on insulin secretion is antagonized by the anti-insulin effect at the peripheral level, however. Similarly, glucocorticoids and estrogens evoke greater insulin secretion while inducing peripheral insulin resistance—in part by decreasing insulin receptors on target cells.

Insulin secretion is constantly modulated by the autonomic nervous system.[102,109] The parasympathetic arm, through the vagus, directly stimulates insulin release. Modulation of insulin secretion by the sympathetic arm depends on whether α- *or* β-adrenergic receptors are activated. Activation of β_2 receptors by agents such as isoproterenol stimulates insulin secretion by a process that involves cyclic AMP generation. Blockade of β-adrenergic receptors by propranolol blunts basal and stimulated insulin release. Conversely, activation of α-adrenergic receptors blunts insulin secretion, and blockade of these receptors by agents such as phentolamine augments basal and glucose-stimulated insulin release. Epinephrine and norepinephrine stimulate predominantly α-adrenergic receptors in islets, resulting in impaired insulin secretion—as observed during stress or in patients with pheochromocytoma.[102]

In summary, in normal humans insulin secretion is constantly modulated by the quantity, quality, and frequency of nutrient intake; by the hormonal milieu; and by autonomic impulses. The ingestion of nutrients, principally carbohydrate and protein, produces intestinal hormonal signals that prime and initiate insulin release. The entry of glucose into the beta cell, the phosphorylation of glucose, and the generation of adenosine triphosphate (ATP) by this or other nutrients result in insulin release. This sequence involves cyclic AMP, β-adrenergic receptors, and ions—principally calcium and potassium. Glucose metabolism within the beta cell provides energy for further synthesis and release of insulin.[103]

Insulin Action

Insulin action on target cells in tissues such as liver, adipocytes, and muscle begins by binding to specific insulin receptors located on the cell membrane. Binding to these receptors is saturable, occurs with a high energy of association (affinity), and is pH and temperature dependent.[110-114] The insulin receptor is a heterodimeric glycoprotein consisting of two α and two β subunits linked by disulfide bonds (Figure 19-8). The α subunit, with a molecular mass of approximately 125,000 kd, acts as the binding site—whereas the β subunit, with a molecular mass of approximately 90,000 kd, possesses tyrosine kinase activity for endogenous and exogenous substrates (see Figures 19-8 and 19-9).

This ability to phosphorylate proteins may underlie some of the manifold actions of insulin. Among the classes of proteins phosphorylated are insulin receptor substrates 1 through 3 (considered an important insulin-signaling effector molecule) and pp 185, another substrate of the insulin receptor (see Figure 19-9). Other insulin mediators may be involved in insulin action. This action may also be mediated in part by hydrolysis of glycan phosphoinositides in the cell plasma membrane. The insulin receptor gene has been cloned and localized to chromosome 19, whereas the structurally related insulin-like growth factor-1 (IGF-1) receptor has been localized to chromosome 15.[110-114]

Under normal conditions, only a small proportion of the total available cell receptors need be occupied to achieve maximal biologic response. Thus, ordinarily there are spare receptors. Insulin receptors display two phenomena: down-regulation, in which high ambient insulin concentrations reduce the number of available receptors, and negative cooperativity, in which the occupancy of a receptor reduces the affinity of adjoining receptor sites. Scatchard analysis of insulin-binding data in in vitro systems reveals curvilinear plots compatible with negative cooperativity or with two classes of receptors: high-affinity/low-capacity and low-affinity/high-capacity. Total receptor number and the affinities of both classes of receptor sites can be calculated with use of these Scatchard plots.

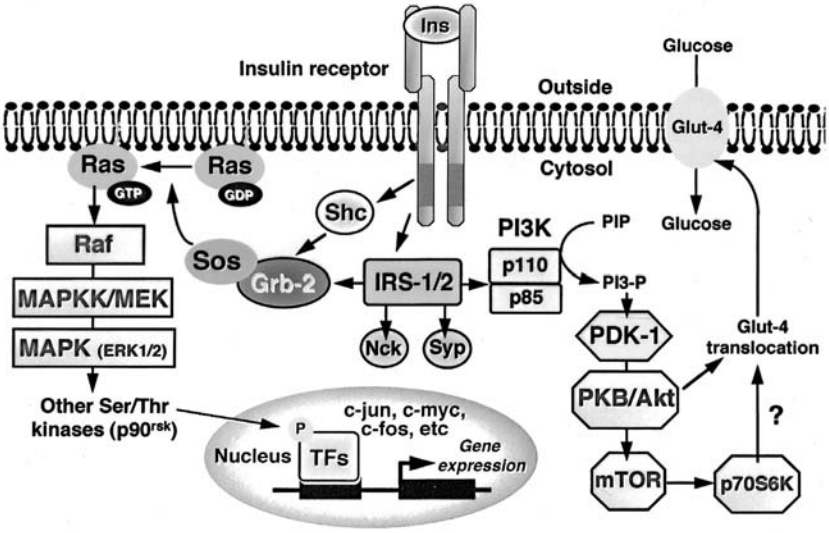

FIGURE 19-9 ■ Schema of insulin receptor signal transduction pathways. ERK, extracellular regulated kinase; Glut-4, glucose transporter 4; Grb-2, growth factor receptor binding protein 2; Ins, insulin; IRS, insulin receptor substrate; MAPK, mitogen-activated protein kinase; MAPKK, mitogen-activated protein kinase kinase; MEK, map/Erk kinase; mTOR, target of rapamycin; P13K, phosphoinositol-3-kinase; p70S6K, p70S6 kinase (small ribosomal subunit of protein-6-kinase); PDK-1, phospholipid-dependent kinase 1; PKB, protein kinase B; Ras, rat sarcoma; Shc, Sh2 cytosolic adaptor; SOs, son of sevenless; Syp, now called SHP-2 (for SH-2-containing phosphatase). (Courtesy of L. Mandarino, PhD, University of Texas Health Science Center, San Antonio.)

After binding to the cell surface, the receptor-insulin complex is internalized within the cell and processed by lysosomal enzymes, with release of free insulin and potential recycling of the receptor back to the cell membrane. Binding of insulin to the cell surface receptor, perhaps with the participation of internalization that permits insulin action at the level of the nucleus, leads to the complex biochemical processes characteristic of insulin action in a given tissue. The ultimate mechanism or mechanisms by which insulin exerts its effects beyond receptor binding and phosphorylation remain unknown.

With postreceptor events assumed to be normal, however, the biologic response to insulin in a tissue is a function of the number of receptor/insulin complexes formed—which in turn is directly related to the circulating insulin concentration and to the receptor concentration. Thus, a

reduction in receptor number could be compensated for by an increase in insulin concentration as long as the critical number of receptors necessary to produce maximal biologic response remains. Conversely, reduced insulin concentration could be compensated for by an increase in receptor number, provided the minimum amount of insulin necessary to produce a maximal biologic response is present.

Insulin receptors and their signaling proteins (see Figures 19-8 and 19-9) are widely distributed in various tissues. Using targeted deletions of individual components or various combinations of components of the insulin receptor pathway has provided remarkable insight into the contribution of liver, muscle, fat, the beta cell, and brain to overall glucose homeostasis.[110-114] Key concepts that have emerged are that the insulin receptor signal cascade on beta cells is critically important in maintaining normal insulin secretion. Thus, mutations causing insulin resistance at the beta cell eventually lead to relative hypoinsulinemia that can interact with the insulin resistance in peripheral tissues to produce the hallmark of type 2 diabetes (i.e., peripheral insulin resistance plus relative insulinopenia).

In addition, studies with targeted deletion of the insulin receptor in the brain—the so-called NIRKO mouse (neuron-specific insulin receptor knockout)—demonstrate that these animals developed obesity, increased body fat, insulin resistance with modest hyperinsulinemia, and elevated levels of triglycerides. Reproductive function in both males and females is impaired as a result of abnormal regulation of luteinizing hormone secretion, and serum leptin levels are elevated.[114] Thus, insulin signaling in the brain joins the emerging list of factors important in regulating energy homeostasis and reproduction.[114]

Primary defects in insulin receptor number or affinity may produce the same profound derangements in intermediary metabolism as deficient insulin secretion, and similar disturbances may result despite normal insulin concentration and normal receptor characteristics if postreceptor steps are defective.[115] Insulin signaling for the regulation of metabolism has been the subject of considerable research and is extensively reviewed.[113,115] Examples of each type of defect in the individual components of this integrated system that comprises insulin biosynthesis, secretion, and action exist and can account for the metabolic abnormalities that characterize diabetes mellitus. An approach based on the principles of insulin biosynthesis secretion and action also permits a rational classification of diabetes mellitus.

Pathophysiology

Normal insulin secretion in response to feeding is exquisitely modulated by the interplay of neural, hormonal, and substrate-related mechanisms to permit controlled disposition of ingested foodstuff as energy for immediate or future use. Mobilization of energy during the fasted state depends on low plasma levels of insulin. Thus, in normal metabolism there are regular swings between the postprandial high-insulin anabolic state and the fasted low-insulin catabolic state that affect three major tissues: liver, muscle, and adipose tissue (Table 19-7).

Insulin is the key anabolic hormone that promotes the synthesis and storage of carbohydrates, lipids, and proteins while simultaneously restraining their degradation. The uptake of glucose, fatty acids, and amino acids is stimulated—as is the activity or expression of enzymes that promote glycogen, fat, and protein synthesis. Conversely, the activity or expression of enzymes that break down these metabolites is restrained. All of these anabolic actions of insulin are reversed during the low-insulin state of starvation. Type 1 diabetes mellitus, as it evolves, becomes a permanent low-insulin catabolic (starvation) state in which feeding cannot reverse but rather exaggerates these catabolic processes.

It is important to emphasize that liver is more sensitive than muscle or fat to a given concentration of insulin. That is, endogenous glucose production from the liver

TABLE 19-7 **Influence of Feeding (High Insulin) or Fasting (Low Insulin) on Some Metabolic Processes in Liver, Muscle, and Adipose Tissue***

	High Plasma Insulin (Postprandial State)	Low Plasma Insulin (Fasted State)
Liver	Glucose uptake	Glucose production
	Glycogen synthesis	Glycogenolysis
	Absence of gluconeogenesis	Gluconeogenesis
	Lipogenesis	Absence of lipogenesis
	Absence of ketogenesis	Ketogenesis
Muscle	Glucose uptake	Absence of glucose uptake
	Glucose oxidation	Fatty acid and ketone oxidation
	Glycogen synthesis	Glycogenolysis
	Protein synthesis	Proteolysis and amino acid release
Adipose tissue	Glucose uptake	Absence of glucose uptake
	Lipid synthesis	Lipolysis and fatty acid release
	Triglyceride uptake	Absence of triglyceride uptake

*Insulin is considered the major factor governing these metabolic processes. Diabetes mellitus may be viewed as a permanent low-insulin state that if untreated results in exaggerated fasting.

by means of glycogenolysis and gluconeogenesis can be restrained at insulin concentrations that do not fully augment glucose utilization by peripheral tissues. Consequently, with progressive failure of insulin secretion the initial manifestation is postprandial hyperglycemia. Fasting hyperglycemia is a late manifestation that reflects severe insulin deficiency and indicates excessive endogenous glucose production. [116]

Although insulin deficiency is the primary defect, several secondary changes that involve the stress hormones (i.e., epinephrine, cortisol, growth hormone, and glucagon) accelerate and exaggerate the rate and magnitude of metabolic decompensation.

Increased plasma concentrations of these counterregulatory hormones magnify metabolic derangements by further impairing insulin secretion (e.g., epinephrine), by antagonizing its action (e.g., epinephrine, cortisol, and growth hormone), and by promoting glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis (e.g., glucagon, epinephrine, growth hormone, and cortisol) while decreasing glucose utilization and glucose clearance (e.g., epinephrine, growth hormone, and cortisol).[117] With progressive insulin deficiency, especially with concurrently elevated stress hormones, excessive glucose production and impairment of its utilization result in hyperglycemia with glucosuria when the renal threshold of approximately 180 mg/dL is exceeded.

The resultant osmotic diuresis produces polyuria, urinary losses of electrolytes, dehydration, and compensatory polydipsia. These evolving manifestations, especially dehydration, represent physiologic stress—resulting in hypersecretion of epinephrine, glucagon, cortisol, and growth hormone that amplifies and perpetuates metabolic derangements and accelerates metabolic decompensation. The acute stress of trauma or infection may likewise accelerate metabolic decompensation to ketoacidosis in evolving or established diabetes. [117]

Hyperosmolality, commonly encountered as a result of progressive hyperglycemia, contributes to the symptomatology—especially to cerebral obtundation in diabetic ketoacidosis. Serum osmolality can be estimated with the following formula.

$$\text{Serum osmolality (mOsm/kg)} = (\text{serum Na [mEq/L]} + \text{K [mEq/L]}) \times 2 + \text{Glucose mmol/L (Note that 1 mmol/L of glucose is equivalent to 18 mg/dL.)}$$

Consideration of serum osmolality has important implications in the treatment of diabetic ketoacidosis. The combination of insulin deficiency and elevated plasma values of the counterregulatory hormones is also responsible for accelerated lipolysis and impaired lipid synthesis, with resulting increased plasma concentrations of total lipids, cholesterol, triglycerides, and free fatty acids. The hormonal interplay of insulin deficiency and glucagon excess shunts the free fatty acids into ketone body formation. The rate of formation of these ketone bodies, principally β-hydroxybutyrate and acetoacetate, exceeds the capacity for peripheral utilization and for their renal excretion. Accumulation of these ketoacids results in metabolic acidosis and in compensatory rapid deep breathing in an attempt to excrete excess carbon dioxide (Kussmaul respiration).

Acetone, formed by nonenzymatic conversion of acetoacetate, is responsible for the characteristic fruity odor of the breath. Ketones are excreted in the urine in association with cations and thus further increase losses of water and electrolytes (Figure 19-10 and Tables 19-8 and 19-9). With progressive dehydration, acidosis, hyperosmolality, and diminished cerebral oxygen utilization, consciousness becomes impaired—with the patient ultimately becoming comatose. Thus, insulin deficiency produces a profound catabolic state—an exaggerated starvation in which all of the initial clinical features can be explained on the basis of known alterations in intermediary metabolism mediated by insulin deficiency in combination with counterregulatory hormone excess. Because the counterregulatory hormonal changes are usually secondary, the severity and duration of the symptoms reflect the extent of primary insulinopenia. [116,117]

Clinical Manifestations of Diabetes Mellitus

The classic presentation of diabetes in children is a history of polyuria, polydipsia, polyphagia, and weight loss. Polyuria may be heralded by the recurrence of bedwetting in a previously toilet trained child and polydipsia by a child constantly requesting fluids to drink. Unexplained weight loss should raise suspicion of the existence of diabetes that should be confirmed or excluded by measurement of blood glucose concentration first in the postprandial and later in the fasting state. The urine should also be checked for the presence of glucosuria. The duration of these symptoms varies but is often less than 1 month. Most children who are diagnosed with T1DM have been seen by a physician within a week or so of diagnosis. However, diabetes was not considered, and a glucose measurement in blood or urine was not performed.[118,119]

An insidious onset with lethargy, weakness, and weight loss is also quite common. The loss of weight despite increased dietary intake is readily explicable by the following example. The average healthy 10-year-old child has a daily intake of 2000 or more calories, of which approximately 50% are derived from carbohydrates. With the development of diabetes, daily losses of water and glucose may be as much as 5 L and 250 g, respectively. This represents 1000 calories lost in the urine, or 50% of average daily caloric intake. Therefore, despite the child's compensatory increased intake of food and water, the calories cannot be utilized, excessive caloric losses continue, and increasing catabolism and weight loss ensue.

Pyogenic skin infections and candidal vaginitis in girls or candidal balanitis in uncircumcised boys are occasionally present at the time of diagnosis of diabetes. They are rarely the sole clinical manifestations of diabetes in children, and a careful history will invariably reveal the coexistence of polyuria, polydipsia, and perhaps weight loss. Ketoacidosis is responsible for the initial presentation of many (about 25% to 40%) diabetic children. Ketoacidosis is likely to be present more often in children younger than 5 years of age because the diagnosis may not be suspected

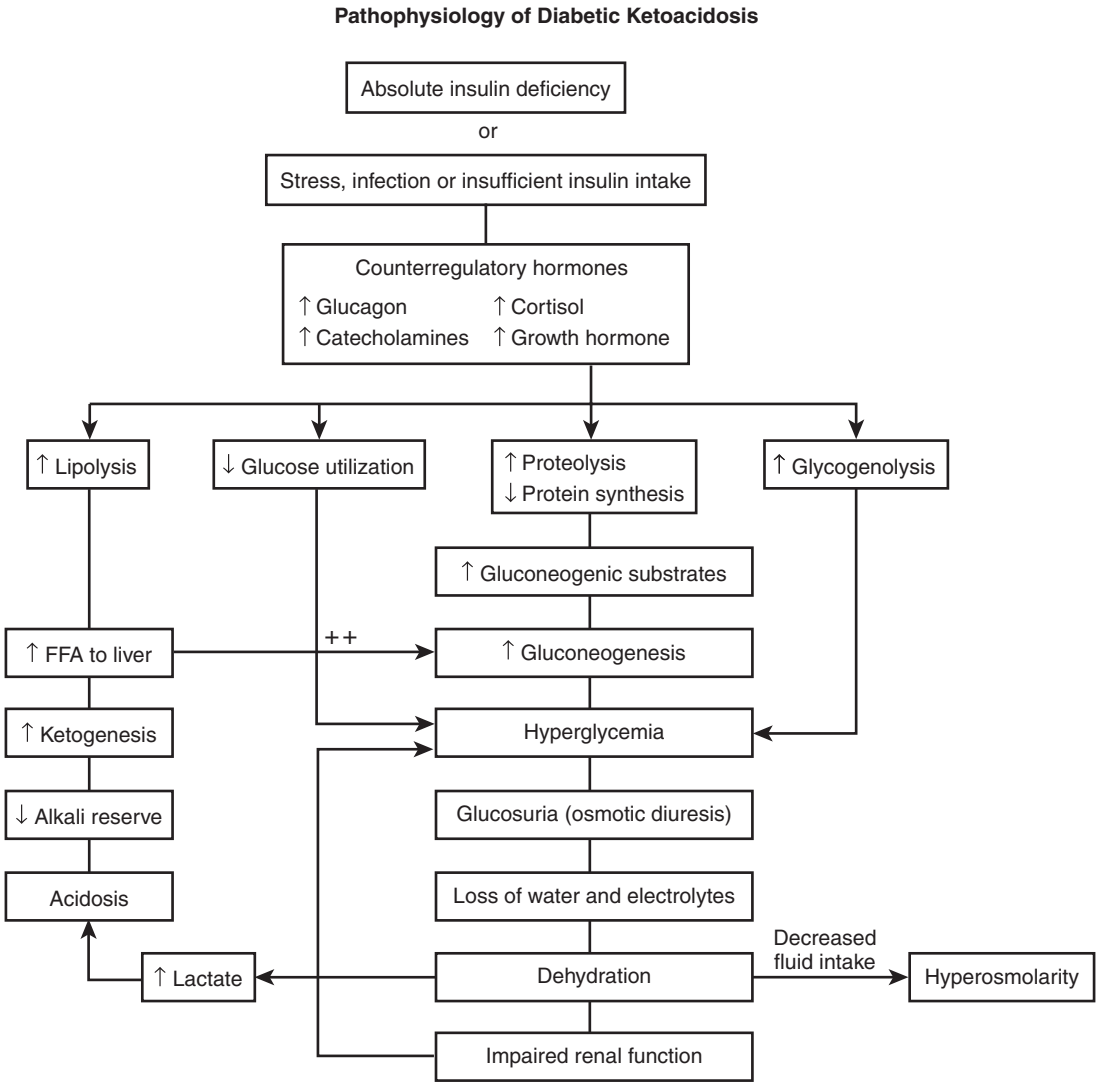

FIGURE 19-10 ■ The pathophysiology of diabetic ketoacidosis is illustrated as a function of absolute insulin deficiency or insufficient insulin in the presence of major stress such as an infection, which leads to increases in the four major counterregulatory hormones. Together, these changes increase glucose production via glycogenolysis and gluconeogenesis, which together result in hyperglycemia, osmotic diuresis, and dehydration. Simultaneously increased lipolysis leads to ketone body production and acidosis in combination with increased lactic acid from dehydration. See text for greater detail.

TABLE 19-8 **Fluid and Electrolyte Maintenance Requirements and Estimated Losses in Diabetic Ketoacidosis**

	Approximate Daily Maintenance Requirements*	Approximate Accumulated Losses†
Water	1500 mL/m^2	100 mL/kg (range, 60-100 mL/kg)
Sodium	45 mEq/m^2	6 mEq/kg (range, 5-13 mEq/kg)
Potassium	35 mEq/m^2	5 mEq/kg (range, 4-6 mEq/kg)
Chloride	30 mEq/m^2	4 mEq/kg (range, 3-9 mEq/kg)
Phosphate	10 mEq/m^2	3 mEq/kg (range, 2-5 mEq/kg)

*Maintenance is expressed in surface area to permit uniformity because fluid requirements change as weight increases.
†Losses are expressed per unit of body weight because the losses remain relatively constant in relation to total body weight.

and a history of polyuria and polydipsia may be difficult to elicit.[118-126] The early manifestations may be relatively mild and consist of vomiting, polyuria, and dehydration.

In more prolonged and severe cases, Kussmaul respiration is present—and there is an odor of acetone on the breath. Kussmaul respiration may be confused with bronchiolitis or asthma and be treated with steroids or adrenergic agents that worsen diabetes. Abdominal pain or rigidity may be present and may mimic appendicitis or pancreatitis. Cerebral obtundation and (ultimately) coma ensue and are related to the degree of hyperosmolarity. Laboratory findings include glucosuria, ketonuria, hyperglycemia, ketonemia, and metabolic acidosis. Leukocytosis is common, and nonspecific serum amylase levels may be elevated. The serum lipase level is usually not elevated. In those with abdominal pain, it should not be assumed that these findings are evidence of a surgical emergency before

TABLE 19-9 **Fluid Electrolyte Therapy for Diabetic Ketoacidosis: Recommendations for Replacement of Fluid**

Replacement Fluids	Approximate Accumulated Losses with 10% Dehydration	Approximate Requirements for Maintenance (36 Hours)	Approximate Totals for Replacement and Maintenance (36 Hours)
Water (mL)	3000	2250	5500
Sodium (mEq)	180	65	250
Potassium (mEq)	150	50	200
Chloride (mEq)	120	45	165
Phosphate (mEq)	90	15	100

Replacement Schedule (Continuous Intravenous Infusion)

Approximate Duration	Fluid (Composition)	Sodium (mEq)	Potassium (mEq)	Chloride (mEq)	Phosphate (mEq)
Hour 1	500 mL of 0.9% NaCl (isotonic saline)	75	—	75	—
Hour 2p	500 mL of 0.45% NaCl (0.5 isotonic saline) plus 20 mEq of KCl	35	20	55	—
Hour 3-12 (200 mL/hr for 10 hours)	2000 mL of 0.45% NaCl with 30 mEq/L of potassium phosphate	150	60	150	40
Subtotal initial 12 hours	3000 mL	260	80	280	40
Next 24 hours 100 mL/hr	2400 mL of 5% glucose in 0.2% NaCl with 40 mEq/L of potassium phosphate	75	100	75	60
Total over 36 hours	5400 mL	335	180	355	100

Note: Maintenance requirements remain the same. Losses and for maintenance of a 30-kg (surface area, 1.0 m^2) child with assumed 10% dehydration (duration of treatment, 36 hours). All replacement values should be halved if dehydration is estimated to be 5%.
Additional guidelines:

- A diabetic flow sheet with laboratory data appropriately recorded must be maintained in the patient's chart.
- Insulin therapy by continuous low-dose intravenous method: priming dose—bolus injection of 0.1 U/kg of regular insulin IV followed immediately by continuous IV infusion of 0.1 U/kg/hr of regular insulin beginning with second hour.
- Directions for making insulin infusion: Add 50 units of regular insulin to 500 mL of isotonic saline. Flush 50 mL through the tubing to saturate insulin-binding sites. For 30-kg patient, infuse at rate of 30 mL/hr. When the blood glucose concentration approaches 300 mg/dL, continue the insulin infusion at a reduced rate or add glucose to the infusate until acidosis is resolved and then start insulin therapy by subcutaneous injections of 0.2 to 0.4 U/kg of insulin at intervals of 6 hours.
- Bicarbonate therapy: For pH ≥ 7.10, no therapy is necessary. For pH 7.00 to 7.10, 40 mEq/m^2 of bicarbonate over 2 hours; then reevaluate. For pH ≤ 7.00, 80 mEq/m^2 of bicarbonate over 2 hours; then reevaluate. For new diabetics younger than 2 years of age with diabetic ketoacidosis and 10% dehydration or any diabetic with pH ≤ 7.00, coma or blood glucose ≥ 1000 mg/dL should be managed in an intensive care unit or equivalent setting.

a period of appropriate fluid, electrolyte, and insulin therapy to correct dehydration and acidosis. The abdominal manifestations frequently disappear after several hours of such treatment.

Diagnosis

The diagnosis of diabetes mellitus must be considered in children who have the following manifestations: those who have a history suggestive of diabetes, especially symptoms of polyuria with polydipsia, and failure to gain weight or a weight loss despite a healthy appetite; those who have confirmed glucosuria; and those who have clinical manifestations of metabolic acidosis with or without stupor or coma. In all instances, the diagnosis of diabetes mellitus is dependent on the demonstration of hyperglycemia in association with glucosuria with or without ketonuria. When classic symptoms of polyuria and polydipsia are associated with hyperglycemia and glucosuria that meet the criteria for diagnosing diabetes mellitus as defined by the American Diabetes Association (ADA) or World Health Organization (WHO), a glucose tolerance test is contraindicated.

Renal glucosuria may be an isolated congenital disorder or a manifestation of the Fanconi syndrome and other renal tubular disorders owing to severe heavy metal intoxication, ingestion of certain drugs (e.g., outdated tetracycline), or inborn errors of metabolism (e.g., cystinosis). When vomiting, diarrhea, and inadequate intake of food are complicating factors in any of these conditions, starvation ketosis may ensue and simulate diabetic ketoacidosis. The absence of hyperglycemia eliminates the possibility of diabetes. It is also important to recognize that not all urinary sugar is glucose, and infrequently galactosemia, pentosuria, and the fructosuria will require consideration as diagnostic possibilities.

The discovery of glucosuria, with or without a mild degree of hyperglycemia, during a hospital admission for trauma or infection (or even during the associated emotional upheaval) may herald the existence of diabetes. In most of these instances, the glucosuria remits during recovery.[1] Because this circumstance may indicate a

limited capacity for insulin secretion, which is unmasked by elevated plasma concentrations of stress hormones, these patients should be rechecked at a later date for the possibility of hyperglycemia, clinical features of diabetes mellitus, and family history of diabetes.

A family history of diabetes mellitus in two preceding generations should suggest the possibility of a MODY syndrome; absence of the common antibodies to beta cells such as IA2, GAD65, or ICA, strengthens the possibility of a diagnosis of MODY.[12,13] Under these circumstances, a glucose tolerance test may be useful to establish a diagnosis. Glucose tolerance testing should be performed several weeks after recovery from the acute illness, with a glucose loading dose adjusted for weight. Evidence indicates that the test is most likely to be abnormal in those with HLA DR3 and DR4, in whom ICA or insulin autoantibodies are detected, or who have MODY.[12,13] Transient hyperglycemia is common in patients with asthma treated with epinephrine and steroids. Further testing in such patients is not indicated. Screening procedures, such as postprandial determinations of blood glucose or oral glucose tolerance tests, have yielded low detection rates in children—even among those considered at risk, such as siblings of diabetic children. Accordingly, such screening procedures are not recommended in children.

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) is a medical emergency and represents a life-threatening decompensation of metabolism that requires prompt recognition and appropriate treatment, with careful monitoring of clinical and biochemical indices. DKA must be differentiated from acidosis and coma from other causes. These include hypoglycemia, uremia, gastroenteritis with metabolic acidosis, lactic acidosis, salicylate intoxication, encephalitis, and other intracranial lesions. Diabetic ketoacidosis exists when there is hyperglycemia (glucose 300 mg/dL), ketonemia (β-OH butyrate $>$ 4 mEq/L) via formal laboratory or bedside ketone meter measurement or ketones strongly positive at greater than 1:2 dilution of serum, acidosis (pH 7.30 or less and bicarbonate 15 mEq/L or less), glucosuria, and ketonuria in addition to the clinical features of tachypnea (Kussmaul respiration) and cerebral obtundation. The severity of DKA is defined by the degree of acidosis; pH 7.2 to 7.3 or HCO3 10 to 15 mEq/L is defined as mild; pH 7.1 to 7.2 or HCO3 5 to 10 mEq/L is moderate; pH $<$ 7.1 or HCO3 $<$ 5 is defined as severe.

Precipitating factors, even for the initial presentation, include stress (e.g., trauma), infections, vomiting, and major psychological disturbances. Recurrent episodes of ketoacidosis in established diabetics often represent deliberate errors in recommended insulin dosage, unusual stress responses that indicate psychological disturbances, and at times pleas to be removed from a home environment perceived to be stressful or intolerable. Diabetic ketoacidosis should also be distinguished from nonketotic hyperosmolar coma. which occurs in children with T2DM and is increasingly recognized.[118-139]

Nonketotic hyperosmolar coma is a syndrome characterized by severe hyperglycemia (blood glucose concentration of more than 600 mg/dL), absence of or only very slight ketosis, nonketotic acidosis, severe dehydration, depressed sensorium or frank coma, and various neurologic signs that may include grand mal seizures, hyperthermia, hemiparesis, and positive Babinski signs. Respiration is usually shallow, but coexistent metabolic (lactic) acidosis may be manifested by Kussmaul breathing. Serum osmolarity is commonly 350 mOsm/kg or higher. In children, this condition is relatively infrequent and when reported there has been a high incidence of preexisting neurologic damage. The profound hyperglycemia may develop over a period of days, and initially the obligatory osmotic polyuria and dehydration may be partially compensated for by increased fluid intake. With progression, thirst becomes impaired—possibly because of alteration of the hypothalamic thirst center by hyperosmolarity and possibly in some instances because of a preexisting defect in the hypothalamic osmo-regulating mechanism.[118-140] Nonketotic hyperglycemia with coma has been a feature of presentation in youth with T2DM and is often associated with morbid obesity. Some of these obese patients may present with ketoacidosis as the initial clinical presentation.

The low production of ketones is attributed mainly to the hyperosmolarity, which in vitro blunts the lipolytic effect of epinephrine, and to the concomitant antilipolytic effect of residual insulin. Blunting of lipolysis by the therapeutic use of β-adrenergic blockers may also contribute to the syndrome. The key difference between diabetic ketoacidosis and hyperglycemic hyperosmolar nonketotic coma appears to be the degree of insulinopenia, which is nearly absolute in ketoacidosis but with sufficient residual activity in hyperglycemic hyperosmolar nonketotic coma to limit lipolysis in adipose tissue but inadequate to permit normal peripheral glucose utilization at a time of increased glucose production induced by the stress hormones. As indicated, prerenal azotemia and decreased thirst contribute to this syndrome in adults and in children. Depression of consciousness is closely correlated with the degree of hyperosmolarity in this condition, as well as in diabetic ketoacidosis. Hemoconcentration may also predispose to cerebral arterial and venous thromboses.[126-127]

Treatment of nonketotic hyperosmolar coma is directed at repletion of the vascular volume deficit and correction of the hyperosmolar state (see "Diabetic Ketoacidosis" for management). Patients who are hypotensive should be started on isotonic saline (0.9% NaCl) until the condition is stable. Then, treatment should proceed as for DKA with the following caveats: extending the period of fluid repair to 36 to 48 hours; Infuse insulin at half the amount used in DKA (i.e., 0.05 U/kg/hr).[125,126] When the blood glucose concentration approaches 300 mg/dL, the hydrating fluid should be changed to 5% dextrose in 0.2 N saline. Approximately 20 mEq/L of potassium chloride, or more if indicated, should be added to each of these fluids to prevent hypokalemia. Serum potassium and plasma glucose concentrations should be monitored at 2-hour intervals for the first 12 hours and at 4-hour intervals for the next 24 hours to permit appropriate adjustments of administered potassium and insulin.[126-127]

Insulin can be given by continuous intravenous infusion, beginning with the second hour of fluid therapy. Because blood glucose may decrease dramatically with fluid therapy alone, the intravenous loading dose

should be 0.05 U/kg of fast-acting insulin followed by 0.05 U/kg/hr of the same insulin—rather than 0.1 U/kg/hr as advocated for diabetic ketoacidosis. Most now advocate that the initial insulin loading dose be omitted. During the recovery period, therapy with insulin and diet and monitoring of the patient are as described for patients recovering from diabetic ketoacidosis (see Table 19-9).

Treatment of Diabetes Mellitus

The management of type 1 diabetes may be divided into three phases, depending on the initial presentation: ketoacidosis, the postacidotic transition period for establishment of metabolic control, and the continuing phase of guidance of the diabetic child and his or her family for daily living with diabetes integrating insulin regimens, nutritional intake, exercise, and glucose monitoring to achieve as near normal glucose control as is feasible. Each of these phases has separate goals, although in practice they merge into a continuum. For purposes of management, the transition period corresponds to presentations with polyuria, polydipsia, and weight loss but without biochemical decompensation to ketoacidosis.

Treatment of Diabetic Ketoacidosis

The pathophysiology and treatment of diabetic ketoacidosis were extensively reviewed and published as a consensus conference. The views and recommendations are endorsed by the Lawson Wilkins Pediatric Endocrine Society, the European Society for Pediatric Endocrinology, the International Society of Pediatric and Adolescent Diabetes (ISPAD), and others. Similar guidelines for management have now also been recommended by the American Diabetes Association. These recommendations have been incorporated into the guidelines published and regularly updated by ISPAD.[119]

The immediate aims of therapy are expansion of intravascular volume; correction of deficits in fluid, electrolyte, and acid-base status; initiation of insulin therapy to correct intermediary metabolism; and the exclusion of a treatable precipitating event such as infection or trauma. Treatment should be instituted as soon as the clinical diagnosis is confirmed by the presence of hyperglycemia and ketonemia. Determinations of blood pH and electrolytes should also be obtained. An electrocardiogram is useful to provide a rapid reference for the existence of hyperkalemia.

If sepsis is suspected as a possible precipitating factor, a blood culture should be obtained and the urine should be examined for the presence of bacteria and leukocytes. A flow sheet is essential to record chronologically the rate and composition of fluid input and urine output, the amount of insulin administered, and the acid-base and electrolyte values of the blood. Catheterization of the bladder is not routinely recommended in children. Bag collection or condom drainage permits an assessment of urinary output, but catheterization may be indicated in comatose patients.[118-139]

Fluid and Electrolyte Therapy

The expansion of reduced intravascular volume and correction of depleted fluid and electrolyte stores are important in the treatment of diabetic ketoacidosis (see Table 19-9 and Box 19-2). It must be stressed, however,

BOX 19-2 Steps in Management of Diabetic Ketoacidosis

1. Confirm diagnosis.
Obtain:
   - Blood glucose
   - Serum electrolytes
   - Acid-base status: pH, HCO_3^2

Consider:
   - Urine microscopy/culture
   - Chest radiograph
   - Blood culture
   - Throat culture
   - Electrocardiogram

Intensive care–like setting:
   - pH ≤ 7.00
   - Age 2 years
   - Unconscious
   - Blood glucose ≥ 1000 mg/dL

2. Begin intravenous fluids.
   - 20 mL/kg of 0.9% (normal), saline (NaCl) over 1 hour
3. Reassess the patient: What precipitated this episode?
   - Delayed diagnosis
   - Infection
   - Noncompliance
   - Trauma
4. Follow protocol guidelines in Table 10-11. Begin insulin 0.1 U/kg/hr with hour 2 of IV therapy as outlined in Table 10-11.
5. Measure glucose every 2 hours; electrolytes/acid-base every 2 to 4 hours for the first 24 hours.
6. Continue treatment with insulin even if glucose approaches 300 mg/dL (17 mM) as long as acidosis persists. Consider adding 5% to 10% glucose in IV line or occasionally reducing insulin to 0.05 U/kg/hr.
7. If acidosis is not resolving (or improving) despite fluids and insulin of 0.1 U/kg/hr, consider:
   - Severe sepsis causing lactic acidosis and/or insulin degradation
   - Error in insulin dose
8. In children younger than 10 years (especially, 5 years), anticipate possible clinical cerebral edema after 4 to 6 hours of treatment. The following herald evolving edema:
   - Headache
   - Change in consciousness level/response
   - Unequal dilated pupils
   - Delirium
   - Incontinence
   - Vomiting
   - Bradycardia
9. If cerebral edema is clinically apparent:
   - Reduce IV rate.
   - Give mannitol 1 g/kg IV (10-20 g/m^2).
   - Repeat in 2 to 4 hours if indicated.

that exogenous insulin is essential to arrest further metabolic decompensation and restore intermediary metabolism.[141-145] Dehydration is commonly approximately 10%. Initial fluid therapy can be based on this estimate, with subsequent adjustments to be related to clinical and laboratory data. The initial hydrating fluid should be isotonic saline (0.9%). Because of the hyperglycemia, hyperosmolarity is universal in diabetic ketoacidosis. Thus, even 0.9% saline is hypotonic relative to the patient's serum osmolality. Some investigators maintain infusion with fluids that are isotonic such as 0.9% saline and report low morbidity and mortality with such regimens.[118-123]

A gradual decline in osmolality is desirable because too rapid a decline has been implicated in the development of cerebral edema, one of the major complications of therapy in children. For the same reason, the rate of fluid replacement is adjusted to provide the total calculated deficit plus maintenance requirement over 48 hours after the initial rehydration with normal isotonic saline. In addition, glucose (5% solution in 0.2 to 0.5 N saline) is administered when blood glucose concentration approaches 300 mg/dL to limit the decline of serum osmolality in an attempt to reduce the risk of developing cerebral edema (see Box 19-2). Insulin should be continued until ketoacidosis is resolved and the pH is equal to or greater than 7.3 or until the bicarbonate concentration in plasma is equal to or greater than 18 mEq/L, because blood glucose corrects more rapidly than ketoacidosis. As long as acidosis persists, insulin infusion should be maintained at the same rate (and, if necessary, with 5% to 10% glucose added to the infusate) to maintain blood glucose at approximately 300 mg/dL.

Cerebral Edema

Cerebral edema is an unusual but potentially devastating complication of diabetic ketoacidosis and its management in childhood. There is considerable debate and several hypotheses have been proposed, but there is presently no consensus as to the precise cause of this syndrome. It remains unproved whether cerebral edema during treatment of diabetic ketoacidosis can be predicted on the basis of clinical and biochemical indices and whether physicians contribute to it by their mode of management through the choice and composition of the hydrating fluid, its rate of administration, and the controlled rate of decline of blood glucose.

The incidence of cerebral edema is reported to occur in 0.5% to 1.5% of all episodes of diabetic ketoacidosis. It is more common in younger children, especially at initial presentation.[118,137] The duration and severity of symptoms and signs before initiating treatment are the major identifiable factors.[121] If cerebral edema develops during treatment for diabetic ketoacidosis, mortality and morbidity are high. Although mortality has declined from previously reported rates of 40% to 90% to a more recently reported rate of 20%, cerebral edema remains the cause of about half of all deaths in children with diabetes mellitus. Morbidity from cerebral edema also remains high. About one fourth of the survivors may have permanent neurologic sequelae.[119] Prompt recognition and intervention with mannitol or other hyperosmolar agents, respiratory support by means of endotracheal intubation, and hyperventilation may be lifesaving. Awareness, early recognition, and treatment are responsible for the reported decline in mortality cited previously.[140] Subclinical cerebral edema may be more common than hitherto appreciated.[123] Randomized prospective trials of management of diabetic ketoacidosis are not ethically feasible, but in the most rigorous and extensive retrospective analysis involving some 6000 episodes of diabetic ketoacidosis, the following risk factors were identified: young age, duration and severity of symptoms before starting treatment, low PCO_2, high serum urea nitrogen, lack of an increase in serum sodium during therapy, and treatment with bicarbonate.[118] All of the biochemical risk factors in this study may reflect the initial severity of biochemical derangement. Thus, avoidance of diabetic ketoacidosis (especially in young children) by early recognition of the signs and symptoms of diabetes mellitus is the best way to prevent cerebral edema.

The duration and severity of symptoms before therapy may predispose to cerebral ischemia, to which younger children would be more prone because of the higher metabolic rate and hence higher oxygen requirement of a child's brain relative to an adult's. In addition, there may be a longer time to accumulate so-called idiogenic osmoles in the brain. Many children may have evidence of raised intracranial pressure on imaging studies (e.g., computed tomography), but only a minority develop clinical cerebral edema. [134]

Moreover, early studies in dogs and in adult men demonstrated that intracranial pressure rose in all during fluid replacement therapy for diabetic ketoacidosis.[135] Thus, given the hyperbolic pressure/volume relationship of the intracranial space and the likely shift of water into the intracellular compartment during therapy, it is considered prudent to advocate the use of normal saline (or equivalent volume expanders) during initial therapy to limit the rate of infusion to no more than twice-daily maintenance requirement and not to exceed 4 L/m^2/day, to carefully monitor the decline in blood glucose not to exceed about 100 mg/dL/hr, and to carefully monitor the clinical status of the patient. The managing team must be prepared to intervene at the bedside with mannitol or other volume expanders.

Finally, it should be noted that abnormalities in the clotting-fibrinolytic pathway (e.g., protein S and C deficiency, factor V Leiden) are not uncommon in the general population and may contribute to cerebral thrombosis/ischemia in the setting of dehydration, hyperviscosity, and increased platelet adhesiveness that exists in diabetic ketoacidosis.[118,137] There is also evidence that the osmotic mechanisms described previously, the so-called cytotoxic mechanism, may not be the only operative theory. Vasogenic mechanisms with disruption of vascular permeability in the cerebral blood-brain barrier may also be operative. The latter comes from studies via perfusion and diffusion magnetic resonance imaging (MRI) that show a decrease in the apparent diffusion coefficient after recovery (i.e., more pericellular and not intracellular water during DKA treatment).[122] Moreover, in that study one

in five episodes of cerebral edema was evident at initial presentation before any fluid or insulin therapy could have contributed to water accumulation in the brain. The two proposed mechanisms are not mutually exclusive and may allow more treatment options in time.

Cerebral edema may be present at initial presentation or early in the course of treatment, but it usually becomes apparent several hours after therapy has begun and when there is improvement in blood glucose level, acid-base status, and clinical state of hydration. Both early and late appearances of cerebral edema have been reported.[124] A previously alert patient may become drowsy, complain of headache, have abnormal neurologic findings (including papilledema), progress to coma, and have respiratory arrest with herniation of the brainstem. Recovery may occur with prompt recognition and treatment with intravenous mannitol. Survival and neurologic outcome are markedly improved with prompt recognition and intervention as outlined (Table 19-10). Although clinically apparent cerebral edema is often fatal, subclinical cerebral edema is present in many patients during therapy for ketoacidosis.[123] A series of bedside clinical observations may facilitate the recognition and prediction of those developing cerebral edema during therapy for DKA. The series of major and minor criteria proposed by Muir and colleagues remains uncorroborated.[133]

Electrolytes

Potassium should be administered early. Total body potassium may be considerably depleted during acidosis, even when the serum potassium concentration is normal or elevated. Although potassium moves from intracellular to extracellular sites during acidosis, the reverse occurs during correction of acidosis—particularly when exogenous insulin and glucose are available in the circulation. This shift of potassium back to the intracellular compartment may result in life-threatening hypokalemia. Therefore, after the initial fluid replacement of approximately 20 mL/kg of isotonic saline (0.9%) has been provided, potassium should be added to subsequent infusates if urinary output is adequate. Serum potassium concentration should then be monitored, initially at 1 to 2 hours intervals and periodically thereafter. Complete replacement of body potassium stores may not occur until after the patient has resumed oral feeding.

An electrocardiogram provides a rapid assessment of serum potassium concentration. T waves are peaked in hyperkalemia and are low and associated with U waves in hypokalemia. Because the total potassium deficit cannot be replaced within the initial 24 hours of treatment, potassium supplementation should continue as long as fluids are administered intravenously (see Table 19-9).

It is almost inevitable that the patient will receive an excess of chloride, which may aggravate acidosis. The extent of acidosis, however, can be reduced by substitution of phosphate—which is also significantly depleted in diabetic ketoacidosis. Moreover, phosphate in conjunction with glycolysis is essential to the formation of 2,3-diphosphoglycerate (2,3-DPG)—which governs the oxygen dissociation curve. During deficiency of 2,3-DPG, the oxygen dissociation curve is shifted to the left (i.e., more oxygen is retained by hemoglobin and less is available to tissues, a situation that predisposes to lactic acidosis).

Acidosis per se tends to shift the oxygen dissociation curve toward the right (Bohr effect) and thus partially "compensates" for 2,3-DPG deficiency. As acidosis resulting from the accumulation of ketones is corrected by the provision of insulin, with or without administration of bicarbonate, the effects of 2,3-DPG deficiency may no longer be compensated for and the release of oxygen to tissues may again be impaired. Exogenous phosphate, by contributing to the formation of 2,3-DPG, permits the oxygen dissociation curve to shift to the right and thus facilitates release of oxygen to tissues and aids in the correction of acidosis. Furthermore, resistance to insulin action is associated with hypophosphatemia. Therefore, the use of phosphate is recommended (the administration of potassium phosphate is outlined in Box 19-2). Because the excessive use of phosphate may result in hypocalcemia, serum calcium should be measured periodically.[136] Symptomatic hypocalcemia should be corrected with calcium gluconate, and some of the potassium chloride should be temporarily substituted for potassium phosphate.

TABLE 19-10 **Pharmacodynamic Properties of Common Insulin Formulations**

Category	Onset (Hour)	Peak (Hour)	Duration (Hour)
Rapid-acting insulin lispro, aspart, and glulisine	0.25-0.5	0.5-1	3-5
Short-acting regular	0.5-1	2-4	4-8

NPH, Neutral protamine Hagedorn.

Alkali Therapy

With provision of fluids, electrolytes, glucose, and insulin, metabolic acidosis is usually corrected through the interruption of ketogenesis, the metabolism of ketones to bicarbonate, and the generation of bicarbonate by the distal renal tubule. Concern regarding the therapeutic administration of bicarbonate centers on four issues: alkalosis, by shifting the oxygen dissociation curve to the left, may diminish the release of oxygen to tissues and therefore predispose to lactic acidosis; alkalosis accelerates the entry of potassium into cells and therefore may produce hypokalemia; the provision of bicarbonate according to the calculated base deficit overcorrects and may result in alkalosis; and perhaps most important, bicarbonate may lead to worsening of cerebral acidosis during the time when the plasma pH is being restored to normal because HCO_3^- combines with H^+ and dissociates to CO_2 and H_2O to form H_2CO_3.

Although bicarbonate passes the blood-brain barrier slowly, CO_2 diffuses freely, thereby potentially exacerbating cerebral acidosis and possibly cerebral depression. On the other hand, severe acidosis (with blood pH of about 7.1) diminishes respiratory minute volume, may produce hypotension by peripheral vasodilation, impairs myocardial function, and may be a factor in insulin resistance. For these reasons, administration of bicarbonate is recommended only at pH of about 7.1 or less (see Table 19-9). At pH of 7 to 7.1, we recommend that 40 mEq of HCO_3^-/m^2 (at pH of less than 7, 80 mEq of HCO_3^-/m^2) should be infused over a period of 2 hours. Acid-base status should then be reevaluated before further alkali therapy. Bicarbonate should not be given by bolus infusion because it may precipitate cardiac arrhythmias. [118,119,137]

Insulin Therapy

The continuous low-dose intravenous infusion method, in which a priming dose of 0.1 U/kg of regular insulin is followed by a constant infusion of 0.1 U/kg/hr, is outlined in Table 19-9. This method is effective, simple, and physiologically sound—and has gained acceptance as the recommended method for administering insulin during diabetic ketoacidosis. It provides a constant steady concentration of insulin in plasma that approximates the peak attained in normal individuals during an oral glucose tolerance test. Some practitioners recommend insulin to be given at 0.05 U/kg/hr and claim equal efficacy in correcting acidosis without the rapid decline in glucose concentration. Controlled trials comparing the 0.1 U/kg/hr with the smaller 0.05 U/kg/hr have not been performed. Also, the priming dose of insulin is not recommended as essential.[118]

Presumably, the same steady concentration is attained at the cellular level and permits a steady metabolic response without the fluctuations that must occur with intermittent injections of insulin. Concern that the insulin may adhere to glass and tubing has proved to be unfounded, and effective delivery of insulin can be provided without the addition of albumin or gelatin to the infusate. Although insulin infusion can be provided by gravity drip without the use of a special pump, such a pump is helpful and used in most intensive care unit (ICU) settings. A separate infusion set for insulin connected to the infusion line used for fluid and electrolyte therapy is recommended so that adjustments in the dosage of each can be made independently. After the amount of insulin has been calculated, for the initial 6 to 8 hours this quantity is diluted in a 50-mL syringe containing 0.9% saline infused via a separate pump but connected to the fluid infusate (see Table 19-9 for specific instructions).

When the blood glucose concentration approaches 300 mg/dL, the ongoing potassium requirement is added to 5% glucose in 0.2 to 0.5 N saline (see Table 19-9) and the rate of insulin infusion may be reduced from 0.1 to 0.05 U/kg/hr, provided acidosis is correcting. The rate of insulin infusion should, however, be periodically adjusted based on recovery of acidosis and the blood glucose response of each individual. [118,119,137]

In treating diabetic ketoacidosis, it is regularly observed that blood glucose concentration corrects more quickly than pH or plasma bicarbonate.[137,138] Insulin must be provided by infusion or subcutaneous injection as long as acidosis persists, even if glucose approaches 300 mg/dL. It may be necessary to add glucose to the infusate while continuing insulin infusion at a rate of 0.05 to 0.1 U/kg/hr until acidosis is corrected. If acidosis persists despite these measures, a cause such as gram-negative sepsis should be considered.

The essential steps in managing diabetic ketoacidosis are summarized in Table 19-9 and Box 19-2. When acidosis is corrected, the continuous infusion may be discontinued and insulin immediately given by subcutaneous injection at a dosage of 0.2 to 0.4 U/kg every 6 to 8 hours while the glucose infusion is maintained until the child can fully tolerate food. Subcutaneous injections of regular insulin at dosages of 0.2 to 0.4 U/kg every 6 to 8 hours before meals should be continued for a full 24-hour day after the child is eating. The blood glucose level should be monitored before and 2 hours after each meal, with the insulin dose adjusted to maintain blood glucose concentration in the range of 80 to 180 mg/dL. The total dose of regular or fast-acting insulin used in this representative day serves as a guide for subsequent insulin treatment with a combination of intermediate of long-acting as well as short-acting insulin, as described later in the chapter.

Ketonemia and ketonuria may persist despite clinical improvement. The nitroprusside reaction routinely used to measure ketones reacts with acetoacetate and weakly with acetone but not with β-hydroxybutyrate. The usual ratio of β-hydroxybutyrate to acetoacetate is approximately 3:1 but is commonly 8:1 or more in diabetic ketoacidosis. With correction of acidosis, β-hydroxybutyrate dissociates to acetoacetate—which is identified by the nitroprusside reaction. Therefore, persistence of ketonuria for 1 or more days may not reliably reflect the clinical improvement and should not be interpreted as an index of poor therapeutic response. Bedside meters for measuring β-OH butyrate in blood have been introduced in some units.[139] A campaign of advertising the symptoms and signs of diabetes in childhood to schools and primary care providers

was reported to markedly reduce the rates of DKA at diagnosis over a period of 8 years.[140]

TREATMENT OF TYPE 1 DIABETES MELLITUS (T1DM)

General Principles

Optimal management of the child with T1 and T2DM requires an integrated approach, taking into account the overall level of functioning of the child and family, the nutritional and lifestyle patterns specific to that child, and attention to the overall developmental stages of childhood and adolescence. There is no one appropriate insulin regimen or meal plan. The overriding principle should be that the diabetes care plan should fit wherever possible into the surrounding home and school environments, and that the primary childhood tasks of education, socialization, growth, and maturity continue unhindered by the extra responsibilities diabetes care entails.

This daunting task of assisting families in managing diabetes is best accomplished by a multidisciplinary team, consisting of physicians, nurse educators and practitioners, dietitians, and mental health professionals, all trained and experienced in the nuances of diabetes care in children. Children with diabetes should be seen by the team at frequent intervals (usually every 3 months in established patients) for assessment of glycemic control, growth, and development; evaluation for related disorders and complications; education; troubleshooting; problem solving; and screening for adjustment problems that may affect diabetes or the overall health of the child.

Goals of Therapy

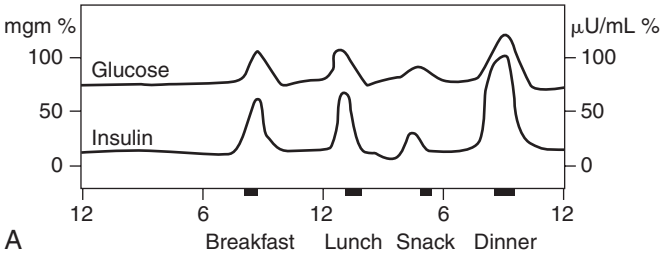
The Diabetes Control and Complications Trial (DCCT) established that intensive glycemic management leading to near normal glucose and A1c levels significantly reduced the risk of developing long-term complications and the benefits of this reduced risk outweighed the threefold increase in the risk of severe hypoglycemia. [141] Slowing the development of early retinopathy was observed in the DCCT subgroup of intensively treated adolescents, as well as in adults in the study.[142] In the Epidemiology of Diabetes Interventions and Complications (EDIC) Study, the observational follow-up to the DCCT, a continued increase in risk of complications was seen in the former conventional treatment group years after the end of the randomized control trial despite improved metabolic control in the former conventional treatment group, indicating that near normal glucose and A1c levels should be achieved and maintained in patients with T1D as early in the course of the disease as possible.[143] As a result of this evidence, current recommendations mandate that youth with T1DM should aim to achieve plasma glucose and HbA1c levels as close to normal as possible, as early in the course of the disease as possible, and with as few severe hypoglycemic events as possible.

With respect to specific targets, the American Diabetes Association treatment guidelines indicate that HbA1c targets should be adjusted based on the age of the child: namely $< 8.5\%$ in children < 8 years of age, $< 8\%$ in 7- to 12-year-olds, and $< 7.5\%$ in teenagers.[144] Higher HbA1c levels were suggested for very young children because of the potential risk of recurrent hypoglycemia on the developing brain. There are many problems with this approach, including the emerging evidence that chronic hyperglycemia is also detrimental to the developing brain. In contrast, the International Society for Pediatric and Adolescent Diabetes (ISPAD) guidelines recommend a target HbA1c of $< 7.5\%$ for all pediatric patients with strong emphasis placed on individualizing glucose targets to promote normoglycemia while preventing severe or frequent hypoglycemia.[145]

Types of Insulin

Currently available insulins are classified based on their duration of action as rapid, short, intermediate, and long acting, and each is available in a concentration of 100 U/mL (U-100). A higher concentration (U-500) of human regular insulin is available for the patient who has severe insulin resistance. Appropriate dilutions can be prepared for younger patients requiring low doses. The development of recombinant DNA technology to synthesize human insulin and human insulin analogs has changed the face of insulin treatment.

The aim of insulin replacement therapy is to simulate the normal pattern of insulin secretion as closely as possible (Figure 19-11 and 19-12). This aim can best be achieved



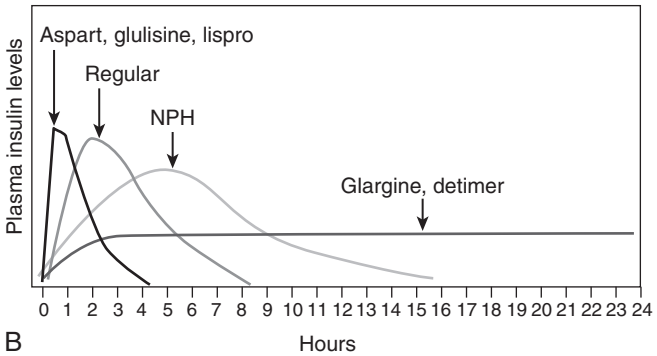


FIGURE 19-11 ■ **A** and **B,** Representation of the normal relationships among food intake, blood glucose, and serum insulin concentration. Note that glucose concentration is maintained between 80 and 140 mg/dL. Note also the precise release of insulin that has passed through the portal circulation synchronous with and proportional to the food-induced glycemic excursions. Compare and contrast these patterns with the time pattern of insulin action after subcutaneous injection of Aspart/glulisine/lispro, Regular, NPH, and glargine/detemir insulins.

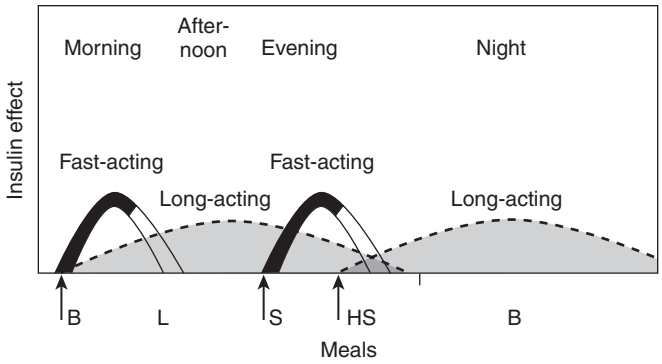

FIGURE 19-12 ■ Three-dose insulin regimen. The morning dose is composed of a combination short- and intermediate-acting insulin of one half to two thirds of the total daily dose. The short-acting dose before supper covers the anticipated glycemic elevation with dinner. The long-acting insulin is not given until bedtime so that the peak effect is delayed. (Redrawn from Schade, D. S., et al. (1983). *Intensive insulin therapy.* Belle Mead, NJ: Excerptal Medica.)

through the use basal-bolus therapy using multiple daily injections (MDI) or continuous subcutaneous insulin infusion (CSII) pump therapy. Until recently, options for insulin formulations were limited. Today, there are more than 10 varieties of biosynthetic human and analog insulins, including human regular insulin, human NPH insulin, long-acting insulin analogs, rapid-acting insulin analogs, and several kinds of premixed insulins (see Table 19-10).

Human Regular Insulin

Human regular insulin was a mainstay of insulin management of youth with T1D until the early 2000s when the advent of rapid-acting insulin analogs virtually eliminated its use in children and adolescents, except for intravenous administration. The delayed absorption and prolonged duration of action of the large premeal bolus doses of regular insulin that are required by adolescents with T1D to overcome the insulin resistance of puberty contributed to problems with hyper- and hypoglycemia in this age group.[142] Regular insulin remains the insulin of choice for intravenous infusion in the treatment of diabetic ketoacidosis. A special U-500 (500 units/mL) formulation of regular insulin as is available for use in patients with severe insulin resistance who require very large daily doses of insulin.

Rapid-Acting Analogs

Lispro (Eli Lilly), aspart (Novo Nordisk), and glulisine (Sanofi) insulins are produced by amino acid substitutions in the C-terminal region of the B-chain that reduce the affinity of insulin molecules to self-aggregate into hexamers. These modifications allow more rapid absorption of the analog into the bloodstream after subcutaneous injection. In comparison to regular insulin, the faster absorption of rapid-acting analogs results higher and sharper peaks and shorter duration of action, pharmacokinetic and pharmacodynamic effects that reduce the risk of late postprandial hypoglycemia and temper early postmeal hyperglycemia.[146,147] Puberty does not appear alter the pharmacokinetics of premeal boluses of rapid analogs, but the insulin resistance of puberty reduces the ability of these insulins to stimulate glucose metabolism.[148] Rapid-acting insulin may be safely mixed with intermediate-acting insulins, but mixing with long-acting insulin is not recommended, as such mixing markedly attenuates the peak action of the rapid-acting analog.[149,150] All three rapid-acting analogs may be used in an insulin pump, and studies have shown them to be safe and effective.[151,152] Lispro and aspart insulin may be diluted to concentrations less than U-100 such as U-50 or U-25 using diluents obtained from the manufacturer. Diluted insulin is used in very young children and others who are sensitive to insulin and could benefit from the more accurate dosing. Rapid-acting insulin analogs can be given intravenously, but they have not been shown to be superior to regular insulin.[153]

Intermediate-Acting Insulin

Neutral protamine Hagedorn (NPH) is now the only available intermediate-acting insulin. Although the delay in peak action of NPH given before breakfast provides a means to cover lunchtime glucose excursions, NPH is less than satisfactory for overnight basal insulin replacement.[154] As with regular insulin, the advent of long-acting insulin analogs has largely replaced NPH in basal-bolus MDI treatment in pediatrics. However, the combination of NPH in the morning before breakfast and long-acting insulin before dinner has been shown to be an effective initial treatment of newly diagnosed children and adolescents with T1DM.[155]

Long-Acting Insulin Analogs

Glargine (Lantus manufactured by Sanofi) and detemir (Levemir manufactured by Novo Nordisk) were the first two commercially available long-acting insulin analogs that were developed to meet the body's basal insulin requirements for regulating hepatic glucose production. Insulin glargine is an analog of human insulin with C-terminal elongation of the beta chain by two arginine residues and replacement of asparagine in position A21 by glycine. This analog is soluble in the acidic solution in which it is packaged but relatively insoluble in the physiologic pH of the extracellular fluid. Consequently, microprecipitates of glargine insulin are formed following subcutaneous injection, which markedly delays its absorption into the systemic circulation. The action of insulin detemir is prolonged by the addition of a fatty acid side chain that promotes reversible binding with albumin in the interstitial fluid and in the circulation.

Pharmacokinetic and pharmacodynamic studies have demonstrated that these long-acting insulin analogs have flat and prolonged time-action profiles. However, compared to glargine, detemir has been shown to have a more consistent pharmacokinetic profile in children and a more consistent pharmacodynamic profile in adults with T1DM.[156,157] Anecdotal evidence suggests that basal insulin replacement with insulin detemir is more likely

to require two daily injections more frequently than treatment with insulin glargine.

Insulin degludec is a new, ultra-long-acting insulin that is a product of coupling of Des-B30 threonine insulin to fatty acid side chains. After injection, degludec self-associates, forming long chains of insulin that dissociate very slowly. Plasma insulin levels rise reach peak concentrations 10 to 12 hours after an injection and the half-life is between 17 to 21 hours, roughly double the duration of action of insulin glargine. There is little information regarding the use of this insulin in pediatrics at this time.

Premixed Insulin

Various premixed insulin formulations, combining either rapid-acting insulin analogs or regular insulin with NPH or intermediate-acting insulin analogs, are currently available. The percentage of rapid acting/regular to intermediate acting varies with the formulation. The practical advantage of premixed insulins to cover both short- and intermediate-term insulin needs in a single shot is also their greatest limitation. There is less flexibility when using premixed insulin for adjusting the individual insulin components, and this can be particularly problematic in young children or those with variable food intake. Use of premixed insulin has been generally limited to patients and families who have difficulties managing more complicated treatment regimens.

Syringes versus Pens

Insulin syringes come in a variety of sizes that are particularly useful in young children. In addition to the traditional 100-unit (1-mL) syringe marked in 2-unit increments, 50-unit (0.5-mL) and 30-unit (0.3-mL) syringes are available that are marked in single-unit increments, and 30-unit syringes with ½-unit markings can also be ordered. These syringes are available with needle lengths from 8 to 13 mm. Insulin pens are also available, both in as disposable pens and a reusable pens with disposable cartridges. Currently, the disposable pens only allow for 1-unit doses, which may be problematic for very young children who might need ½-unit dosing. On the other hand, there are reusable cartridge pens that allow for ½-unit dosing.

Initiating Insulin Therapy

Most newly diagnosed patients who present with symptoms of diabetes or are in diabetic ketoacidosis (DKA) require upward of 1 U/kg/day at the start of insulin treatment. For asymptomatic patients who are "incidentally" diagnosed with diabetes during a routine sports physical or a well-child exam, starting doses may only need to be ~0.5 U/kg/day. The goal of initial insulin therapy in children with T1D should be to achieve near normoglycemia over the first few weeks of treatment in order to give the child the opportunity to enter the "honeymoon," or partial remission phase. The honeymoon period results from a combination of improved function of residual beta cells and reversal of the insulin resistance that accompanies uncontrolled diabetes. Prompt achievement of optimal control rather than the methods used to achieve good control appears to be the most important factor in obtaining these outcomes.[158] The ability to achieve target A1c levels with little or no severe hypoglycemia is greatly enhanced in T1D patients with residual beta-cell function.[159]

Some centers admit all newly diagnosed patients to the hospital for initial diabetes education and insulin dose titration, but others have effective outpatient treatment protocols. During the 2 to 3 weeks following discharge, insulin doses are titrated toward target premeal glucose values of 70 to 130 mg/dL during daily telephone contact; patients are seen in follow-up clinic visits, approximately 2, 6, 13, 26, 39, and 52 weeks following diagnosis.

INSULIN REGIMENS

Plasma insulin levels in nondiabetic individuals are characterized by relatively low basal levels on which are superimposed meal-stimulated spikes in insulin concentrations. Current intensive treatment regimens attempt to simulate this pattern of plasma insulin fluctuations by employing a basal-bolus approach to insulin replacement. Because exogenous insulins are injected or infused subcutaneously rather than directly into the portal vein, their rates of absorption may be variable. Also, the dose that is injected is determined empirically, so it lacks the precision of endogenously secreted insulin. Thus, no insulin replacement regimen will precisely duplicate the pattern of normal insulin secretion; there will be periods of increased plasma insulin concentrations that may produce hypoglycemia and periods of low insulin levels that lead hyperglycemia. Therefore, the goal of current insulin regimens is to minimize the frequency and severity of excursions into the hyper- and hypoglycemic range.

The DCCT and EDIC studies established basal-bolus therapy using either MDI or CSII as the gold standard of treatment of T1D. However, insulin only works if the youngster receives it, and other factors must be addressed when determining the best insulin regimen for an individual patient. These factors include the availability of an adult parent/guardian to supervise insulin administration, the ability to count carbohydrates and monitor blood glucose (BG) levels, and the willingness to wear a pump or take four or more injections of insulin daily.

Multiple Daily Injection (MDI) Regimens

MDI regimens attempt to replicate normal insulin secretion through the use of a long-acting insulin analog to replace basal insulin needs along with bolus injections of rapid-acting insulin analog to cover food intake and to correct elevations in blood glucose levels. Either once or twice daily glargine or detemir may be used for basal insulin coverage. Typically, basal insulin accounts for approximately 40% to 50% of the insulin total daily dose (TDD). However, children younger than 5 years of age often require basal insulin doses that are 30% to 40% of TDD, and there is considerable variability between patients. Once-daily glargine or detemir may be given

either in the morning or in the evening. Although this has not been well studied in pediatric patients, patients treated with detemir may be more likely to need twice-daily injections than those treated with glargine. Some pediatric practitioners mix long- and rapid-acting insulin in order to reduce the number of injections, but studies indicate that such mixing markedly blunts and delays the absorption and action of the rapid-acting insulin component of the mixture.[149,150]

Any one of the rapid-acting insulin analogs may be used to cover bolus insulin needs. Ideally, the rapid-acting insulin bolus is given 10 to 15 minutes before eating, but this is a difficult goal to achieve in many youth with T1D. For the most precise dosing of bolus insulin, it is necessary to use an insulin-to-carbohydrate (ICR) ratio and insulin sensitivity or correction factor, as well as the rate and direction of change in sensor glucose levels in patients using continuous glucose monitoring devices. The ICR is defined as the grams of carbohydrate that 1 unit of insulin will cover. This ratio may be determined using the 500 rule; namely, dividing 500 by the total daily insulin dose (TDD) will give a starting point for the carbohydrate ratio. For example, in a teenager with a TDD of 50 units, 1 unit of insulin will cover 10 grams of carbohydrate (500/50 = 10). It should also be noted that the ICR frequently differs by time of day, as more insulin is often needed per gram of carbohydrate before breakfast and less may be given to cover bedtime snacks. Accuracy in determining the carbohydrate content of meals is of utmost importance but often a problem in adolescents. Teens tend to underestimate the number of carbohydrates in their meal, and refresher meetings with a dietitian can reinforce the importance of maintaining mastery of this skill.

In addition to meal coverage, a correction dose of rapid-acting insulin should be given at meal times in order to "fix" an elevated blood glucose levels. Correction doses may also be given at other points in the day for the same reason. Traditional "sliding scale" insulin doses based on blood glucose levels have given way to a more sophisticated dosing algorithms based on an insulin sensitivity factor (ISF); namely, how much will blood glucose be lowered by 1 unit of insulin. The ISF may be determined using the 1800 rule: divide 1800 by the TDD. The correction dose can then be calculated according to the following equation:

$$\frac{\text{(Actual BG} - \text{Target BG)/ISF}}{\text{Number of units of insulin}} =$$

No matter how they are initially calculated, ICRs and ISFs are subsequently adjusted based on glucose monitoring results.

Particular advantages of basal-bolus MDI regimens are that they try to mirror the physiologic model of insulin secretion, increase flexibility in the timing and size of meals, and provide more opportunities to "course correct" throughout the day in response to abnormal glucose excursions. A particular disadvantage of these regimens is that they require a large number of daily injections. Indeed, because of the flat time-action profile of the long-acting basal insulin analogs, basal-bolus MDI treatment puts a premium on compliance with premeal bolus dosing. Without bolus doses of rapid-acting insulin, long-acting basal insulin alone cannot prevent marked postprandial hyperglycemia. However, strict adherence to premeal bolus dosing is difficult for teenagers with T1D, even when it is made as easy as possible to accomplish with an insulin pump. These are some of the reasons why mean A1c levels in pediatric patients, especially adolescents, with T1DM, remain well above the target levels recommended by the ADA and ISPAD (Box 19-3).[160]

Insulin Pump Therapy

The first successful studies of effectiveness of CSII were carried out in children in the 1980s,[161] but it was not until the early 2000s that the use of CSII in pediatrics took hold.[162] Since then, CSII has been shown to be more effective in lowering A1c compared to injection therapy in randomized and nonrandomized pediatric studies and to be associated with improved patient satisfaction and reduced frequency of hypoglycemia.[163] Some of the practical benefits of CSII compared to MDI are listed in Box 19-4. From the pediatric practitioner perspective, the memory function that records all pump-related activities is especially important. A specific risk of pump therapy is that prolonged accidental or purposeful interruption of insulin delivery over several hours can lead to the development of ketones and DKA because the patients are only receiving rapid-acting insulin.[164] This risk can be reduced or eliminated by regular blood glucose testing and standard patient protocols for managing hyperglycemia.

Indications for Pumps in Pediatrics

In 2006, an international consensus conference of leading pediatric diabetes specialists was convened to develop

BOX 19-3 Levels of Treatment: Biochemical and Clinical Characteristics

Minimal

- HbA1c 11%-13%, GHb 13%-15%
- Many SMBG values of 300 mg/dL
- Almost constantly positive urine glucose tests
- Intermittent spontaneous ketonuria

Average

- HbA1c 8%-9%, GHb 10%-11%
- Premeal SMBG 160-200 mg/dL
- Intermittent positive urine glucose
- Rare ketonuria

Intensive

- HbA1c 6%-7%, GHb 7%-9%
- Premeal SMBG 70-120 mg/dL; postmeal SMBG, 180 mg/dL
- Essentially no positive urine glucose or ketones

GHb, glycosylated hemoglobin; HbA1c, glycohemoglobin; SMBG, self-monitored blood glucose.

BOX 19-4 Practical Benefits of CSII

- Basal infusion rates adjustable up to every 30 minutes
- Programmable temporary basal rates
- Preprogrammable alternate basal rate profiles
- One site insertion every 2 to 3 days (versus many injections each day)
- Dose calculator
- Pump history functions and ability to upload data to data management systems
- Customizable square wave and dual wave boluses
- Ability to program temporary basal rates for sick days and during and after exercise
- Ability to deliver very small (0.025 to 0.05 units) doses of insulin

treatment guidelines for the use of CSII in children and adolescents.[165] These experts agreed that CSII was indicated for pediatric patients who had the following conditions:

- Elevated A1c levels on injection therapy
- Frequent severe hypoglycemia
- Widely fluctuating glucose levels (regardless of A1c)
- A treatment regimen that compromises lifestyle
- The presence of microvascular complications or risk factors for macrovascular complications

CSII was also thought to be beneficial in athletes, very young children, adolescents with eating disorders, patients with a pronounced dawn effect, ketosis-prone patients, pregnant teens (ideally preconception), and children with pronounced needle phobia.[165]

Ideal candidates for CSII include motivated families who are committed to monitoring the BG at least four times per day and have a working understanding of basic diabetes management, especially carbohydrate counting and using ICR and ISF to calculate insulin doses. HbA1c level also plays a role in determining readiness for CSII, although it is less important than the factors listed earlier. We generally prefer to have A1c levels below 8.5% before transition to pump treatment. The age of the patient and duration of diabetes should not be factors in determining when patients will transition from injections to CSII. In fact, it is increasingly clear that infants, toddlers, and preschoolers are probably the ideal pediatric patients for CSII, because it lowers A1c, reduces the frequency of severe hypoglycemic episodes, and improves the quality of life of parents.[166,167] Moreover, starting newly diagnosed patients immediately on pump therapy is an increasingly common practice.

Pump Features

Insulin pump therapy uses only a rapid-acting insulin analog to deliver 24/7 insulin coverage. A reservoir for the pump is filled with several days' worth of insulin. In conventional pumps, the reservoir attaches to a variable length of tubing, which in turn attaches to a small catheter or steel needle that is inserted into the subcutaneous tissue. Most common sites for insertion include the buttocks, abdomen, upper leg/hip, and some children use their arms. Insertion of the infusion set is done by either the child or caregiver and should be done every 2 to 3 days or whenever persistently high BG values indicate a potential site failure. The Omni Pod is a "patch pump" in which both the mechanics to drive the pump and the insulin are contained in a disposable "pod." This pod is attached to the surface of the skin and includes an integrated catheter, which allows for subcutaneous delivery of the insulin. Insulin doses programmed by the patient/caregiver throughout the day are delivered by way of a hand held device, which wirelessly communicates with the patch.

Most currently available insulin pumps are "smart" pumps into which both ICRs and ISFs are programmed to create a bolus calculator. Some pumps have the ability to receive and integrate blood glucose values into their bolus calculator through a wireless link with a specific blood glucose meter. Bolus doses can be administered over a few minutes or as square-wave and dual-wave boluses over a longer period of time. Ideally, bolus doses should be delivered 10 to 15 minutes before the meal in order to minimize postmeal excursions.[168] In young children and picky eaters, a small priming bolus of insulin can be given before the meal, followed by additional bolus doses depending on how many carbohydrates are actually consumed.

Basal insulin needs are covered by the rapid-acting insulin, which is delivered through a preprogrammed "basal pattern." This pattern can be made up of multiple different rates, which allow for a waxing/waning pattern of basal insulin delivery. In addition, most pumps allow for multiple 24-hour basal patterns to be preprogrammed and stored in the memory. For example, some of our adolescents have a basal pattern for school days and one for weekends to account for their tendency wake up much later on weekends and holidays. Finally, temporary changes can be made to the basal insulin pattern, which can be an effective tool for dealing with exercise or sick day management.

NPH-Based Treatment Regimens

The "split-mixed" regimen consisting of two daily doses of NPH and regular insulin that were mixed together in the same syringe was a standard approach to insulin replacement in pediatrics for decades. The regular insulin component was replaced by rapid-acting insulin analogs when lispro insulin was introduced. Patients started on this approach generally receive two thirds of the total daily dose before breakfast and one third before dinner. Each injection starts with approximately two thirds of NPH and one third of rapid-acting analog. Individual components of the regimen are subsequently adjusted based on blood glucose testing results.

This conventional treatment regimen is almost always inadequate for patients with T1DM who have no residual endogenous insulin secretion due the limitations of both the pre-breakfast dose of NPH to cover lunch and the pre-dinner dose of NPH to provide basal insulin replacement during the overnight period. The conventional twice a day regimen can still play a role in newly diagnosed patients—who frequently go through a "honeymoon" or partial remission period of diabetes.

During the honeymoon, insulin requirements rapidly decrease and the doses of rapid-acting insulin may even be discontinued due to low pre-lunch and bedtime glucose levels. A major reason the two daily injections regimen is effective during the honeymoon period is that stimulation of endogenous insulin secretion curbs postmeal glucose excursions and it provides much of the overnight basal insulin requirements, leading to normal fasting blood glucose values. Conversely, increased and more labile pre-breakfast glucose levels often herald the loss of the relatively small amount of residual endogenous insulin secretion required for overnight glucose control. An alternative to the twice-a-day NPH is to retain the pre-breakfast mixture of NPH and rapid-acting insulin, cover dinner with rapid-acting analog, and use glargine or detemir (given before supper or bedtime) for overnight basal replacement. This modified twice-a-day conventional insulin regimen has been shown to be effective in achieving target A1c levels during the first year of treatment of T1D.[155]

Blood Glucose Monitoring

The safety and success of any insulin regimen depend on frequent monitoring of blood glucose levels. Intensive diabetes control would have been impossible without the development of accurate and easy-to-use home glucose meters and HbA1c levels in adults and children with T1DM are inversely correlated with the daily frequency of blood glucose monitoring. Many brands of glucose meters are commercially available, most of which are accurate to within about 5% to 10% of laboratory measurements.[169,170] Current models utilize glucose-oxidase-based electrochemical methods. The meters are fast and require very small volumes of blood (0.1 mL). The smaller blood volume requirement has allowed alternate site testing (e.g., forearm), which may minimize discomfort and improve adherence to self-monitoring regimens.

A key component of intensive insulin management is regular adjustment of insulin doses based on changes in glucose control and on daily activity. Frequent blood glucose monitoring, with a minimum of four tests per day, premeals, and at bedtime, should be the goal. In addition to the traditional four blood glucose tests, many patients benefit from strategically adding further tests, such as 2 hours after meals, overnight and before/after exercise in order to develop a more robust picture of daily glucose trends. Testing should also be done whenever the symptoms of hypoglycemia occur.

The special challenge of managing T1D during childhood and adolescence is that insulin requirements are always changing. Thus, simply measuring blood glucose and giving immediate correction doses are insufficient for long-term glycemic control in pediatrics. Instead, parents and patients need to be instructed on how to recognize trends that indicate that patients have outgrown their insulin dose(s) and how to make their own adjustments in the regimen.[171] Pattern recognition requires maintaining and reviewing an electronic of written log of blood glucose levels over time. Unfortunately, evidence indicates that too few families are downloading and reviewing glucose meter data and making insulin self-adjustments.[172]

Continuous Glucose Monitoring

Even when families regularly test blood glucose levels, they only see the "tip of the iceberg" when it comes to daily fluctuations in glucose levels.[173] Thus, the introduction of real-time continuous glucose monitoring (CGM) systems has the potential to revolutionize insulin management. Currently available CGM devices are inserted subcutaneously and measure interstitial fluid glucose concentrations using glucose-oxidase–based electrochemical methods. Sensor glucose are reported in real time ~ every 5 minutes with rate of change values and 1- to 24-hour retrospective profiles. This wealth of information allows for adjustments in insulin doses based on a retrospective analysis as well as immediate, in the moment adjustments. Web-based data managing systems are available to assist patients and clinicians in evaluating sensor data alone or in combination with insulin pump data.[174]

JDRF CGM Randomized Control Trials demonstrated that adults who used CGM the on a nearly daily basis significantly lowered HbA1c levels without increasing the risk of hypoglycemia and those who have already achieved A1c targets can better maintain this level of control with the use of CGM.[175] This held true for youth who were willing to wear the sensor almost every day as well. Unfortunately, far fewer children and adolescents were able to achieve the goal of almost daily wear. Indeed, in current pediatric practice in the United States, < 5% of pediatric patients are currently using CGM.[172] Thus, improvements in the CGM devices, including integration in sensor-augmented pump systems, are needed for these devices to fulfill their promise in improving clinical outcomes in children and adolescents with T1D.

Medical Nutrition Therapy

Proper nutritional management is critical to the short- and long-term health of children with diabetes. Generally, terms such as *diet* should be avoided in favor of *meal plan* or *healthy food choices*—both for the negative connotation associated with the former and for the simple fact that nutritional requirements for normal growth and development are the same in diabetic and nondiabetic children. Moreover, reasonably accurate estimations of the carbohydrate content of meals are important to optimal glycemic control with current basal-bolus treatment regimes. Indeed, the popularity of basal-bolus therapies and the use of carbohydrate counting to adjust the dose of rapid-acting insulin taken with each meal have fundamentally changed the treatment paradigm.

The traditional approach of adjusting the patient's lifestyle around fixed insulin doses and fixed amounts of carbohydrate intake with each meal has been replaced by a more flexible approach that attempts to adjust the insulin regimen to the patient's lifestyle. The day-to-day variations in appetite in children and adolescents make the latter approach more likely to be successful. It is

important to note that in some patients and some families, the traditional approach of trying to consume consistent carbohydrate servings per meal/snack may be more successful because it fits their personalities and lifestyle better.

The currently favored model of nutritional therapy is carbohydrate counting, based on the conceptual model of matching carbohydrate "doses" to insulin doses.[176,177] As the total carbohydrate content of foods (rather than the type of carbohydrate) has the greatest impact on blood glucose, the amount of carbohydrates ingested per meal or snack needs to be estimated as accurately as possible. Although the protein and fat contents of meals do affect the pattern of postmeal glucose excursions,[178,179] they are not usually counted in order to simplify the procedure. Food labeling requirements have simplified the process, as most foods are clearly labeled with the number of carbohydrate grams per serving and the serving size. Foods less easily quantified may be weighed or estimated, and eating out may be a particular problem. Although the prohibition of "sweets" has been done away with, we still recommend that patients drink diet rather than regular sodas.

In the flexible approach to nutrition counseling, there is no set intake. Rather, the child and parents decide the meal content. The carbohydrates are counted and an insulin dose is calculated based on a ratio of the number of insulin units per grams of carbohydrate determined by the empirical trial-and-error method. Actual insulin-carbohydrate ratios vary from child to child and in the same child according to the time of day. Breakfast often requires relatively more insulin than lunch or dinner. Carbohydrate counting can also be used in the traditional approach to dietary treatment to provide consistent carbohydrate servings per meal/snack. Indeed, a simple approach that stresses consistency in the timing and size of meals may be effective at the time of diagnosis of diabetes—when parents and patients are too overwhelmed to be able to learn more advanced nutritional concepts.[180]

The American Diabetes Association's recommendations regarding general nutritional principles in diabetes also take into consideration the long-term goal of preventing the macrovascular and microvascular complications of diabetes.[180] Consequently, heart-healthy diets low in cholesterol and saturated fats are encouraged. Long-term goals of nutritional management of diabetes include maintenance of nutrient intake balance of about 50% carbohydrate, 20% protein, and 30% fat (of which no more than 10% should be saturated). Most important, growth and weight gain should be monitored—and regular follow-up with a dietitian trained in diabetes management should be encouraged to individualize a meal plan for each child based on his or her needs and food preferences. We face an epidemic of childhood obesity in developed countries, and one of the adverse consequences of intensive insulin treatment is that 30% to 35% of pediatric patients with T1D in the United States are overweight or obese.[172] Thus, any tendency for body mass index (BMI) Z scores to increase excessively needs to be dealt with promptly.

Exercise

Establishment and maintenance of an active lifestyle should be a goal for all children, but especially children with diabetes, in order to enhance cardiovascular health. Exercise and increased physical fitness are associated with improved insulin sensitivity and glucose utilization, the clinical correlates of which are lower insulin requirements, lower blood pressures, and better lipid profiles. Improvements in physical fitness are also frequently associated with greater self-esteem and increased motivation to participate in diabetes care.

Despite its benefits, acute bouts of exercise in children with T1DM actually make regulation of blood glucose levels more difficult. Hypoglycemia is a common complication during exercise,[181] and excessive snacking to prevent hypoglycemia can result in hyperglycemia and negate some of the metabolic and cardiovascular benefits of exercise. These difficulties are compounded by the irregular pattern of physical activity that characterizes most youth who are not participating in organized sports or regimented training programs and by conventional methods of diabetes management that feature fixed basal insulin replacement doses. The Diabetes Research in Children Network demonstrated that the risk of nocturnal hypoglycemia nearly doubled in youth with T1D following antecedent afternoon exercise versus sedentary days.[182]

The effects of exercise must be carefully considered in the context of the entire diabetes care plan. Children participating in school sports or other programs should be counseled to monitor blood glucose before, during, and after exercise in order to optimize glycemic management. In addition, patients and parents should be aware that late hypoglycemic effects of afternoon exercise are often observed 7 to 11 hours after the bout of exercise in the afternoon,[183] a phenomenon that appears to be due to an increase in nonoxidative glucose disposal during sleep, which may serve to support repletion of muscle glycogen stores.[183]

In pump patients, simply suspending the basal infusion rate can markedly reduce the risk of hypoglycemia during exercise[181]—and similar benefits may accrue from reducing the overnight basal rates after very active days. Studies that have examined methods of managing glycemia during exercise illustrate that there is an almost infinite number of combinations of conditions that need to be considered. Because of this complexity, trial and error remains the principal method of managing glucose levels during and after exercise in children and adolescents with T1DM.[184]

Residual β-Cell Function (The Honeymoon Period)

After the initiation of insulin treatment in newly diagnosed patients, secretory function of residual beta cells improves and the insulin resistance and glucotoxicity of decompensated diabetes are reversed—heralding the onset of the partial remission (honeymoon period) of T1DM.[185] Most patients require a progressive reduction in their daily dose of insulin from ≥ 1 to ≤ 0.5 U/kg.

A minority of children (fewer than 5% of patients) can even maintain normoglycemia for a time without any administered insulin. Although opinion varies, we do not discontinue insulin treatment unless a daily dose of 0.1 U/kg still causes hypoglycemia.

The duration of the honeymoon phase in children with T1DM is variable but the lowest HbA1c levels and total daily insulin doses (TDD) are usually observed between 3 and 6 months postdiagnosis and both often rise between 9 and 15 months.[186] With current MDI and CSII treatment methods, the large majority of youth with T1D retain substantial residual insulin secretion, as measured by C-peptide responses to mixed meal tolerance tests, during the first year of their disease, and this can be extended for several years thereafter with maintenance of optimal glycemic control.[187] In comparison to patients who are C-peptide negative, patients with residual beta-cell function have lower HbA1c levels and total daily insulin doses—as well as a reduced risk of hypoglycemia.[188] These clinical and metabolic benefits serve as a strong rationale for current research involving immune interventions directed at preserving beta-cell function in newly diagnosed patients.[189] On the other hand, earlier and more aggressive application of sensor-augmented pump therapy around the time of diagnosis does not appear to confer any advantages over standard MDI and CSII with respect to HbA1c levels or C-peptide responsiveness in youth with T1DM.[158]

Hypoglycemia

The dark side of intensive treatment regimens that are effective in lowering HbA1c levels is that they also increase the risk of hypoglycemia. In the DCCT, intensive therapy was associated with an approximate threefold increased risk for severe hypoglycemia versus conventional treatment and, irrespective of treatment group, the rate of severe hypoglycemia was about 50% higher for adolescents than for adults.[143] Hypoglycemia has become the most significant barrier to the pursuit and maintenance of tight glycemic control among people with T1DM, and effectively managing of the risk for hypoglycemia is especially important in the treatment of children and adolescents with this disease.

The American Diabetes Association defines biochemical hypoglycemia (with or without symptoms) as any plasma glucose level < 70 mg/dL.[190] In nondiabetic adults, this is the plasma glucose level at which counterregulatory hormone responses engage and at which awareness of symptoms normally occurs. It should be noted, however, that such responses may be triggered at higher glucose levels in healthy 8- to 16-year-olds and in children and adolescents with T1DM who have poor glycemic control.[191]

The two main mechanisms that cause symptoms and signs of hypoglycemia are an outpouring of catecholamines (which results in pallor, sweating, apprehension, trembling, and tachycardia) and the effects of cerebral glucopenia, which include hunger, drowsiness, mental confusion, seizures, and coma. Mood and personality changes may be more subtle cerebral glucopenic effects that provide an early clue that plasma glucose has fallen to a dangerous level. Symptomatic episodes in which patients are able to treat themselves without the assistance of others are considered minor or mild hypoglycemia, whereas episodes in which there is sufficient cognitive impairment that treatment requires the assistance of another person are considered major or severe hypoglycemic events. Hypoglycemic events that cause seizures or coma are usually classified as a subset of severe hypoglycemia. In severe hypoglycemia, ingestion of carbohydrates may be precluded due to loss of consciousness, seizures, or coma—and treatment may require administration of a glucagon injection or IV glucose infusion.

In nondiabetic children, the initial response to falling plasma glucose levels is a prompt suppression of insulin secretion. If plasma glucose continues to fall and threshold values for release of anti-insulin counterregulatory hormones are reached, there are abrupt increases in circulating concentrations of glucagon and epinephrine. Plasma growth hormone and cortisol levels also increase, but these hormones are less important in acutely counteracting the effects of insulin. Defective counterregulation occurs in patients with T1DM because exogenously supplied insulin levels do not decrease in response to low blood glucose levels and the ability to secrete glucagon in response to hypoglycemia is lost early in the course of the disease.[185,192] Consequently, patients with T1DM depend on sympathetic nervous system responses—especially increases in plasma epinephrine levels—to prevent hypoglycemia.

The episodes of mild hypoglycemia that frequently accompany intensive treatment blunt catecholamine responses and symptom awareness to subsequent hypoglycemic challenges. This phenomenon has been called hypoglycemia-associated autonomic failure (HAAF).[193,194] Studies have shown that such defects in counterregulatory hormone responses are common in both young children and adolescents with T1DM who are well controlled.[195] Catecholamine responses to hypoglycemia are also impaired during sleep, which is an important reason why most of the severe hypoglycemia events occur during the night.[196] As noted earlier, bouts of exercise in the afternoon sharply increase the risk of hypoglycemia on the following night.[184]

The use of basal-bolus therapy with insulin analogs and insulin pumps has reduced the frequency of severe hypoglycemia somewhat but has by no means eliminated this problem. HbA1c levels can be reduced in patients who use CGM with or without integration in sensor-augmented pump system without increasing the risk of hypoglycemia, but severe hypoglycemia remains a significant problem.[175] In the T1D Exchange Clinic Registry that includes >10,000 children with T1D, one in 20 patients reported having at least one seizure or coma event related to hypoglycemia in the prior 12 months.[172] It is also noteworthy that the risk of severe hypoglycemia in patients with HbA1c levels $> 9.5\%$ in this cohort was similar to that in patients with HaA1c levels $< 8\%$. These data indicate that poor-control, per se, is not an effective strategy for reducing the risk of hypoglycemia.[172]

It is important that the patient and family recognize early symptoms and signs of hypoglycemia and known

precipitating factors. Mild episodes should be immediately treated with 10 to 15 g of carbohydrate (e.g., glucose tablets, juice, or glucose gel). Parents and school nurses also need to be instructed on how to perform injections of glucagon (0.5 to 1.0 mg) when the patient has lost consciousness and is unable to swallow exogenous carbohydrate. If exercise has been the precipitating factor, the patient should be instructed about preventive measures.

Sick Day Management

Children with intercurrent illnesses, such as infections or vomiting, should be closely monitored for elevations in blood glucose levels and ketonuria. On sick days, blood glucose levels should be checked every 2 hours—and the urine should be checked for ketones with every void. Supplemental doses of rapid-acting insulin (0.1 to 0.3 U/kg) should be given every 2 to 4 hours for elevations in glucose or ketones. Even in the absence of marked hyperglycemia, the presence of ketones indicates insulin deficiency and therefore the need for supplemental insulin.

Adequate fluid intake is essential to prevent dehydration and hasten the excretion of ketones. Fluids such as flat soda, clear soups, popsicles, and gelatin water are recommended to provide some electrolyte and carbohydrate replacement. In the child tolerating oral rehydration, a fluid "dose" of 1 ounce per year of age per hour serves as a rough guideline, the sugar content of which depends on the serum glucose. For blood glucose values $>$ 200 mg/dL, sugar-free fluids should be given. For those levels between 140 and 200 mg/dL, a mixture of sugar-free and sugar-containing fluids should be given. For blood sugar $<$ 140 mg/dL, only sugar-containing fluids should be given.

If emesis precludes normal oral intake, the intermediate or long-acting insulin should be discontinued and small frequent doses of short- or rapid-acting insulin should be given. In pump-treated patients, higher or lower temporary basal rates may also be used, depending on changes in glucose and ketone levels. Once the ketones have cleared and the child is tolerating an oral diet, the family may resume the normal routine. If vomiting is persistent and ketones remain moderate or large after several supplemental insulin doses, arrangements should be made for potential hydration and evaluation in a hospital emergency department.

Special attention should be paid to persistent hyperglycemia in patients using pump therapy, as use of this modality of insulin administration is a risk factor for diabetic ketoacidosis (DKA). Because only rapid-acting insulin is administered, an interruption of insulin delivery will result in increases in blood and urine ketone levels in 4 to 6 hours.[164] These interruptions are most commonly caused by problems with the infusion set such as kinking or occlusion of the subcutaneous catheter. Thus, assessment of hyperglycemia and any symptoms of nausea and vomiting must include an evaluation of the integrity of the infusion set and infusion site.

Associated Autoimmune Diseases

Patients with T1DM are at increased risk for other autoimmune diseases. These are detailed in Chapter 20 , in the discussion of multiple endocrine deficiency syndromes. Chronic lymphocytic thyroiditis is frequently associated with T1DM in children, and as many as one in five may have thyroid antibodies in their serum. Only a small proportion of these patients develop clinical hypothyroidism, however. The interval between the diagnosis of diabetes and that of thyroid disease averages about 5 years. Physicians should anticipate the possibility of hypothyroidism in patients with T1DM by periodic examination of the thyroid gland and measurement of serum thyroid-stimulating hormone (TSH) concentration.

When diabetes and thyroid disease coexist, the possibility of adrenal insufficiency should be considered. This may be heralded by decreased insulin requirements, increased pigmentation of the skin and buccal mucosa, salt craving, weakness, and postural hypotension. Rarely, frank Addisonian crisis is the first evidence of adrenal failure. This syndrome generally occurs in the second decade of life or later.

Celiac disease affects from 1.5% to 4.5% of children with T1DM, and most of them are not aware of any gastrointestinal symptoms. Early diagnosis requires screening of tissue transglutaminase antibodies, which have high degrees of reproducibility, specificity, and sensitivity if total circulating IgA concentrations are not abnormally low. Antibody-positive children should be referred to a pediatric gastroenterologist for confirmation by small bowel biopsy, as well as for counseling and disease management. When typical signs and symptoms of malabsorption are present or the patient has frequent hypoglycemia or unexplained behavioral mood swings, dietary intervention is indicated. When symptoms are minimal or absent, the decision to introduce gluten-free diets with their additional restrictive and inconvenient burdens on the patient and family are less clear-cut.[197] To guide their decision, the parents and older children need to be made aware of the risk of bowel malignancies in untreated celiac disease in later life and of other long-term complications of this disease.

Associated Psychosocial Problems

Diabetes in a child affects the lifestyle and interpersonal relationships of the entire family. Guidelines for psychosocial management and support of families with childhood diabetes have been published. Feelings of anxiety and guilt are common in parents. Similar feelings, coupled with denial and rejection, are equally common in children—particularly during the rebellious teenage years. These issues are not unique to T1DM but are observed in families with children who have other chronic disorders difficult to treat. These stresses are often exaggerated in single-parent low-income families and impair their ability to effectively carry out needed self-management tasks, resulting in poor metabolic control.[198] Language and cultural barriers are additional obstacles in immigrant families.[199]

Psychosocial difficulties and conflict between patients and parents may result in nonadherence to instructions regarding healthy food choices, insulin therapy, and frequency of blood glucose monitoring. In this era of basal-bolus insulin therapy, missing premeal bolus doses is the most common cause of elevated HbA1c levels, especially in adolescents. Consequently, one of the major advantages of CSII over MDI in pediatric patients is that the bolus history function of current insulin pumps provides a record of the number of daily bolus doses that were actually administered.[200] Deliberate overdosage with insulin resulting in hypoglycemia or omission of insulin to limit weight gain (also referred to as "diabolemia") may be pleas for psychological help. Occasionally, they may be manifestations of suicidal intent. Frequent admissions to the hospital for ketoacidosis or hypoglycemia should arouse suspicion of underlying emotional and family conflict. Feelings of being different or of being alone are also common.

The clinician managing a child or adolescent with diabetes should be aware of his or her pivotal role as counselor and advisor and should anticipate the common emotional problems of the patient. When emotional problems are clearly responsible for poor compliance with the medical regimen, referral for psychological help is indicated. In pediatric centers, psychologists form part of the management team for children with diabetes. Although clinical depression is one of the most common comorbidities in youth with T1DM, problems in this area may not be evident during routine clinic visits, especially in preteens who may present as somewhat withdrawn rather than rebellious.[201] As a result, treatment guidelines suggest that screening questionnaires for depressive symptoms should be administered to youth with T1DM on a regular basis.[202] However, it has been difficult to implement this recommendation in most clinical practices.

Outpatient Care

The importance of frequent follow-up by the diabetes health care team cannot be overemphasized. Children and adolescents with T1DM should be routinely cared for at a diabetes center that uses a multidisciplinary team knowledgeable about and experienced in the management of young patients. This team should ideally consist of pediatric diabetologists, diabetes nurse specialists, nutritionists, and social workers or psychologists.

The American Diabetes Association has published guidelines for care of the child and adolescent with diabetes.[144] Regular follow-up visits with the physician or diabetes nurse specialist/practitioner every 2 to 3 months are recommended for most patients. The main purpose of these visits is to ensure that the patient is achieving primary treatment goals. Outpatient visits provide an opportunity to review glucose monitoring (and CGM profiles), to adjust the treatment regimen, and to assess child and family adjustment. At each visit, glucose records should be reviewed and appropriate dosage or schedule changes should be instituted. The nutritionist and psychologist or social worker also gives follow-up advice and support.

A detailed interim history should include questions relating to general health, energy, fatigue, polyuria or nocturia, intercurrent illnesses, hypoglycemic episodes, and the presence of symptoms such as abdominal pain, bloating, or diarrhea. It is important to remember the comorbidities of other autoimmune disorders that occur with an increased frequency in children with T1DM: thyroiditis, adrenal insufficiency, and celiac disease. The child should be weighed and measured at each visit, and blood pressure documented. Physical examination of the child should focus on the general organ systems and on examination of the skin and insulin injection/pump insertion sites for signs of lipohypertrophy or pigmentary changes, palpation of the thyroid, and determination of the stage of sexual development stage.

Lipoatrophy was commonly observed in the past but is now a rare complication of insulin therapy.[203] A deceleration in growth, delay in sexual development, or finding of goiter may herald hypothyroidism. The astute clinician should also consider that frequent unexplained hypoglycemia or reduction in insulin requirements in the absence of exercise or activity might be subtle indicators of hypothyroidism or adrenal insufficiency. Similarly, although a history of having frequent foul-smelling greasy stools is a more obvious indicator of celiac disease, the majority of cases are asymptomatic.

Measurement of glycosylated hemoglobin (HbA1c) provides the gold standard by which to judge the adequacy of the insulin regimen and use of point-of-service methods that can be performed in the office in a few minutes offers the opportunity to make immediate changes in the insulin regimen while the patient is being seen. Results of point of care measurements compare favorably with laboratory methods.[204] Even more important, the results of this test delivered during face-to-face encounters with the clinician serve as the quarterly "report cards" for the child and the parents. Teenagers may not be able to identify with the concept of working hard on their diabetes to be healthier many years in the future, but most are able to understand good grades. Thus, the HbA1c level provides a tangible outcome with which they can identify. The goal of treatment is to achieve HbA1c levels as close to normal as possible. Based on DCCT results and ISPAD recommendations, our general goal of therapy is to try to keep all patients under 7.5%. HbA1c levels are determined at least every 3 months.

Routine screening for associated autoimmune diseases with T4, thyroid-stimulating hormone (TSH), and tissue transglutaminase IgA every 1 to 2 years is recommended. Monitoring of the diabetic child for potential complications and cardiovascular risk factors is another important function of the clinic visit. The normal urinary albumin to creatinine ratio is < 30 mg albumin to gm creatinine, microalbuminuria is 30 to 300 mg/gm, and macroalbuminuria is > 300 mg/gm. Elevated spot samples should be confirmed at least a second positive. Preferably this would be either a first morning void or a timed overnight collection rule out benign orthostatic proteinuria. If the confirmatory test also demonstrates microalbuminuria, treatment with angiotensin-converting enzyme inhibitor or angiotensin receptor blocker therapy or referral to

pediatric nephrologist is indicated. All diabetic children with hypertension, regardless of albumin excretion status, should be considered candidates for these medications, as well. Although there are no specific guidelines for diabetic children,[205] current recommendations for nondiabetic children are that blood pressures above the 90th percentile for age warrant lifestyle intervention and those about the 95th merit the use of pharmacologic agents.

Other screening studies for complications of diabetes include measurement of serum lipid concentrations. The current standards of care for adults with diabetes indicate that low-density lipoprotein (LDL) concentrations should be maintained below 100 mg/dL, whereas pharmacologic therapy for dyslipidemia in children with diabetes is not recommended unless dietary interventions fail to lower LDL concentrations below 130 mg/dL. The American Diabetes Association recommends that annual dilated retinal examinations be obtained in patients who are over 10 years or age and have had T1DM for 3 or more years. On the other hand, the yield from such examinations is very low in children and adolescents who have normal blood pressure, HbA1c levels that meet current targets, and who are without microalbuminuria.[206]

Management During Surgery

Management objectives during surgery are the prevention of hypoglycemia, excessive loss of fluids, and ketosis during anesthesia. The regimens described here are generally applicable, but vigilance and individual adjustments for each patient are necessary to achieve these goals. Evidence-based, controlled studies of perioperative care have not been carried out in children, but detailed expert reviews of management have been published in the anesthesia and pediatric diabetes literature.[207,208]

The most reliable and straightforward approach to achieving management objectives during major elective or emergency surgery is to use intravenous infusions of glucose and insulin during the perioperative period. For surgical emergencies that can be briefly delayed, such as acute appendicitis, rehydration and metabolic balance should be restored before the operation. Elective major operations should be performed first thing in the morning, and the glucose and insulin infusions should be started 2 hours or more prior to proceeding to the operating room. For elective surgeries, an infusion of 5% glucose in 0.45% or 0.9% saline solution is begun on the morning of surgery—and 1 unit of regular insulin is infused intravenously for each 4 to 6 g of administered glucose. One unit of regular insulin for every 2 to 4 g of exogenous glucose may be required in surgical emergencies due to elevated circulating concentrations of stress hormones or in insulin-resistant obese diabetic patients.

The rate at which intravenous fluids are administered should be sufficient to provide maintenance fluid requirements plus estimated losses during surgery and other fluid deficits. The blood glucose concentration should be monitored at periodic intervals before, during, and after surgery. Concentrations of 120 to 150 mg/dL should be the goal. This can be achieved by varying the rate of infusion of the glucose and electrolyte mixture or the rate of insulin administration. The intravenous insulin and glucose infusions can be continued until the patient is awake and capable of taking regular meals, at which time their usual injection or insulin pump regimen can be reinstituted. Use of continuous glucose monitoring devices during surgery in children and adolescents has not been adequately studied.

In patients who receive NPH insulin in the morning and are undergoing surgery of short duration, a standard and effective approach is as follows: on the morning of surgery, half of the usual morning dose of NPH insulin is administered subcutaneously, the usual dose of rapid-acting insulin is omitted unless needed to correct hyperglycemia, and a maintenance intravenous infusion of the electrolyte and glucose solution is initiated if needed. Similarly, in patients on insulin pump therapy who are undergoing short procedures, the continuous subcutaneous infusion of insulin (CSII) can be continued at the usual or slightly reduced overnight basal rate. Insulin pump-treated patients can also be maintained on CSII for major procedures as long as the integrity of the infusion and infusion site is ensured.

The nighttime dose of glargine or detemir insulin may provide sufficient basal insulin coverage for surgery in patients who receive these long-acting insulins before dinner or bedtime. A reduction in the glargine or detemir dose by 20% to 30% on the night prior to surgery should be considered in patients who have had a tendency to low pre-breakfast plasma glucose levels. With all three regimens, a correction dose of rapid-acting insulin can be given subcutaneously immediately after the procedure if needed for hyperglycemia—and repeated as needed to balance initial oral intake (e.g., carbohydrate-containing clear liquids). When the intravenous infusion is discontinued and the patient is ready to resume regular meals, the usual treatment regimen is reinstituted.

THE FUTURE IS NOW: CLOSED-LOOP INSULIN DELIVERY

A number of investigator groups and pump and sensor manufacturers are developing closed-loop systems that combine external insulin pumps with current CGM devices. These systems utilize controller algorithms that automatically regulate insulin infusion rates delivered by the pump based on sensor glucose readings every 1 to 5 minutes. These automated insulin infusion systems will have to be easily managed by the patient, protected against system problems that lead to an overdelivery of insulin, and able to respond to challenges of human physiology during normal daily activities, such as exercise and psychological stress. Although it has already been demonstrated that closed-loop systems can control glucose levels effectively in short-term, inpatient, clinical research center studies,[168] much work needs to be done to ensure the safety of these systems before they will be ready for outpatient use.

The Paradigm Veo (Medtronic) insulin pump represents the first small step toward automated control of insulin delivery. The low-glucose-suspend feature of this sensor-augmented pump system allows the basal rate of

the patient's pump to be suspended for up to 2 hours if the patient fails to respond to the sensor's low-glucose alarm. This system has been tested in adults and children with T1D and has been found to significantly decrease the extent and duration of nocturnal hypoglycemia in patients with T1DM.[209] Importantly, almost all of the study participants reported that they felt safer and less anxious at night.[209]

Because of their increasingly important role in managing T1DM in childhood, a detailed description and discussion of pump therapy follows this section; Box 19-4 and Tables 19-11 and 19-12 summarize several key elements of pump therapy.

Non-autoimmune Type 1 Diabetes

Not all forms of apparently classic type 1 diabetes mellitus have associated markers of autoimmunity.[210] In one report, among children presenting with newly diagnosed diabetes mellitus, fewer of those younger than 5 years of age at diagnosis had positive titers of islet cell and GAD antibodies—and fewer had a honeymoon phase within 6 months—compared with a group with onset at a mean age of 10 years.[48] Similarly, Japanese investigators have reported that some patients with idiopathic type 1 diabetes mellitus have a non-autoimmune fulminant disorder with abrupt onset characterized by absence of circulating antibodies, evidence of insulinitis in pancreatic biopsies, and high concentrations of pancreatic enzymes—suggesting an acute inflammatory process in the pancreas.[49,50]

MODY syndromes may also be initially considered to be T1DM.[12,13] However, a strong family history of vertically transmitted DM in two to three generations, absence of autoimmune markers, and relatively milder features of diabetes should alert the physician to the possibility of a monogenic form of diabetes such as MODY.

CSII-Based Treatment Regiments

The use of insulin pumps (continuous subcutaneous insulin infusion [CSII]) has increased dramatically in children and adolescents with type 1 diabetes (T1D) since the 1990s. The T1D Exchange study group has reported that 33% of children < 6 years of age, 47% of children aged 6 to 12 years, 50% of adolescents aged 13 to 17 years, and 52% of patients aged 18 to 25 years used an insulin pump in the cohort of 20,555 participants (11,641 younger than age 18 years) from the United States.[211] This is matched by the 36.6% of 30,708 children and adolescents with T1D from Germany and Austria,[212] and with many other countries in the European Union and Israel reporting similar insulin

TABLE 19-11 **Pump Options and Features**

Pump	Minimal Basal Rate Increments (U/hr)	Minimal Bolus Dose Increments (Units)	Maximum Bolus Dose (Units)	Insulin Reservoir Capacity (Units)	Additional Features
Accu-Chek Spirit	0.1	0.1	25	315	Reversible display Includes personal digital assistant (PDA) device to calculate boluses and w/ database of foods Comes with backup pump AA battery Accu-Chek 360°(not Windows 7/Mac)

TABLE 19-12 The Stepwise Initiation of Pump Therapy at the Yale Children's Diabetes Program

2-6 Weeks before Start
- Review pros/cons of pump therapy
- Determine which model is best
- Initiate insurance process to secure coverage of pump
- Refer patient to on-line training resources or give them manual to review

1-2 Weeks before Start
- Have patient (depending on age) and/or caregivers complete on-line or written training
- Invite school nurse, baby sitters, other caregivers to pump training
- Family is contacted by official trainer from pump company to arrange the 1st of 2 visits
- Family receives insulin pump and should take pump out of box and start practicing button pushing techniques
- 1st visit with official trainer to review ins/outs of pump model, practice button pushing, site insertion and review DM management principles for pump users (may be done at family home or nearby site for convenience)

Day of Start
- Typically scheduled for a Monday or Tuesday morning
- Usually done at clinic building
- Hold AM long-acting insulin
- Initiate pump with insulin and family performs first site change
- Families instructed to test BG: before meals, 2H PP, HS, 12A and 3A

Week Following Start
- Daily phone contact with nurse practitioner to titrate doses
- Follow-up visit and/or phone contact with official trainer for first site change

2-4 weeks after Start
- Clinic visit to review DM management principles for pumpers
- Identify any areas for reinforcement
- Return to regular clinic schedule for quarterly follow-up

pump use in children and adolescents. Several tertiary pediatric centers report the use of insulin pumps as the predominant treatment modality in their pediatric population.[213] CSII has several practical benefits over MDI, including programmable basal insulin rates with multiple basal rate profiles and the possibility of temporary basal rates, adjustable "dual-wave" boluses, same injection site over 2 to 3 days (versus multiple daily injections), dose calculators, and the possibility of data upload, all of which facilitate the day-to-day management of the disease.

The use of insulin pumps is associated with improved metabolic control, lower glycated hemoglobin, or less hypoglycemia in many,[214,215] but not all,[216,217] clinical trials. Large cohort studies including several thousand pediatric patients have described a significant correlation between better metabolic control and the use of insulin pumps.[211,212] Additionally, the quality of life assessed by PedsQL-T1DM questionnaire is significantly associated with the use of insulin pumps,[218] and preliminary data suggest better cognition, mood, and behavior.[219,220]

Selection criteria for insulin pump therapy[221] in the pediatric patient population broadened as experience and data on its use accumulated.[222] Commonly, poor glycemic control, frequent hypoglycemia, increased glucose variability regardless of HbA1c, compromised quality of life, and increased risk of chronic complications are listed. Self-blood glucose monitoring (SBGM) is still an important prerequisite, as is parental support. Young age, frequent SBGM, and lower HbA1c at pump initiation are associated with better long-term metabolic control.[223] Conversely, female gender, age older than 10 years in girls, and poor metabolic control at pump initiation are associated with higher risk for attrition from insulin pump therapy.[224] Interestingly, children with inadequate metabolic control on MDI may experience the highest decrease in their HbA1c when switched to an insulin pump.[225] In preschool children, initiating the insulin pump therapy at the disease onset may help patients to maintain lower HbA1c for up to 8 years.[226]

Insulin pump therapy initialization is a structured multistep process involving the whole (extended) patient's family and a diabetes team ideally including a pediatric endocrinologist, a pediatric diabetes nurse educator, a specialized dietitian, a child psychologist, and a social worker. Additionally, adequate training of daycare personnel, a nanny, or school personnel is of crucial importance.[227]

Basal Insulin Rates

A continuous sequence of small boluses approximately every 10 minutes of a short-acting insulin analog provides basal insulin required for suppressing liver gluconeogenesis and ketogenesis and maintaining basal normoglycemia. Age-specific daily patterns of basal rates differ considerably in dose and distribution.[228,229] As insulin resistance increases with age, so does the insulin dose. Although preschool children often need highest basal rates between 10 p.m. and 2 a.m., this pattern changes as puberty approaches when the highest insulin requirement usually starts after 4 a.m. and lasts till wakeup.

When switching a patient from MDI to CSII, the total basal rate dose usually is calculated based on the previous dose of the long-acting insulin analog and is usually reduced by 10% to 20% if HbA1c was $< 8\%$. Alternatively, the total daily insulin dose is reduced by 20% to 30% and then half is administered as the basal rate. Some clinicians calculate the basal rate dose arbitrarily as approximately 0.4 units of insulin per kilogram body weight, especially when the dose of the long-acting insulin analog or the total daily insulin dose when treated with injections was evidently not appropriate and achieved poor metabolic control.

Programming multiple basal rates in the pediatric population seems prudent, as this was associated with better metabolic control.[230] Several initial approaches are used[231] with likely similar success, as basal rates should be subsequently verified and personalized.

In infants and toddlers, a flat initial basal rate may be appropriate and tailored to individual need in the first week of insulin pump use. As modern insulin pumps can deliver as little as 0.025 units of insulin per hour, diluting insulin is rarely needed. Intermittent programming of 0 units of insulin per hour for shorter periods of up to 2 hours is sometimes used for neonates. A higher basal insulin rate will be needed around midnight with a lower rate applied in the afternoon. For older children and adolescents, the day may be divided into five parts: from midnight to 4 a.m., covering the period with least basal insulin requirement, from 4 to 7 a.m. covering the dawn phenomenon period, from 7 a.m. to 1 p.m. covering the morning, from 1 to 8 p.m. covering the afternoon, and from 8 p.m. to midnight covering the evening.[231] Sometimes, an additional time frame for the dusk phenomenon may be needed from 5 to 8 p.m.[232] Several basal rate patterns may be needed for different situations: a standard pattern for regular weekdays, a weekend or leisure pattern with lower basal insulin rates during the morning (e.g., less stress from school or work or more activity), and a "sick days" basal rate pattern with 30% more insulin throughout the 24 hours.[233]

Verifying Basal Insulin Rate Settings

The ideal basal rate will keep the blood glucose levels within the desire range during fasting. The need for basal insulin changes with time and depends on insulin sensitivity that varies with age, lifestyle, growth, and several other fluctuating influences. Basal insulin rates can be best verified when food intake is omitted. The nighttime basal insulin rates may be verified first, as the overnight glucose concentration profile is usually of greatest concern. On an uneventful day after an early dinner (at 5 to 6 p.m.) that was meticulously covered by an appropriate bolus, SBGM is performed every 2 to 3 hours from 10 p.m. till wakeup. If the BG changes for more than ±40 mg/dL (2 mM), the basal rate approximately 1 hour prior to the BG change is adjusted for ±10% to 20%. Similarly, a morning basal SBGM profile is performed after an uneventful night, skipping the breakfast and morning snack with SBGM every 2 to 3 hours until lunch. Finally, an afternoon basal SBGM profile is performed after an uneventful morning, skipping lunch, with SBGM every 2 to 3 hours until dinner. Basal insulin rates are adjusted as described for the night basal profile. If the BG level fells below or above the usual range between 70 to 180 mg/dL, the condition is treated, the basal profile testing is discontinued, the basal rate is adjusted accordingly, and the basal rate SBGM profile retested in a couple of days. In preschool children basal rates can be verified in shorter time intervals, as only one meal per day can be omitted. Some verify basal profiles without omitting meals but rather after eating standardized small meals covered by appropriate boluses. Continuous glucose monitoring (CGM) can be of obvious assistance and can reduce the frequency of SBGM. Frequent phone contacts with the diabetes team are prudent in the first weeks after insulin pump initialization to individually fine-tune basal insulin rates.[233]

Temporary Basal Rates and Basal Insulin Suspend

With little insulin in the body between boluses, reducing or stopping the basal insulin rate is an efficient way to prevent hypoglycemia during physical activity or sport.[234] Smart pumps can show the amount of remaining insulin in the body after a bolus (so-called active insulin), which can be of considerable help in preventing exercise-associated hypoglycemia, as "active insulin" can be covered with additional carbohydrates.

Bolus Insulin Dosages

Careful and more frequent dosing of insulin for covering food and correcting high BG levels is associated with better metabolic control when using insulin pumps.[235] Modern insulin pumps can assist calculations of bolus insulin reducing errors[236] and incorporating physiologic variability of insulin sensitivity during the course of the day.

Bolus Insulin for Food Coverage

Principles of calculating boluses for food are same as for MDI, with the additional possibility of more precise dosing down to 0.025 units of insulin in some insulin pumps. Solid practical knowledge of carbohydrate counting is paramount. The arbitrary formula of 500 divided by the total daily insulin dose for older children and adolescents (300 or 200 for preschool children or toddlers, respectively) can help in determining the initial insulin-to-carbohydrates ratio (ICR). The ICR can be higher (one unit of insulin covers fewer carbohydrates) in the morning, sometimes by 30% to 100% as compared to midday, and slightly higher again in the evening. Bolus calculators are incorporated into modern pumps and do all required calculations based on preset ICRs, the current BG, the planned amount of carbohydrate ingestion, and the glucose target range, typically between 70 and 120 mg/dL (3.9 and 6.5 mM).

Advanced food-bolus determination incorporates protein counting (15 grams of carbohydrates for each additional 100 g of protein after the first 100 g)[237] and the use of prolonged or "dual-wave" bolus administration, which is associated with better postprandial glucose control after ingestion of food with low glycemic index.[238]

Preferably, the bolus is administrated 15 to 20 minutes before the meal as the postprandial peak of BG precedes the peak of rapid-acting insulin analog action.[239,240] As eating habits in smaller children may be unpredictable, a "split-bolus" approach may be used for optimal postprandial control with only 10% to 20% of the calculated bolus administrated 15 to 20 minutes prior to the meal for covering "certainly" ingested food, and the rest administrated after the meal according to the amount actually consumed.

ICRs should be verified on a regular basis with hourly postprandial SBGM or CGM, aiming at BG < 180 mg/dL (10 mM).

Missed prandial boluses, particularly during the school hours, are the most common cause of suboptimal metabolic control.[241] Parental and school-personnel supervision and support is valuable.

Bolus Insulin for Correction of Hyperglycemia

Insulin sensitivity factor (ISF) can be estimated by dividing 1800 by the total daily dose in older children and adolescents (2000 or 2200 in preschool children and toddlers, respectively). Again, bolus calculators incorporated into smart insulin pumps calculate correction boluses based on the preset ISF, current BG level, preset BG target range, and the amount of "active insulin" from previously administered correction boluses. The amount of "active insulin" calculated by the insulin pump bolus calculator depends on the setting of the insulin action time, commonly set to 3 hours for boluses used in pediatric population. A shorter insulin action time setting allows for more aggressive correction bolusing.

Also ISFs are regularly verified with SBGM 2 to 4 hours post correction or with CGM. It is advisable to avoid correction boluses less than 2 hours apart as insulin accumulation (stacking) may occur and provoke hypoglycemia.[242]

Specific Considerations and Acute Complications of Insulin Pump Therapy

Regular physical activity is strongly advised but challenging in youngsters with T1D, particularly in relation to hypoglycemia during and after it.[243,244] The biggest advantage of CSII may be related to its possibility of reducing physical activity–related hypoglycemia.[245,246] Basal insulin rate can be stopped or diminished by setting a temporary basal rate immediately prior and during the physical activity, depending on its intensity and duration. The presence of "active insulin" from previous boluses can be verified and an appropriate carbohydrate snack added prior to the physical activity in addition to basal insulin rate modification, effectively preventing hypoglycemia. Finally, strenuous or prolonged exercise often results in delayed hypoglycemia, which can be prevented by a diminished temporary basal insulin rate programmed for several hours post physical activity. Hypoglycemia can therefore be prevented without an excessive use of additional carbohydrates and thus a negative energy balance can be maintained, which is of particular importance for body weight management.

Reduction of hypoglycemia with sensible use of insulin pump therapy was demonstrated in several studies[247,248] and has many important practical implications that must be discussed during the training of the family. The possibilities of insulin stacking after too frequent correction bolusing, inappropriate counting of carbohydrates, and insulin modifications related to an acute illness (e.g., vomiting), eating disorder, or to physical activity are the most important issues that should be taken into consideration.

Diabetic ketoacidosis (DKA) was traditionally considered as a risk associated with CSII; however, studies report less DKA with the use of modern insulin pump.[248,249] As only rapid-acting insulin analogs are used in insulin pumps, significant ketonemia may develop 4 to 6 hours after discontinuation of CSII.[250] Partial or complete disconnection of the infusion set and plugging or kinking of the subcutaneous catheter are the most common causes. A DKA rescue plan must be included in the structured education provided to patients and caregivers. Blood or urine ketones must be checked if two consecutive BG levels or the fasting BG levels are $>$ 275 mg/dL ($>$ 15 mM), and the possibility of infusion set problems considered. Infusion set must be replaced and an appropriate correction bolus administered, alternatively with an insulin pen injector, if the functioning of the infusion set is not certain. If ketonemia is $>$ 1.5 mM, an increased temporary basal rate of 150% to 200% may be needed until blood ketones are normalized. Additional fluid intake is advisable. If ketonemia is associated with an acute illness or remains unexplained, contact with the on-call diabetes team is warranted.

Maintaining normoglycemia during acute severe illness has been demonstrated in adults,[251] along with the danger of hypoglycemia. Despite the lacking published evidence for children, teams in PICU and NICU need appropriate training for maintaining stable glycemic control with CSII during acute severe illness.[252] Anesthesiologists often suggest a switch to intravenous insulin during prolonged surgery, which with frequent BG level determination provides a well-established and safe treatment modality. CSII should be restarted just prior to the termination of intravenous insulin administration. Discontinuing CSII during intermittent hospitalizations on various pediatric or surgery wards is usually associated with poor metabolic control and should be discouraged. A pediatric endocrinology team should be involved in the appropriate care of hospitalized children with diabetes.

Insulin Pump Therapy in Kindergarten and School

Most schools in developed societies accept chronically ill children and provide necessary care either enforced through law and regulations or voluntarily. A structured plan for school personnel and diabetes-related education similar to the one for caregivers facilitate cooperation among parents, the diabetes team, and the school. A cooperative spirit aimed at the best interests of the child with T1D usually yields optimum long-term results. The diabetes team serves as facilitator and coordinator in the collaboration between parents and the school personnel. Ideally, basic training for school personnel includes but is not limited to SBGM and appropriate recording, management of hypoglycemia including discontinuation of insulin delivery, rescue carbohydrates and administration of glucagon, management of hyperglycemia including correction boluses and ketones checking, carbohydrate counting and determining boluses, and management of physical activity.[227,253,254]

Despite significant improvements in metabolic control with the routine use of CSII in pediatric populations, most young people with type 1 diabetes still do not reach target metabolic control,[255] with hypoglycemia and DKA remaining as problems.[256] More emphasis on psychosocial support and successful parenting[257] are needed in view of challenging modern environments to which children and adolescents are often exposed.

TYPE 2 DIABETES MELLITUS

Typical

Type 2 diabetes mellitus, formerly known as NIDDM, is a heterogeneous disorder characterized by defective insulin secretion that progressively fails to compensate for insulin resistance.[258] The cause of insulin resistance is usually obesity,[258-263] although agents such as growth hormone and cortisol also antagonize insulin action and may unmask inadequately compensated insulin secretion. The high concentrations of placental growth hormones during mid to late gestation likewise may unmask inadequate insulin secretion, resulting in gestational diabetes—a harbinger of permanent diabetes later in life.

The mechanism of insulin resistance caused by obesity may in part relate to changes in fatty acid metabolism that interfere with normal glucose metabolism, and in part to factors synthesized within fat cells that antagonize insulin action.[264] Most notable are the hormones adiponectin, leptin, and resistin,[264] which are produced by fat cells and are a likely major link between obesity and diabetes. The sensing of insulin resistance induced by obesity results in the production by the liver and fat cells of a protein, betatrophin, which stimulates beta cell expansion and increased insulin secretion in mice by altering the expression of genes regulating the cell cycle. Genetic regulation of the ability to overcome insulin resistance by producing this and other proteins may be another mechanism that predisposes or protects from T2DM.[265,266] Thus, in addition to the genetic components responsible for impaired insulin secretion (which are being investigated, progressively identified, and presently cannot be changed),[267-271] the key modifiable factor responsible for the epidemic of type 2 diabetes in children is the epidemic of obesity increasingly recognized throughout the world.[271-275]

Type 2 diabetes mellitus is being increasingly recognized in children, particularly obese adolescents and especially but not exclusively in certain ethnic groups such as Native American Indians, African Americans, Mexican Americans, and Southeast Asians in the developing world.[271-275] Here, too, an epidemic of obesity is responsible for a rapid increase in the proportion of patients with type 2 diabetes—representing up to half of the newly presenting cases in one major medical center in the United States.[271,272] These patients often have a family history of type 2 diabetes, may have acanthosis nigricans, are more commonly girls, and often have poor metabolic control that predisposes them to the earlier appearance of microvascular and macrovascular complications.[272] They may present initially in diabetic ketoacidosis suggesting type 1 diabetes, but after recovery they may manifest a prolonged "honeymoon phase"—the so-called atypical diabetes mellitus (ADM), or type 2 diabetes, as documented by significant insulin or C-peptide levels not consistent with type 1 diabetes. They also lack markers of islet autoimmunity and the classic HLA associations. [272]

In those with a family history of type 2 diabetes mellitus, insulin resistance (as shown by impaired insulin-stimulated glucose disposal and higher insulin values during oral glucose tolerance or so-called hyperglycemic clamps) is demonstrable in the first decade of life before clinically demonstrable changes in glucose tolerance.[271-272] The sites of this presumably genetic impairment in insulin sensitivity has not yet been identified but clearly precedes clinical diabetes mellitus brought about by obesity-induced insulin resistance.[271,272] There may be other factors that induce insulin resistance.

There also are an emerging number of newly identified genetic factors associated with impaired insulin secretion and action. Genome-wide scans have consistently identified three major genetic linkages: the ATP-regulated potassium channel KATP, especially the Kir 6.2 subunit encoded by the KCNJ11 gene; the peroxisome proliferator-activated receptor γ (PPARG); and transcription factor 7 like 2 (TCF7L2.[274-276] The development of sophisticated arrays that permit genotyping of literally hundreds of thousands of polymorphisms has revealed additional loci of genetic markers in T2DM, including a polymorphism in the zinc transporter SLC30A8 (expressed only on pancreatic β cells) and genes potentially involved in pancreatic development (IDE, KIF11, HHEX) or function (EXT2-ALX4).[268-270,272-275] These sophisticated genetic screening approaches are likely to identify more of the complex genetic traits that underlie T2DM. From a practical point of view, type 2 diabetes mellitus in children and adolescents should be viewed as a major public health issue—and without effective lifestyle interventions (such as weight reduction combined with regular exercise), treatment options are limited and only modestly successful.[271,272] Exogenous insulin may be necessary to control blood glucose initially, but its appetite-stimulating effects challenge attempts at weight reduction. Sulfonylureas may be temporarily helpful, as may meglitinide—which acutely increase insulin secretion.

Metformin, which sensitizes tissue to insulin action and diminishes hepatic glucose production, is the most frequently used agent for treating type 2 diabetes in children. The U.S. Food and Drug Administration (FDA) has approved it for use for those over 10 years of age. The FDA has not approved for use in children thiazolidinediones (glitazones) that sensitize tissue to insulin, but nevertheless they have reportedly been used.[276,277] These agents are potentially hepatotoxic, and the original product was withdrawn for this reason. Newer glitazones (such as rosiglitazone) are under investigation in adolescents with T2DM, although rosiglitazone itself is under scrutiny for potential harmful effects on cardiac function.[276] Alpha-glucosidase inhibitors that slow carbohydrate absorption and lipase inhibitors to diminish fat absorption are available, but none has undergone clinical trials in children/adolescents for efficacy and compliance. This represents a major deficiency in our ability to treat type 2 diabetes mellitus in children.[271,272]

GENETIC DEFECTS OF BETA CELL FUNCTION

MODY Syndromes

Although MODY was originally conceptualized as a form of maturity-onset (i.e., type 2) diabetes, the MODY syndromes are best considered a group of disorders of

monogenic defect in beta cell function. Affected patients may have modest elevation of glucose, may remain asymptomatic for many years, and may become clinically apparent during intercurrent illness or pregnancy that unmasks the limited insulin secretion.[12,13] Clinical criteria used to establish the diagnosis include the following.

- Dominant inheritance with at least two (and preferably three) consecutive affected generations
- Onset before age 25 to 30 years
- Evidence of significant but impaired residual insulin secretion reflected in C-peptide levels whether or not the patient is being treated with insulin

At least six specific genetic defects have been identified (Table 19-13), although more are included in the Online Mendelian Inheritance in Man (OMIM) database. Moreover, milder defects in the K_{ATP} genes KCNJ11 and ABCC8 as well as defects in the insulin gene itself have been found in patients who fulfill the criteria for a diagnosis of MODY. Of these genetic defects that together account for no more than 2% to 5% of type 2 diabetes, about two thirds (65%) are MODY 3 (HNF1α), 10% are MODY 2 (glucokinase defect), and the remainder constitute the other defects. Mild stable hyperglycemia may be present from birth and not require treatment except during stress, such as infections in an infant or child or pregnancy in a young adult.

With glucokinase deficiency, microvascular complications of diabetes are rare. In the other common forms of MODY, such as MODY3 and MODY1, however, onset is usually in the early teens to 20s, glucose intolerance may become progressively worse and hence require treatment, and microvascular complications may develop later in life. Renal cysts or other reno pelvic anomalies may occur in MODY 5 (HNF1β). Notably, if the genetic defect in IPF1 (insulin promoter factor-1, MODY 4) is homozygous, pancreatic agenesis results and this is a cause for permanent neonatal diabetes associated with exocrine as well as endocrine insufficiency (see Chapter 9). Likewise, homozygous mutations in glucokinase have been associated with congenital diabetes. By contrast, gain-of-function mutations in glucokinase cause persistent hyperinsulinemic hypoglycemia of infancy (see Chapter 6 ***). Thus, the MODY syndromes are monogenic defects of islet cell formation (MODY 4) or of transcription factors (MODY 1, 3, 5, and 6)—or a defect in the functional glucose sensor glucokinase (MODY 2).[12,13,277]

Table 19-14 compares and contrasts the four most common types of diabetes found in adolescents: type 1, type 2, atypical diabetes mellitus, and MODY. The monogenic MODY syndromes have been extensively reviewed in terms of chemical, biochemical, and molecular analyses.[12,13,277] Other monogenic defects reportedly associated with a type 2 clinical picture include mutation in GLUT2 and the glycogen synthase genes.[278,279]

Other Forms of Monogenic Diabetes

Mitochondrial Diabetes

Mitochondrial genetic defects that cause diabetes are commonly but not invariably associated with neuromuscular disorders, including deafness, migraine, seizures, and mental retardation. For example, the MELAS (mitochondrial encephalopathy, lactic acidosis, and strokelike episodes) syndrome may initially present in childhood with short stature, go on to deafness in teen years, and develop diabetes and encephalopathy in midlife. Diabetes mellitus may be the only manifestation of a mitochondrial disorder encoded by a gene defect within the mitochondria

TABLE 19-13 **Protein/Gene Mutations Causing Maturity-Onset Diabetes of the Young**

MODY Type	Protein Mutated	Gene/Gene Location	Gene Function with Respect to the Beta Cell
MODY 1	Hepatocyte nuclear factor-4α	HNF4α; 20q12-q13.1	Binds to HNF1α and IPF1 promoter; regulates HNF1α and IPF1 gene transcription
MODY 2	Glucokinase	GCK; 7p15-p13	Catalyzes conversion of glucose to glucose 6-phosphate
MODY 3	Hepatocyte nuclear factor-1α	HNF1α; 12q24.2	Binds to A3/A4 box of insulin gene promoter; regulates insulin gene transcription
MODY 4	Insulin promoter factor-1	IPF1; 13q12.1	Binds to A5, A3/A4, A2, and A1 boxes of insulin gene promoter; regulates insulin gene transcription
MODY 5	Hepatocyte nuclear factor-1β	HNF1β, TCF2; 17cen-q21.3	Regulates HNF4α gene transcription
MODY 6	Neuro-D1/beta-2	Neuro-D1; 2q32; beta-2	Transcription factor for normal insulin secretion and normal development of pancreatic islets

TCF2, transcription factor-2, hepatic; also known as LF-B3, variant hepatic nuclear factor.

TABLE 19-14 **Comparison of the Common Forms of Youth-Onset Diabetes**

Characteristic	Type 1 Diabetes	Type 2 Diabetes	Classic MODY	Atypical Diabetes Mellitus
Age at onset	Peaks at 5 and 15 years of age	Teenage years, young adults	< 25 years of age	> 40 years of age
Predominant ethnic groups affected	White	Hispanic, African American, Native American	White	African American
Male-to-female ratio	1.1:1	1:1.5	1:1	1:3
Severity at onset	Acute, severe, insulin required	Subtle, insulin not required	Subtle, insulin not required	Acute, severe, insulin required
Islet autoimmunity	Present	Absent	Absent	Absent
HLA-DR3, -DR4	Very common	No increased frequency	No increased frequency	No increased frequency
Ketosis, DKA	Common	Uncommon	Rare	Common at onset
Long-term course	Insulin-dependent	Non-insulin-dependent	Non-insulin-dependent	Non-insulin-dependent
Prevalence of obesity	Uncommon	≥ 90%	Uncommon	40%
Proportion of cases of 100% youth-onset diabetes	Most common form of youth-onset diabetes	Rising in frequency; ± as common as type 1 diabetes in specific populations	≤ 5% of youth-onset diabetes in whites	≤ 10% of cases of youth-onset diabetes in African Americans
Percentage of probands with an affected first-degree relative	≤ 15%	Variable but common	100%	> 75%
Mode of inheritance	Nonmendelian, generally sporadic	Nonmendelian but strongly familial	Autosomal dominant	Autosomal dominant
Number of genes controlling inheritance	Polygenic	Polygenic	Monogenic	Monogenic
Pathogenesis	Autoimmune beta cell destruction: insulinopenia	Insulin resistance plus relative insulinopenia	Insulinopenia	Insulinopenia

DKA, diabetic ketoacidosis; MODY, maturity-onset diabetes of the young.

(all of which are maternally inherited) or a nuclear DNA-encoded gene necessary to the oxidative phosphorylation sequence within mitochondria.

This defective energy pathway leads to progressive impairment of insulin secretion, and thus an initially mild hyperglycemia may progressively worsen. This is the case with the most common form of diabetes caused by a mitochondrial gene mutation at nucleotide pair (np) 3243 of the mitochondrial genome, often associated with deafness. Remarkably, this same genetic defect may be associated with the MELAS syndrome. Initially, patients with np 3243 mutations can be controlled by diet alone but later may require insulin. Diabetes mellitus presenting in infancy and severe from the outset and requiring insulin may be associated with mitochondrial DNA deletions, as seen in the Kearns-Sayre syndrome and Pearson syndrome.[280,281] Figure 19-7 identifies the critical role of energy production by the mitochondrial oxidative phosphorylation pathway for normal insulin secretion.

Defects in this pathway may be responsible for transient or permanent neonatal diabetes mellitus, especially those that involve activating mutations in the KATP channel subunits Kir 6.2(KCNJ11) and its regulatory subunit sulfonylurea receptor SUR1 (ABCC8). Inactivating mutations in the KATP subunits cause neonatal hyperinsulinemic hypoglycemia of variable severity, as described in detail in Chapter 6. Diabetes in the mitochondrial syndromes is generally well controlled by exogenous insulin. [281]

Wolfram Syndrome

Wolfram syndrome is characterized by diabetes insipidus, diabetes mellitus, optic atrophy, and deafness (DIDMOAD).[282,283] There is a selective loss of beta cells, which is responsible for the diabetes mellitus. Genetic linkage studies in consanguineous families with autosomal-recessive inheritance led to the positional cloning of a gene on the short arm of chromosome 4 (termed *WFS1*, and now identified as Wolframin).

Although the function of this gene is not entirely understood, it is expressed in many tissues (most abundantly in beta cells, compared with the exocrine pancreas). Mutations in Wolframin have been identified in many families with Wolfram syndrome. Affected individuals are usually compound heterozygotes. The Wolframin gene may have a role in beta cell and neural tissue survival, and there does not appear to be a correlation between the observed mutation and severity of disease. Defects in Wolframin have been implicated in the idiopathic common nonimmune form of type 1 diabetes mellitus.[282] A second locus of Wolfram syndrome has been mapped

to the long arm of chromosome 4 in several consanguineous Jordanian families.[282] In these patients, diabetes insipidus was not a feature—but upper gastrointestinal bleeding and ulceration were prominent.

Although a mitochondrial form of Wolfram syndrome has been proposed, a defect in mitochondrial DNA could not be confirmed in one large cohort.[283] It has been suggested that diabetes mellitus (before age 15) and progressive optic atrophy are highly predictive of Wolfram syndrome. The sequence of appearance of the stigmata is non-autoimmune type 1 diabetes in the first decade of life, central diabetes insipidus and sensorineural deafness in two thirds to three fourths of the patients in the second decade, renal tract anomalies in approximately half in the third decade, and neurologic complications such as cerebellar ataxia and myoclonus in half to two-thirds in the fourth decade. Other features include primary gonadal atrophy in the majority of males and a progressive neurodegenerative course with neurorespiratory death at a median age of 30 years. Depression has been reported as a frequent feature of relatives of patients with Wolfram syndrome. [282]

Thiamine-Responsive Diabetes Mellitus (Roger Syndrome)

This syndrome is characterized by megaloblastic anemia, diabetes mellitus, and sensorineural deafness—all of which may respond to vitamin B_1 (thiamine). Diabetes mellitus is mild to moderate, insulin secretion may improve with thiamine therapy, and there are no associated autoimmune markers. It may be caused by a defect in the thiamine transporter,[284,285] which has now been identified as being caused by mutations in the SLC19A gene. This gene encodes the membrane-bound thiamine transporter THTR-1.

Uptake of thiamine by the combined pathways of an active high-affinity carrier and a passive low-affinity carrier leads to accumulation of intracellular thiamine, which is then converted to its active form, thiamine pyrophosphate. This cofactor enables proper function of transketolase, which is important in the pentose phosphate shunt, the key to ribose synthesis and hence nucleic acid production and of pyruvate dehydrogenase, α ketoglutarate dehydrogenase, and branched chain acid dehydrogenase—all of which are key to oxidative decarboxylation. Mutations in the high-affinity transporter THTR-1 lead to cell death in those cells that have a high rate of nucleic acid turnover (such as bone marrow cells) and activity (such as pancreatic beta cells), thereby explaining the association of thiamine-responsive anemia with diabetes in those affected by this mutation.

Drug or Chemical Induced

A number of drugs and chemical agents may be toxic to the beta cell. Best known for the diabetogenic effects are the immunosuppressive drugs cyclosporine, sirolimus, and tacrolimus, which are toxic to beta cells—causing insulin-dependent diabetes in a significant proportion of patients treated with these agents for organ transplantation. Their toxicity to pancreatic beta cells is compounded by the use of immunosuppressive glucocorticoids, which antagonize insulin action to unmask diabetes.

Streptozotocin and the rodenticide Vacor are also beta cell toxic, causing diabetes. Box 19-1 lists other agents that may induce diabetes. Among these, L-asparaginase (used in chemotherapy for leukemia) and diazoxide (used to treat persistent hyperinsulinemic hypoglycemia in infancy) may cause diabetes. All of these agents, especially glucocorticoids, may combine to unmask clinical diabetes mellitus.[286-288]

Diseases of the Exocrine Pancreas

Cystic fibrosis (CF) is one of the most common inborn errors of metabolism, involving the chloride channel encoded on chromosome 7 and affecting approximately 1 in 2500 live-born white infants. The increasing survival of patients with CF and the increased use of glucocorticoids to suppress bronchopulmonary inflammation have brought to the fore an entity termed *cystic fibrosis–related diabetes* (CFRD), characterized by variable impairment of carbohydrate intolerance.

Some have mild diabetes mellitus clinically apparent only while receiving steroids, whereas others require insulin for a nonimmune form of insulinopenic diabetes mellitus. Up to 75% of adults with CF have CFRD. Islet amyloid is prominent, both insulin secretion and insulin sensitivity may be impaired, and diabetic ketoacidosis may occur—as may microvascular complications. When fasting hyperglycemia (7 mM = 126 mg/dL or higher) is documented, therapy with insulin is indicated. Insulin also facilitates optimal nutrition and growth and hence promotes a sense of well-being. The diagnostic and management criteria for CFRD have been extensively reviewed.[15,289]

Ionizing Radiation to the Abdomen

Ionizing radiation to the abdomen during childhood for a condition such as nephroblastoma has been associated with the development of diabetes mellitus some 20 years later in 5% to 10% of children so treated. [290]

Pancreatectomy

Extensive pancreatectomy performed for the management of severe hyperinsulinemic hypoglycemia of infancy is associated with diabetes in approximately 50% or more of long-term survivors.[21]

Virus Infections

Several viruses have been implicated in the cause of type 1 diabetes mellitus in children. Coxsackievirus B_4 has been shown in one case report as likely fulfilling Koch's postulates for a direct beta cell toxic effect in causing acute fulminant diabetes mellitus. In other cases of coxsackievirus infections (as well as with the established association among rubella, cytomegaloviruses, and enteroviruses), molecular mimicry between antigenic determinants in the virus and certain islet cell antigens has been implicated as the mechanism leading to an

autoimmune form of type 1 diabetes mellitus. Finally, a superantigen-triggered immune response has been suggested for some viral infections and may be the mechanism related to the acute onset of diabetes mellitus with the hemolytic-uremic syndrome.[20,57,291,292]

GENETIC DEFECTS IN INSULIN ACTION

Type A Insulin Resistance with Acanthosis Nigricans

This syndrome is characterized by severe insulin resistance, acanthosis nigricans in the absence of obesity, or lipoatrophy. Affected females also have hyperandrogenism, possibly as a secondary manifestation of the hyperinsulinemia with stimulation of androgen synthesis by ovarian theca cells. Glucose intolerance is variable and includes symptomatic diabetes. The hyperandrogenism presents as clinical and biochemical findings suggestive of polycystic ovary syndrome.

Some patients (predominantly black females with obesity, acanthosis nigricans, and accelerated growth suggestive of gigantism) may represent insulin resistance owing to obesity, with down-regulation of the insulin receptor. The gigantism may represent a "spillover" effect of insulin acting through the insulin-like growth factor-1 receptor rather than the insulin receptor.[293,294]

Type B Insulin Resistance

Type B insulin resistance is a rare syndrome associated with evidence of immune dysfunction (such as the defined autoimmune disease rheumatoid arthritis) or of nonspecific features of autoimmunity (such as elevated sedimentation rate or high levels of antinuclear antibodies). As with other autoimmune disorders, females are predominantly affected. An insulin-resistant diabetes develops together with acanthosis nigricans and features of PCOS (such as hirsutism).

The syndrome is due to serum autoantibodies against the insulin receptor whose function becomes impaired. However, the receptor may be activated by the presumed conformational changes induced by the antibody and cause severe hypoglycemia rather than diabetes. Treatment may require high doses of insulin to try to control the hyperglycemia, along with immunosuppressive drugs to suppress antibody production.

Leprechaunism (Donohue Syndrome)

Leprechaunism is a syndrome characterized by intrauterine growth retardation, fasting hypoglycemia, and postprandial hyperglycemia in association with profound resistance to insulin in a patient whose serum concentrations of insulin may be 100-fold that of comparable age-matched infants during an oral glucose tolerance test. Various defects of the insulin receptor have been described, thereby attesting to the important role of insulin and its receptor in fetal growth and possibly in morphogenesis. Even a probable complete absence of functional insulin receptors caused by homozygous inheritance of missense mutation in the insulin receptor, however, resulted in normal organogenesis and a live-born infant who had a severe form of leprechaunism. Most of these patients die during the first year of life. [295]

Rabson-Mendenhall Syndrome

The Rabson-Mendenhall syndrome is defined by clinical features that appear to be intermediate between those of acanthosis nigricans with insulin resistance type A and leprechaunism. Features include extreme insulin resistance, acanthosis nigricans, abnormalities of the teeth and nails, and pineal hyperplasia. It is not clear whether this syndrome is entirely distinct from leprechaunism. However, patients with Rabson-Mendenhall syndrome tend to live beyond the first year of life. Defects in the insulin receptor gene have been described in this syndrome.[296]

Lipoatrophic Diabetes

Lipoatrophic diabetes presents an interesting paradox. Whereas classic type 2 diabetes mellitus is generally associated with an excess of fat and its metabolic consequences (as described previously), a paucity of fat also causes severe insulin resistance and marked metabolic disturbances. Table 19-15 lists the genetic syndromes associated with lipoatrophic diabetes. A primary cause has been identified in the form called familial partial lipoatrophy (also known as Dunnigan syndrome). This is a gene defect localized to chromosome 1q21-22 and its product lamin A/C.

This autosomal disease usually manifests peripubertally as subcutaneous fat in the extremities and trunk but with progressively more fat in the face and neck as puberty progresses. Visceral and interfascicular fat also increases. Females seem to develop diabetes mellitus and dyslipidemia earlier and more severely than males. It is unclear why and how the lamin A/C mutations cause this lipoatrophy syndrome, especially as mutations in this gene also are associated with a progressive form of muscular dystrophy (Emery-Dreifuss syndrome), cardiomyopathy, and cardiac conduction defects.[297,298] The gene altered in Berardinelli-Seip congenital lipodystrophy has been localized to chromosome 11q13.274.[298] In addition, defects in genes encoding the enzyme AGPAT2, the endoprotease ZMPSTE24, the kinase AKT2, the nuclear receptor PPARγ, and the protein BSCL 2 have been found in patients with lipodystrophies. [297,298]

ACQUIRED DEFECTS IN INSULIN ACTION

These defects range from hormonal disorders such as pheochromocytoma and Cushing syndrome that antagonize insulin action to disease to drug-acquired forms of lipodystrophy. Anti-insulin receptor antibodies may be found in some collagen vascular disorders and can cause a type 2 diabetes mellitus syndrome characterized by acanthosis nigricans and severe insulin resistance. This is generally referred to as acanthosis nigricans with insulin resistance type B. The type A syndrome consists of a variety of insulin receptor mutations, some of which were

TABLE 19-15 **Genetic Syndromes of Lipoatrophy**

Syndrome	Lipoatrophy	Gene/Locus	Inheritance	OMIM
Primary Lipoatrophy Syndromes				
Congenital generalized lipoatrophy (Seip-Berardinelli)	Generalized See text for details.	9q34 Gmg3lg; 11q13p	AR	269700
Dunnigan syndrome	Familial partial See text for details.	1q21-22 Lamin A/C	AD	151660

described earlier. The type B syndrome is rarely described in childhood.[299]

GENETIC SYNDROMES WITH DIABETES AND INSULIN RESISTANCE OR INSULIN DEFICIENCY

A number of genetic syndromes are associated with diabetes mellitus. In children, four relatively common genetic syndromes may be associated with diabetes. In trisomy 21 (Down syndrome) and Turner syndrome (a single normal X chromosome) there is an increased incidence of autoimmune disorders, especially of the thyroid. Type 1 diabetes mellitus also has a higher prevalence in patients with Down syndrome than in the general population.

In Turner syndrome, insulin secretory reserve may be limited such that treatment with growth hormone (now common) can result in impaired glucose tolerance or type 2 diabetes. In Klinefelter syndrome (XXY), insulin resistance is a major feature—but autoimmune associations have been described. In Prader-Willi syndrome, the reported high frequency of diabetes mellitus may not be caused simply by the insulin resistance as part of the obesity of this syndrome but possibly by a primary defect in insulin secretion.[300-303]

Alström syndrome consists of retinal dystrophy, sensorineural deafness, obesity and associated diabetes, cardiomyopathy, hypertriglyceridemia, liver disease, and urologic abnormalities. Severe insulin resistance may lead to acanthosis and diabetes. Mutations in the gene ALMS1 have been identified in these patients.[304] Bardet-Biedl syndrome also has atypical retinitis pigmentosa as a key feature, along with central obesity, polydactyly, mental retardation, hypogonadism, and renal dysfunction. Eleven loci have been linked to this syndrome, with abnormalities in cilia-like structures a central theme.[305] The association of these and other syndromes with diabetes (listed in Box 19-1) can be ascertained by searching the Online Mendelian Inheritance in Man database (OMIM, available at www.ncbi.nlm.nih.gov/omim).

Gestational Diabetes

Gestational diabetes is a disease of the second and third trimesters of pregnancy that is due to congenital or acquired defects in insulin secretion that result in the inability to compensate for the increased demands of insulin as a result of the counter-insulin effects of placental growth hormones.[306]

Neonatal Diabetes

Discoveries in the molecular basis for pancreas formation and regulation of insulin secretion have propelled the syndromes of neonatal diabetes from the backwater of rarity to the forefront of research. These syndromes probably occur more frequently than previously considered, and they may have an overall incidence of about

1:100,000 births.[307-323] Moreover, some of those with activating mutations in KATP channel subunits Kir 6.2 or SUR1 lend themselves to treatment with oral sulfonylurea hypoglycemic drugs such as glibenclamide—which results in endogenous insulin secretion with near-normal glycemic control and at least partial reversal of neuromuscular manifestations.[12,307-323] These entities are described in detail in Chapter 9.

Impaired Glucose Tolerance

The term *impaired glucose tolerance* is used to characterize individuals who have a plasma glucose concentration in excess of 140 mg/dL but less than 200 mg/dL at 2 hours after initiation of the standard oral glucose tolerance test but do not have symptoms of diabetes or fasting hyperglycemia. Such a constellation may represent the earliest phase of a gene defect in insulin secretion or action or be a step in evolving diabetes mellitus type 1. The hyperglycemia may be a chance discovery during an intercurrent illness, during therapy with corticosteroids, or as part of a screening of close relatives of patients with defined genetic syndromes.

In those who have impaired glucose tolerance but do not have fasting hyperglycemia, repeated oral glucose tolerance tests are not recommended. Investigations in such children indicate that the degree of impaired glucose tolerance tends to remain stable except in those who have markedly subnormal insulin response.[324] The arbitrarily designated response that identifies impaired glucose tolerance is defined as a fasting plasma glucose value of less than 110 mg/dL and a value at 2 hours of more than 140 mg/dL. The determination of serum insulin responses during the glucose tolerance test is not a prerequisite for reaching a diagnosis. Because the magnitude of the insulin response may have prognostic value, however, some investigators perform insulin determination tests.[237]

Pancreas and Islet Transplantation

In an attempt to cure insulin-dependent diabetes, transplantation of a segment of the pancreas or of isolated islets has been increasingly performed in humans.[325,326] These procedures are technically demanding and associated with the risks and complications of rejection and its treatment by immunosuppression. Therefore, segmental pancreas transplantation is generally performed in association with transplantation of a kidney for a patient with end-stage renal disease owing to diabetic nephropathy in whom the immunosuppressive regimen is indicated for the renal transplant.

Several thousand such transplants have been performed worldwide since the late 1980s. With experience and newer immunosuppressive agents, functional survival of the pancreatic graft may be achieved for as long as several years—during which patients may be in metabolic control with no or minimal exogenous insulin and reversal of some of the microvascular complications. Because children and adolescents with diabetes mellitus are not likely to have end-stage renal disease as a result of diabetes, however, pancreas transplantation as a primary treatment cannot be recommended (nor its risks justified) in children.

Attempts to transplant isolated islets have been equally challenging because of techniques to harvest sufficient islets and the issue of rejection.[327] Some of the newer antirejection drugs, notably cyclosporine and tacrolimus, are toxic to the islets of Langerhans—impairing insulin secretion and even causing diabetes.[327] The Edmonton protocol for islet transplantation avoids steroid and uses an anti-IL-2 receptor antibody and tacrolimus instead of other immunosuppressants.[326] Initial success had been promising, but long-term survival of the graft beyond 3 to 5 years is most unusual—and there have been serious side effects of the procedure as well as failure to restore hypoglycemia unawareness.[326] Hence, this islet transplantation protocol cannot be recommended in children.

Research continues to improve techniques for the yield, viability, and loss of immunogenicity of islets of Langerhans for transplantation. Transplantation has been investigated of islets coated or microencapsulated with a film of protective chemicals that permit diffusion of insulin and nutrients but prevent T-cell contact and therefore avoid rejection.[328] These novel approaches have been frustrated in the long term by overgrowth of fibroblasts that progressively impair glucose sensing by the islets and insulin diffusion from them. Should these technical problems be overcome, or methods to avoid rejection become established, transplantation of pancreas or islets as primary treatment for diabetes may be entertained after their risks are carefully compared with and weighed against potential benefits—especially in children. Islet regeneration by modulating the immune response is also under scrutiny.[329,330]

CONCLUDING REMARKS

Progress continues to be spectacular in understanding and treating diabetes mellitus. We have moved from a glimmer of understanding that diabetes is a syndrome of broad categories (insulin dependent and non-insulin dependent) to an understanding of disease susceptibility and disease causality at a molecular level. Type 1 diabetes is acknowledged to be an autoimmune disease with major susceptibility loci in the HLA complex. Positional cloning and genome wide association techniques have identified other gene markers, and we now recognize the importance of mitochondrial gene defects in some types of insulin-dependent diabetes that may not be autoimmune. The predisposition of the beta cell to autoimmune destruction (homicide) versus a predisposition to apoptosis (suicide) is the topic of intensive debate and investigation and raises questions about our accepted paradigms of this disease.[43,44,81] More spectacular has been the unraveling of the molecular basis of neonatal diabetes and its treatment, including the use of sulfonylureas. Not surprisingly, this knowledge is being rapidly applied to predict the likelihood of disease appearance in individuals whose susceptibility can be quantified by the presence of certain antibodies and by limitations in first-phase insulin response. Population surveys in individuals not known to be at risk for diabetes have just begun. We are in the early

stages of attempts to prevent the disease, reminiscent of the early trials examining the relationship between control and microvascular complications.

The monumental DCCT and European studies have irrefutably established the link, requiring new standards of care. Progress and understanding of insulin secretion and insulin action have been equally spectacular for the insights provided in defining non–insulin-dependent forms of diabetes at physiologic, biochemical, and molecular levels. Therapy with human insulin is now standard. Trials with improved insulin-delivery systems, including computerized artificial pancreas as well as pancreas and islet transplantation, are in progress. The FDA in the United States has approved one artificial pancreas system for use, and improvements in these devices are bound to change the course and treatment of T1DM. The beneficiaries of these advances are our patients, whose interests will continue to be best served by bidirectional scientific inquiry from bench to bedside.

QUESTIONS

1. Complications of DKA may include all except which of the following?
   a. Cerebral edema
   b. Mucormycosis infection
   c. Prerenal failure
   d. ARDS
   e. Venous thrombosis

Answer: b

2. A 13-year-old male with a past history of learning disability is admitted in coma. His weight is 86 kg, BP 110/80, pulse 134, capillary refill 4 seconds. Glucose is 936 mg/dL (52 mM); pH 7.24, HCO_3^- 15 mm, serum Na 140 mEq, K 4.5 mEq, BUN 30 mg/dL, and creatinine 1.2 mg/dL. Urine examination reveals glucose > 2% and trace ketones. After initial rehydration with 0.9% saline with two bolus injections of 10 cc/kg over 3 hours, therapy should continue with which of the following?
   a. Normal saline infusion plus insulin 0.1 U/kg/hr
   b. 0.5 N saline plus insulin 0.1 U/kg/hr
   c. Normal saline plus insulin 0.05 U/kg/hr
   d. 0.5 N saline plus 20 mEq/L KCl
   e. 0.5 N saline plus KCl 20 mEq/L plus insulin 0.05 U/kg/hr

Answer: d

3. A 15-year-old girl who has had type 1 diabetes mellitus for 3 years and confirmed Hashimoto thyroiditis for 2 years experiences repeated episodes of hypoglycemia unrelated to exercise. In addition to reducing the insulin dose, which of the following steps is most appropriate?
   a. Check fT_4, TSH, and thyroid antibodies to ensure compliance with thyroid medication.
   b. Check thyroid function, cortisol, and TTG IgA in a fasting morning sample.
   c. Check TSH, adrenocorticotropic hormone (ACTH) and TTG IgA in a late afternoon (4 to 6 p.m.) blood sample.
   d. Check thyroid function, ACTH, and TTG IgA in a fasting morning sample.
   e. Referral to a psychologist to rule out an eating disorder.

Answer: c

4. The genes predisposing to T_{1a}DM include all except which of the following?
   a. HLA DR
   b. PTPN22
   c. AIRE
   d. PTPN11
   e. CTLA4

Answer: d

5. Which of the following genes is implicated in both T1aDM and T2DM?
   a. KCNJ11
   b. ZnT8
   c. TCF7L2
   d. PPARγ
   e. Insulin

Answer: e

6. HbA1c is commonly used as a means to monitor average blood glucose in the preceding 6 to 8 weeks. An inappropriately low HbA1c may be obtained in all except which of the following conditions?
   a. Hemolytic anemia
   b. Thalassemia major
   c. Sickle cell disease
   d. "Slow glycator" syndrome
   e. Renal failure

Answer: b

CHAPTER 20

Autoimmune Polyglandular Syndromes

Michael J. Haller, MD • William E. Winter, MD, FCAP, DABCC, FACB • Desmond A. Schatz, MD

CHAPTER OUTLINE

INTRODUCTION

The autoimmune polyglandular syndromes (APS I and II) are uncommon constellations of organ-specific autoimmune diseases characterized by the occurrence of more than one autoimmune disease in an affected individual (Table 20-1). More commonly, autoimmune disease of endocrine glands occurs in only a single organ, but multiorgan involvement of both endocrine and nonendocrine organs and tissues may be present.

Tolerance is an active state in which the immune system does not mount a reaction against self-antigens.[1-4] If tolerance is not established or is lost, autoimmunity and subsequent disease may result. Although the breakdown in self-tolerance remains mostly unexplained, our improved understanding of the complex interplay between genetics and environment and the resultant aberrant immunologic processes has identified a number of possible mechanisms.[5] To comprehend these mechanisms, a brief overview of how tolerance is maintained is essential.

MECHANISMS UNDERLYING GENERATION OF AUTOIMMUNITY

Introduction

In a normal immune response, the host organism must differentiate self from nonself, initiate an immune response to nonself, and eliminate nonself to protect the host from injury, organ dysfunction, and even death.[1-4] Endogenous antigens represent self, whereas exogenous antigens represent nonself. The adaptive immune system assumes all exogenous antigens are potentially harmful and acts to eliminate nonself. Self-nonself discrimination is carried out by the adaptive (specific) immune system through the use of T- and B-cell surface receptors.[6-8] These receptors recognize distinctive peptides (e.g., the T-cell receptors) or epitopes (e.g., the B-cell antibody receptors) and are the keys to the specificity of the adaptive immune response. Whereas B cells and their receptors recognize soluble antigen or antigens on cell surfaces, T cells and their receptors only perceive short polypeptides presented by specialized cell-surface molecules encoded by the major histocompatibility complex (MHC).[9-11] The human MHC is termed the human leukocyte antigen (HLA) complex. Class I MHC (e.g., HLA-A, HLA-B, and HLA-C molecules) present peptides predominantly derived from the cell cytoplasm to T cells. T cells are classified on the basis of their cluster of differentiation (CD) surface proteins, which bind differentially to antigens presented on class I and class II MHC. For example, CD8 cells, considered "cytotoxic" T cells, typically recognize targets presented on class I MHC. In addition, more "professional" antigen presenting cells known as dendritic cells and defined by a combination of CD markers and the characteristic presence of numerous membrane processes that extend out from the cell body can present peptides of extracellular

TABLE 20-1 **The Autoimmune Polyglandular Syndromes I and II**

	APS I	APS II
Comparative frequency	Less common	More common
Onset	Infancy/early childhood	Late childhood, adulthood
Heredity	Autosomal recessive	Polygenic
Gender	Males = females	Female predominance
Genetics	AIRE gene; no HLA association	HLA associated; DR/DQ
Hypoparathyroidism	77%-89%	None
Mucocutaneous candidiasis	73%-100%	None
Ectodermal dysplasia	77%	None
Addison disease	60%-86%	70%-100%
Type 1 diabetes	4%-18%	41%-52%
Autoimmune thyroid disease	8%-40%	70%
Pernicious anemia	12%-15%	2%-25%
Gonadal failure		
Females	30%-60%	3.5%-10%
Males	7%-17%	5%
Vitiligo	4%-13%	4%-5%
Alopecia	27%	2%
Autoimmune hepatitis	10%-15%	Rare
Malabsorption	10%-18%	Rare

origin via class I MHC molecules. Conversely, CD4 cells typically are activated when peptides derived from the extracellular space are presented via class II MHC (e.g., HLA-DP, HLA-DQ, and HLA-DR molecules).

Regulation of T-cell self-tolerance occurs at two distinct but interdependent levels: centrally and peripherally (described in detail later). Central tolerance occurs in the thymus via positive and negative selection of self-reactive T cells, whereas peripheral tolerance occurs in both lymphoid and nonlymphoid tissues (Figures 20-1 and 20-2). Although many of the mechanisms involved in establishing tolerance remain poorly understood, nearly 15 years of characterizing the autoimmune regulatory gene (AIRE) has improved understanding of positive and negative T-cell selection.[4] The AIRE gene, which codes for a transcription factor found in the medulla of the thymus, plays a critical role in the ectopic expression of tissue-specific antigens, which regulate negative selection of autoreactive T effector cells.[12,13] Deletions in the mouse AIRE homologue result in multiorgan autoimmunity, whereas mutations in the human AIRE gene result in APS I.[14,15]

Tolerance is initially developed in utero. During gestation and early life, tolerance is most easily induced by exposure of the host to a specific antigen. Although the thymus atrophies during puberty, residual thymic tissue provides for T-cell development throughout life. T cells do not require exposure to large doses of antigen to achieve tolerance during their thymic development. However, larger doses of antigen are required to induce B-cell tolerance, and B-cell tolerance is often short lived. B cells and T cells are produced by the bone marrow continuously throughout life. Tolerance is immunologically specific, learned or acquired, most easily induced in immature or developing lymphocytes, and can be induced in mature lymphocytes when costimulatory signals are absent at the time of peptide recognition by the T lymphocyte.

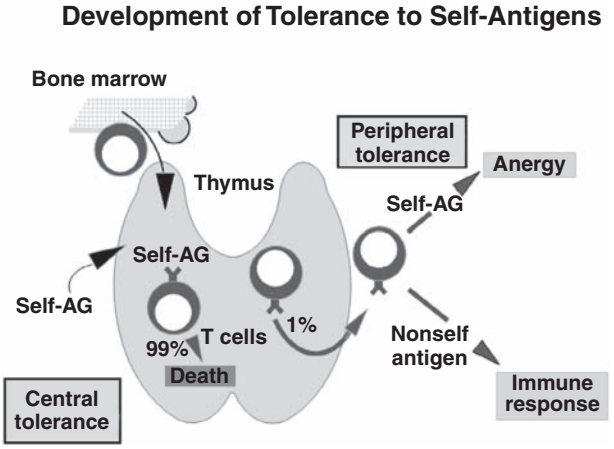

FIGURE 20-1 ■ Normal tolerance pathways. T-cell precursors initially arise in the bone marrow. These progenitors enter the thymus, and developing T cells encounter self-antigens. Strong self-antigen stimulation of developing T cells induces apoptosis, with approximately 99% of all developing T cells dying. This is central immunologic tolerance where strongly antiself reactive T cells are eliminated. Naïve T cells that do leave the thymus can be subsequently tolerized to self-antigens if they encounter self-antigen without the normal costimulatory signals (B7.1/B7.2-CD28, see Figure 20-3). Induction of tolerance outside the thymus is termed *peripheral tolerance* (top right) and is a complementary mechanism to central tolerance. Peripheral tolerance is functionally expressed as anergy: autoreactive cells are present but are inactive (top right). If nonself-antigen is encountered, a normal immune response ensues (bottom right).

Central T-Cell Tolerance

T cells are primarily educated to distinguish self and nonself in the thymus.[16-19] Central T-cell tolerance is the process by which antiself T cells are eliminated in the thymus. As many as 99% of developing thymocytes die in the thymus and never reach the periphery.

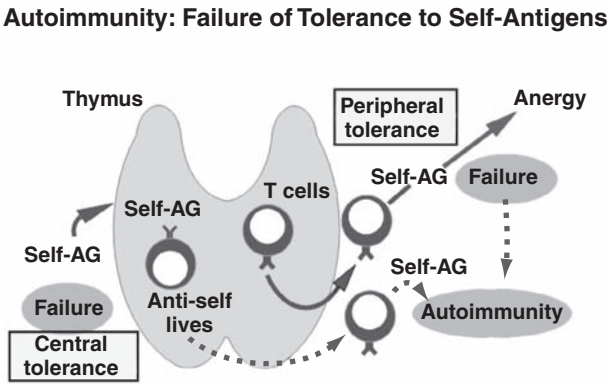

FIGURE 20-2 ■ Autoimmunity: failure of tolerance to self-antigens. With a failure of central tolerance (bottom left), antiself T cells survive that should not normally survive. When these antiself T cells leave the thymus, they are able to produce autoimmunity (dotted arrows). Alternatively, with a failure of peripheral tolerance (top right), if anergy does not occur after contact with self-antigen, an autoimmune response can occur.

T-cell tolerance is a function of the selection of the T-cell receptor (TCR) repertoire that exits the thymus. In the thymic cortex CD4+, CD8+ (double positive) T cells bearing alpha/beta TCRs that bind to self-MHC initially survive (positive selection). In this way the thymus initially chooses for survival T cells that bind to self-MHC as opposed to TCRs that might bind to other self molecules leading to noneffective communication. This positive selection resulting from self peptide-MHC presentation is carried out by thymic nurse epithelial cells in the cortex. At the corticomedullary junction of the thymus, if such saved TCRs bind to self-MHC too tightly, autoreactivity is possible and these T cells then undergo negative selection and suffer apoptotic death. The cells inducing negative selection are macrophages and dendritic cells. This process of positive selection for MHC binding in the thymic cortex and negative selection (at the thymic corticomedullary border) against tight binding to self-peptides accounts for central (thymic) immunologic tolerance.[3,5,13,20]

Peripheral T-Cell Tolerance

Once in the circulation and secondary lymphoid organs (e.g., lymph nodes and spleen), naïve T cells still require multiple signals to become activated.[7] The initial signal is the presentation of antigen-specific peptides to T-cell receptors by MHC molecules. CD4 and CD8 molecules on these T-cell subsets serve as antigen-nonspecific coreceptors binding to nonpolymorphic portions of the class II MHC molecules and class I MHC molecules, respectively. The second signal is antigen nonspecific and is provided by the B7.1 (CD80) and B7.2 (CD86) molecules of the antigen-presenting cell interacting with the CD28 molecule on the T-cell surface.

When the T cell perceives both signals, a cascade of intracellular signaling events occur, leading to T-cell activation. Activated CD4 T cells express numerous cytokines, cytokine receptors, and CTLA-4. Activated CD4 T cells then down-regulate T-cell receptor expression and acquire class II MHC expression. It is unknown why activated human T cells express class II MHC (activated T cells in mice do not express class II MHC). CTLA-4 expression by the activated T cell and its interaction with B7.1/B7.2 provides an immunosuppressive signal to the T cell, thereby down-regulating the T-cell immune responses. Thus, CTLA-4 and CD28 act antithetically: B7.1/B7.2-CD28 turns on T cells, whereas B7.1/B7.2-CTLA-4 down-regulates the T cell (Figure 20-3).

Helper CD4 T cells have classically been subdivided into two distinct lineages: (1) Th1 cells, which activate cell-mediated and some antibody responses, and (2) Th2 cells, which predominantly activate antibody-mediated responses.[21] However, additional T-cell lineages exist (i.e., Th17 cells, T-follicular helper cells, and regulatory T cells) and data have described remarkable plasticity in their cytokine expression, suggesting shifting T-cell functionalities depending on environmental cues.[22] Although overly simplistic, Th1 subsets can be thought of as cells that activate macrophages, natural killer cells, and B cells and secrete predominantly IL-2, interferon gamma (IFN-γ), tumor necrosis factor–beta (TNF-β), and IL-12. Th2 cells elaborate IL-4, IL-5, IL-6, IL-10, and IL-13. Crosstalk between Th1 and Th2 cells occurs; for example, IFN-γ from Th1 cells suppresses Th2 cells and IL-10 from Th2 cells inhibits Th1 cells. Another subset of CD4 T cells has been described as regulatory T cells that secrete the immunomodulatory cytokines IL-10 or transforming growth factor–beta (TGF-β). Regulatory T cells include $CD4^+CD25^+FoxP3^+$ T cells, Tr1, and Th3 cells. Tr1 and Th3 cells express CD4 but do not express CD25 (the IL-2 receptor alpha chain). Tr1 cells secrete IL-10 and TGF-β, whereas Th3 cells secrete IL-4, IL-10, and TGF-β. Although $CD4^+CD25^+FoxP3^+$ T cells can secrete both IL-10 and TGF-β, their regulatory action on autoreactive T cells appears to occur through cell-to-cell contact. Upon activation, CD8 T cells, often with the help of Th1 cells

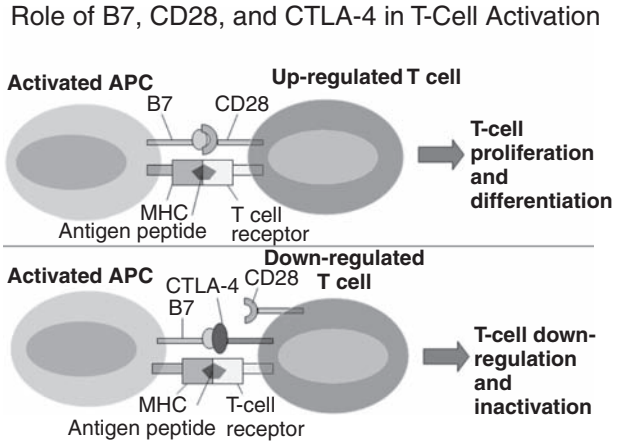

FIGURE 20-3 ■ Role of B7, CD28, and CTLA-4 in T-cell activation. Activated antigen presenting cells (APC) present antigen peptides on the major histocompatibility complex (MHC) molecules and express B7, including B7.1 (CD80) and B7.2 (CD86), costimulators. When B7.1 or B7.2 is bound by CD28 and MHC plus peptide is bound by a T-cell receptor, T-cell proliferation and differentiation of naïve T cells ensues. Conversely, activated T cells express CTLA-4 and bind to B7 (either B7.1 or B7.2] inducing down-regulation and inactivation of T cells.

supplying IFN-γ to up-regulate B7 expression on antigen presenting cells, become functional cytotoxic T killer cells.

The requirement for two signals to activate naïve T cells accounts for peripheral T-cell tolerance. When the naïve T cell perceives antigen peptide presented by MHC molecules without the necessary costimulatory signal (e.g., B7.1/B7.2-CD28), the T cell becomes unresponsive. This state of unresponsiveness is termed anergy. The T cell may also undergo apoptosis (programmed cell death) to be completely removed from the T-cell repertoire. Anergic T cells can generally not be restimulated with antigen peptide displayed by the antigen-presenting cell. Tolerance may also exist because the T-cell receptor does not come into contact with the relevant peptide. This has been termed "T-cell ignorance."

Ongoing characterization of regulatory T cells has improved our understanding of peripheral tolerance. Regulatory T cells play a critical role in suppressing the activity of effector T cells that escape negative selection to self-antigen in the thymus.[23] Functional regulatory T cells are able to anergize previously self-reactive T effector cells, resulting in improved tolerance to self. The expression of the forkhead transcription factor, FoxP3, is specific for identification of the $CD4^+CD25^+$ cell (T_{reg}) population. First identified in the *Scurfy* mouse, a mouse model of immune dysfunction and polyendocrinopathy, abnormal FoxP3 expression is now known to be responsible for the failure in tolerance in humans affected with a similar polyendocrinopathy discussed later.[24-26] The absence of normal FoxP3 expression in humans leads to an extremely rare, X-linked, recessively inherited, and typically fatal autoimmune lymphoproliferative disease known as immune dysregulation, polyendocrinopathy, enteropathy, and X-linked inheritance (IPEX).[27,28] Defects in the forkhead transcription factor FoxP3 that are responsible for IPEX map to Xp11.23-Xq13.3.

B-Cell Tolerance

B cells are partially educated in the bone marrow to be anergized or undergo apoptosis in response to self-antigen when they are at the stage of development of the naïve immature B cell (central B-cell tolerance). In the bone marrow, naïve immature B cells that see multivalent antigens become anergized (unresponsiveness to subsequent stimulation), whereas exposure to highly polyvalent antigens can induce apoptosis.[29]

Naïve immature B cells express IgM on their surface and are not yet IgM and IgD positive as observed in naïve mature B cells. Anergized B cells do not instantly die but will live no longer than unstimulated naïve immature B cells. Naïve mature B cells expressing IgM and IgD on their surface require T-cell help to realize their full potential through affinity maturation and class switching. The absence of T-cell help leads to B-cell tolerance.

Autoimmune Diseases

The organ-specific nature of many autoimmune diseases results from abnormal immune system recognition of tissue-specific self-antigens. In many autoimmune endocrinopathies, the target molecule is either a tissue-specific or tissue-limited (i.e., the protein is not unique to one tissue but is clearly restricted in its distribution) enzyme or cell-surface receptor[30,31] (Table 20-2).

The criteria for classification of a disease as autoimmune are not universally agreed upon.[32] However, major criteria that are generally accepted as strong evidence that the disease is autoimmune include (1) detection of autoantibodies or autoreactive T cells including lymphocytic infiltration of the targeted tissue or organ, (2) disease transfer with antibodies or lymphocytes, (3) disease recurrence in transplanted tissue, and (4) ability to abrogate the disease process with immunosuppression or immunomodulation. Few, if any, human autoimmune diseases meet all four of these criteria. Further information that is supportive of, but not diagnostic for, an autoimmune disease includes (1) increased disease frequency in women compared to men, (2) the presence of other organ-specific autoimmune diseases in affected individuals, and (3) increased frequencies of particular HLA alleles in affected individuals.

Defects in Tolerance that Cause Autoimmune Diseases

Several hypotheses explaining defects in tolerance have been proposed.[33] Theoretically autoimmunity may develop because (1) tolerance never developed to specific self-antigens or (2) established tolerance was lost. If self-antigen is not efficiently presented in the thymus, tolerance may not be established during T-cell education within the thymic cortex.[34] For example, variations in the insulin gene VNTR (variable number of tandem repeats), ~500 base pairs upstream of the insulin gene promoter, influence the extent of insulin gene expression in the thymic cortex. The risk of developing type 1 diabetes is enhanced when certain VNTR alleles are present, which leads to lower mRNA expression of insulin in the thymus. Specifically, certain protective class III alleles are associated with increased thymic expression of insulin and a decreased risk of developing type 1 diabetes, whereas class I alleles are associated with decreased thymic expression of insulin and an increased risk of developing diabetes.[35] Failure to delete specific autoreactive T cells clones predisposes patients to autoimmunity. If autoimmunity does result from defects in thymic tolerance, the defects must be antigen specific because organ-specific autoimmune diseases are usually extremely selective. For example, in type 1 diabetes, whereas the beta cells are attacked and ultimately destroyed by a cell-mediated autoimmune process, the remaining islet cells including alpha cells, delta cells, and pancreatic polypeptide-producing cells are unscathed.

Defects in peripheral tolerance could result from concurrent T-cell stimulation by self-antigen/MHC plus T-cell costimulation (e.g., B7.1/B7.2-CD28) leading to aberrant T-cell activation and an autoimmune response. If tolerance has not been developed because an antigen is sequestered intracellularly or is not expressed in the thymus during T-cell ontogeny, T-cell reactivity in the periphery would not be abrogated. However, several

TABLE 20-2 **Autoantigens in Autoimmune Endocrine and Associated Diseases**

Disease	Autoantigens	Putative Autoantigens
Mucocutaneous candidiasis		IL-17A IL-17F IL-22
Hypoparathyroidism		NALP5 (specific for APS) CaSR
Addison disease	P450c21	P450c17 P450scc
Hashimoto thyroiditis	Thyroperoxidase Thyroglobulin	
Graves disease	Thyrotropin receptor	
Diabetes	Insulin Glutamic acid decarboxylase$_{65}$ IA-2 (ICA 512) IA-2β ZnT8	Proinsulin Carboxypeptidase H ICA69 Glima 38
Premature gonadal failure	P450scc	P450c17 3β hydroxysteroid dehydrogenase
Pernicious anemia	H^+/K^+ ATPase pump Intrinsic factor	
Myasthenia gravis	Acetylcholine receptor α chain	
Vitiligo		Tyrosinase Tyrosinase related protein-2 L-amino acid decarboxylase
Celiac disease	Endomysium transglutaminase	Reticulin Deamidate gliadin
Autoimmune hepatitis	Liver kidney microsome 1	L-amino acid decarboxylase Tryptophan hydroxylase

IL, interleukin; NALP5, NLR family, pyrin domain containing 5; NLR, NACHT, leucine rich; NACHT, nucleotide oligomerization domain-like receptors; CaSR, calcium sensing receptor; IA-2, protein tyrosine phosphatase-like protein; ZnT8, zinc transporter 8; ICA, islet cell autoantigen.

antigens initially thought to be sequestered intracellularly have now been shown to circulate in low concentrations in normal individuals. Thyroglobulin is such a self-antigen in autoimmune thyroid disease. The development of thyroglobulin autoantibodies was believed to follow the release of thyroglobulin from the thyroid gland following viral infection or trauma. "Immunization" with thyroglobulin would hypothetically lead to an antithyroglobulin humoral response and autoimmune thyroid disease would follow. However, we now know that thyroglobulin does circulate in low but appreciable quantities in normal individuals who show no serologic evidence of thyroid autoimmunity. Furthermore, thyroid follicular cell destruction in Hashimoto thyroiditis is cell mediated and not humorally mediated.

If sequestered antigens do play a role in autoimmune disease, viral infections, trauma, ischemia, or irradiation are all mechanisms that could disturb cellular integrity and lead to the release of intracellular antigens.[36] Some self-antigens may never normally come into contact with the immune system unless there is a breakdown of anatomic barriers within the body. An example is the occurrence of autoimmunity to the eye following orbital trauma. Although a rare consequence of orbital damage, initiation of an autoimmune response to eye proteins in adjacent lymph nodes can generate autoreactive T cells that can invade and damage the contralateral eye ("sympathetic ophthalmia").[37,38] Removal of the inciting damaged tissues and immunosuppression may be required to sustain vision in the undamaged eye. Similarly, transient autoantibody reactivity to cardiac myosin following myocardial infarction has also been described.[39]

Tolerance may not develop, hypothetically, if self-antigen expression is delayed during negative selection. When the self-antigen is ultimately expressed, if tolerance has not previously been established, the autoantigen is perceived as foreign and autoreactivity develops. No spontaneous examples of this process have been described. However, in experimental systems where transgenes are placed under control of promoters that can be turned on by exogenous agents such as metals, autoreactivity can be elicited when gene expression is stimulated after the neonatal period.

Alteration of self-antigens as a result of infection or neoplasia is believed to be a plausible theory explaining some types of autoimmunity. As environmental triggers,

viral infections could lead to modification of self-proteins and neoantigen expression (e.g., a new antigen is present on self-cells). Alternatively, a self-antigen may be partially degraded leading to a "new" antigenic target for the adaptive immune system. This new antigen is recognized as foreign by the immune system and the immune response to these new antigens results in autoimmunity.

Some self-cells/tissues may suffer unintended autoimmune damage when substances bind to the cells and elicit an initial immune response. For example, certain drugs bind to red blood cells and result in an immune hemolytic anemia. If an antibody response to the red-cell-bound drug is elicited, the antigen-antibody complex present on the red blood cell can lead to red blood cell destruction. This can occur either through red blood cell phagocytosis by the monocyte-macrophage system or via complement-mediated lysis of the red blood cell. Thus, the red blood cell is an innocent bystander to the antidrug humoral immune response. Theoretically this could also occur with viruses that serendipitously attach to tissues.

Molecular mimicry is one of the most popular explanations for autoimmunity.[36,40] Due to exposure to a dietary, viral, or bacterial antigen (e.g., infection) and molecular mimicry (similarity) between the self-antigen and the foreign antigen, the immune response to the foreign antigen leads to cross reactivity with self-antigen, autoimmunity, and disease.[40-43] For this theory to work, tolerance must not previously exist to the self-antigen. This might be true if the self-antigen is truly sequestered and the immune system has never developed tolerance to the self-antigen. Alternatively, the self-antigen peptides may be present in too low a concentration to elicit an immune response and initial immune system tolerization has not occurred. Only with infection or novel dietary exposure would there be a sufficient degree of self-immunization to develop immune autoreactivity. With immune autoreactivity, self is now recognized as foreign during the response to the cross-reactive pathogen. If the self-antigen is a cell surface antigen, the "pathogen-induced" autoantibodies could fix to self and produce disease via complement fixation, or the antibodies could act as opsonins for fixed or circulating phagocytes (antibody-dependent-cell cytotoxicity). In rheumatic fever, cross-reactivity between Streptococcus M protein and cardiac myosin have been described. In ankylosing spondylitis, cross-reactions between Klebsiella nitrogenase and HLA-B27 have been described. In rheumatoid arthritis there is cross-reactivity between cartilage protein and a mycobacterial proteoglycan wall component.

Aberrant class II MHC expression was a theory in vogue in the mid-1980s. In this hypothesis, cells elicit autoimmune reactions by presenting their own self-peptides via self-expressed class II MHC molecules. Indeed class II MHC expression has been identified on various cells that are targets of autoimmune-mediated cell destruction. Examples include β cells in type 1 diabetes, biliary tract cells in primary biliary cirrhosis, and thyroid follicular cells in Hashimoto thyroiditis. However, there are strong counterarguments to this theory. First, class II MHC molecules do not present intracytoplasmic antigens, which are often targets of attack. Instead, class II MHC molecules present peptides derived from extracellular proteins. Second, accessory molecules are typically needed to activate naïve T cells. If, for example, β cells present peptides via their class II MHC molecules without B7.1 and B7.2, the naïve T cells seeing these peptides in the absence of B7 will actually be tolerized. Indeed, aberrant (or ectopic) class II MHC expression may be a mechanism cells use to actually induce a state of tolerance to down-regulate an immune response. Aberrant class II MHC expression may therefore serve an anti-inflammatory role in modulating an immune response to a lower level of intensity. Costimulator expression (e.g., B7.1/B7.2) is highly regulated even among professional antigen-presenting cells. For example in the basal state, neither macrophages nor B cells express B7. Upon phagocytosis of bacteria species, macrophages will express both class II MHC and B7. Although B cells express class II MHC in their basal state, internalization of bacterial antigen bound to their cell surface receptor antibody molecules will induce B7 expression.

Some cases of autoimmunity may result from superantigens initiating an antiself immune response as part of the polyclonal immune activation process. Superantigens are polyclonal T-cell stimulators that have the ability to cross-link TCR beta chains and MHC molecules. Superantigens have been reported to activate as many as one third of all T cells in the body. In such cases, systemic disease can develop from massive cytokine release (e.g., the systemic inflammatory response syndrome [SIRS]). This is the case in toxic shock syndrome, wherein a staphylococcal exotoxin acts as a superantigen. Mycobacterial antigens have also been proposed as possible superantigens in Crohn disease.[44] This theory presupposes that T cells bearing antiself TCRs have not been deleted or permanently anergized. T cells with antiself receptors may be stimulated, and if they encounter self-antigen, they may further proliferate to develop an autoimmune response.

Similar to polyclonal T-cell activation, polyclonal B-cell stimulation has also been implicated in humoral autoimmunity. Indeed, autoreactive B cells can be found in normal individuals. If an autoreactive clone of B cells encounters self-antigen and a costimulator (which might be nonspecific, e.g., a virus such as Epstein-Barr virus or a bacterial product such as lipopolysaccharide), autoantibodies could be produced, bypassing the need for T-cell help.

However, which of these speculative theories applies to the APS is unknown. Human disease most often results from an interaction of environmental and genetic factors.[45-47] Many environmental factors are implicated in various autoimmune diseases: wheat gliadin ingestion and celiac disease, penicillamine exposure and myasthenia gravis, methimazole and autoimmune hypoglycemia from insulin autoantibodies (seen primarily in Japanese patients), and amiodarone and thyroiditis. Even cancer can be associated with the development of autoimmunity: thymoma and myasthenia gravis,[48] ovarian teratoma and N-methyl-D-aspartate (NDMA) receptor meditated encephalitis,[49] and breast cancer and stiff

person syndrome.[50] Despite remarkable improvements in our understanding of immunology, many achieved through meticulous studies of APS, the mechanisms whereby the complex interaction of genes, environment, and immune system lead to autoimmunity remain to be fully elucidated.

CLASSIFICATION OF THE AUTOIMMUNE POLYGLANDULAR SYNDROMES

APS I, also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), is an autosomal recessive disorder mapped to a single gene (the autoimmune regulator or AIRE gene) on chromosome 21q22.3.[14,15] The presence of two of the following three conditions are prerequisites for the diagnosis of APS I: (1) adrenocortical failure (Addison disease) or serologic evidence of adrenalitis (adrenal autoantibodies), (2) hypoparathyroidism, and (3) chronic mucocutaneous candidiasis.[45,46,51-54] APS II is defined by the coexistence of autoimmune adrenocortical insufficiency or serologic evidence of adrenalitis with autoimmune thyroiditis (Schmidt syndrome) or type 1 diabetes mellitus (Carpenter syndrome: Schmidt syndrome plus type 1 diabetes) or serologic evidence of either thyroid or islet autoimmunity[45,55-58] (Figure 20-4). The presence of thyroiditis without adrenal disease but associated with either type 1 diabetes, pernicious anemia, vitiligo, or alopecia has been referred to by some authors as APS III, whereas additional combinations of autoimmune disease have been referred to as APS IV (i.e., vitiligo plus alopecia, type 1 diabetes plus celiac disease, or type 1 diabetes and vitiligo).[59] However, because APS III and IV differ from APS II only by the presence or absence of adrenocortical disease (and share similar susceptibility genes and immunologic features), we do not recognize APS III or IV as unique syndromes and consider them extensions of the APS II constellation.

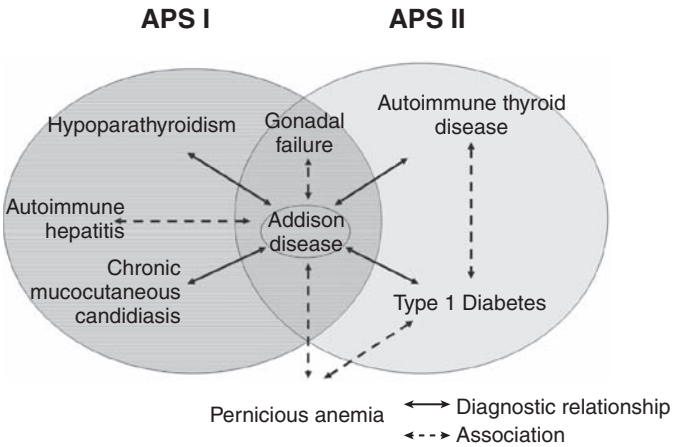

FIGURE 20-4 ■ Diagnostic relationships and common associations in APS I and APS II. The solid lines indicate diagnostic relationships. The dashed lines indicate common associations. The diagnosis of APS I depends on the coexistence of Addison disease (or adrenal autoantibodies) plus either hypoparathyroidism or chronic mucocutaneous candidiasis or both. The diagnosis of APS II depends on the coexistence of Addison disease (or adrenal autoantibodies) plus either autoimmune thyroid disease or type 1 diabetes or both (or their associated autoantibodies).

CLINICAL ASPECTS

APS I

The major disease components, frequencies, and differences between APS I and II are shown in Table 20-1. Although the disease is not common, the largest cohorts of patients have been reported from Finland, the United States, and among Iranian Jews.[51,52,54,60,61] The Finnish cohort of 91 subjects is the largest and most well characterized APS I group of patients in the world.[52]

Persistent mucocutaneous candidiasis is usually the first sign (60% of all APS I patients) and usually appears during the first year or two of life. In the Finnish cohort, 50% developed candidiasis by age 5 years, 94% by age 20 years, and 100% by 40 years of age.[52] All patients with refractory mucocutaneous candidiasis should be thoroughly investigated not only for a T-lymphocyte abnormality (absolute lymphocyte count, enumeration of T-cell subpopulations, assessment of T-cell function) but also for the presence of a polyendocrinopathy. Candidal infections in the diaper area are found early in life, with vulvovaginal candidiasis developing at puberty in females. Colonization of the gut by Candida can lead to intermittent abdominal pain and diarrhea. Infection of the nails with chronic candidiasis may lead to a darkened discoloration, thickening, or erosion. Retrosternal pain in patients with oral candidiasis suggests esophageal candidiasis and can be confirmed by esophagoscopy. Chronic oral mucosal candidiasis must be treated aggressively as candidiasis associated carcinoma of the oral mucosa or esophagus was reported in 7 of the 55 Finnish APS I patients over 25 years of age (note that 5 of the 7 were also smokers).[51,62]

Oral mucous membranes must therefore be protected from exposures that can increase susceptibility to candidal infections. Specifically, patients should be advised to avoid hard, sharp, or spicy foods, as well as whitening toothpastes or abrasives. Dentures or orthodontics can provide additional surfaces for Candidal growth.[51] Data suggest that prolonged therapy with fluconazole, ketoconazole, and miconazole leads to reduced azole susceptibility.[63,64] As such, azole therapy should be limited to two to three courses per year utilizing two polyene antifungals. Specifically, a 1- to 2-minute swish with 2 mL of nystatin followed by an amphotericin B lozenge that is allowed to dissolve without chewing should be given four times daily for 4 to 6 weeks.[51,64] When candidiasis is recurrent, pulse prophylaxis should follow using a 1-week course of either polyene (as described previously) every 3 weeks. Alternatively, 1 week of twice-daily chlorhexidine mouth rinse has also been used as prophylaxis.[51] If topical therapy fails, a 1-week course of high-dose fluconazole (200 to 300 mg in adults) is typically efficacious, though intravenous antifungal therapy may occasionally be required.

Hypoparathyroidism is typically the first endocrinopathy to develop in APS I and eventually occurs in more than 85% of patients. Hypoparathyroidism usually presents after the onset of mucocutaneous candidiasis but before puberty with 33% of APS I patients diagnosed with hypoparathyroidism by 5 years, 66% by 10 years, and nearly 85% by age 30. Severe hypocalcemia as evidenced by seizures, carpopedal spasms, muscle twitching, and laryngospasm may be presenting features of APS I, although these symptoms may be masked in the presence of adrenal insufficiency. Hypocalcemia, hyperphosphatemia and a low intact parathyroid hormone (PTH) level are diagnostic of hypoparathyroidism. Standard therapy consists of calcium salts and activated vitamin D (see Chapter 18 for management). Although data suggest that twice-daily administration of synthetic parathyroid hormone may provide optimal therapy,[65] this approach has not yet been approved by the U.S. Food and Drug Administration (FDA).

Autoimmune adrenocortical insufficiency (Addison disease) is the third major component of APS I and typically occurs after mucocutaneous candidiasis and hypoparathyroidism have been diagnosed. Over 85% of APS I patients will eventually develop adrenal insufficiency. Unfortunately, adrenal insufficiency is often initially missed clinically with the diagnosis commonly made late or at the time of a life-threatening adrenal crisis. In the Finnish cohort of APS I patients, 40% had Addison disease by 10 years and nearly 80% by 30 years.[52] Deficiencies of cortisol, aldosterone, and adrenal androgens may present simultaneously or may evolve over months to years. The initial symptoms of adrenal insufficiency are often nonspecific, mimicking psychiatric or gastrointestinal disease. These include fatigue, weight loss, myalgias, arthralgias, behavioral changes, nausea and vomiting, abdominal pain, and diarrhea. Over time, hyperpigmentation (due to elevated adrenocorticotropic hormone [ACTH]) in non–sun-exposed areas and postural hypotension can usually be found on careful examination. Unexplained hypotonic dehydration should raise the suspicion of Addison disease. Adrenal crises with hyponatremia, hyperkalemia, acidosis, and hypoglycemia may be fatal unless recognized and treated appropriately. As discussed in detail further, adrenal autoantibodies are used to predict adrenal cortical failure. If present, morning cortisol and renin measurements as well as ACTH stimulation testing may be used diagnostically in asymptomatic patients.

Autoimmune gonadal failure occurs in over 50% of women with APS I by age 20 years; less than 25% of males develop testicular insufficiency.[52] Gonadal failure often presents with primary amenorrhea in young women, though menstrual irregularities, polycystic ovaries, or infertility may be presenting features.[52,66] As with autoimmune adrenalitis, gonadal failure can be predicted by the presence of steroidal cell autoantibodies.[67]

Ectodermal dystrophy unrelated to hypoparathyroidism or mucocutaneous candidiasis has been extensively documented in the Finnish cohort. Dental enamel hypoplasia of permanent (but not deciduous) teeth as well as nail dystrophy is commonly found. There may be complete absence of the enamel or transverse hypoplastic bands alternating with zones of well-formed enamel. Dystrophy of nails is manifest by 0.5 to 1 mm pits. Nearly a third of the Finnish patients also had calcification of the tympanic membranes,[68] and 20% to 25% develop keratitis.[52]

As shown in Table 20-1, and in contrast to patients with APS II, type 1 diabetes and thyrogastric autoimmunity (a descriptive term for the combination of autoimmune thyroid disease and atrophic gastritis) are associated with APS I but occur far less frequently than in APS II. When present, thyroiditis is typically atrophic rather than goitrous. Gastric-parietal cell autoimmunity, which leads to atrophic gastritis with resultant achlorhydria and intrinsic factor deficiency, typically presents as iron deficiency anemia or vitamin B_{12}-deficient pernicious anemia. Whereas iron deficiency anemia is microcytic and vitamin B_{12}-deficient anemia is macrocytic, combined iron and vitamin B_{12} deficiency can be normocytic. It is also important to recognize that the spinal cord consequences of vitamin B_{12} deficiency can occur in the absence of anemia. Atrophic gastritis occurs in 15% to 30% of APS I cases with a mean age of onset of 16 years.[52,68]

Nonendocrine organ-specific diseases include alopecia, vitiligo, autoimmune hepatitis, and malabsorption. All types of alopecia may occur. Progression to alopecia totalis (total loss of scalp hair) or universalis (total loss of all body hair including eyelashes, eyebrows, and scalp hair), which are most common, usually occurs before puberty. Vitiligo presents initially as small, pale pigment-lacking skin patches. These may be missed unless specifically sought. Ultraviolet light examination of the skin may be necessary. The appearance of clay-colored stools, dark urine, and jaundice confirms the diagnosis of chronic active autoimmune hepatitis, unrelated to infectious hepatitis. Hepatitis occurs in 10% to 15% of APS I patients and is the leading cause of death. Consequently, all patients suspected of having APS I should have their liver function regularly monitored. Autoimmune hepatitis is typically treated with glucocorticoids until stabilized and with azathioprine if steroids can be successfully weaned.[51] Malabsorption, which may occur intermittently (and typically of fat), has been linked to hypoparathyroidism, bacterial and fungal overgrowth, gluten sensitivity (celiac disease), and IgA deficiency. There have also been rare reports of APS I with diabetes insipidus, growth hormone deficiency, ACTH deficiency, rheumatoid arthritis, Sjögren disease, tubulointerstitial nephritis, autoimmune bronchiolitis, and myopathy.[51,69,70]

APS II

APS II is the most common of the autoimmune polyendocrinopathies (excluding the coincidences of type 1 diabetes and autoimmune thyroid disease). Associated with HLA-DR3 and DR4 as well as HLA-DQA1 and DQB1, APS II does not have a single defining gene mutation like APS I. Unlike APS I, APS II usually has its onset in adulthood, particularly during the third or fourth decades, and is at least three times more common in females than males, whereas APS I is equally common in males and females. In 1926, Schmidt first described the association of adrenocortical and thyroid gland failure,

and in 1964, Carpenter extended this description to include insulin-dependent diabetes mellitus.[55,56] In 1957, the autoimmune nature of these diseases was suggested by Doniach and Roitt's discovery of thyroglobulin autoantibodies in patients with Hashimoto thyroiditis.[71] APS II was originally defined by the occurrence of adrenocortical insufficiency (Addison disease) with autoimmune thyroid disease or type 1 diabetes mellitus. This female bias in APS II is almost certainly related to the coexistence of autoimmune thyroid disease (AITD). Adrenocortical failure is the presentation in approximately 50% of APS II cases. The disease usually has its onset between ages 20 and 50 years, although it is not unusual to find cases before or after these ages.[58,72,73] Several of the disease components may be present at diagnosis. Type 1 diabetes coexists in nearly 50% of patients with Addison disease, whereas AITD coexists in about two thirds of patients with Addison disease. Thus, type 1 diabetes and AITD should be vigorously pursued in any patient presenting with Addison disease.

The most common component of the APS II to occur as an isolated condition is AITD. AITD affects nearly 4.5% of the U.S. population[74] with 80% to 90% of all cases occurring in females. AITD has an increased incidence during the teen years with a peak appearing in the fifth and sixth decades. Chronic lymphocytic thyroiditis (Hashimoto disease) is by far the most common form of AITD, although Graves disease may also occur. Postpartum thyroiditis is best considered to be a transient manifestation of autoimmune thyroiditis following childbirth. Manifestations of postpartum thyroiditis can vary from hypo to hyperthyroidism and discrete periods of hypo- and hyperthyroidism can be seen in individual affected women. Postpartum thyroiditis affects ~5% of all pregnancies with a frequency of ~10% in pregnancies of women with type 1 diabetes. Postpartum thyroiditis usually remits by 1 year following delivery. Several studies have reported on the coexistence of anti-islet immunity (3% to 8%) or even overt type 1 diabetes and AITD.[75,76] Just 1% of patients with otherwise isolated thyroiditis have serologic evidence of adrenal autoimmunity.

Although "polyglandular syndrome" involvement in patients with autoimmune thyroid disease is infrequent, thyroid autoimmunity or a family history of thyroiditis is common in patients with pernicious anemia, vitiligo, alopecia, myasthenia gravis, and Sjögren syndrome.[77-79] More patients with APS I than APS II have vitiligo, but because APS I is far less common, most patients with vitiligo who have another autoimmune disease have APS II. Approximately 20% to 40% of vitiligo patients have another component of APS II, with thyrogastric autoimmunity (concurrent autoimmune thyroid disease and lymphocytic gastritis) being the most common.[80,81] Up to 15% of patients with alopecia (areata, totalis, universalis) and 5% of their first-degree relatives have thyroid disease. Most patients with vitiligo are asymptomatic, and evidence of concurrent autoimmunity can only be ascertained by autoantibody screening. Segmental vitiligo with involvement of dermatomal regions is not associated with autoimmunity.[82]

Nearly 30% of patients with myasthenia gravis (autoimmune disease characterized by muscle weakness worsening during muscular contraction and associated with antiacetylcholine receptor autoantibodies) have AITD. Both Hashimoto thyroiditis and Graves disease may occur in patients with myasthenia.[83,84] Interestingly, patients with concomitant AITD tend to have milder expression of their myasthenia and a lower incidence of thymic disease and acetylcholine receptor α-chain autoantibodies. However, the incidence of ocular myasthenia is higher in patients with Graves disease.

Type 1 diabetes mellitus is a diagnostic component of APS II.[85] The worldwide incidence of type 1 diabetes continues to rise, particularly in children less than 5 years of age. The disease has a peak incidence during the teen years with a smaller but increasing incidence occurring in the preschool years.[86] Nevertheless, the disease may have its onset at any age. Approximately 10% to 15% of "type 2 diabetes" patients with disease onset after 40 years actually have slowly progressive autoimmune disease (latent autoimmune diabetes of adults [LADA]).[87] Unlike APS II, in which there is a female gender bias despite the occurrence of type 1 diabetes, no gender bias is present in patients with isolated type 1 diabetes. AITD (denoted by the presence of thyroperoxidase or thyroglobulin autoantibodies) occurs in 20% to 25% of patients with type 1 diabetes with women representing nearly two thirds of the autoantibody-positive patients.[72] Despite the high prevalence of thyroid autoantibodies, less than 20% of patients with thyroid autoantibodies have evidence of thyroid dysfunction defined as an elevated thyroid-stimulating hormone (TSH) concentration. Gastric parietal cell autoantibodies (PCA) are present in approximately 10% of females and 5% of males with type 1 diabetes.[88] Although pernicious anemia typically affects women after the fifth decade, children with PCA should be closely monitored for the development of pernicious anemia. Atrophic gastritis may lead to the development of a megaloblastic anemia due an inability to produce intrinsic factor with the consequent inability to absorb vitamin B_{12}. Iron deficiency anemia may occur in both adolescents and adults due to an impaired ability to absorb iron consequent to decreased acid production (achlorhydria).[89] Adrenocortical autoimmunity is much less frequent among patients with type 1 diabetes, with serologic evidence reported in 1.5% of cases.[90,91] Tissue transglutaminase or endomysial autoantibodies suggestive of celiac disease are present in 3% to 7% patients with type 1 diabetes.[92] Celiac disease should be suspected in patients with unexplained diarrhea, weight loss, failure to gain weight, or failure to thrive and should be confirmed by intestinal biopsy.[93,94]

Approximately 10% of women less than 40 years of age with APS II develop ovarian failure. Ovarian failure may present as either primary or secondary amenorrhea. In females with biopsy-proven lymphocytic oophoritis, adrenocortical failure or subclinical adrenal autoimmunity is often present.[95] In contrast, progression to gonadal failure is very rare among males with Addison disease.

Pituitary involvement is occasionally seen in APS II.[96,97] Hypophysitis and empty sella syndrome have been described, usually leading to isolated failure of secretion of growth hormone (GH), ACTH, TSH, follicle-stimulating hormone (FSH), or luteinizing hormone (LH).

Several nonendocrinologic conditions have also been reported in association with APS II. These include ulcerative colitis,[98] primary biliary cirrhosis,[99] sarcoidosis,[100,101] achalasia,[102] myositis,[103] and neuropathy.[104]

*I*mmune Dysregulation, *P*olyendocrinopathy, *E*nteropathy, and *X*-linked Inheritance (IPEX)

Neonatal onset type 1 diabetes, dermatitis, enteropathy, thyroiditis, hemolytic anemia, and thrombocytopenia are all part of the rare IPEX constellation. Enhanced understanding of the regulatory T-cell function and the role *FOXP3* has led to its characterization. Patients with IPEX have an absence of FoxP3 expression.[105-108] To date, only long-term immunosuppression or bone marrow transplantation, with the goal of enhancing regulatory T-cell function, have been effective therapies for IPEX. Sustained expression of FoxP3 may reprogram effector T cells to act as regulatory T cells.[109,110] Approaches aimed at enhancing the function of regulatory T cells may potentially be applied to treating all autoimmune diseases.

DIAGNOSTIC APPROACH AND FOLLOW-UP

The approach to diagnosing polyglandular syndromes is threefold (1): autoantibody screening to (i) verify the autoimmune nature of the suspected endocrinopathy and (ii) test for the involvement of other organs and tissues; (2) full assessment of endocrine function in patients with confirmed autoantibodies and autoantibody-negative subjects in whom disease may be suspected clinically; (3) mutation analysis to both confirm the diagnosis and screen siblings and other relatives for their potential carrier status.

Recognition of multiorgan autoimmune diseases prior to their symptomatic phases is vital in minimize associated morbidity and mortality. A thorough history and physical examination should always be performed and a high index of suspicion should be maintained. In addition, family history of multiorgan autoimmune disease should increase the suspicion for a potential APS.

As discussed later, perhaps the greatest single achievement in the early diagnosis of APS I patients since the early 2000s has been the discovery of the association of autoantibodies to type 1 interferons and APS I.[111] *Although not indicative of a tissue-specific immune attack, autoantibodies to interferon (α and ω)* provide a nearly 100% sensitive and specific screening test for APS I.[112-114] The presence of autoantibodies to interferons should be followed by confirmatory testing for AIRE mutations as well as testing for tissue specific autoantibodies (Figure 20-5). These include 21-hydroxylase or adrenal cortex cytoplasmic

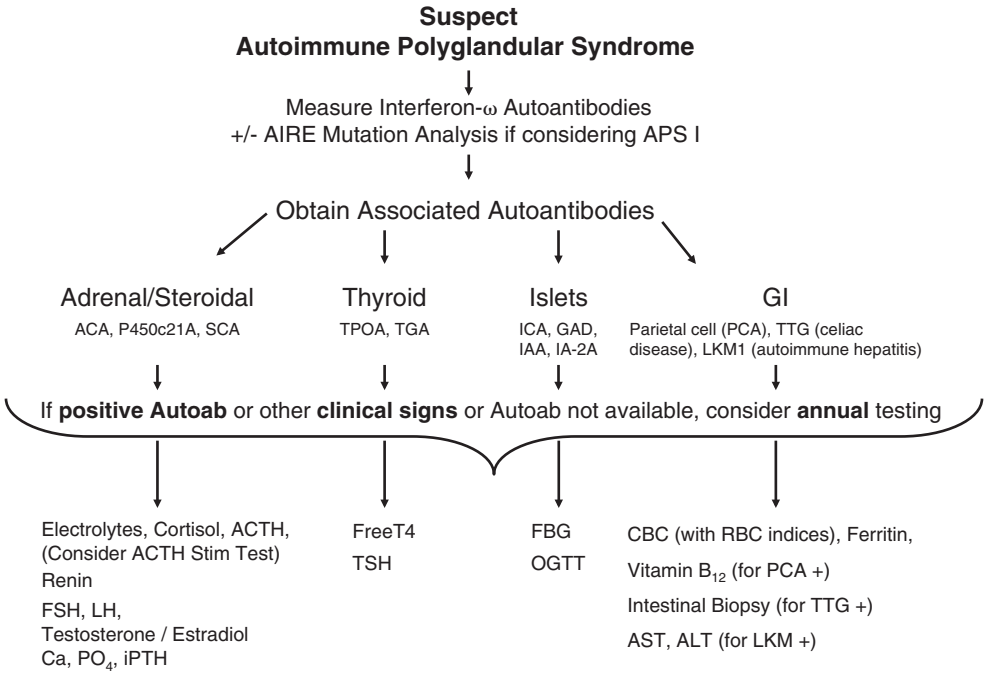

FIGURE 20-5 ■ Antibody and end-organ testing in patients with suspected APS. This flow diagram shows which autoantibodies should be obtained when APS is suspected due to clinical signs and symptoms. Given its sensitivity and specificity, primary screening with interferon-ω antibodies is likely adequate if APS is suspected. That said, we recommend autoantibody testing in subjects with a suspected APS-related disease (adrenalitis, chronic mucocutaneous candidiasis, or autoimmune hypoparathyroidism) at the time of initial diagnosis. We also recommend autoantibody testing in subjects with two or more associated autoimmune diseases (i.e., T1D and autoimmune thyroiditis). Unfortunately, data are lacking to provide firm recommendations regarding the need for repeat autoantibody testing in patients who are initially autoantibody negative. However, if antibodies are negative, we recommend repeat autoantibody testing in early puberty if clinical signs or symptoms of APS persist. For those who are antibody positive, annual testing of end-organ function should be obtained as shown. When autoantibody assays are unavailable, clinicians must use frequent testing of disease-specific end points to identify associated comorbidities.

autoantibodies (for autoimmune Addison disease), GADA, IA-2A, IAA , and more recently ZnT8 autoantibodies (for type 1 diabetes), thyroperoxidase and thyroglobulin autoantibodies (for autoimmune thyroid disease), steroidal cell autoantibodies (for ovarian failure), and transglutaminase or endomysial autoantibodies (for celiac disease). In addition, although not readily available, autoantibodies to 17-hydroxylase, side-chain cleavage enzyme and 3-hydroxysteroid dehydrogenase can be used to detect gonadal and adrenal autoimmunity. Autoantibodies to NALP5 (NLR family, pyrin domain containing 5; NLR = NACHT, leucine rich; NACHT = nucleotide oligomerization domain-like receptors) and the calcium-sensing receptor (putative parathyroid autoantigens) document risk for autoimmune hypoparathyroidism,[115,116] and antibodies to human pituitary enolase may provide evidence of autoimmune hypophysitis.[117] Notably, measurement of certain autoantibodies may not be available to all clinicians and require individualized approaches to screening and follow-up. In addition, although autoantibodies have yet to be identified, data suggest a number of cytokines (IL-17A, IL-17F, and IL-22) may act as autoantigens associated with mucocutaneous candidiasis.[118] Although there is a clear link between the presence of organ-specific autoantibodies and either the presence of preexisting disease or subsequent progression to disease, the number of associated disorders that will develop and their age of appearance are unpredictable. Consequently, long-term follow-up is necessary in both autoantibody-positive and negative subjects.

All patients with a single autoimmune disease must be considered at risk for other autoimmune diseases. Whether and when to screen for other autoantibodies is based on the likelihood of finding another autoimmune disease, cost effectiveness, and the likelihood that screening will prevent morbidity and mortality from other diseases (e.g., diabetic ketoacidosis, Addisonian crisis, or hypocalcemia with seizures) in the future.

Because of the high incidence of AITD in patients with type 1 diabetes, we recommend that such patients have thyroperoxidase and thyroglobulin autoantibodies measured biannually. We prefer this approach over the assessment of thyrotropin (TSH) levels, because autoantibody seroconversion is a much earlier event in the evolution of thyroid disease and their presence would warrant more frequent monitoring (every 6 to 12 months). Measuring both thyroid autoantibodies has close to 90% sensitivity for the detection of AITD. That said, some clinicians prefer to follow at-risk patients by means of TSH given that treatment is typically not initiated until the TSH becomes elevated.

Screening for all components of APS is not recommended in patients with isolated autoimmune thyroid disease. However, several reports have demonstrated an increased incidence of parietal cell autoantibodies in such patients.[89,119] Thus, screening for parietal cell autoantibodies in children with AITD should be considered. In hypothyroid patients with confirmed APS, evidence for adrenal autoimmunity must be sought before starting thyroid hormone replacement therapy because thyroid hormone replacement can precipitate an adrenal crisis in patients with marginal adrenocortical function (by increasing metabolism and catabolism of steroid hormones).

Delayed diagnoses and even preventable deaths still occur in patients with undiagnosed adrenocortical failure. As mentioned previously, the presentation is often vague and nonspecific until an Addisonian crisis ensues. In patients with type 1 diabetes, unexplained hypoglycemia or other unexplained improvement in blood glucose control might be a clue to the diagnosis of Addison disease. Improved sensitivity to injected insulin and improved glycemia may represent the loss of counterregulatory (anti-insulin) activity associated with glucocorticoid deficiency.

All patients with prolonged or unexplained chronic mucocutaneous candidiasis or hypoparathyroidism should be evaluated for APS I. Screening for APS should also be considered in females with premature ovarian failure.

Assessment of end organ function in any patient with positive autoantibodies is recommended annually (see Figure 20-5). Fasting or 2-hour postprandial blood glucose testing, calcium, phosphate, and PTH and TSH levels can effectively assess pancreatic islet, parathyroid, and thyroid function in asymptomatic individuals. Due to its limited sensitivity, we do not recommend the use of HbA1c as a screening tool for T1D. Elevated FSH and LH levels with concomitant low sex steroids confirm gonadal failure. Serial assessments of hemoglobin, hematocrit, and red blood cell indices can assess progression to atrophic gastritis in patients with gastric autoimmunity. The findings of a megaloblastic anemia with an elevated mean corpuscular volume (MCV) suggest vitamin B_{12} deficiency, whereas a microcytic hypochromic anemia suggests iron deficiency. Vitamin B_{12} levels should be followed in all patients with parietal cell autoantibodies as neuropathy can develop without anemia. Before starting therapy, both vitaminB_{12} level and an iron profile should be obtained. Methylmalonic acid levels are not routinely needed in patients with gastric autoimmunity but may be helpful if vitamin B_{12} levels are borderline low.[120] Liver function tests and antimitochondrial autoantibodies should be obtained in patients with APS I. Patients with tissue transglutaminase or endomysial autoantibodies are frequently asymptomatic and should be referred to a gastroenterologist to discuss the need for an intestinal biopsy and potential confirmation of celiac disease.

Low early morning cortisol levels, electrolyte abnormalities (hyponatremia/hyperkalemia), and hypoglycemia represent late changes occurring at or just before the onset of adrenal insufficiency. Just as the natural history of pre–type 1 diabetes is well characterized (see Chapter 19), a similar pattern is seen prior to the development of adrenocortical insufficiency (Figure 20-6). Four stages have been described subsequent to the detection of adrenal autoantibodies: stage 1: increased plasma renin activity with normal to low aldosterone; stage 2: decreased cortisol response after

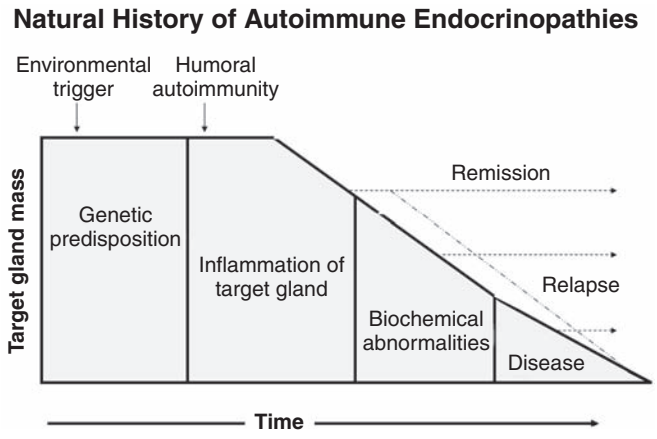

FIGURE 20-6 ■ Proposed model of the natural history of an organ-specific autoimmune disease. In genetically susceptible individuals, the onset of autoimmunity (identified by the presence of serum autoantibodies) is thought to be triggered by environmental agents. These organ-specific autoantibodies can be identified months to years before the disease becomes clinically manifest, allowing for the prediction and early diagnosis of the disease before the clinical manifestations or metabolic abnormalities can usually be detected.

parenteral ACTH administration; stage 3: elevated basal ACTH; and stage 4: low basal cortisol (Table 20-3).[121,122] In individuals with adrenocortical autoantibodies, screening with a measurement of the morning cortisol concentration should be done. If normal, mid-afternoon ACTH and supine renin levels should be measured. Complete assessment of adrenocortical function should be carried out in those with ACTH levels > 55 pg/mL or in those with elevated renin concentrations.

TREATMENT

Hormone replacement or other therapies for the component diseases of APS I and APS II are similar whether the ailments occur in isolation or in association with other conditions. Specific therapies are described in the individual chapters.

GENETICS OF APS I

APS I is inherited in an autosomal recessive fashion.[123] Unlike APS II, specific HLA alleles are not associated with APS I.[124] APS I has been mapped to chromosome 21q22.1 and the AIRE gene subsequently cloned.[14] Patients with APS I are homozygous (possess two mutated copies) for the AIRE gene with their parents being heterozygous for the mutated gene. AIRE is expressed in the thymus, lymph nodes, and fetal liver as well as in pancreas, adrenal cortex, and testes. The gene spans 11.9 kb, contains 14 exons, and the protein is 545 amino acids.[15]

Initially, five AIRE mutations were described: one nonsense mutation and four frameshift mutations.[14,124] Now, more than 70 mutations in the AIRE gene have been reported; mutations are present in over 98% of patients with APS I.[53,125-127] Multiple shared and unique mutations have been defined in Sardinians, Britons, Italians, Finns, Japanese, and North Americans.[54,128,129] Sequence analysis demonstrates that the AIRE transcribed protein displays features common to many transcription factors.[3,130] Further understanding of the AIRE protein's function may provide fundamental insights into the nature of autoimmunity.

GENETICS OF APS II

Whereas APS I displays an autosomal recessive Mendelian pattern of inheritance, APS II is not inherited as a single gene mutation. APS II is much more typical of other autoimmune endocrinopathies where cases can occur either sporadically or within families with APS II.

Overall, like patients with type 1 diabetes, patients with APS II have similar HLA associations, especially having increased frequencies of HLA-DR3 (DQB1*0201), DR4 (DQB1*0302), and DQA1*0301.[85,131] This is not surprising, as type 1 diabetes, a frequent component of APS II, is strongly HLA associated. However, when patients with type 1 diabetes are removed from the APS II subject group, the association between HLA-DR alleles and APS II disappears. Thus HLA-DR, in the absence of type 1 diabetes, is not a major locus for the development of APS II. Previous studies have shown that Addison disease and type 1 diabetes not only share the major risk DR3/DR4 genotype but also that Addison disease is particularly associated with DRB1*0404 and DRB1*0301 haplotypes.[132] It is estimated that 1 in 20 patients with type 1 diabetes with this haplotype will have adrenal autoantibodies.[133,134] Another high-risk allele for Addison disease is DRB5 (DQB1*0301). Graves disease is more

TABLE 20-3 **Stages in the Development of Autoimmune Addison Disease**

Stage	Renin	Aldosterone	Basal Cortisol	Cortisol Post ACTH	Basal ACTH
1	Elevated	N or Low	N	N	N
2	Elevated	N or Low	N	Low	N
3	Elevated	N or Low	N	Low	Elevated
4	Elevated	Low	Low*	Low	Elevated

ACTH, adrenocorticotropic hormone; N, normal.

often associated with HLA-DR3 as opposed to Hashimoto thyroiditis, which is associated with HLA-DR4 or DR5.[135,136] Autoimmune hypoparathyroidism and mucocutaneous candidiasis do not display associations with specific HLA alleles.

Because the association of APS II with specific HLA alleles is only modest, other genes must be important in providing susceptibility. To identify non-HLA genes that influence susceptibility to APS II, genome-wide scan or linkage studies are necessary. The G allele of the CTLA-4 exon 1 A/G diallelic polymorphism has been associated with Addison disease in APS II and less strongly associated with isolated Addison disease.[137]

AUTOANTIBODIES IN AUTOIMMUNE POLYGLANDULAR SYNDROMES

Autoantibodies are antibodies, predominantly IgG, that bind to self (auto)antigens. Autoantibodies may be pathogenic as observed in Graves disease or myasthenia gravis. In Graves disease, agonistic autoantibodies directed against the thyroid follicular cell TSH receptor stimulate overproduction of thyroid hormone causing hyperthyroidism.[138] In myasthenia gravis, autoantibodies directed against the motor end plate acetylcholine receptor located on myocytes stimulate internalization of the acetylcholine receptor producing muscular weakness. Usually, however, autoantibodies serve solely as serologic markers of autoimmunity such as in type 1 diabetes where islet cell autoantibodies (ICA), insulin autoantibodies (IAA), glutamic acid decarboxylase autoantibodies (GADA), insulinoma associated autoantibodies (IA-2A), and autoantibodies to the zinc transporter 8 (ZnT8A) are indicators of ongoing autoimmunity.[139,140] Interestingly, in patients with APS I, GADA are not as predictive of the subsequent development of type 1 diabetes.[51]

Detection of autoantibodies in the autoimmune polyglandular syndromes serves several important functions. First, detection of autoantibodies allows for a specific autoimmune diagnosis to be established.[141] Second, autoantibody detection in asymptomatic individuals indicates an increased risk for the later development of clinical disease.[90] Third, the presence of an autoantibody or one autoimmune disease in an individual may suggest an increased risk for other associated autoimmune diseases.

Non–Organ-Specific Autoantibodies

Anti-Interferon Autoantibodies (AIA)

Autoantibodies to interferons (α and ω) provide a highly sensitive screening test for APS I. First used clinically as indicators of risk for myasthenia gravis and thymoma, high-titer AIA were unexpectedly found in 60/60 Finnish APS I patients and 16/16 Norwegian APS I patients.[111] Notably, AIA were typically detected (using stored serum samples) in known APS I patients prior to the onset of organ specific autoantibodies. In fact, several APS I patients developed AIA prior to the onset of mucocutaneous candidiasis. As further evidence of the specificity of AIA, subjects with AIRE mutations but lacking classic features of APS I (mucocutaneous candidiasis, hypoparathyroidism, or adrenal insufficiency) have also demonstrated high titers to AIA. As such, AIA are likely to become the primary screening test for APS I. The specificity of AIA for APS I suggests that interferon-γ (an interferon without detectable autoantibodies in APS I patients) could provide effective immunotherapy in APS I patients.[111] Finally, AIA can be detected by a competitive immunoassay.[114]

Autoantibodies to IL-17A, IL-17F, and IL-22

Mucocutaneous candidiasis is often the presenting clinical abnormality in APS I. Although anti-interferon antibodies can predict APS I, they do not predict the order or severity of the known APS I components. Disease or organ specific autoantibodies are therefore needed to provide patients and physicians with optimal anticipatory guidance. Improvements in our understanding of host defense to Candida led several groups to hypothesize that autoantibodies to specific cytokines, IL-17A, IL-17F, and IL-22, may both predict and explain the mucocutaneous candidiasis associated with APS I. In one study, 33/33 patients with APS I and mucocutanous candidiasis demonstrated high titer autoantibodies to IL-17A, IL-17F, and IL-22 (versus 0/37 controls), and 0/103 patients with isolated autoimmune diseases were positive.[118] These observations have subsequently been confirmed in other cohorts and indeed suggest that autoantibodies to IL-17A, IL-17F, and IL-22 may be a useful tool in predicting mucocutaneous candidiasis.[142,143] Currently these autoantibodies are only used in the research setting. Recall that under normal circumstances IL-17 and IL-22 are involved in the activities of Th17 cells that enhance local cellular innate immunity.

Organ-Specific Autoantibodies

Adrenal Cytoplasmic Autoantibodies (ACA)

Adrenal cytoplasmic autoantibodies (ACA) were first detected using a complement-fixation technique with saline extracts of adrenal tissue and soon afterward by indirect immunofluorescence.[144] Usually all layers of the adrenal cortex (but not the medulla) fluoresce.[121] The microsomal localization of autoantigens has been confirmed using ultracentrifuged cellular components.[145] Other assays for adrenal autoantibodies include solid-phase radioimmunoassays and nonradioactive enzyme-linked immunoabsorbent assays.[122,146]

Up to 75% to 80% of subjects with new-onset Addison disease exhibit ACA.[121] Approximately 50% of asymptomatic ACA-positive individuals develop Addison disease in less than 3 years. In a follow-up of 20 ACA-positive children followed for up to 11 years, the cumulative risk for developing Addison disease was 100%.[121] ACA are also predictive of the subsequent development of Addison disease in adults, although less frequently than in children. Higher titers of ACA and complement fixing ACA have been associated with an increased risk of displaying clinical disease.[147]

Autoantibodies to the surface of adrenal cortical cells have been described but are not detected routinely because of the difficulty in obtaining fresh human or animal adrenal tissue that can be used for such assays. However, almost 90% of individuals with Addison disease were reported to exhibit such autoantibodies.[148]

ACA are detected in all forms of autoimmune Addison disease, be it isolated Addison disease or as part of APS I or APS II. As stated previously, subjects with other forms of organ-specific autoimmune disease exhibit increased frequencies of ACA, which are highly predictive of the subsequent development of adrenal insufficiency.

Adrenal Enzyme Autoantibodies

Typical of many organ-specific autoimmune diseases, major autoantigens that serve as targets of autoantibodies in APS are enzymes. Such enzymes are expressed in the tissues that are being targeted for humoral or cell-mediated autoimmune attack. Examples of various autoimmune diseases where enzymes are targeted are illustrated in Table 20-2. A discussion of adrenal hormone synthesis can be found in Chapter 13.

21-hydroxylase (P450c21) is a major autoantigen recognized by sera from patients with Addison disease.[149] There is a strong correlation between positivity for ACA and P450c21 autoantibodies, and P450c21 autoantibodies appear to be an even more sensitive indicator of disease.[150] Other enzymes have been identified as autoantigens in patients with either isolated autoimmune Addison disease or APS including P450 cholesterol side chain cleavage enzyme (P450scc), 17α-hydroxylase (P450c17), and 3β-hydroxysteroid dehydrogenase (which is not a P450 enzyme).[150]

Adrenal Enzyme Autoantibodies in APS I

Although autoantibodies to P450c21 (21-hydroxylase), P450ssc (side-chain cleavage enzyme), and P450c17 (17-hydroxylase) have been reported, autoantibodies to P450c21 are most commonly identified in patients with adrenal autoimmunity. Nearly 75% of APS I and APS II patients have P450c21 autoantibodies present.[121]

The autoantigenic epitopes of the P450c21 enzyme are located in the C-terminal end and in a central region of the enzyme.[151] It has been reported that two of four epitopes recognized by P450c17 autoantibodies cross-reacted with P450c21, indicating that reactivity to one of these autoantigens could actually reflect molecular mimicry between such epitopes.[152] Except for the N-terminal amino acids 1-40 and the C-terminal amino acids 456-521, immunoreactive epitopes have been described throughout P450c21.[153]

Higher titers of both ACA and P450c21 autoantibodies appear to correlate with both greater impairment of adrenocortical function and the predicted development of Addison disease.[121] As with many autoimmune diseases, an inverse correlation exists between autoantibody titer and duration of disease in patients with Addison disease.[154] This is consistent with the concept that once an autoantigen is completely destroyed, the immune system is no longer stimulated to produce autoantibodies.

Adrenal Enzyme Autoantibodies in APS II

When clinical or preclinical Addison disease is present, there is no unique combination of adrenal or gonadal antibodies that separate APS I from APS II.[141,155,156] The differentiation of APS I from APS II is made either on clinical grounds or, in asymptomatic patients, by detecting concomitant autoantibodies associated with APS II. Furthermore, there are no unique epitopes recognized by P450c21 autoantibodies that allow differentiation of isolated Addison disease versus APS I or APS II.[157] However, APS I can be distinguished from APS II via molecular diagnostic tests for mutation in the AIRE gene.

Steroidal Cell/Gonadal Autoantibodies (SCA)

Some individuals with ACA have sera that cross-react with reproductive-steroid-producing tissues including the theca interna of the graafian follicle, Leydig cells of the testis, or syncytiotrophoblastic layer of the placenta.[134,158] Sera that recognize antigens in both adrenal and reproductive-steroid–producing tissues whose immunoreactivity cannot be absorbed with adrenal extracts are termed SCA. Such variability in immunoreactivity likely represents differences in autoantigen density or epitope availability differences among the tissues.

In asymptomatic patients, SCA are associated with an increased risk of developing primary autoimmune gonadal failure. In women, this usually manifests as either primary amenorrhea or premature menopause. Men are usually asymptomatic. When ACA are present in the absence of SCA, gonadal failure is rare.[134] Overall, approximately one third of individuals with ACA have SCA (using ovary, testis, or placenta as the antigen source). SCA are more common in APS I than in APS II patients. It is estimated that 60% of subjects with APS I and Addison disease express SCA, compared to 30% of patients with APS II.

Premature ovarian failure independent of APS may can also occur as a consequence of autoimmunity.[159] However, Addison disease coexists in approximately 2% to 10% of women with autoimmune-mediated premature ovarian failure.[160] Like other organ-specific autoimmune diseases, autoimmune ovarian failure is characterized histologically by ovarian infiltration with inflammatory cells.[161] Many patients with either isolated premature ovarian failure or premature ovarian failure associated with APS express SCA.[162] Five of 5 women with SCA, all of whom also had ACA consistent with an autoimmune polyglandular syndrome, manifested ovarian failure.[163]

SCA, depending on the assay used, have been reported in 4% to 87% of women with premature ovarian failure.[158,164,165] SCA are also predictive of later gonadal failure in APS women with normal menses at the time of initial study. It has been reported that 100% (11 of 11) of APS I patients who were positive for SCA developed primary ovarian failure during a follow-up period of up to 12 years.[163] Autoantibodies reacting strongly to the pig zona pellucida as determined by indirect immunofluorescence were observed in 6 of 22 women with infertility.[166]

The nature of the ovarian autoantigens in premature ovarian failure is controversial. Because the adrenal cortex and gonad share several synthetic pathways common to cells producing both adrenocortical steroids and sex steroids, humoral autoimmunity to shared autoantigens might be expected in patients with both Addison disease and gonadal failure. The synthesis of sex and adrenal steroids requires P450scc, 3β-hydroxysteroid dehydrogenase, and P450c17. Data are, however, contradictory. In one study, SCA activity was removed by preabsorption with recombinant human 3β-hydroxysteroid dehydrogenase, suggesting that this enzyme was a major autoantigen detected by SCA-positive sera.[167] Another study suggested that SCA correlated best with reactivity to P450scc and a 51-kilodalton autoantigen that binds to the aromatic L-amino acid decarboxylase present in granulosa cells, placenta, liver, and pancreatic beta cells.[168]

Autoantibodies in Hypoparathyroidism

Autoimmune hypoparathyroidism is a characteristic disorder essentially unique to APS I. Hypoparathyroidism is absent in subjects with APS II. In the original report of parathyroid autoantibodies detected using indirect immunofluorescence, nearly 40% of patients with autoimmune hypoparathyroidism were found to have parathyroid cytoplasmic autoantibodies versus 6% of controls.[169,170] However, other laboratories did not confirm the initial reports of the existence of such parathyroid cytoplasmic autoantibodies.[171,172] It was shown that autoantibodies detected by indirect immunofluorescence directed against the parathyroid gland could be preabsorbed with human mitochondria, indicating that such autoantibodies were not tissue specific.[172]

Several different antiparathyroid autoantibodies have been reported in patients with hypoparathyroidism. These include autoantibodies that may bind to cultured bovine endothelial cells.[173,174] Unrelated to APS I or APS II, autoantibodies that bind to anti-PTH antibodies (employed in a PTH immunoassay—i.e., anti-idiotypic PTH autoantibodies) have been described.[175] Autoantibodies to the extracellular domain of the calcium receptor have also been described.[116,176] In contrast, autoantibodies that block the calcium receptor have been described that cause hyperparathyroidism (e.g., "autoimmune hypercalcemia").[177] More recently, screening of human parathyroid complementary DNA libraries with sera from patients with known APS I and hypoparathyroidism identified NACHT leucine-rich repeat protein 5 (NALP5) as an important parathyroid autoantigen. Autoantibodies were detected in 49% of patients with APS I and hypoparathyroidism but were absent in all 293 controls.[115] Notably, NALP5 autoantibodies appear to be specific for hypoparathyroidism related to APS I, as they are rarely (0.69%) seen is patients with idiopathic hypoparathyroidism.[178]

Other Autoantibodies in APS I and II

In addition to the autoantibodies discussed in detail earlier, autoantibodies to tyrosine hydroxylase have been reported in ~40% of patients with APS I and correlate with alopecia areata.[179] Antibodies to liver/kidney microsome type 1 (LKM1) are found in nearly 100% of patients with type 2 autoimmune hepatitis.[180] Forty percent of such patients have associated autoimmune disease commonly seen in APS I. The hepatic autoantigens P450IA2 and P4502A6 have been reported as targets of these antibodies. Autoantibodies to aromatic L-amino acid decarboxylase have also been recognized in APS I and isolated cases of Addison disease.[168] Finally, pteridine-dependent hydroxylases have also been proposed as autoantigens in APS I.[181]

SUMMARY

The autoimmune polyglandular syndromes result from a loss of tolerance to self-antigens. A thorough understanding of tolerance induction and defects in tolerance is required to fully understand the immunopathogenesis of APS. APS I, an autosomal recessive disorder mapped to the AIRE gene, is defined by the presence of at least two of the following three findings: (1) adrenocortical autoimmunity, (2) hypoparathyroidism, or (3) mucocutaneous candidiasis. APS II is defined by the coexistence of autoimmune adrenocortical insufficiency or serologic evidence of adrenalitis with autoimmune thyroiditis or type 1 diabetes mellitus. The occurrence of any one component disease of an APS may be linked to the occurrence of others through shared autoimmunity background genes that lead to a loss of tolerance. As such, a high index of suspicion should be maintained whenever one autoimmune disorder is diagnosed. For example, in type 1 diabetes, it is routine to screen for thyroid autoimmunity and celiac disease.

Treatment of APS should be aimed at optimal management of the specific underlying diseases. Screening for the presence of associated autoimmune disorders should be performed regularly. An improved understanding of the interaction among susceptibility genes, environmental triggers, and the development of impaired immune tolerance should prove to be the best path to improved diagnostic and therapeutic modalities in the care of patients with APS.

QUESTIONS

1. Mutations in which one of the following genes causes autoimmune polyglandular syndrome type 1?
   a. Menin
   b. Ret proto-oncogene
   c. Autoimmune regulator
   d. Hepatic nuclear factor-1
   e. Nuclear factor kappa B

Answer: c

2. Genetic predisposition to autoimmune polyglandular syndrome type 2 (especially when type 1 diabetes is present) is most strongly associated with which one of the following loci?
   a. MHC class I genes
   b. MHC class II genes
   c. MHC class III genes
   d. CTLA-4
   e. Insulin gene

Answer: b

3. Which one of the following autoantibodies is the strongest predictor of the development of pernicious anemia?
   a. Autoantibodies to thyroperoxidase
   b. Autoantibodies to the acetylcholine receptor alpha chain
   c. Autoantibodies to voltage-gated Ca^{2+} channel
   d. Autoantibodies to extrinsic factor
   e. Autoantibodies to the Na^+/H^+ ATPase pump

Answer: e

4. Which one of the following autoantibodies is the strongest predictor of the development of Hashimoto thyroiditis?
   a. Autoantibodies to thyroperoxidase
   b. Autoantibodies to thyroglobulin
   c. Autoantibodies to the Na^+/I^- symporter
   d. Autoantibodies to intrinsic factor
   e. Autoantibodies to the TSH receptor

Answer: a

5. Which one of the following autoantibodies is most specific for Graves disease?
   a. Autoantibodies to thyroperoxidase
   b. Autoantibodies to thyroglobulin
   c. Autoantibodies to the Na^+/I^- symporter
   d. Autoantibodies to intrinsic factor
   e. Autoantibodies to the TSH receptor

Answer: e

6. What is the major target autoantigen in autoimmune Addison disease?
   a. Galactose-1-phosphate uridylyltransferase
   b. 21-hydroxylase
   c. Glutamic acid decarboxylase
   d. Phenylalanine hydroxylase
   e. 11 beta-hydroxylase

Answer: b

7. Which one of the following problems occurs in autoimmune polyglandular syndrome type 1 but not in autoimmune polyglandular syndrome type 2?
   a. Ectodermal dysplasia
   b. Pernicious anemia
   c. Vitiligo
   d. Addison disease
   e. Autoimmune thyroid disease

Answer: a

8. A child presents with a hypocalcemia seizure and extensive candidal infection of the nails. What is the most likely diagnosis?
   a. Addison disease
   b. Autoimmune thyroid disease
   c. Autoimmune polyglandular syndrome type 1
   d. Autoimmune polyglandular syndrome type 2
   e. Multiple endocrine neoplasia syndrome type 2B

Answer: c

9. What is the risk of a sibling of the above child being similarly affected?
   a. $< 1\%$
   b. $\sim 5\%$
   c. $\sim 25\%$
   d. $\sim 50\%$
   e. $\sim 100\%$

Answer: c

10. Which one of the following findings is the earliest biochemical evidence of Addison disease?
    a. Low AM cortisol
    b. Low cortisol response to cosyntropin
    c. Elevated basal ACTH
    d. Elevated renin

Answer: d

CHAPTER 21

Hypoglycemia in the Toddler and Child

David R. Langdon, MD • Charles A. Stanley, MD • Mark A. Sperling, MD

CHAPTER OUTLINE

INTRODUCTION

Hypoglycemia is less common than hyperglycemia after early infancy, but it can be caused by a greater variety of problems and conditions and can be especially harmful to a developing brain. As the growing infant goes longer between feedings, a variety of endocrine and metabolic adaptations maintain a steady fuel supply. Depending on inherent severity, congenital defects of these systems can first manifest hypoglycemia later in infancy, and acquired defects can produce hypoglycemia in older children and adults. However, throughout life the many forms of hyperinsulinism are among the most important and dangerous causes. This chapter describes an approach to diagnosis based on identifying which system of endocrine/metabolic adaptation is responsible for the failure to maintain normal fuel homeostasis. Key diagnostic information is often best derived from specimens obtained immediately before reversing hypoglycemia (the so-called critical samples).

Different definitions of hypoglycemia serve different purposes,[1,2] and the effects of specific plasma glucose levels may vary among patients, especially those with previous hypo- and hyperglycemia. As there is no exact correspondence between risk of harm and either severity of symptoms or specific plasma glucose level, hypoglycemia should be treated as an emergency. Defensive hormonal and autonomic responses are triggered at glucose levels between 55 mg/dL and 68 mg/dL,[3-6] and major neuroglycopenic manifestations can occur below 50 mg/dL.[7,8] Thus a plasma glucose level of 55 serves as a reasonable threshold for diagnostic investigation and therapeutic reversal. A plasma glucose concentration between 70 and 100 mg/dL should be the target range for acute and ongoing management of hypoglycemia.

PHYSIOLOGIC DEVELOPMENT OF GLUCOSE METABOLISM DURING INFANCY AND CHILDHOOD

Glucose Utilization and Production

As a meal is digested, glucose is in ample supply, but during postabsorptive fasting, glucose production must match glucose utilization rates that are markedly higher per kilogram of body weight in infants than in adults, due to their larger brain size relative to body weight.[9] Bier and coworkers showed by stable isotope measurements of glucose turnover rates that the brains of infants and children

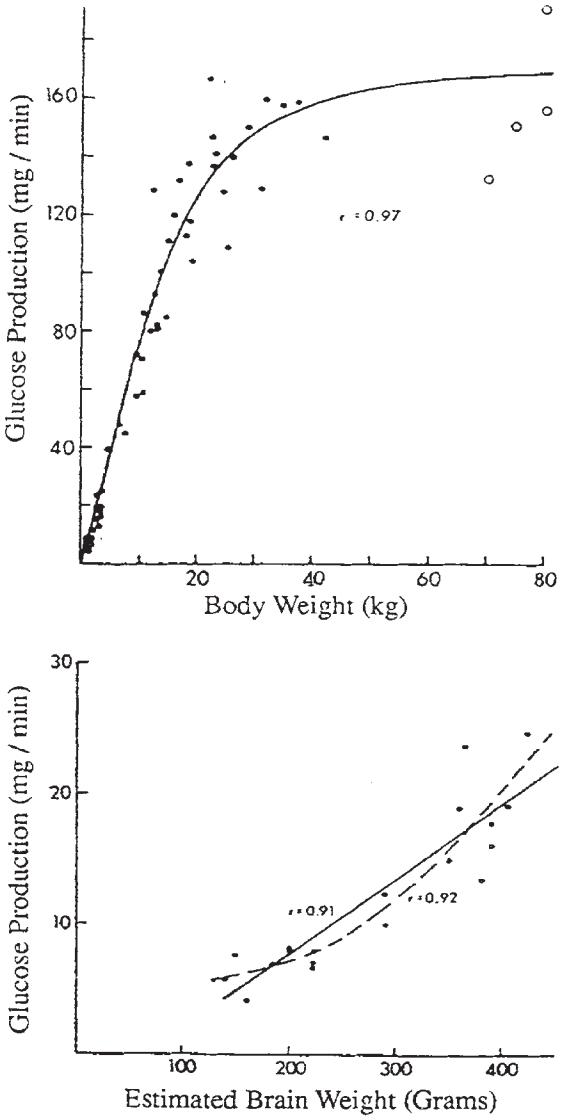

FIGURE 21-1 ■ Glucose production as a function of body weight (top) and estimated brain weight (bottom). Note the change in slope at approximately 40 kg of body weight when brain growth is complete. (From Bier, D. M., Leake, R. D., Haymond, M. W., et al. (1977). Measurement of "true" glucose production rates in infancy and childhood, with 6,6-dideuteroglucose. *Diabetes, 20,* 1016.)

use glucose at rates of 4 to 6 mg/kg/min, equivalent to almost all endogenous glucose production during fasting.[10] (Figure 21-1) The rate of glucose production by the liver is linearly correlated with estimated brain weight at all ages. Muscle amino acids are the principal source of gluconeogenic precursors during fasting, but the substantially smaller muscle mass of infants relative to body mass limits the duration of fasting.[11]

Because brain growth is nearly complete as the body reaches 40 kg at 10 to 12 years of age, little additional glucose production is needed in adolescents and adults, and glucose can be maintained above 70 mg/dL for progressively longer durations. Infants from 1 week to 1 year of age should be able to tolerate 15 to 18 hours of fasting before plasma glucose concentrations fall below 70.[12,13] By 1 year of age, a normal child should be able to fast up to 24 hours.[14-16] By 5 years of age, a fast of up to 36 hours may be tolerated, whereas most adults can maintain fasting glucose above 70 mg/dL for 48 to 72 hours.[17] Hypoglycemia induced by fasting of shorter duration than expected for age should, therefore, alert the clinician to the possibility of an underlying disorder.[18]

Fasting Adaptation to Longer Feeding Intervals

With feeding, plasma insulin concentrations rise from values of 3 to 10 μU/mL to peaks of 20 to 50 μU/mL and stimulate glycogen synthesis, inhibit gluconeogenesis, and enhance peripheral (muscle) glucose uptake (Table 21-1). Simultaneously, triglyceride synthesis is activated and lipolysis and ketogenesis are curtailed. In the postabsorptive state, plasma glucose levels decline, and at an average threshold of 81 mg/dL (4.5 mmol/L) insulin secretion is reduced.[7] Coupled with a rise in counter-regulatory hormones (glucagon and epinephrine) that begins to occur as the glucose reaches 68 mg/dL (3.8 mmol/L) and sympathetic activation at 55 (3 mmol/L), the fall in insulin levels reverses the anabolic pathways to ensure adequate supplies of glucose, fatty acids, and ketones (Box 21-1).[19,20] The fatty acids mobilized from adipose tissue serve as alternative fuels for muscle, including cardiac muscle, thereby sparing glucose for brain metabolism. Glucose utilization is further spared by partial oxidation of fatty acids to ketones in the liver, which are then released to serve as substrate for the brain.[21]

The first phase in the metabolic defense against hypoglycemia is hepatic glycogenolysis (Figure 21-2). In infants, liver glycogen stores may provide glucose for up to 4 hours. As the child grows, glycogen reserves relative to brain glucose utilization are greater and may provide glucose for up to 8 hours of fasting. Glucagon and epinephrine, as insulin levels are suppressed, trigger glycogenolysis. Deficiency of these two hormones is unusual except in children on beta-blocker drugs. Therefore, hypoglycemia occurring early in fasting suggests either excess insulin secretion or a primary disorder in glycogenolysis.

TABLE 21-1 **Hormonal Regulation of Fasting Metabolic Systems**

Hormone	Hepatic Glycogenolysis	Hepatic Gluconeogenesis	Adipose Tissue Lipolysis	Hepatic Ketogenesis
Insulin	Inhibits	Inhibits	Inhibits	Inhibits
Glucagon	Stimulates			Stimulates
Epinephrine	Stimulates	Stimulates	Stimulates	Stimulates
Growth hormone		Stimulates	Stimulates	
Cortisol		Stimulates		

BOX 21-1 Symptoms of Hypoglycemia

Neurogenic Symptoms Due to Activation of Autonomic Nervous System

- Sweating
- Shakiness, trembling
- Tachycardia
- Anxiety, nervousness
- Weakness
- Hunger
- Nausea, vomiting
- Pallor
- Hypothermia

Neuroglycopenic Symptoms Due to Decreased Cerebral Glucose Use

- Headache
- Visual disturbances
- Lethargy, lassitude
- Restlessness, irritability
- Difficulty with speech and thinking, inability to concentrate
- Mental confusion
- Somnolence, stupor, prolonged sleep
- Loss of consciousness, coma
- Hypothermia
- Twitching, convulsions, "epilepsy"
- Bizarre neurologic signs
- Motor disturbances
- Sensory disturbances
- Loss of intellectual ability
- Personality changes
- Bizarre behavior
- Outburst of temper
- Psychological disintegration
- Manic behavior
- Depression
- Psychoses
- Permanent mental or neurologic damage

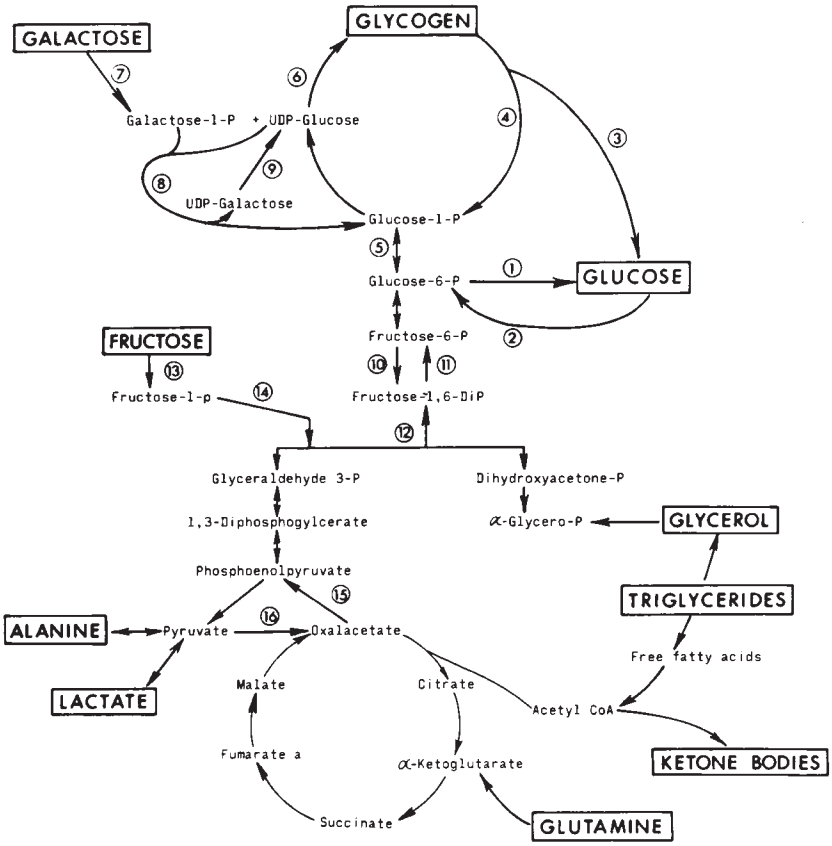

FIGURE 21-2 ■ Contribution of major fasting systems to brain metabolism over time. Key metabolic pathways of intermediary metabolism. Disruption of the elements of these pathways may be pathogenetic in the development of hypoglycemia. Not shown is the hormonal control of these pathways. Indicated are (1) glucose 6-phosphatase, (2) glucokinase, (3) amylo-1,6-glucosidase, (4) phosphorylase, (5) phosphoglucomutase, (6) glycogen synthetase, (7) galactokinase, (8) galactose 1-phosphate uridyl transferase, (9) uridine diphosphogalactose-4-epimerase, (10) phosphofructokinase, (11) fructose 1,6- diphosphatase, (12) fructose 1,6-diphosphate aldolase, (13) fructokinase, (14) fructose 1-phosphate aldolase, (15) phosphoenolpyruvate carboxykinase, and (16) pyruvate carboxylase. UDP, uridine diphosphate. (From Pagliara, A. S., Karl, I. E., Haymond, M., & Kipnis, D. M. (1973). Hypoglycemia in infancy and childhood. *J Pediatr*, *82*, 365–379, 558–577.)

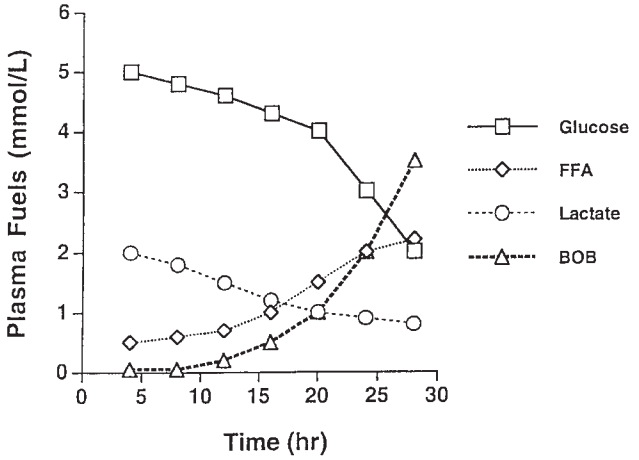

FIGURE 21-3 ■ Changes in major metabolic fuels during fasting in a normal infant. Note that plasma glucose declines toward hypoglycemic values by 24 hours as hepatic glycogen reserves are depleted. The level of lactate, a representative gluconeogenic substrate, declines gradually during the fast. Late in fasting, levels of plasma free fatty acids (FFA) increase as lipolysis is activated—followed by an increase in β-hydroxybutyrate as rates of hepatic fatty acid oxidation and ketogenesis increase.

As glycogen stores become depleted, there is a greater reliance on gluconeogenesis to maintain plasma glucose levels. The main gluconeogenic precursors are amino acids, especially alanine, most of which is generated from skeletal muscle. To prevent excessive breakdown of muscle protein, adipose tissue provides an additional fuel source in the form of triglycerides hydrolyzed to glycerol, which the liver can use for gluconeogenesis, and free fatty acids, which become the major fuel source for the body at later stages of fasting. Mitochondrial fatty acid oxidation (FAO) in the liver produces ketone bodies (β-hydroxybutyrate and acetoacetate) that can be used especially by the brain but also by muscle, including cardiac muscle, for energy production (Figure 21-3). This decreases glucose utilization by these organs and helps ensure an adequate supply of glucose to the brain and to tissues that use only glucose as fuel (e.g., red blood cells). Breakdown of adipose tissue triglycerides (lipolysis) is triggered by secretion of the counter-regulatory hormones (epinephrine and growth hormone [GH]) and by declining levels of insulin. In infants, elevation of plasma ketones begins by 12 to 18 hours into fasting. In older children, ketonemia may not appear until 18 to 24 hours of fasting.[22] Cortisol, produced during stress, can further accelerate gluconeogenesis.

Defects in gluconeogenesis (e.g., fructose-1,6-bisphosphatase deficiency) will usually become manifest only after glycogen stores have been depleted and will thus not occur in the recently fed state. FAO disorders can be triggered by more prolonged fasting. In the first months of life, feeding intervals gradually increase from the typical 2 to 3 hours for the on-demand breastfed infant to 4 hours, and eventually to 8 to 12 hours as nighttime feedings are omitted. For this reason, disorders of gluconeogenesis and FAO rarely present as hypoglycemia in the newborn period when feeding is frequent, but rather later in infancy as fasting is prolonged (or, rarely, immediately after birth before lactation is established). Congenital or acquired deficiencies of the counter-regulatory hormones that facilitate these processes (cortisol and growth hormone) may also result in hypoglycemia—in the newborn period if congenital and severe or later in infancy when longer periods of fasting occur. Combined deficiency of cortisol (adrenocorticotropic hormone [ACTH]) and GH in hypopituitarism may produce earlier onset and more severe hypoglycemia than occurs with isolated hormone deficiencies.

SYMPTOMS, SIGNS, AND EFFECTS OF HYPOGLYCEMIA

Neuroendocrine defenses against hypoglycemia consist of the counter-regulatory hormones that shift metabolic processes toward glucose production and the autonomic responses that provide most of the recognizable symptoms. Counter-regulatory hormones rise as the plasma glucose drops below an average of 68 mg/dL, though the rise of these hormones is not usually clinically detectable nor rapidly measurable (Table 21-2).[5,19,20,23] Of the

TABLE 21-2 **Mean Thresholds of Hypoglycemic Defenses and Effects**

	Plasma Glucose		References
	MG/DL	MMOL/L	
Reduction of insulin secretion	80-85	4.4-4.7	20
Slight slowing of auditory response time	72	4	44
Increased glucagon and epinephrine release	68	3.8	5, 20, 42, 486
Increased cortisol and growth hormone release	60	3.3	5, 20, 42, 486

Obviously impaired cognitive function	49	2.7	5, 486
Reduced level of consciousness, seizures	30-40	1.7-2.2	7
Neuronal death and brain damage	< 18	< 1	7

counter-regulatory hormones, glucagon and epinephrine exert the largest immediate effects on glucose metabolism cortisol and growth hormone effects are slower, and the many other hormones (e.g., prolactin, vasopressin) that rise in response to hypoglycemia are less important still. Control of the counter-regulatory responses is at least partially local, with intra-islet control of glucagon release by release of insulin suppression, and multiple effects on glucose metabolism and eating behavior are influenced by glucose sensing in the portal vein.[24-26] However, the primary site of glucose sensing and response is in the ventromedial nucleus of the hypothalamus.[27]

Clinically recognizable signs and symptoms of hypoglycemia occur at slightly lower plasma glucose levels and most fall into one of two categories: autonomic or neuroglycopenic (see Box 21-1). Autonomic manifestations resulting from activation of the sympathetic nervous system, typically at a plasma glucose threshold of 55 mg/dL (3 mmo/L), provide the most recognizable signal to a person that glucose is falling and food is needed.[7,28] Adrenergic symptoms such as tachycardia, tremor, and anxiety are produced both by local sympathetic neural effects and by the peripheral effects of epinephrine released from the adrenals. Cholinergic symptoms include sweating, hunger, and paresthesias.[28] Hypothermia often occurs with prolonged hypoglycemia in older children and adults; evidence suggests a neurogenic mechanism.[29,30]

The trigger for counter-regulatory responses is the plasma glucose level itself. The rate of glucose fall and the level of insulin have little effect.[5,31] Activation thresholds for these neuroendocrine responses (both the counter-regulatory hormones and sympathetic activation) have been best established for healthy young adults and vary only slightly by sex,[32] age,[33] exercise,[34] sleep,[35] and nutritional status (Figure 21-4).[36] Certain drugs can dampen (e.g., beta-blockers) or amplify (e.g., caffeine) the responses.[37]

The most clinically important alterations of neuroendocrine response thresholds result from prior hypo- and hyperglycemia. Even a single episode of moderately severe hypoglycemia can blunt or lower the activation thresholds for 24 hours or more.[38-40] Prolonged or recurrent hypoglycemia can so reduce the autonomic responses (termed *hypoglycemia-associated autonomic failure* [HAAF]) that neuroglycopenic effects may be the sole clinical manifestation of severe hypoglycemia.[41] The effect can be demonstrated not just in adults and children with diabetes but also in nondiabetic adults and in infants with recurrent hypoglycemia due to hyperinsulinism.[40] Conversely, chronic hyperglycemia is associated with higher glucose thresholds for counter-regulatory responses.[42,43]

Neuroglycopenic effects become progressively more severe as glucose deprivation affects brain function. For the affected person, neuroglycopenic effects are less recognizable than the autonomic symptoms and are better characterized as a continuum of increasing impairment than a single "threshold." However, prior hypoglycemia does not lower the threshold levels for the objectively measurable neuroglycopenic effects.[20] A plasma glucose decline from 87 to 72 mg/dL increases the latency of

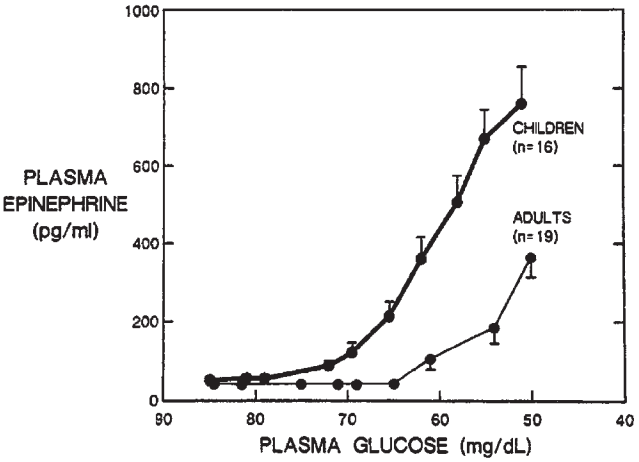

FIGURE 21-4 ■ Plasma epinephrine response of children and adults to step decreases in blood glucose concentration during a hyperinsulinemic clamp procedure. Note that the increase in epinephrine concentration occurs at a significantly higher glucose concentration in children than in adults. In addition, at comparable glycemia of less than 60 mg/dL, epinephrine responses in children are approximately threefold higher than in adults. (From Jones, T. W., Borg, W. P., Boulware, S. D., et al. (1995). Enhanced adrenomedullary response and increased susceptibility to neuroglycopenia: mechanisms underlying the adverse effects of sugar ingestion in healthy children. *J Pediatr, 126,* 171.)

P300 waves, an auditory event-related potential said to be a sensitive and specific test of cognitive function that occurs at glucose levels above the neurogenic symptom threshold.[44] Subclinical epileptiform electroencephalographic changes occur in most children at glucose levels approaching 55 mg/dL (3.1 mmol/L).[45] More obvious cognitive effects, such as slower response times and impaired judgment, occur at an average threshold of 49 mg/dL (2.7 mmol/L).[7,46,47] At even mildly lower plasma glucose levels, lethargy or confusion become evident, followed by seizures and coma. In infants and young children, neuroglycopenic manifestations may involve twitching, poor feeding, irritability, high-pitched crying, or even vomiting.[48] With prolonged hypoglycemia in older children and adults, bizarre, uncharacteristic, or "automatic" behavior (including physical aggression or, rarely, criminal offenses) can occur.[49-51] All of these cognitive, behavioral, and consciousness effects are typically completely reversed when the glucose level is raised, though subtle neuropsychological impairment may be measurable days later.[52]

More severe and prolonged glucose deprivation produces brain damage from neuronal death.[7,53,54] In experiments with primates, 5 to 6 hours of glucose levels below 20 mg/dL (1.1 mmol/L) reliably produced severe damage.[7] Severe hypoglycemia causes characteristic pathologic changes in cortical tissue and white matter, though the cerebellum and brainstem are usually spared.[55] Magnetic resonance imaging changes characteristic of hypoglycemic damage can be seen in both infants and adults.[56,57] Permanent cognitive impairment is measurable in many children and adults with a history of recurrent, severe hypoglycemia.[58-62]

Facilitated glucose transport across the blood-brain barrier, mediated by the glucose transporter-1, is dependent on the arterial plasma glucose concentration and

independent of insulin. Reduction of neurogenic symptoms with repeated hypoglycemia does not depend on increased glucose transport.[63] The conditions in which ketones or lactate can be used as alternate fuels during hypoglycemia are uncertain, but the ability to replace glucose is limited.[64-67] A final intracerebral defense during hypoglycemia is afforded by small stores of astrocyte glycogen that can be converted to lactate and may provide up to 20 minutes of fuel support for neuronal function.[68,69]

Other signs and symptoms of hypoglycemia are not as clearly related to the counter-regulatory or neurogenic defenses, or to the neuroglycopenic effects. The younger the child, the more nonspecific the manifestations may be, including cyanosis, bradycardia, apnea, and apparent respiratory distress.[48,70]

DEFINITION OF HYPOGLYCEMIA

A clinically useful definition of hypoglycemia cannot be based simply on a single value of plasma glucose concentration.[1,71] For children and adults, hypoglycemia is best defined as a plasma glucose concentration low enough to elicit defensive neuroendocrine responses or to impair brain function. Counter-regulatory hormones rise at an average threshold of 68 mg/dL, and autonomic effects and the most recognizable symptoms of hypoglycemia occur at an average threshold of 55, but, as noted previously, these responses can be blunted or the thresholds shifted by prior hypo- and hyperglycemia. Brain function is slightly affected at plasma glucose levels as high as 70, and more clearly at an average threshold of 49 but these effects may be less obvious in young children.

The Endocrine Society has developed guidelines for the evaluation and management of adult hypoglycemia, which emphasize the value of Whipple's triad for confirming hypoglycemia in adults: (1) symptoms or signs of hypoglycemia occurring with (2) a low measured blood glucose and (3) resolving when glucose is raised.[71] Although this is also a useful approach for older children, Whipple's triad may be less applicable to infants and young children, in whom the observable effects of hypoglycemia can be less specific, who are too young to report symptoms, and for whom establishing a threshold definition of hypoglycemia has been difficult.[72-75] Despite the frequency with which hypoglycemia is not accompanied by obvious symptoms in infants, evidence of harm to the brain from prolonged or recurrent hypoglycemia suggests the same clinical thresholds and treatment goals are applicable to young and old alike.

For the purposes of this chapter and for clinical practice, two hypoglycemia thresholds are used: a level sufficiently low for obtaining diagnostic tests and a level that is the goal for treatment. For diagnostic purposes, a plasma glucose value of less than 55 mg/dL (3 mmol/L) is sufficiently low for obtaining samples for determining the etiology of the hypoglycemia and for terminating provocative tests. In contrast, the lower limit of the plasma glucose range for therapeutic purposes should be 70 mg/dL (3.9 mmol/L), which is also the lower end of the "target range" for therapy in diabetic patients. Setting $\geq$ 70 mg/dL as the therapeutic goal is especially important to avoid periods of low glucose that may blunt the neuroendocrine and symptomatic responses to hypoglycemia and lead to greater susceptibility to subsequent episodes of hypoglycemia.

Plasma glucose values must be interpreted with an awareness of numerous physiologic, technical, and artifactual sources of variation. Because whole-blood glucose levels are 10% to 15% less than plasma concentrations, it is preferable to consistently refer to plasma glucose concentrations.[76] As blood from large veins will have lower glucose values than simultaneous blood from arteries, especially postprandially, it is important of refer to arterialized venous plasma glucose concentrations as the standard.[77] When blood is drawn but not immediately separated, glucose levels decline due to red cell glycolysis; this is a common cause of artifactually low glucose levels reported in metabolic panels run by commercial labs.[78] Glucose meters originally designed for diabetes management are useful for screening purposes, but none of the currently available meters is sufficiently accurate for a diagnosis of hypoglycemia without laboratory corroboration.[79] Any meter plasma glucose level $<$ 60 mg/dL should be confirmed by an accurate laboratory determination of plasma glucose.[80]

MAJOR CAUSES OF HYPOGLYCEMIA IN THE INFANT, CHILD, AND YOUNG ADULT

Hyperinsulinism

Hyperinsulinism is the most common and the most severe form of hypoglycemia in infancy.[81-83] The hypoglycemia of hyperinsulinism is particularly dangerous to the brain because it is associated with inadequate amounts of all brain fuels (low plasma ketones and glucose).[62] Although 60% of patients with congenital hyperinsulinism present in the first week of life, milder forms continue to be a significant cause of hypoglycemia throughout infancy and later. Despite a lengthening list of known genetic causes of congenital hyperinsulinism, many infants have forms for which the underlying mechanism remains unknown.[84,85]

Congenital hyperinsulinism often becomes evident after the first months of life, when the feeding intervals lengthen and night feedings are omitted. Such infants may present with early morning seizures or lethargy. Many will have a history of hypoglycemia in the newborn period that was not fully appreciated or will have a history of previous seizures.[86] Some of these children may have previously unexplained developmental delay. In dominant forms of hyperinsulinism, a parent or other relative may report a more subtle history of hypoglycemia.[87] Defects of adenosine triphosphate (ATP)-sensitive potassium channel (KATP channel) are the most common form of congenital hyperinsulinism, but a growing number of other defects in insulin secretion are being identified. As outlined in Chapter 5, all of the genetic causes of hyperinsulinism may initially present in the older infant and child.[88-90]

Hypoglycemia due to hyperinsulinism after the neonatal period is likely to present as recurrent episodes of neuroglycopenic symptoms in an otherwise well child. The hypoglycemia may be mild or severe, occurring after overnight fasting or in a "reactive" pattern 2 to 3 hours

after a meal. Obvious adrenergic signs (pallor, perspiration) are common but not invariably present; seizures are frequent. The diagnosis of hyperinsulinism is suggested when hypoglycemia is accompanied by the absence of hyperketonemia and injection of glucagon is followed by a large increase in plasma glucose. A critical specimen obtained during hypoglycemia that demonstrates measurable amounts of insulin, C peptide, or proinsulin (Table 21-3) can be conclusive. However, it is not always easy to demonstrate elevated insulin levels.[91]

Standard insulin assays may not detect exogenous insulin analogs such as lispro, aspart, glargine, glulisine, and detemir.[92] Plasma free fatty acids and beta-hydroxybutyrate (βOHB) are inappropriately low during hypoglycemia due to hyperinsulinism, as is insulin-like growth-factor-binding protein-1 (IGFBP1).[93] A glycemic response to glucagon at the time of hypoglycemia is strong evidence of hyperinsulinism as well.[12,94,95] Because of the increased glucose utilization of hyperinsulinism, a glucose infusion rate above 8 mg/kg/min may be needed to maintain glucose above 70 mg/dL in young infants. However, this is usually more difficult to demonstrate or is inconsistently present in older children.

KATP Channel Hyperinsulinism

Two genes, SUR1 and Kir6.2, encode the two subunits of the adenosine triphosphate KATP channel in the plasma membrane of the beta cell. Potassium efflux through this channel hyperpolarizes the beta cell plasma membrane and is a key negative regulator of insulin secretion; defects that impede potassium efflux or inhibit KATP channel activity cause excessive insulin secretion. As described in Chapter 5, three distinct defects of these genes are known to cause hyperinsulinism:

- Autosomal-recessive inheritance of two KATP mutations produces a severe neonatal onset of disease that is unresponsive to diazoxide. These mutations are associated with diffuse histologic changes in the pancreatic islets.[96]
- A clone of beta cells possessing a single recessive mutation on the paternal chromosome may lose the normal maternal allele, resulting in homozygosity for a recessive KATP channel mutation.[89] This "two-hit defect" produces a focal area of adenomatosis in the pancreas.
- Rarer, dominantly inherited autosomal mutations usually cause a milder form of KATP hyperinsulinism that often presents after infancy and responds to diazoxide. Dominant KATP mutations that produce severe, diazoxide-unresponsive disease have also been reported.[97,98]

The diffuse and focal forms of KATP hyperinsulinism account for more than 90% of cases of congenital hyperinsulinism in infancy and are similar in their clinical manifestations. Both may require surgery to maintain safe glucose levels. After confirmation of hyperinsulinemic hypoglycemia by the criteria presented in Table 21-3 and exclusion of the more rare forms described in the following discussion, a KATP channel defect can be presumed the most likely diagnosis. While blood is being tested for specific mutations (e.g., www.genetests.org), management may proceed without molecular confirmation. Treatment measures able to maintain blood glucose levels above 70 mg/dL without surgery are referred to as "medical management" (Table 21-4).

Diazoxide (5 to 15 mg/kg/day) is the first-line drug, but it is often ineffective for KATP hyperinsulinism. Octreotide may be given by subcutaneous injection or infusion at 15 to 20 μg/kg/day.[99] Calcium channel blockers have occasionally been tried but are generally not considered effective.[100] If medical management does not maintain the plasma glucose concentration > 70 mg/dL with a normal feeding schedule, surgery may be necessary.

TABLE 21-3 **Fasting Test Results Consistent with Insulinoma**

	Normal	Indicative of Hyperinsulinism	Typical of Insulinoma
Time to glucose nadir, hours	> 48	< 48	2-48
Glucose, mmol/L	> 2.2	< 2.5	1.4-3
Glucose, mg/dL	> 40	< 45	25-55
Insulin, pmol/L	< 18	> 18	6-200
Insulin, μU/mL	< 2.5	> 2.5	3-42
Proinsulin, pmol/L	< 5	> 5	10-800
Proinsulin, ng/mL	< 0.2	> 0.2	0.1-9
C-peptide, nmol/L	< 0.2	> 0.2	0.2-1.8
C-peptide, ng/mL	< 1	> 1	1-9
βOHB, mmol/L	> 2.7	< 2.7	< 2
Glucose peak after glucagon	< 1.4 < 25	> 1.4 > 25	1.5-5.4 27-90

Values are compiled from several large series of mostly adult patients.[193,195,198,488] Levels were obtained at time of symptomatic hypoglycemia or when glucose fell below 2.5. Levels for normal patients are at the end of a 48- or 72-hour fast. In each series, up to 3% of patients were 12 to 20 years old, though fasting longer than 24 hours is rarely necessary for the diagnosis of hypoglycemia in children. Normal ranges are somewhat assay specific and not precisely arithmetically convertible. In each series, a few patients in each category fell outside these ranges for single parameters, so diagnoses should not be based on single values near the edges of expected ranges.

TABLE 21-4 **Disorders of Glycogen Storage Causing Hypoglycemia**

GSD		Protein	Gene	Inheritance	Relative Incidence	Fasting Hypoglycemia
0	Glycogen synthase deficiency	Glycogen synthase	*GYS2* on 12p12.2	AR	U	Usually mild
Ia	von Gierke disease	Glucose 6-phosphatase	*G6PC* on 17q21	AR	C	Universal, severe
Ib		Glucose 6-phosphate translocase	*SLC37A4* on 11q23	AR	R	Universal, severe
IIIa	Cori or Forbes disease, debrancher deficiency, limit dextrinosis	Amylo-1,6-glucosidase in liver and muscle	*AGL* on 1p21	AR	C	Mild to moderate
IIIb	Cori or Forbes disease, debrancher deficiency, limit dextrinosis	Amylo-1,6-glucosidase in liver	*AGL* on 1p21	AR	R	Mild to moderate
IV	Andersen disease, amylopectinosis	Branching enzyme	*GBE* on 3p12.2	AR	U	With advanced liver failure
VI	Hers disease	Glycogen phosphorylase	*PYGL* on 14q22.2	AR	U	Mild
IXa	Hug or Huijing disease	α subunit of phos b kinase	*PHKA2* on Xp22.13	XL	C	Mild to moderate
IXb		β subunit of phos b kinase	*PHKB* on 16q12.1	AR	R	Mild to moderate
IXc		γ subunit of phos b kinase	*PHKG2* on 16p11.2	AR	R	Mild
XI	Fanconi-Bickel disease	Glucose transporter 2	*GLUT2* on 3q26.2	AR	R	Mild

GSD, glycogen storage disease; AR, autosomal recessive; XL, X-linked. Relative incidence compared to other GSDs: C, common; U, uncommon; R, rare.

Surgical treatment for focal KATP hyperinsulinism is curative, whereas for diffuse disease even a 95% to 99% pancreatectomy may not cure the hypoglycemia (and diabetes is a frequent sequela).[95] ^{18}F-DOPA PET scanning may localize a focal lesion preoperatively, but definitive differentiation of focal and diffuse disease is made intraoperatively by repeated examination of frozen sections.[94] This difficult procedure requires a patient surgeon and a dedicated team of histopathologists.[101-103]

Glutamate Dehydrogenase Hyperinsulinism

Hyperinsulinism can also be caused by activating mutations in the gene (GLUD1 on 10q) for glutamate dehydrogenase (GDH).[90] This disorder, also known as the hyperinsulinism-hyperammonemia syndrome, is a milder form of hyperinsulinism than KATP hyperinsulinism and is more likely to present in late infancy and early childhood than in the newborn period.[104,105] Mutations in GDH cause disease in an autosomal-dominant fashion, but up to 80% cases may be de novo mutations. Severity may vary within a family from seizures in infancy to mild postprandial hypoglycemia in adults. Ingestion of protein without carbohydrate may be especially likely to depress the blood glucose.

Activating mutations of GDH in the beta cell amplify leucine-triggered production of ATP, independent of glucose levels, which then causes closure of KATP channels and insulin release. In the kidney, the same mutation increases oxidation of glutamate to α-ketoglutarate with the production of ammonia. In addition to increased renal ammonia production, the low levels of glutamate in the liver may impair the production of N-acetylglutamate, an important allosteric activator of the urea cycle. Thus, the same mutation causes excessive insulin production in the pancreas, excessive ammonia production by the kidneys, and, possibly, impaired urea synthesis in the liver.[106]

The diagnosis of GDH hyperinsulinism is similar to that of other forms of hyperinsulinism. In addition to the usual laboratory findings of hyperinsulinism, however, persistently elevated ammonia levels (typically 80 to 120 μmol/L) are diagnostic of this disorder.[107] Most patients respond to diazoxide, and surgery is never necessary.[104,108] High ammonia levels do not appear to cause problems in GDH hyperinsulinism because the hyperammonemia is not associated with elevated neuronal glutamine, the substance thought to be principally responsible for the central nervous system (CNS) toxicity evident with other forms of hyperammonemia.[109]

Glucokinase Hyperinsulinism

Glucokinase is the enzyme that serves as the glucose sensor in the beta cells of the pancreas.[110] Gain-of-function mutations can result in a lower glucose threshold for insulin secretion, leading to persistent hypoglycemia, just as loss-of-function mutations produce a higher glucose secretion threshold, causing a common form of mild monogenic diabetes (MODY2).[111] At least 15 different dominantly expressed mutations have been reported.[112] Enzyme activities, glucose thresholds, and clinical severity of these mutations can vary. The more severe mutations tend to be de novo rather than inherited. The in vitro enzyme kinetics of each mutation is of limited value for predicting clinical severity and course.[112]

In some cases, glucokinase mutations have produced neonatal hypoglycemia severe enough to require pancreatic surgery to stabilize glucose levels. Other cases have presented as hypoglycemic seizures in childhood or even reactive hypoglycemia in older relatives. Like the KATP forms of hyperinsulinism, glucokinase mutations can cause apparently transient neonatal hypoglycemia that becomes asymptomatic for many years, only to recur later in life.[113,114] In some cases, older relatives with the same mutations have had milder degrees of severity.[115]

Glucokinase hyperinsulinism (GCK-HI) presents some challenges to diagnosis: when glucose falls below the insulin secretion threshold, free fatty acids and βOHB can rise. In the two GCK-HI patients in whom it was tested, the acute insulin response to intravenous glucose was greater than is usually seen with KATP hyperinsulinism.[86] Ammonia levels are normal, and GCK-HI patients do not have protein-sensitive hypoglycemia. The response to diazoxide has been partial in most patients. Severe cases could not be controlled on diazoxide and required pancreatectomy.[116]

SCHAD (or HADH) Hyperinsulinism

Short chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD or HADH) is an enzyme of mitochondrial fatty acid oxidation that catalyzes oxidation of straight-chain 3-hydroxyacyl-CoAs, and is involved in multipathway complexes with other enzymes in several tissues.[117] Pancreatic beta cells have relatively high levels of SCHAD activity, where it is associated with, and helps negatively regulate, GDH, the enzyme of hyperammonemic hyperinsulinism.[118] Homozygous mutations of the *HADH* gene on chromosome 4 at q22-26 lead to an absence of SCHAD protein, deficient enzyme activity, an elevation of plasma short chain acyl-carnitine metabolites, and an autosomal recessive form of congenital hyperinsulinism.[119]

More than 20 patients, of at least 8 kindreds and with 12 different *HADH* mutations, have been reported with varying degrees of hyperinsulinemic hypoglycemia.[120] Studies of the mouse model of SCHAD-HI suggest that a deficiency of HADH allows amplified activity of glutamate dehydrogenase (GDH), the same enzyme involved in hyperammonemic hyperinsulinism.[118] Some cases have displayed severe hypoglycemia as newborn infants, but some showed no signs of hypoglycemia until several months of age.[121,122] HADH hyperinsulinism resembles other forms of hyperinsulinism, with elevated insulin levels during hypoketotic hypoglycemia. Elevated levels of 3-hydroxybutyryl-carnitine in plasma and 3-hydroxyglutarate in urine have suggested the diagnosis in some patients. Affected patients share some features of hyperammonemic hyperinsulinism, such as a marked sensitivity to protein-induced hypoglycemia, but without the hyperammonemia characteristic of GDH-HI. Unlike other fatty acid oxidation disorders, muscle and liver function have not been clinically affected. Hypoglycemia has been severe enough in some patients to cause brain damage, but treatment with diazoxide was effective in all cases so far described.[120,123,124]

The oldest patient with HADH hypoglycemia was originally reported in 1977 as an instance of glucagon deficiency, in part because of a brisk rise of glucose after glucagon was given. This case was cited as an example of glucagon deficiency for years, before it was recognized that a glycemic response to glucagon was a characteristic feature of hyperinsulinemic hypoglycemia.[125] Reinvestigation of the proband and other family members discovered the *HADH* mutation.[126,127] Although this condition is usually (maybe irreversibly) referred to as a SCHAD deficiency in the endocrine literature, this nomenclature has been criticized as misleading, as another enzyme—a member of the short chain dehydrogenase/reductase superfamily with a role in brain development and perhaps Alzheimer and Parkinson diseases—has been officially and more accurately termed short chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD) for years.[128]

HNF4A Hyperinsulinism

Hepatocyte nuclear factor 4α is a transcription factor important for pancreatic beta cell development and insulin secretion. Heterozygous inactivating mutations of the HNF4A gene are a well-recognized cause of monogenic diabetes (MODY1). Recently it was recognized that these mutations also cause excessive insulin secretion in early life, manifested by fetal macrosomia and persistent neonatal hypoglycemia. Although the diazoxide-responsive hyperinsulinemic hypoglycemia is usually transient, it may persist for several years into childhood.[129] In most cases of HNF4A, the birthweight has been above average, hypoglycemia occurred in the first days of life, and a parent has had a history of monogenic diabetes.[130,131] In one case, diazoxide-responsive hyperinsulinism was recognized on the first day of life, but the infant also developed hepatomegaly and renal Fanconi syndrome in the first year, suggesting that expression of the GLUT2 transporter was impaired by the defect in HNF4A.[132]

HNF1A Hyperinsulinism

Hepatocyte nuclear factor 1 is another transcription factor important for beta cell development. Mutations can cause a common form of monogenic diabetes known as MODY 3. Two cases of mutations causing transient, diazoxide-responsive hyperinsulinemic hypoglycemia presenting at 3 and 20 months of age have been described. In both cases, the specific mutations have been reported in older patients with MODY3 and were inherited from the fathers.[132]

Exercise-Induced Hyperinsulinemic Hypoglycemia

A small number of children (infants to adolescents) have had hypoglycemic seizures or syncope after intense anaerobic exercise such as soccer or swimming.[133] So far, 13 patients belonging to three families have been found with exercise-induced hyperinsulinemic hypoglycemia (EIHI).[134] Clinical presentations have varied, with some having severe hypoglycemic episodes from infancy, some presenting with hypoglycemic syncope after exercise as adolescents, and some only mildly affected as adults. Lab tests in severe episodes have indicated hyperinsulinism, with low ketones

and free fatty acids, and inappropriately measurable insulin.[134] Most patients with EIHI maintained normal glucoses during prolonged fasting. Provocative testing with brief, intense bicycle exercise induced the normal rise in plasma lactate and pyruvate levels, but affected patients' insulin levels rose markedly for about 10 minutes after the exercise, causing hypoglycemia within the next 45 minutes.[135] Intravenous infusion of 300 mmol pyruvate over 3 minutes produced a fivefold elevation of insulin within 3 minutes in patients with EIHI and has been proposed as an alternative diagnostic test. Recurrent hypoglycemia of those more severely affected was only partially preventable with diazoxide treatment.

Excessive insulin secretion in EIHI occurs because the beta cells express abnormal amounts of the MCT1 monocarboxylate transporter due to a mutation of the gene (*SLC16A1*) that normally prevents expression on beta cells. Although pyruvate makes an excellent substrate for ATP production, normal beta cells do not have the MCT1 transporter and hence remain unaffected by high postexercise levels of lactate and pyruvate. EIHI is inherited as an autosomal dominant condition in three of the affected families.[134,136]

This mechanism seems confirmed by the report of a 16-year-old boy with an insulinoma characterized by expression of MCT1 and hyperinsulinemic hypoglycemia induced by exercise and cured by resection of the insulinoma.[137]

Carbohydrate-Deficient Glycoprotein Hyperinsulinism

Congenital disorders of glycosylation (CDG) are caused by deficient glycosylation of proteins or lipids.[138] Many CDGs are known and more are being identified each year. Whole exome sequencing is allowing rapid identification of responsible genes,[139] and a newer gene-based nomenclature system is replacing an older categorization based on transferrin isoelectrofocusing patterns.[140] Hypoglycemia due to hyperinsulinism has been reported in children with three of the earliest identified defects of N-glycosylation: CDG Ia, Ib, and Id (OMIM IDs: 601785, 602579, and 601110). The initial confirmatory test for all of these forms of CDG is abnormal isoelectric focusing of transferrin.

Most cases of CDG hyperinsulinism have been identified in the newborn period, but many have been diagnosed later in infancy or early childhood. CDG hyperinsulinism is usually accompanied by manifestations affecting other organ systems—especially the brain, liver, gut, and skeleton—but cases of all three types have been reported in which hyperinsulinemic hypoglycemia was the presenting or dominant problem.[141-143] The mechanism of excessive insulin production has not been determined.

PMM2-CDG (CDG-Ia) is the most common type of CDG and involves deficient activity of phosphomannomutase 2 resulting from mutations of *PMM2*. Many organ systems can be variably affected.[144] Most patients have severe developmental delay, cerebellar hypoplasia, hypotonia, and seizures. Protein-losing enteropathy and liver disease contribute to failure to thrive. Deficient levels of antithrombin III can cause thromboses. Dysmorphic features can be subtle or obvious, including unusual fat distribution and inverted nipples. Hyperinsulinemic hypoglycemia occurs in only a minority of patients but can be mild or severe enough to warrant pancreatectomy.[141,145]

MPI-CDG (CDG-Ib) involves deficient activity of phosphomannose isomerase resulting from mutations of *MPI*. Although the sialotransferrin pattern resembles that of PMM2-CDG, the central nervous system is spared, and hyperinsulinemic hypoglycemia is a common feature, presenting in the first days of life or later in the first year.[142,146] Hepatic disease and protein-losing enteropathy are usually the dominant clinical problems.[147] Some children have had cyclic vomiting. Clinical severity is variable, and mildly affected adults have been diagnosed. Oral mannose in doses of up to 150 mg/kg/day correct most of the clinical abnormalities, making MPI-CDG the only CGD with a specific treatment.[148]

ALD3-CDG (CDG-Id) involves deficient activity of mannosyltransferase 6 resulting from mutations of *ALD3*. Clinical features resemble those of PMM2-CDG, with severe central nervous system damage. One case with severe neonatal hyperinsulinemic hypoglycemia has been reported; modest beta cell hypertrophy was observed at autopsy.

Uncoupling Protein 2 Hyperinsulinism

Uncoupling protein 2 plays a role in the modulation of oxidative metabolism in mitochondria. Increased UCP2 activity reduces ATP generation. A loss-of-function mutation of *UCP2* has been found to cause enhanced ATP generation and consequently amplified insulin secretion severe enough to cause hyperinsulinemic hypoglycemia. Of the two initial cases, one had developed hypoglycemia shortly after birth, but the other presented with a hypoglycemic seizure at 8 months of age.[149,150] Both cases responded to treatment with diazoxide.

Hyperinsulinism in Tyrosinemia

Hyperinsulinemic hypoglycemia occurs in many infants and young children with type 1 (hepatorenal) tyrosinemia due to deficient fumarylacetoacetate hydrolase activity (OMIM ID: 276700).[151] Problems may include acute liver failure, cirrhosis, hepatomegaly, glomerulosclerosis, renal Fanconi syndrome with rickets, and acute crises with painful neuropathy. Most expanded newborn screening programs detect tyrosinemia. Plasma amino acid screening reveals markedly elevated tyrosine, and urine organic acid screening contains increased succinylacetone. Current treatment options include liver transplant or NTBC [2-(2-Nitro-4-Trifluoromethylbenzoyl)-1,3-Cyclohexanedione]. The mechanism of excessive insulin secretion is not known, but beta cell hyperplasia has been seen in the pancreas. Some infants have been born with macrosomia and cardiac hypertrophy suggestive of fetal insulin excess. Hypoglycemia can be severe enough to threaten the brain, but it responds to diazoxide and improves with age.[152]

AKT2 Hypoglycemia

Hypoglycemia with the characteristics of hyperinsulinism (except excessive insulin secretion) could be expected

to result from excessive activity of insulin receptors or amplification of postreceptor signals. Among the major effects of insulin receptor activation is amplification of intracellular AKT serine/threonine kinase activity; loss of AKT kinase activity produces insulin resistance. Three children with hypoglycemia due to gain of function mutations of AKT2 have been described.[153] Beginning around 6 months of age, all had episodes of severe, symptomatic hypoketotic hypoglycemia characterized by low levels of insulin, proinsulin, and free fatty acids. Other clinical features included large birth weight and postnatal left-sided overgrowth of body or face. The three patients were unrelated and each had the same de novo mutation of *AKT2*. The mutations were postzygotic and mosaic, which probably explains the localized nature of the overgrowth.

Hyperinsulinemic Hypoglycemia Associated with Insulin Resistance

Hypoglycemia accompanying insulin resistance might seem paradoxical, but several forms occur. Insulin resistance can result from defects of the insulin receptor, of downstream signaling, or secondary effects. Recessive mutations of the insulin receptor gene *INSR* at 19p13.2 produce three of the most severe forms of insulin resistance known: Donohue syndrome (OMIM ID: 246200), Rabson-Mendenhall syndrome (OMIM ID: 262190), and type A insulin resistance (OMIM ID: 610549).[154] Clinical features and specific mutations distinguish the three syndromes. Insulin secretion and insulin levels are increased manyfold, and the beta cells are often hyperplastic. Hypoglycemia can occur with all three by mechanisms not entirely understood. Chronic beta cell insulin overproduction may impair the ability to reduce secretion when glucose is falling or may be associated with reduced clearance of circulating insulin.

Infants with Donohue syndrome are diagnosable in the newborn period and most die of infection in the first years of life. Features include intrauterine growth retardation, diminished subcutaneous fat, an unusual face ("leprechaunism"), enlargement of breasts or clitoris, hirsutism, acanthosis, and postprandial hyperglycemia. Hypoglycemia after a few hours of fasting typically begins in the first days after birth and persists throughout life. Despite high insulin levels, and unlike most forms of hyperinsulinemic hypoglycemia, some of the best-studied infants have demonstrated shortened fasting tolerance and accelerated ketosis suggestive of inadequate glycogen stores.[155] Frequent feedings have been the mainstay of management, but diazoxide has been tried in some with variable responses.[156,157]

Children with Rabson-Mendenhall syndrome lack the extreme lipodystrophy and dysmorphic features of Donohue syndrome and typically develop severe, insulin-resistant diabetes mellitus.[158] Additional features of the originally described syndrome include abnormal teeth and skin, hypertrichosis, acanthosis, and pineal hyperplasia. Many have been reported to have hypoglycemia, but more often reactive than fasting. Death in childhood from diabetic ketoacidosis is common.

Postprandial (reactive) hypoglycemia has also been reported in adolescents with type A insulin resistance (acanthosis, polycystic ovary syndrome), in which diabetes mellitus develops more gradually, sometimes as the adolescent reaches adulthood.[154] One unusual familial mutation of the insulin receptor has been described with episodes of postprandial hypoglycemia severe enough to cause seizures, attributed to slower insulin clearance.[159]

Reactive hypoglycemia has also been reported in insulin-resistant conditions due to post-receptor disorders.[160]

Factitious Hyperinsulinism

Instances of factitious hyperinsulinism have been reported in infants and children, typically the result of a caregiver administering insulin or an insulin secretogogue.[161] This is a form of child abuse referred to as Munchausen by proxy or Meadow syndrome.[162] In most reported cases, the parent was a nurse or other medical professional—or family members used insulin or sulfonylureas for diabetes.[162-165] This type of child abuse may be lethal.[166]

Insulin administration may be difficult to detect, particularly because conventional insulin assays vary as to sensitivity for insulin analogues (lispro, aspart, glargine, glulisine, detemir, degludec).[92,167,168] Typically, classic symptoms of hyperinsulinism are present on an irregular basis. Fasting studies in the absence of the caregivers will be normal. As in other forms of excessive insulin, hypoglycemia is accompanied by a suppression of free fatty acids, ketones, and a positive response to glucagon—indicating that glycogen deposits are abundant and their release inhibited by insulin.

In cases in which regular or NPH insulin have been given, insulin levels may be remarkably high at the times of hypoglycemia. The most conclusive evidence of exogenous insulin is the suppression of C peptide to undetectable levels at the time other evidence indicates insulin excess, indicating that endogenous insulin production has been suppressed.[169] Insulinomas may secrete high insulin levels, but proinsulin levels will also be persistently elevated.[170]

Oral hypoglycemic agents that induce insulin secretion, especially sulfonylureas, will cause elevation of both insulin and C peptide.[171-173] Many cases of hypoglycemia occurring or persisting up to 24 hours after single-dose ingestions of sulfonylureas in toddlers and adolescents have been reported.[174,175] Because they induce endogenous insulin secretion, its use is difficult to detect unless suspected because the age suggests ingestion. Routine toxicology screens on blood and urine may not detect sulfonylureas, but if a sample of the suspected drug can be supplied, specific testing can be arranged. Recovery with intravenous glucose support is usual; diazoxide and octreotide have been used in severe cases.

Autoimmune Hypoglycemia

Three types of autoimmune hypoglycemia have been reported, mediated by antibodies to insulin, to insulin receptors, and to beta cells. Hypoglycemia due to anti-insulin antibodies has been described most often in Japanese women ("Hirata disease"[176]), but cases have been reported in both sexes, all ages, and from many regions.[177] Nearly all autoimmune hypoglycemia in infants and children has been of this type.[178-181] The presumed mechanism of hypoglycemia is slow dissociation of

insulin from antibodies during the postprandial or postabsorptive periods. The hypoglycemia is most often reactive, but may be fasting, and has sometimes been severe enough to cause seizures or coma.[182] Metabolic features are those of hyperinsulinism, with low ketone and fatty acid levels, but intermittent ketosis accompanying severe hypoglycemia was reported in two affected children. Measured levels of insulin can be high, but because much of it is not freshly secreted, C-peptide levels are lower than typical of insulinoma or most endogenous hyperinsulinism, though not as undetectable as is usual with exogenous hyperinsulinism.[177] Most older patients with this condition have other autoimmune diseases, and a number of drugs (especially methimazole) have been apparent precipitants.[183] Among treatments reported to improve the hypoglycemia have been courses of glucocorticoids, plasmapheresis, and intravenous immunoglobulin infusions.

Autoimmune hypoglycemia due to antibodies that bind to and activate insulin receptors rather than insulin has occurred almost exclusively in adults, usually in association with acanthosis and type B insulin resistance, or a malignancy or severe inflammatory disorder. Some patients have had both anti-insulin and antireceptor antibodies.[184] A case in an infant has been described.[181] C-peptide and insulin levels (with some exceptions) are typically undetectable. An even rarer form of autoimmune hypoglycemia has been postulated to involve antibodies directed against surface antigens on beta cells, resulting in stimulation of inappropriate insulin release.[185]

Insulinoma

Insulin-secreting adenomas of the pancreas are rare tumors but are the most common cause of new, severe hypoglycemia due to endogenous insulin in otherwise well adolescents and adults. Fewer than 100 childhood cases have been reported since the 1960s, but a few have occurred even in the first year of life.[186,187] Most insulinomas are sporadic, solitary tumors 0.5 to 2 cm in size, but a minority are multiple.[188] About 10% of adult cases are malignant (i.e., metastatic or locally invasive), but childhood insulinomas are only rarely malignant.[189] Surgical excision is usually curative, except in cases with multiple lesions, as in common with MEN1. Diazoxide can temporarily control the hypoglycemia in most.[190,191]

Insulinomas in older children and adults usually present as episodes of neuroglycopenic and autonomic symptoms (e.g., confusion and diaphoresis), often recurring for months before the diagnosis is made.[192,193] Autonomic symptoms may diminish as hypoglycemia recurs (hypoglycemia unawareness).[194] Although some patients have had recurrent seizures or other symptoms for years before diagnosis, there have been no detailed reports of cases in which only autonomic symptoms without neuroglycopenic effects led to the diagnosis of an insulinoma. The hypoglycemic episodes occur most commonly with fasting, but they may be reactive (postprandial) in some patients, and sometimes can be associated with exercise.[193,195,196] Accelerated weight gain in the year prior to diagnosis is common.[192] In many cases the evaluation is initiated by a new hypoglycemic seizure. When symptoms are milder, the initial step of the evaluation is directed toward determining whether the Whipple criteria are fulfilled: measurably low glucose levels at the time of characteristic neuroglycopenic and autonomic symptoms, with relief by carbohydrates.[197] A diagnostic fast may be necessary to confirm a hyperinsulinemic form of hypoglycemia.[191,198] In most cases glucose will fall below 50 mg/dL (2.8 mmol/L) well before 24 hours, and insulin, proinsulin, and C-peptide concentrations will be elevated while βOHB levels remain suppressed. Despite attempts to identify test results or ratios (e.g., insulin:glucose, proinsulin:insulin, C-peptide ratio) that would specifically confirm the presence of an insulinoma, results are characteristic of hyperinsulinism. Typical results reported in large series of adult patients are listed in Table 21-3[199]; results from a much smaller number of pediatric insulinomas have been comparable.[200] When symptoms have been primarily postprandial, a mixed meal tolerance test may be more likely confirmative than a fast.[196]

As no hormone testing distinguishes a solitary, resectable insulinoma from other forms of diffuse endogenous hyperinsulinism or multiple insulinomas, it is helpful to visualize the tumor before surgery.[191] Routine imaging of the pancreas by ultrasound, spiral computed tomography, or magnetic resonance may fail to reveal the tumor in 20% to 40% of patients, especially when it is smaller than 2 cm in size, and many enhanced imaging procedures have been devised.[201,202] Endoscopic ultrasonography has been preferred at many institutions.[203] Positron emission tomography (PET) scanning with various labels may show multicentric or extrapancreatic tumors.[204,205] When imaging fails to reveal a tumor, attempts have been made to localize the tumor to a region of the pancreas by pancreatic arterial stimulation with calcium and venous sampling (PASVS) of insulin levels.[206] Calcium-stimulated venous sampling, like many other localization techniques, has the highest success rates in experienced hands. Intraoperative ultrasonography can reveal most insulinomas not localized preoperatively.[191]

About 5% to 10% of adults with insulinomas, and a higher percentage of children, have multiple endocrine neoplasia syndrome 1 (MEN1, Wermer syndrome).[188,207] MEN1 insulinomas are usually multiple and can occur in childhood.[191] This disorder is characterized by functioning or nonfunctioning adenomas of the parathyroids, pituitary, and pancreas and is inherited in an autosomal-dominant fashion. MEN1 is caused by inactivating mutations of the *MENIN* gene on chromosome 11.[208] Gene testing in affected families can identify children at risk for insulinoma; annual fasting glucose, insulin, and proinsulin are recommended from the age of 5 years.[209]

Hyperinsulinism after Gastrointestinal Surgery

Gastrointestinal hormones and signals—the enteroinsular axis—play an important role in regulating both insulin secretion and sensitivity. Disruption of this system by gastric surgery can result in hypoglycemia from intermittently excessive postprandial insulin release.[210] This "alimentary hypoglycemia" is usually postprandial (i.e., reactive) rather than fasting and is due in large part to an amplified release of glucagon-like peptide 1 (GLP-1).[211]

In young children, postprandial hypoglycemia is common after Nissen fundoplications for gastroesophageal reflux, sometimes accompanying bowel symptoms as part of the "dumping syndrome," and sometimes as isolated neuroglycopenic and autonomic symptoms 1 to 3 hours after meals.[212,213] Hypoglycemia can usually be confirmed during symptoms after a typical feeding or a mixed meal tolerance test. Hypoglycemia can sometimes be abated by dietary measures that slow digestion, such as avoiding simple sugars, providing fat and protein with carbohydrates, or adding pectin or uncooked cornstarch.[214] In more severe cases, hypoglycemia can be prevented with acarbose, an alpha-glucosidase inhibitor that slows starch digestion, or a long-acting somatostatin analog such as octreotide.[215] Acarbose doses between 25 and 100 mg per feeding have been reported to be effective.[216]

Bariatric surgery of older patients can produce a similar phenomenon.[217] Amplified insulin release or improved insulin sensitivity after gastric bypass, banding, or sleeves can produce immediate improvement in patients with type 2 diabetes. However, in some nondiabetic patients, the insulin effect has been severe enough to cause symptomatic hypoglycemia.[218] Dietary measures for slowing digestion are sometimes effective, and both acarbose and octreotide have been used.[210] In a few, continuous feeding or subtotal pancreatectomy has been required to control the hypoglycemia.

Hyperinsulinemic Hypoglycemia Prodromal to Diabetes Mellitus

Although the most common and familiar type of hypoglycemia occurs during treatment of diabetes with insulin or insulin secretagogues, hypoglycemia preceding or accompanying the development of diabetes has been documented in a variety of circumstances. A relationship, "dysinsulinism," between reactive hypoglycemia and common type 2 diabetes was postulated as early as 1930[219] and widely recognized among diabetologists in the middle of the 20th century.[220-224] Pediatric cases were reported.[225] Early diabetes is often characterized by loss of the first-phase insulin response to food, resulting in higher glucose excursions but followed by lower glucose nadirs. In most cases the hypoglycemia does not reach levels low enough to cause neuroglycopenic symptoms. Over subsequent decades, research demonstrated the unreliability of oral glucose tolerance tests (OGTTs) for pursuing purely autonomic postprandial symptoms, which led to diminished interest in this phenomenon, though many laypeople have heard of the relationship.[226]

Instances of both fasting and postprandial hypoglycemia occurring prior to the onset of type 1 diabetes, or during an insulin-free "honeymoon," have also been reported, and mechanisms involving insulin antibodies, excessive second-phase insulin release after defective first-phase insulin release, or insulin release during inflammatory destruction of beta cells are plausible.[227-231]

Although the pathophysiology of cystic fibrosis–related diabetes (CFRD) is distinct from both type 1 and type 2, spontaneous fasting hypoglycemia and reactive hypoglycemia associated with early impairment of glucose tolerance occur, though whether either predicts the progression of CFRD is controversial.[232,233]

Nonislet Tumor Hypoglycemia

Certain non–insulin-secreting tumors are sometimes associated with paraneoplastic hypoglycemia.[234] Most cases have involved large, malignant tumors of mesenchymal, epithelial, or hematopoietic origin, referred to as the Doege-Potter syndrome.[235,236] Cases in children are rarer but have been reported with neuroblastoma and Wilms tumor.[237] The hypoglycemic episodes typically occur while fasting, with inappropriately low free fatty acids, increased glucose utilization, and suppressed hepatic glucose output suggestive of insulin excess. Proinsulin, insulin, and C-peptide levels are low, and diazoxide and somatostatin are ineffective, suggesting activation of insulin receptors by other circulating factors.[238] In most cases, levels of insulin-like growth factor 2 (IGF-2) have been found that are high enough to cross-activate both insulin and insulin-like growth factor 1 (IGF-1) receptors, producing hypoglycemia with the metabolic characteristics of insulin excess.[239] IGF-2 is normally produced in the liver and limited amounts are secreted in blood, bound to IGF-binding protein (IGF-BP3) and the acid-labile subunit (ALS). Tumor-produced IGF-2 can be incompletely processed and bound, hence more active, or structurally abnormal—a large molecular form called "big IGF-2." Stimulation of the insulin receptor causes hypoglycemia, whereas stimulation of the IGF-2 receptor causes down-regulation of growth hormone secretion, resulting in low levels of IGF-1 and IGF-BP3.[240]

The combination of elevated IGF-2 with suppressed IGF-1 and insulin confirms tumor hypoglycemia of this variety and suggests an effective intervention if the tumor cannot be completely removed. Treatment with growth hormone raises IGF-BP3 levels, which reduces the free IGF pool and thereby ameliorates hypoglycemia.[237]

Not all paraneoplastic hypoglycemia is mediated by IGF-2. Hypoglycemia attributed to increased anaerobic glucose metabolism has been reported in lymphomas and leukemias, in association with lactic acidosis.[241,242] Paraneoplastic autoimmune hypoglycemia was described earlier.

Glycogen Storage Diseases

Most glycogen occurs in hepatocytes, where it serves as a glucose reservoir for postabsorptive periods. Glycogenolysis provides a large portion of plasma glucose beginning a few hours after each meal and continuing until it is largely depleted 16 to 24 hours later. Glycogen is resynthesized after meals when glucose and insulin levels rise. Approximately a dozen enzyme systems are involved in movement of glucose into and out of liver cells, glycogen synthesis and glycogenolysis, and defects of these enzymes impair a variety of organs.[243] Traditionally the glycogen storage diseases (GSDs) are numbered and described as defects of specific enzyme activities, but the discovery that multiple proteins and genes are involved in some of the enzyme activities explains the multiple forms and inheritances of some of the specific GSDs. Several of them can interfere with the maintenance of plasma glucose and cause postabsorptive hypoglycemia (see Table 21-4).

Glucose 6-Phosphatase Deficiency (Types 1a and 1b GSD)

Hydrolysis of glucose 6-phosphate to free glucose, catalyzed by glucose 6-phosphatase, is the final step in both the glycogenolytic and gluconeogenic pathways, and impairment of this activity results in severe postabsorptive hypoglycemia. Although hypoglycemia is present from birth, GSD 1 in its classic form (type 1a, with an estimated incidence of 1:100,000),[244] is more often recognized later in the first or second year of life as the hepatomegaly produces an increasingly protuberant abdomen and the child fails to grow. Metabolic acidosis is common and is caused by marked lactic acidosis and mild ketosis. Levels of triglycerides and cholesterol may be high enough to cause lipemic serum and xanthomas.[245] Hypophosphatemia, hyperuricemia, and anomalies of platelet adhesiveness also characterize GSD 1.

Affected children display a remarkable tolerance to their chronic hypoglycemia. Blood glucose values in the range of 20 to 50 mg/dL are associated with few autonomic or neuroglycopenic symptoms of hypoglycemia, reflecting the adaptation of the CNS to alternative sources of fuel (lactate), and the down-regulation of counter-regulatory autonomic responses with prolonged hypoglycemia. However, insulin is appropriately suppressed, and the counter-regulatory hormones—GH, glucagon, cortisol, and catecholamines—are elevated. These hormonal changes stimulate glycogenolysis and gluconeogenesis to produce glucose 6-phosphate, with lactic acidosis reflecting increased formation and decreased utilization of lactate. The hormonal changes also promote exaggerated lipolysis, resulting in elevations of triglycerides and fatty liver.[245]

Depletion of hepatic ATP and inorganic phosphate increases the rate of uric acid production by stimulating the degradation of preformed nucleotides, and reduced clearance of uric acid due to competition with lactic acid for common shared renal tubular secretory sites results in hyperuricemia severe enough to cause damage to kidneys and joints. The defect in platelet adhesiveness and resulting clotting abnormalities are consequences of the hypertriglyceridemia and may be the consequence of ATP depletion. Although the liver in GSD 1 is laden with glycogen and triglycerides, results of liver function tests remain essentially normal other than mild elevations of serum aspartate aminotransferase levels.[243]

Renal tubules and intestinal mucosa also express the enzyme glucose 6-phosphatase. Renal biopsy reveals excessive glycogen deposition. Long-term renal dysfunction can occur with histologic findings remarkably similar to those found in diabetes (focal glomerulosclerosis). Renal manifestations include kidney enlargement, glomerular hyperfiltration, hypercalciuria, and a mild tubular acidosis.[246] Late renal complications may include Fanconi syndrome, nephrocalcinosis, progressive proteinuria, and eventually end-stage renal failure.[247] Intestinal effects are uncommon but can include diarrhea. Nodular liver enlargement and adenomas often develop after the first decade of life.[248]

The clinical heterogeneity reflects the complexity of hepatic glucose 6-phosphatase, a multicomponent system whose enzyme activity is tightly linked to the inner aspect of the endoplasmic reticular membrane. Glucose 6-phosphatase activity depends on three translocase systems that allow entry of glucose 6-phosphate (T1), exit of phosphate (T2), and exit of glucose (T3) from the lumen of the endoplasmic reticulum. Classic deficiency of enzyme activity is termed *type 1a*, whereas deficiency of translocase T1 is termed *type 1b*. Deficiencies of the T2 and T3 transporters might cause GSD and have been tentatively termed GSD 1c and 1d but have not been definitively documented.[243]

Type 1b occurs in children with biochemical features that are similar to those of type 1a but with the addition of neutrophil deficiency, oral lesions, perianal abscesses attributed to the neutropenia, and chronic enteritis indistinguishable from Crohn disease.[243,249] Treatment with granulocyte-macrophage colony-stimulating factor to increase the neutrophil count ameliorates the enteritis.

GSD 1 should be suspected in children with growth failure, protuberant abdomen due to massive hepatomegaly, or hypoglycemia with lactic acidosis. A finding of elevated lactate levels with hypoglycemia combined with an abnormal fed glucagon stimulation test clinches the diagnosis. In the normal child, a 2-hour postprandial (fed) glucagon stimulation test will cause a rise in glucose of 30 mg/dL within 30 minutes and no change in lactate. In a patient with GSD 1, lactate rises (but not glucose). Fructose 1,6-diphosphatase deficiency resembles GSD 1, but the fed glucagon stimulation test will be normal. Liver biopsy with estimation of glucose-6-phosphatase activity was the classic means of definitive diagnosis, but genetic testing for GSD1a and 1b1 is now commercially available.[250]

Treatment regimens have transformed the prognostic outlook for duration and quality of life and have resulted in the reversal of most of the metabolic disturbances in GSD1.[251,252] Acceptance of these regimens, including passage of a nasogastric tube for nocturnal provision of glucose, is excellent, and the long-term outcome of this innovative approach is promising.[253] Patients are fed every 2 hours during the day and have a continuous supply of glucose through a nasogastric tube overnight. The rate of glucose infusion is tailored to the individual but is usually 6 to 8 mg/kg/min (slightly greater than normal hepatic glucose production).[254] Intermittent cornstarch therapy has been successfully used in patients older than 1 year. Uncooked cornstarch is given in doses of 1 to 2 g/kg every 4 hours, and in some children it is given every 6 hours overnight.[255]

Long-term therapy with uncooked cornstarch and overnight tube feedings improves linear growth and diminishes osteoporosis. Most patients require treatment with allopurinol for hyperuricemia. Although there are no controlled trials of the effect of good metabolic control of GSD on renal disease, some evidence supports the hypothesis that good control lessens the degree of renal impairment.[256] This is assumed from an apparent trend toward later onset of renal disease since the adoption of more effective current treatments.[257] Liver transplantation is not routinely recommended but offers the promise of a long-term cure for patients who develop liver nodules that become malignant.[258]

Amylo-1,6-Glucosidase Deficiency (Debrancher Deficiency, GSD Type 3)

A deficiency of debrancher enzyme activity results in GSD type 3, often affecting both liver and muscle. Children with this disease usually present with hepatomegaly and poor growth. Liver function tests (especially transaminases) may be markedly increased. The *AGL* gene locus is on 1p21, and mutation analysis (at least for common mutations) is available from commercial labs.

These patients have an inability to degrade glycogen beyond the 1:4/1:6 branch point, with the result that only the outer 5% to 10% of glucose residues can be released by phosphorylase and the remaining glycogen accumulates as a limit dextrin. In the fed state, glucagon elicits a normal glycemic response but after liver glycogen reaches the limit dextrin stage during fasting, glucagon no longer raises plasma glucose. This partial defect of glycogenolysis results in the development of hypoglycemia and ketosis during fasting, though postabsorptive hypoglycemia is less common and less severe than in GSD type 1. Because gluconeogenic pathways are intact, lactic acidosis, hyperuricemia, and severe lipemia do not occur. Both hypoglycemia and liver disease tend to improve substantially after puberty.

However, debrancher enzyme is a large enzyme with two active sites, with the various mutations resulting in a range of possible clinical effects in muscle and other tissue. Creatinine phosphokinase is often elevated in children with GSD 3 but does not always predict severe myopathy. Children with GSD 3 often have subclinical muscle weakness with subtle signs, but significant proportion will develop more severe and debilitating myopathies in the third decade of life. Severe cases may involve life-threatening cardiomyopathy.

Two dietary regimens have been advocated for GSD type 3.[259] For those with liver involvement alone, frequent feedings and uncooked cornstarch have been recommended in the expectation that an avoidance of prolonged fasting will be sufficient to prevent hypoglycemia and improve growth.[260] However, in patients with liver and muscle involvement, the use of a low-carbohydrate, high-protein diet has been advocated—with the argument that providing glucose by gluconeogenesis from protein precursors reduces the need to deplete muscle alanine stores. There are no large controlled trials comparing the efficacies of the two approaches. Nasogastric or intravenous glucose infusions may occasionally be indicated if caloric intake cannot be maintained during intercurrent illness.

Liver Phosphorylase and Phosphorylase Kinase Deficiency (GSD Types 6 and 9)

Phosphorylase is the key enzyme of glycogenolysis. Deficient activity results in several forms of glycogen storage disease with hepatomegaly and postabsorptive or fasting hypoglycemia. Phosphorylase requires activation by phosphorylase kinase, and similar clinical problems can result from genetic defects of phosphorylase kinase. Disease resulting from mutations of the *PYGL* gene for phosphorylase itself is referred to as GSD 6.[261] Phosphorylase kinase is a large protein consisting of four copies of four different subunits, encoded by four genes.[243] Liver disease resulting from mutations of the genes for phosphorylase kinase is referred to as GSD 9, and three forms have been found to cause hypoglycemia (see Table 21-4).[262,263] Several attempts to number and distinguish these forms of GSD before the underlying gene defects were entirely understood have left a history of contradictory numbering systems and nomenclature.[243]

Although the different forms of GSD 6 and 9 are clinically similar, there is some heterogeneity of features and severity.[262] Hepatomegaly from excessive deposition of glycogen, some growth retardation, and occasional symptomatic hypoglycemia occur. The hypoglycemia is milder than that of GSD 1, and it is not accompanied by marked lactic acidosis or hyperuricemia. Patients with GSD 9b gradually develop a myopathy as well as the liver disease. Gene tests are commercially available. Frequent feedings with a diet low in sugar and higher in complex carbohydrates and protein will suffice for most. Some will need parenteral glucose support for illness or surgery. Patients with GSD 6 and 9 generally do very well, but a few have more severe hypoglycemia with intermittent elevations of lactic acid, and there has been a report of liver cirrhosis in a patient with GSD type 9.[263,264]

Glycogen Synthase Deficiency

Impairment of glycogen synthesis results in reduced rather than excessive glycogen storage, and it does not result in liver enlargement but can still cause intermittent hypoglycemia. Although less common than some of the other GSDs, enough cases of glycogen synthase deficiency have been reported to describe the phenotype.[265,266] Glycogen synthase activity is markedly reduced in liver but normal in muscle. Infants and children with GSD 0 may have symptoms of fasting-induced hypoglycemia and hyperketonemia from infancy. However, a high-carbohydrate meal may result in transient hyperglycemia with glucosuria after meals.[267]

During fasting hypoglycemia, levels of the counterregulatory hormones, including catecholamines, are appropriately elevated or normal—whereas insulin levels are appropriately low. Exogenously administered glucagon produces a glycemic response soon after meals but no response after a 12-hour fast because glycogen synthase activity is markedly reduced in liver but normal in muscle so that the glycemic response soon after meals represents the release of glucose from muscle glycogen stores. Gluconeogenic capacity is intact. In the index case, protein-rich feedings at frequent intervals resulted in dramatic clinical improvement, including improved growth. Since the initial case reports, more patients have been described. Treatment with uncooked cornstarch has been helpful. Although the majority of cases are recessive mutations, one pedigree has been reported in whom the mother of two affected children had some hypoglycemia. This condition mimics the syndrome of ketotic hypoglycemia and should be considered in the differential diagnosis of that syndrome.

Glycogen Branching Enzyme Deficiency (Type 4 GSD)

Deficiency of glycogen branching enzyme results in Andersen disease. The impairment of glycogenolysis is minimal and gluconeogenesis is normal, so hypoglycemia

is a rare problem in infancy. However the progressive liver damage is more severe than in other GSDs, and fasting hypoglycemia has been reported with advanced liver disease in GSD 4.[243]

Fanconi-Bickel Syndrome

Fanconi-Bickel syndrome is an autosomal recessive disease caused by mutations of the *GLUT2* gene that encodes the principal glucose transporter of the hepatocyte membranes.[268] Movement of glucose across the membrane of liver cells is necessary for glucose homeostasis and defects of the membrane glucose transporter can result in both hypoglycemia and glycogen accumulation in the liver. The hypoglycemia is fasting and often accompanied by ketosis. It is attributed to a combination of impaired transport of glucose from the hepatocyte cytoplasm to the blood, and to excessive urinary glucose loss. Postprandial hyperglycemia can occur. The principal renal manifestation is defective proximal tubular reabsorption (Fanconi syndrome), with glucosuria and phosphaturia. Phosphaturia can be severe enough to cause hypophosphatemic rickets. Growth in childhood is poor. Treatment consists of avoidance of excessive sugar, and cornstarch if necessary to support adequate glucose and growth.

Ketotic Hypoglycemia

"Hypoglycemia with ketosis" is a diagnostic category and "ketotic hypoglycemia" a specific diagnosis. Ketosis accompanying new hypoglycemia suggests it has not been caused by any of the many varieties of hyperinsulinemic and reactive hypoglycemia, though not infallibly.[269] A single episode of hypoglycemia and ketosis can occur during the stress and anorexia of an illness like gastroenteritis.[270] Hypoglycemia with ketosis can also occur, sometimes repeatedly until diagnosed, from a variety of inborn errors of carbohydrate metabolism, hormone deficiencies, ingestions, and prolonged starvation. However, most otherwise healthy young children who suffer repeated episodes of morning hypoglycemia and ketosis will be diagnosed with *ketotic hypoglycemia* with no other underlying disease.[271]

Ketotic hypoglycemia has been recognized for nearly a century as a common type of childhood hypoglycemia,[272] with a well-characterized presentation and course but an incompletely understood pathophysiology.[273-275] Usually this condition presents as recurrent episodes of morning hypoglycemia in the second or third year of life—but onset as early as 6 months has been reported. The condition usually remits spontaneously by the age of 8 to 9 years. The classic history is of a child who has eaten poorly or misses an evening meal, is difficult to rouse from sleep the next morning, and displays neuroglycopenic symptoms that may range from lethargy to seizure. Hypoglycemic episodes are especially likely to occur during an illness, when food intake is limited.

At the time of documented hypoglycemia, high levels of ketones are found in plasma and urine and plasma insulin concentrations are low (typically under 2 μU/mL using a high-sensitivity assay). It remains unsettled whether these children display an accelerated, but qualitatively normal, metabolic response to fasting (i.e., one tail of the normal distribution) or whether ketotic hypoglycemia is a heterogeneous group of metabolic disorders of limited substrate availability awaiting further delineation.[276,277]

Several studies have shown that ketotic hypoglycemia reflects underproduction rather than overutilization of glucose.[278] Children with ketotic hypoglycemia have plasma alanine concentrations that are reduced in the basal state after an overnight fast and fall still farther with prolonged fasting.[21,279] Infusions of alanine, fructose, or glycerol produce a rise in plasma glucose concentration without significant changes in blood lactate or pyruvate levels, indicating that the entire gluconeogenic pathway from the level of pyruvate is intact, and suggesting that a deficiency of substrate rather than a defect in gluconeogenesis is involved.[280]

Glycogenolytic pathways are also intact because glucagon induces a normal glycemic response in affected children during the fed state but not at the time of hypoglycemia. Plasma glycerol levels are normal in these children, in both the fed and fasted states. The metabolic response to infusion of β-hydroxybutyrate does not differ from that of normal children. Finally, the levels of hormones that counter hypoglycemia are appropriately elevated, whereas insulin levels are appropriately low.[275]

Alanine is the major amino acid used for gluconeogenesis. Its formation and release from muscle during periods of caloric restriction is enhanced by the presence of a glucose-alanine cycle, as well as by de novo formation from other substrates such as branched chain amino acids. Although defects in any of the complex steps involved in protein catabolism, oxidative deamination of amino acids, transamination, alanine synthesis, or alanine or glutamine efflux from muscle could contribute to ketotic hypoglycemia, no specific defects can be demonstrated in the majority of children with ketotic hypoglycemia. It was pointed out in the original description of this syndrome that children with ketotic hypoglycemia are frequently smaller than age-matched controls and often have a history of transient neonatal hypoglycemia. Thus, a compromised supply of gluconeogenic substrate may simply reflect the reduced reserve of a small muscle mass at an age when glucose demands per unit of body weight to support brain metabolism are relatively high.

Ketosis represents the attempt at switching to an alternate fuel supply. Those with ketotic hypoglycemia may represent the low end of the spectrum of capacity to tolerate fasting.[277] Similar relative intolerance to fasting is present in normal children, who cannot maintain normal blood glucose levels after 20 to 36 hours of fasting (compared with the capacity of adults for prolonged fasting). Spontaneous remission by age 8 to 9 years might be explained by the increase in muscle bulk relative to brain size, with a resultant increase in the supply of endogenous substrate and the relative decrease in glucose requirement per unit of body mass with increasing age.

Ketotic hypoglycemia should be considered only a diagnosis of exclusion, as episodic hypoglycemia with ketosis can occur with deficiencies of several hormones or a variety of defects of gluconeogenesis or glycogen metabolism, especially hypopituitarism and glycogen storage diseases.[281,282] The diagnosis of ketotic hypoglycemia is confirmed by a

supervised fast. Hypoglycemia with elevated plasma free fatty acids, β-hydroxybutyrate, and acetoacetate develops within 14 to 24 hours in most of these children, whereas normal children of similar age can withstand fasting without developing hypoglycemia for at least 24 hours.

Episodes of ketotic hypoglycemia can be prevented or minimized by avoidance of prolonged fasting. The overnight fast should be shortened to less than 10 to 12 hours with a carbohydrate bedtime snack and prompt breakfast. When episodes have been triggered by illness, parents may test the child's urine for ketones—the appearance of which precedes the hypoglycemia by several hours and indicates a need for high-carbohydrate liquids. If these cannot be tolerated, the child should be taken to the emergency department for intravenous glucose. A letter of explanation and treatment recommendation may expedite the emergency department response.

Hormone Deficiency

Four primary counter-regulatory hormones—glucagon, epinephrine, cortisol, and growth hormone—help maintain blood glucose levels and can produce hyperglycemia in excess. In experimental circumstances, glucagon and epinephrine are the primary hormonal defenses against hypoglycemia, yet spontaneous deficiencies of only cortisol and GH are clearly demonstrable causes of clinically significant hypoglycemia in childhood.

Growth Hormone Deficiency and Hypopituitarism

Although growth hormone has been shown to play only a minor role in defending glucose levels against acute insulin-induced hypoglycemia, it is more important in supporting glucose during prolonged fasting by limiting insulin sensitivity, reducing glucose utilization, and inducing lipolysis.[283-285] The occurrence of symptomatic and asymptomatic hypoglycemia in both isolated growth hormone deficiency and in multiple pituitary deficiencies was recognized as soon as growth hormone was measurable and the clinical features of hypopituitarism were delineated.[286,287-289]

In the newborn period, hypopituitarism can produce persistent or recurrent hypoglycemia.[290] Some infants may require a glucose infusion rate high enough to resemble congenital hyperinsulinism.[291] In males, a microphallus may provide a clue to coexistent pituitary gonadotropin deficiency. Neonatal jaundice is a common accompaniment of congenital hypopituitarism and may result from either indirect or combined hyperbilirubinemia. Cholestatic jaundice with liver enzyme elevation may suggest neonatal hepatitis but can occur solely from congenital hypopituitarism.[292] The diagnosis of congenital growth hormone deficiency cannot be based on a single growth hormone obtained during hypoglycemia[293] but is usually based on a combination of clinical evidence, including pituitary or other midline defects by imaging.[294]

Morning hypoglycemia with ketosis is a potential presenting indicator of isolated idiopathic GH deficiency in young children.[295,296] Insulin levels are quite low, and glycemic response to glucagon during spontaneous hypoglycemia is poor. However, the degree of ketosis at time of hypoglycemia may be lower than in the more common type of ketotic hypoglycemia, perhaps reflecting the increased insulin sensitivity, and this relative deficiency of alternate fuel generation may make the hypoglycemia of GH deficiency more dangerous to the brain.[297] Low GH levels at the time of spontaneous or fasting-induced hypoglycemia are suggestive of deficiency, though this is an inconsistent and often unreliable finding.[293,298] Poor growth and low IGF-1 levels may be more reliable clues after early infancy, and the diagnosis of GH deficiency severe enough to cause hypoglycemia can be confirmed by low GH responses to standard provocative tests. Hypoglycemia has been reported in older children and adults with either isolated GH deficiency or multiple pituitary deficiencies, usually precipitated by stress, starvation, or exercise.[288,299]

Growth Hormone Resistance and IGF-1 Deficiency

Recurrent fasting hypoglycemia is common in the most extreme form of growth hormone resistance due to genetic absence of the GH receptor (Laron dwarfism).[300,301] The hypoglycemia tends to improve in adolescence, though still can occur with prolonged fasting. Similar frequencies of hypoglycemia (45% or more) have been reported in the two largest populations with this condition in Israel and Ecuador, suggesting it may not be the entire explanation for the lower intelligence levels described in the Israeli patients. The vulnerability to fasting hypoglycemia improves with treatment with synthetic insulin-like growth factor 1 (mecasermin), though one of the insulin-like effects of the treatment can be hypoglycemia within an hour of the injection if the child has not eaten.

Cortisol and Adrenocorticotropin Deficiencies

Although cortisol seems to play a secondary role in counter-regulatory responses to acute hypoglycemia, it supports glucose production during fasting and stress by increasing gluconeogenic enzyme activities and by mobilizing precursors.[4,302] Cortisol also plays an indirect role in hypoglycemia defense by enabling epinephrine release from the adrenal medullas: activity of phenylethanolamine N-methyl transferase (PNMT), the enzyme that converts norepinephrine to epinephrine in the adrenal medulla, depends on cortisol.[303] Cortisol deficiency amplifies insulin sensitivity, so the diminishing insulin requirement and increasing hypoglycemia is a long-recognized presentation of Addison's disease in developing in insulin-dependent diabetes.[304]

Fasting or postabsorptive hypoglycemia can occur in all forms of glucocorticoid deficiency, but it is more common in some patients and circumstances than others. Younger patients, especially infants, are more vulnerable than adolescents and adults.[305] Hypoglycemia is most likely to occur after prolonged fasting or during the stress of illness, especially if the usual daily glucocorticoid replacement has been interrupted by illness.[306,307]

ACTH deficiency or unresponsiveness is more likely to produce hypoglycemia than primary adrenal failure, especially as part of congenital hypopituitarism with growth

hormone deficiency. Congenital ACTH deficiency presenting with early hypoglycemia has been reported with mutations of several genes involved in pituitary development (POU1F1, PROP1, TPIT).[294,308,309] Some of the patients have had other pituitary deficiencies. In some of them, ACTH insufficiency was not clinically apparent in early infancy when initial testing was performed, but it became clinically apparent later in childhood.

An increasing number of specific genetic defects resulting in isolated ACTH deficiency or resistance have been identified as well. Red hair and early-onset obesity are better known than ACTH deficiency in POMC mutations, but at least one death has been described.[310] Hypoglycemia in an infant due to ACTH deficiency has been attributed to a defect of prohormone cleavage.[311] Idiopathic ACTH deficiency can be acquired in childhood, adolescence, or later adult life.[312] Circumstantial evidence such as an association with autoimmune thyroiditis suggests autoimmune hypophysitis as a common cause. In some instances, antipituitary antibodies have been demonstrated.[313] Hyperpigmentation accompanies other manifestations of adrenal insufficiency in ACTH resistance.[314]

Iatrogenic suppression of adrenal function is one of the most common causes of glucocorticoid insufficiency, but it may be overlooked because the obvious electrolyte abnormalities of mineralocorticoid deficiency are absent. An adrenal crisis with prostration, vomiting, hypotension, and hypoglycemia can be triggered by a stressful event in a child recently weaned from high-dose glucocorticoid therapy and has been reported even on alternate day low-dose therapy.[232] More often, hypoglycemia and milder manifestations may be caused by the inhaled and nasal glucocorticoid preparations that have become the mainstay of allergy treatment for millions of otherwise healthy children.[233] Although most tolerate it well, ongoing combined use of topical and inhaled glucocorticoid preparations can cause enough adrenal suppression to produce episodic hypoglycemia and interference with growth in older children.[315] Absence of the 0800 cortisol peak in a child receiving topical or inhaled glucocorticoids suggests this possibility.

Hypoglycemia is a less common presentation of primary adrenal insufficiency, but it often occurs during illness or starvation in patients already being treated with replacement glucocorticoids.[305,306] Primary adrenal insufficiency often accompanied by deficient epinephrine responses to hypoglycemia, and hypoglycemia manifested by neuroglycopenic rather than adrenergic symptoms may be less recognizable.[316] The most common form of primary adrenal insufficiency is congenital adrenal hyperplasia, and surveys and case reports document hypoglycemia as a relatively frequent manifestation during treatment.[305,317,318]

Diagnosis of cortisol or ACTH deficiency as a cause of a child's hypoglycemia cannot be based on a single low cortisol during hypoglycemia, but on other clinical evidence or standard adrenal stimulation tests.[293] Primary adrenal insufficiency is best sought by measurement of ACTH concentrations, which will be elevated even when the cortisol concentration itself remains in the normal range, similar to the elevation of TSH that occurs in early (subclinical) hypothyroidism while T_4 or fT_4 is still within the normal range.

Epinephrine and Glucagon Deficiencies

The importance of epinephrine and glucagon in the counter-regulatory responses to hypoglycemia suggests that isolated deficiency of either hormone would be likely to cause hypoglycemia, but no instances of hypoglycemia caused by isolated, primary deficiency of either hormone have been well-demonstrated in children.

Although there have been case reports of reduced epinephrine excretion in patients with hypoglycemia, evidence from patients with diabetes and insulinomas suggests that repeated hypoglycemia is more likely to cause diminished epinephrine excretion than vice versa. A reduction in insulin-induced hypoglycemia restores normal catecholamine responses. Much attention was paid to below average epinephrine responses in ketotic hypoglycemia in the early investigations, but no primary defects of epinephrine were demonstrated.[319,320] Defective epinephrine responses accompany adrenal insufficiency but can be at least partly restored by adequate glucocorticoid replacement.

Perhaps the best candidate for an example of hypoglycemia caused by epinephrine deficiency in childhood is the occasional episode of severe hypoglycemia, usually fasting, occurring in a young child taking propranolol or another beta-blocker (either therapeutically or accidentally).[321]

Impaired glucagon secretion also increases the vulnerability to hypoglycemia of people with type 1 diabetes, but no well-documented case of childhood hypoglycemia due to isolated glucagon deficiency has been reported. Insulin within islets is a major regulator of glucagon secretion, such that most forms of hyperinsulinism are accompanied by reversible suppression of glucagon. [125] The case most often cited has since been recognized as an instance of familial SCHAD hyperinsulinism.[126,127]

Genetic Disorders of Gluconeogenesis

In the early postabsorptive hours, glucose is maintained by both glycogenolysis and gluconeogenesis. As fasting continues more than 12 to 16 hours and liver glycogen is depleted, gluconeogenesis contributes an increasing proportion of circulating glucose. Alanine from muscle is the principal early substrate for gluconeogenesis, but lactic acid, oxidized to pyruvic acid, also contributes to the maintenance of normoglycemia via the Cori cycle, especially in larger children and adults. While substrate shortage can result in ketotic hypoglycemia during fasting, genetic defects of the four major enzymes of gluconeogenesis (pyruvate carboxylase, phosphoenolpyruvate carboxykinase, fructose 1,6-diphosphatase, and glucose 6-phosphatase) can do so as well. Deficiency of glucose 6-phosphatase produces the severe hypoglycemia of type 1 GSD, described previously. Lactic acidosis is a common feature of these defects of the last steps of gluconeogenesis.

Pyruvate Carboxylase Deficiency

Pyruvate carboxylase is a biotin-containing protein of four subunits that binds pyruvate, ATP, HCO_3, and acetyl CoA, and produces oxaloacetate. It is a major regulatory enzyme

at the beginning of the gluconeogenic pathway. Activation is dependent on acetyl CoA, and occurs principally during mobilization of fatty acids during fasting. Several forms of deficiency have been described, typically presenting as severe lactic acidosis and encephalopathy in early infancy, usually with metabolic decompensation during illness.[322] Hepatomegaly is common. Hypoglycemia has been reported in several forms of pyruvate carboxylase deficiency but is not invariably present.[323,324] Urine contains large amounts of α-ketoglutarate. The diagnosis can be confirmed by direct sequencing of the *PC* gene on 11q13. Management consists of frequent carbohydrate meals and intravenous dextrose support during illness.

Phosphoenolpyruvate Carboxykinase Deficiency

Phosphoenolpyruvate carboxykinase (PEPCK) enables conversion of oxaloacetate to phosphoenolpyruvate. Cytosolic and mitochondrial isoforms are encoded by *PEPCK1* and *PEPCK2*, respectively. Autosomal recessive deficiencies of both have been described with hypoglycemia but are rare.[322] Deficiency of the cytosolic form was described in 1976 in a patient with severe hypoglycemia and fatty infiltration of the liver.[325,326] The hypoglycemia was found in the second day of life and had features of hyperinsulinism, but did not respond to diazoxide. Deficiency of the mitochondrial form in several children has caused lactic acidosis, hypoglycemia, and liver failure in the first year of life.[327]

Fructose 1,6-Diphosphatase Deficiency

Fructose 1,6-diphosphatase (FDPase, or fructose 1,6-bisphosphatase) catalyzes the irreversible splitting of fructose 1,6-diphosphate to fructose-6-phosphate. It is encoded by *FBP1* on chromosome 9q22.32. This is a key enzyme of gluconeogenesis; deficiency impairs the formation of glucose from lactate, glycerol, and gluconeogenic amino acids such as alanine. Some of the clinical features of deficiency of FDPase resemble those of deficiency of glucose 6-phosphatase (GSD 1), another major enzyme of gluconeogenesis, though glycogenolysis is not affected in FDPase deficiency.

Hypoglycemia due to FDPase deficiency was first described in 1970 by Baker and Winegrad.[328] FDPase deficiency presents typically in the first days of life, but up to 50% of cases present later than this. Typical manifestations include hyperventilation from lactic acidosis and ketoacidosis, seizures and coma from hypoglycemia, and hepatomegaly. Attacks are precipitated in infancy and childhood by prolonged fasting and intercurrent illness rather than by fructose ingestion. Unlike in hereditary fructose intolerance, liver dysfunction and renal tubular dysfunction are rare. Uric acid is elevated. The diagnosis is suspected when fasting leads to hypoglycemia and lactic acidosis, with poor glycemic response to glucagon. The diagnosis may be confirmed by enzyme studies from liver biopsy material or by gene test. It may be differentiated from GSD type 1 by the fed glucagon stimulation test. Acute treatment is by intravenous glucose and bicarbonate infusion. Chronic treatment is avoidance of prolonged fasting and a reduction but not total elimination of fructose from the diet.[329]

Hereditary Fructose Intolerance

Hereditary fructose intolerance (HFI) was first described as an idiosyncrasy to fructose[330] and was later determined to be caused by mutation of the gene for aldolase B (*ALDOB* at 9q31.1).[331,332] Aldolase splits fructose 1-phosphate to dihydroxy-acetone phosphate and glyceraldehyde, substrates for gluconeogenesis via fructose 1,6-diphosphate. Fructose 1-phosphate accumulates in liver and kidney cells causing phosphate depletion and gradual long-term organ damage. Phosphate depletion further contributes to hypoglycemia by impairing glycogenolysis.[333] Although discussed here with FDPase deficiency, the hypoglycemia of HFI occurs in the hours after fructose ingestion and in timing is more a reactive than a fasting hypoglycemia.

HFI presents in infancy, after fructose is introduced to the diet in fruit or sucrose. Fructose ingestion induces vomiting, abdominal pain, diarrhea, and hypoglycemia.[334] With substantial ingestion, lactic and uric acids and magnesium rise, and phosphorus, potassium, and bicarbonate fall. Severity of symptoms is somewhat proportional to the amount of fructose and in early infancy large amounts may produce shock, acute liver failure, and death. Acute treatment of hypoglycemia by intravenous glucose rapidly reverses symptoms, and the patient remains healthy if fructose exposure is discontinued. Chronic fructose ingestion causes failure to thrive and increasing liver dysfunction. The earliest renal effect is proximal tubular damage with glucosuria and phosphaturia, but prolonged exposure to fructose can lead to kidney failure.

Fructose challenge is potentially dangerous and not necessary to make the diagnosis as the gene test is commercially available if clinical evidence suggests HFI.[329] Chronic treatment is the avoidance of all fructose-containing food (such as sucrose and high-fructose corn syrup); as sorbitol is metabolized to fructose, it needs to be excluded as well.[329]

Defects of Fatty Acid Oxidation

Fatty acid oxidation (FAO) provides a significant proportion of energy required to sustain normal glucose levels during fasting. Glycerol serves as a direct substrate for gluconeogenesis, and mitochondrial oxidation of acyl-CoA derived from free fatty acid metabolism produces ketones (β-hydroxybutyrate [BOHB] and acetoacetate [AcAc]) and reduces glucose consumption by muscle and other peripheral tissues. The key steps in carnitine uptake, mitochondrial transport, and oxidation of fatty acids are outlined in Chapter 6. The spectrum of genetic disorders of mitochondrial fatty acid transport and oxidation is remarkably wide, with specific disorders affecting every organ system at any age to produce many different presenting problems. Newborn screening and improved methods of investigation are demonstrating that disorders of fatty acid metabolism and mitochondrial function are relatively common.[335]

Hypoglycemia can be severe and persistent, manifest in the first days of life (Chapter 6), or may appear at several months of age as feeding intervals lengthen. Defects of FAO are especially likely to become clinically apparent

during the accelerated starvation of catabolic illness associated with vomiting. Because FAO and ketone body generation is impaired, hypoglycemia associated with FAO disorders is usually hypoketotic. The hypoglycemia may be accompanied by an encephalopathy that has mimicked Reye syndrome and does not always immediately respond to glucose.[336,337] Unrecognized, such episodes may be fatal and may resemble sudden infant death syndrome.[338] Diagnosis is often suggested an abnormal plasma acylcarnitine profile or abnormal urine organic acids (especially dicarboxylic aciduria). Confirmation can be made by metabolic studies of liver tissue or cultured fibroblasts and increasingly by genotyping.

Cardiac and skeletal muscle weakness is a prominent feature with certain defects, principally long-chain acyl CoA dehydrogenase, carnitine transport deficiency, and carnitine transferase deficiency. In patients with carnitine transport deficiency, supplementation with carnitine may improve the clinical features—including improvement in the cardiomyopathy over a period of weeks to months.[339]

The primary treatment of these disorders of FAO is avoidance of fasting. In older children, fasting of as long as 10 to 12 hours may be possible without the manifestations. Once an index case has been identified, acute illness with fasting should be treated by rapid institution of intravenous glucose to reverse an evolving episode or to prevent its occurrence.

Several drugs or chemicals that interfere with FAO may mimic the features of inherited defects in FAO, including hypoglycemia. Principal among these is the use of valproic acid, which has been associated with unusual episodes of hypoglycemia with a Reye-like syndrome and hypoketosis. Elevation of ammonia levels and secondary carnitine deficiency may make this side effect appear similar to an FAO defect, leading some to recommend carnitine as a supplement for infants receiving valproic acid.[99] Urine organic acids and an acyl carnitine profile will easily distinguish these conditions.

Plant toxins can occasionally produce hypoglycemia by impairing fatty acid oxidation as well. Hypoglycine, a component of unripe ackee fruit found in the Caribbean and Africa, causes hypoglycemia by interfering with FAO.[100] Atractyloside, found in certain Mediterranean plants, uncouples oxidative phosphorylation in the mitochondria.[101]

Defects of Organic or Amino Acid Metabolism

Hypoglycemia may occur with several inborn errors of organic acid and amino acid metabolism. Many of these are diagnosed in the newborn period by extended newborn screening tests based on mass spectrometry. In some patients with defects of organic or amino acid metabolism, hypoglycemia is a common manifestation presenting in early infancy; in most of the others it is atypical, infrequent, or mild. [340]

Hypoglycemia usually occurs during episodes of encephalopathic metabolic decompensation, sometimes spontaneous and sometimes triggered by a stressful illness or starvation. Vomiting and sometimes tachypnea may be prominent symptoms. Many of the conditions result in impairment of physical growth or neuromuscular development even when severe episodes are infrequent. The major clue to diagnosis is usually a pattern of characteristically abnormal organic acids in the urine. In most cases, management (or at least hypoglycemia prevention) consists of providing intravenous glucose at the onset of illness or at the earliest signs of decompensation.

Hypoglycemia also occurs in association with advanced liver disease in neonatal hemochromatosis, tyrosinosis type 1, S-adenosylhomocysteine hydrolase deficiency, type 3 glycogenosis, and some of the disorders of mitochondrial function. Though galactosemia results in a depletion of hepatic phosphate that is similar to the aldolase deficiency of hereditary fructose intolerance, hypoglycemia is uncommon until liver damage is advanced.

Hypoglycemia accompanied by ketosis and lactic acidosis has also been reported in late-onset maple syrup urine disease and glycerol kinase deficiency. In disorders of ketolysis (deficiencies of succinyl CoA transferase and 3-ketothiolase), ketone levels may be quite high but lactic acidosis may not be present.

Hypoglycemia in Fasting, Starvation, Illness, and Stress

Under controlled conditions, well-nourished children can maintain glucose above 70 mg/dL (3.9 mM) for increasing durations between meals. As fasting is prolonged and ketosis supplies a greater proportion of fuel, plasma glucose levels will fall below 50 mg/dL (2.8 mM) in some healthy children and young women without autonomic or neuroglycopenic symptoms or apparent ill effects.[17,22,341] This is occasionally found with preoperative fasting.[342,343] In uncontrolled, real-life illnesses, alterations of carbohydrate metabolism can occur that are less predictable and benign. Most operate to enhance peripheral glucose uptake and utilization, to increase glucose production, and to depress glycogen formation and insulin sensitivity, resulting in hyperglycemia or hypoglycemia, depending on the patient's nutritional state, severity and duration of illness, and other factors.[344] Rewarming after hypothermia and salt-water near-drowning are examples of severe stresses in which hypoglycemia has been repeatedly observed.[345,346]

Hypoglycemia During Starvation and Malnutrition

The ability to maintain euglycemia is compromised by malnutrition, and hypoglycemia in malnourished infants and adults can be both dangerous and difficult to reverse, even with intravenous glucose.[347,348] In African children with kwashiorkor, hypoglycemia has been reported to be both common and a predictor of death.[349] In the developed world, anorexia nervosa is one of the most common causes of severe malnutrition and hypoglycemia is common and occasionally severe.[350-353]

Hypoglycemia with Prolonged Exercise

Glucose is utilized at a higher rate by muscle during prolonged exercise. Insulin sensitivity is acutely enhanced, at least partly by myocytes secreting a peptide (irisin) that stimulates energy expenditure by adipocytes.[354,355] Hypoglycemia is normally prevented by increased secretion of

catecholamines.[356-358] However, hypoglycemia has long been recognized as an occasional effect of intense exercise even in presumably healthy adults and can be prevented by complex carbohydrates but not extra sugar.[359] Cases of hypoglycemia severe enough to cause seizures after a marathon or comparable exercise have been reported.[360-362] Demonstration that exercise can acutely reverse the compensatory insulin resistance of starvation provides a likely explanation for many. [363] With the discovery of exercise-induced hyperinsulinism (described previously), it may be that at least some of these instances reflect unsuspected disorders of metabolism.[137]

Diarrheal Illness

Hypoglycemia may occur in infants and children with severe diarrhea.[270] It is uncommon in previously healthy children with acute viral gastroenteritis (e.g., rotavirus) unless there has been a period of starvation (as occurs after prolonged use of water or sugar-free fluids).[364] Hypoglycemia in this setting is usually ketotic and has a good outcome. However, it is important that the history of prolonged starvation be confirmed and disorders of fatty acid oxidation be ruled out, as hypoglycemia is uncommon in healthy children. In one survey of sequential emergency department patients with hypoglycemia, 28% had a significant unsuspected metabolic or hormonal disorder.[281]

When diarrhea develops in malnourished children, such as during cholera or shigella outbreaks in the Third World, hypoglycemia is a dangerous problem.[365,366] During severe malnutrition, gluconeogenic substrates such as alanine and lactate are significantly reduced, the capacity to generate glucose by gluconeogenesis is markedly diminished, and alternative fuels such as ketones and lactate are also reduced. In this situation, almost half of patients with hypoglycemia plus diarrhea died with an encephalopathic picture—indicating that hypoglycemia in the malnourished child is a poor prognostic sign.[367]

Sepsis

Severe hypoglycemia is a potential presentation of sepsis, especially meningococcemia.[368,369] Animal research suggests that septicemia may produce early hyperglycemia followed by a drop of blood sugar attributed to increased glucose uptake by multiple organs, and that cytokines like tumor necrosis factor may amplify glucose uptake.[370] Limited measurements on humans indicate appropriate suppression of insulin and elevation of counter-regulatory hormones as well as cytokines.[371]

Specific Infections

Hypoglycemia has been described as occurring in approximately one third of children with severe malaria.[372] As in those with diarrhea and hypoglycemia, there is increased mortality in children with malaria associated with hypoglycemia. Insulin levels in such children were reported to be appropriately low, whereas ketones, lactate, and alanine levels were high—suggesting impaired gluconeogenesis.[373] Provision of glucose is therefore indicated for such patients. In addition, the therapy for malaria (in particular, quinine) may aggravate hypoglycemia because of its ability to stimulate insulin release.[374]

Hypoglycemia has been repeatedly reported in pertussis infection, with some animal evidence suggesting a hyperinsulinemic hypoglycemia rather than simply a fasting effect.[375] Though infant insulin levels after pertussis immunization have been reported slightly higher, no instances of hypoglycemia have been attributed to pertussis immunization.[171]

Hypoglycemia in Organ System Disease

Hypoglycemia is common in critically ill patients of all ages[376,377] and can occur in failure or severe disease of nearly every major organ system.

The liver is the principal source of glucose during postabsorptive periods, and under experimental conditions, hypoglycemia occurs after a loss of 80% of the liver. Hypoglycemia in human liver disease is less predictable. In cirrhosis and progressive liver failure, glucose levels usually remain normal even into hepatic coma. However, fasting hypoglycemia can occur sporadically in many forms of liver disease, with little dependence on the severity of liver impairment by other measures.

Hypoglycemia has been reported in adults and children with drug injury, poisoning,[378] infectious hepatitis,[379,380] suppurative cholangitis,[381] and poor hepatic perfusion.[382,383] Hypoglycemia can occur as an occasional complication of various rare genetic diseases that affect the liver. For example, citrin deficiency has an intermediate, childhood-onset form characterized by growth retardation, episodic neurologic and behavioral abnormalities with hyperammonemia, and sometimes hypoglycemia.[384]

Renal gluconeogenesis also normally contributes to maintenance of blood glucose during fasting, and hypoglycemia may occur in patients with end-stage chronic renal failure.[382,385-387] Because autonomic responses to hypoglycemia are often impaired in chronic renal failure, neuroglycopenic manifestations typically predominate. In many cases, hypoglycemia occurs as a complication of dialysis or other circumstances and the existence of a specific "uremic hypoglycemia" has been challenged.[388]

Many cases of fasting hypoglycemia associated with both acute and chronic pancreatitis have been reported in adults and children.[364,389-391] Both hypoglycemia and hyperglycemia were recognized complications of mumps pancreatitis in children.[390,392]

The causes of hypoglycemia associated with severe heart disease, both cyanotic congenital heart disease in young children[393] and congestive heart failure in older children,[394-396] are complex, with evidence of both increased glucose uptake and impaired gluconeogenesis. In infants, hypoglycemia can cause heart failure that improves with restoration of normal glucose levels.[397]

Skeletal muscle contributes substrates to gluconeogenesis during fasting, and fasting hypoglycemia occurs with several forms of muscular dystrophy and spinal muscle atrophy characterized by reduced muscle mass.[398-401] A novel mechanism for hypoglycemia due to intracranial disease would be alteration of the afferent or efferent limbs of hypothalamic glucose sensing; this can be demonstrated in rodents and has been invoked in

rare cases of hypoglycemia accompanying brain tumors and trauma.[402,403]

Hypoglycemia accompanied by lactic acidosis has been reported as both uncommon presentations and end-stage events in patients with acute and chronic leukemias and lymphomas.[404] However, children on prolonged chemotherapy regimens have been found to have a high rate of fasting hypoglycemia due to depleted glycogen and gluconeogenic precursors and to direct effects of oral purine analogs.[405-407]

Hypoglycemia in the Intensive Care Unit

New, symptomatic hypoglycemia in a previously well child is uncommon and usually attributable to a single, identifiable diagnosis. In contrast, hypoglycemia occurs in up to 10% of critically ill children, is often asymptomatic, and is associated with poorer outcomes.[376,408] In addition to processes specific to the underlying diseases, multiple contributing factors may include substrate depletion, accelerated glucose consumption, undernutrition, impaired gluconeogenesis, cytokine effects, and adrenal insufficiency. Iatrogenic factors such as misplaced infusion lines, changes of intravenous dextrose, or drug effects need to be considered.[409] Factors affecting measurement reliability (e.g., altered hematocrit, oxygenation, line draws, drugs) are more common in the intensive care unit (ICU).[410] Finally, the treating physician should not forget the possibility that an acute illness is unmasking a previously compensated disorder of glucose metabolism, especially in a young child.[281]

Insulin use is the most common cause of hypoglycemia in the ICU. With evidence suggesting that outcomes from stroke, myocardial infarction, surgery, and infection are better with suppression of hyperglycemia, intensive care physicians have striven for tighter glycemic control, and the frequency and risks of hypoglycemia are being scrutinized.[411] It is not clear that iatrogenic hypoglycemia during intensive glycemic control has the same association with adverse outcome reported with spontaneous ICU hypoglycemia.[412] One study detected no neurocognitive outcome differences in children a few years after surgical management with or without aggressive glycemic control.[413] A variety of methods and algorithms have been devised to reduce the hypoglycemia risk,[414] and it seems likely that these will be further improved in the near future with continuous glucose sensors and limited closed-loop systems.[376]

Hypoglycemia Induced by Exogenous Agents

Insulin and various diabetes medications that stimulate insulin release are the most common exogenous causes of hypoglycemia at all ages, as discussed earlier in this chapter. Although the literature of the 20th century contains reports of hypoglycemia associated with hundreds of other agents, the evidence of a causal relationship is weak for most and represented by very few cases.[171,173,415,416] In children, hypoglycemia due to exogenous agents usually represents accidental ingestions. Ethanol, salicylates, quinine, and beta-blockers such as propranolol are the most frequent single agents implicated in childhood hypoglycemia. Rare cases of hypoglycemia have also been reported with sulfonamide and cotrimoxazole use in children, as well as in hepatic failure due to acetaminophen overdose. Pentamidine is one of the most common nondiabetes medications reported to cause hypoglycemia in adults in therapeutic doses. Hypoglycemia is also an uncommon effect of recreational drugs such as ecstasy and paramethoxyamphetamine.[376]

Alcohol-Induced Hypoglycemia

Ethanol is a notorious cause of severe fasting hypoglycemia in young children and malnourished alcoholic adults, and occasionally in healthy adolescents who are intoxicated.[417] The liver consumes nicotinamide adenine dinucleotide (NAD+) and produces NADH as it oxidizes ethanol. The depletion of NAD+ slows oxidation of lactate to pyruvate, thus impairing gluconeogenesis and the production of glucose during later stages of fasting.[418] In young children who have been fasting overnight, consumption of even small quantities of alcohol can acutely precipitate hypoglycemia.[419] Cases of severe hypoglycemia have occurred from ingestion of mouthwash or skin absorption of rubbing alcohol.[420,421] Numerous home products—including cologne, deodorants, and hand sanitizers—contain substantial amounts of ethanol.[422]

Salicylate Intoxication

In high doses, salicylates have enough hypoglycemic potency that they have been used experimentally to treat diabetes, although the exact mechanism of action remains uncertain.[423] Suggested mechanisms include stimulation of insulin release, inhibition of gluconeogenesis, increased peripheral glucose uptake, and suppression of lipolysis.[424] Infants appear to be more susceptible than older children to salicylate-induced hypoglycemia, and prior to their therapeutic abandonment for young children in the 1980s because of concerns about a role for salicylates in causing Reye syndrome, numerous cases were reported.[425]

Reactive Hypoglycemia and "Spells"

Reactive hypoglycemia refers to symptomatic hypoglycemia occurring 1 to 4 hours after a meal. The pathophysiologic concept is simple and familiar: if insulin secretion after a carbohydrate meal is excessive or prolonged in relation to incoming glucose during digestion, plasma glucose can fall to hypoglycemic levels. Potential causes of a mismatch of insulin secretion and carbohydrate digestion include accelerated carbohydrate digestion, disordered gastrointestinal-beta cell signaling, delayed insulin secretion, abnormal prolongation of insulin action, and abnormal insulin release.

Symptomatic reactive hypoglycemia characterized by a measurably low glucose accompanying neuroglycopenic symptoms (i.e., Whipple's triad) is uncommon, and a specific diagnosis should be sought among the forms of hyperinsulinism discussed earlier in this chapter. Alimentary hyperinsulinism (discussed earlier in the chapter) after Nissen fundoplication or gastric bypass surgery

likely involves both acceleration of carbohydrate digestion and excessive intestinal secretin signaling. Delaying gastric emptying is the primary treatment. Case reports of spontaneous acceleration of gastric emptying have been less convincing.[426,427] The most common form of delayed insulin secretion occurs during the gradual development of type 2 diabetes, when first-phase insulin response is diminishing and postprandial glucose peaks are higher. A similar pattern can occur with more severe forms of insulin resistance, but in these conditions the plasma glucose rarely falls to neuroglycopenic levels and may be difficult to distinguish from the purely autonomic symptoms of idiopathic postprandial syndrome (discussed later). Insulin effects may be delayed and prolonged by antibody binding, as occurs with autoimmune hypoglycemia. In up to 25% of patients with insulinoma, the worst hypoglycemic episodes are reactive rather than fasting. In some forms of genetic hyperinsulinism detected after infancy, postprandial hypoglycemia may be more apparent than fasting hypoglycemia, but in these cases hypoglycemia is triggered by ingestion of protein, not carbohydrates. The initial evaluation should be directed toward obtaining a critical sample during documented hypoglycemia, during admission for a diagnostic fast if necessary.

History of the Reactive Hypoglycemia Controversy

In contrast to the theories presented earlier in this chapter, the popular conception of reactive hypoglycemia as a likely explanation for any postprandial symptoms has persisted since the 1930s. Patients suspicious that they (or their children) have such a condition regularly present to the endocrine clinic. Within a decade of the first successful diagnosis and surgical cure of an insulinoma in 1929,[428] it became clear that not all patients with symptoms of hypoglycemia had demonstrable insulinomas curable by surgery. Seale Harris postulated that in some people an exaggerated insulin response to carbohydrate meals could cause transient hypoglycemia 2 to 4 hours later.[219] In these patients, symptoms could often be alleviated or prevented by more frequent meals containing more protein and less sugar and starch. Some of the patients who demonstrated this pattern seemed to be in the early stages of developing diabetes. Very few had insulinomas, and Allen Whipple is credited with the criteria for identifying patients whose hypoglycemia was potentially dangerous and might be curable by surgery; referred to as Whipple's triad, the criteria include (1) measurably low glucose accompanying (2) symptoms characteristic of hypoglycemia that are (3) relieved by raising the glucose.[197] Nonetheless, diagnoses of reactive hypoglycemia, based solely on symptoms or on OGTT patterns, became epidemic. Various treatment regimens, ranging from benign (frequent snacks, avoiding sugar) to pernicious (oral diabetes drugs, elaborate dietary restrictions, vagotomy, expensive supplements, or "adrenal extracts" of uncontrolled composition), have been offered.

However, further research shed doubt on the nature, and even the existence, of this common form of reactive hypoglycemia.[429] The OGTT pattern often considered characteristic of reactive hypoglycemia, with a nadir below the fasting glucose, occurs in most people.[223,230] A plasma glucose level below 50 mg/dL in the third, fourth, or fifth hour occurs without symptoms in 10% of adults.[430,431] Few of the self-diagnosed patients' symptoms coincided with low glucose levels, and low glucose levels were often not accompanied by symptoms.[432,433] Some showed the same symptoms after a placebo.[431] Symptoms could not be correlated with objective evidence of neuroglycopenia (e.g., electroencephalographic changes). Attempts to identify pathognomonic counter-regulatory hormone responses have been uncontrolled, unconfirmed, or demonstrated patterns indistinguishable from asymptomatic people.[434-438] Few patients with self-diagnosed reactive hypoglycemia show any abnormalities of glucose metabolism as determined by more rigorous tests for hyperinsulinism.[439] A "diabetic pattern" of early hyperglycemia with an exaggerated decline can occur in prediabetic adults but can also be produced by low carbohydrate intake prior to the OGTT.[440] The reproducibility of patterns and symptoms within the normal range is limited.[441] Symptoms provoked by a mixed meal tolerance test differed from those resulting after an OGTT.[442,443] The diagnostic test with a stronger demonstrated association with reactive hypoglycemic symptoms than any measure of glucose metabolism was the Minnesota Multiphasic Personality Test.[433,444,445] These problems led some endocrinologists to reject the entire concept of reactive or "functional hypoglycemia" as illusory or at least unrelated to glucose metabolism, preferring the term *idiopathic postprandial syndrome* as a more accurate descriptor.[443] The American Diabetes Association and the Endocrine Society formulated a position statement in 1973 supporting the need to demonstrate low glucose values at the time of symptoms, as well as improvement after glucose ingestion, in order to validate a diagnosis of hypoglycemia.[446] The value of the Whipple's triad criteria for suspected reactive hypoglycemia was reiterated in the 2009 hypoglycemia guidelines of the Endocrine Society.[71]

Approach to the Patient with Episodic "Hypoglycemic" Symptoms

Pediatric endocrinologists are often asked to evaluate older children and adolescents who have had episodic autonomic or dysphoric symptoms attributed to hypoglycemia. A demonstration of low glucose at the time of neuroglycopenic symptoms warrants a diagnostic fast, as potentially dangerous forms of hypoglycemia are nearly always disorders of fasting.[447] The differential diagnosis list for symptoms suggestive of hypoglycemia is lengthy and includes seizures, hyperventilation, and anxiety attacks[448-451]; syncope with exercise warrants immediate cardiac evaluation.[452] Most adolescents with "spells" referred for hypoglycemia evaluation have simple orthostatic hypotension or vasovagal syncope[453] and, in a few, the more disabling postural orthostatic hypotension syndrome (POTS).[454,455]

If recurrent symptoms are frequent and sufficiently suggestive of hypoglycemia, an attempt should be made to measure plasma glucose concentration during symptoms. Although self-monitoring of plasma glucose by

meter may be useful, results may not be reliable. Because glucose meters often yield erratic patterns, especially in the hands of nondiabetic patients, multiple glucose tests at similar times of the day are needed for comparison. It is important to prepare the parent for interpreting the overall pattern, rather than focusing on one or two unusual glucose values, because healthy people can have occasional high or low glucoses.[456] Normal meter glucoses do not exclude the possibility that symptoms may improve with the standard dietary recommendations for mild reactive hypoglycemia, which are that affected individuals (1) eat breakfast, (2) reduce sugar and starch intake in favor of low-glycemic index carbohydrates but do not restrict carbohydrates, (3) include fat and protein with meals and snacks, and (4) try a morning or afternoon snack.[457] An oral glucose tolerance test is of no value for excluding serious disorders of fasting hypoglycemia and is also not useful for testing the possible benefit of the standard dietary modifications.[458]

Behavior Problems as Effects of Hypoglycemia or Dietary Sugar

Another category of problem often brought to the endocrine clinic as possible hypoglycemia is distressing or aggressive behavior, mood, or school problems that, to the parent, seem either caused by or relieved by sugar. Decades of psychologic,[459,460] social science,[461-463] criminological,[50,464] childrearing,[465] and alternative medicine literature[466] perpetuate the putative connection between problem behavior and hypoglycemia or sugar ingestion. Supportive evidence tends to be poorly controlled or speculative; better-designed studies provide little support for such an effect.[467-470] Although there is evidence that autonomic activity, sleep, mood, and behavior can be affected by dietary carbohydrates in humans and rodents,[471,472] these behavioral effects are not evidence of hypoglycemia and no tests of carbohydrate metabolism will provide guidance for diet or management. Even the link between hyperactive behavior and sugar ingestion evaporates when tested with careful controls.[473,474]

Artifactual Hypoglycemia

When a low glucose level is unexpectedly reported in a "well" child who has an outpatient chemistry profile drawn for reasons unrelated to carbohydrate metabolism, it is most often a spurious result. The most common cause of postphlebotomy artifactual hypoglycemia is glucose consumption by red blood cells during a long delay before measurement.[475,476] This can be reduced but not eliminated by chilling the specimen and by newer collection tubes designed to sequester cells from serum.[477] Fluoride tubes reduce but do not eliminate glucose consumption, and glucose levels may decline by 20% or more when processing is delayed for even a few hours.[478] Unfortunately, postphlebotomy glycolysis consumes a higher proportion of glucose when the specimen contains a low level when drawn. Spurious hypoglycemia is more common when either the red cell or the white cell counts are elevated.[479,480]

Blood glucose meters have an inherent imprecision of at least 15% even under optimal conditions.[79,481] Continuous glucose sensors are being increasingly used to track patterns of glucose, but absolute nadirs are often inaccurate and their usefulness in evaluating hypoglycemia is doubtful.[482-485] Nevertheless, it is important to stress that unexpected low glucose levels should not be ignored because of the possibility that a "fluke" lab test may detect an unrecognized chronic hypoglycemic condition.

FASTING SYSTEM APPROACH TO DIAGNOSIS

The pathophysiology of fasting and the intricate balance of hormonal changes and their effects on intermediary metabolites is the key to discovering the cause of hypoglycemia. Normal infants, children, and adults may develop hypoglycemia if fasted long enough. At the time of hypoglycemia, a blood and urine sample (the critical sample) should demonstrate the normal adaptive changes that occur with time. In an infant or child who presents with unexplained hypoglycemia, the testing of this hypoglycemic sample may be pivotal in making the diagnosis and may avoid prolonged, dangerous, or expensive testing.

History

For a previously well child, the timing of hypoglycemia in relation to the child's last meal may provide a useful clue. Hypoglycemia occurring in the immediate postprandial period—reactive hypoglycemia—suggests excess insulin secretion. A previous fundoplication or other gastric surgery suggests alimentary hyperinsulinism. Hypoglycemia occurring in the early postabsorptive hours may be hyperinsulinism but can also occur with the more severe glycogen storage diseases. Hypoglycemia after several hours of fasting suggests disorders of FAO, of gluconeogenesis, or of the hormones that control these processes. The presence of sulfonylureas, insulin, or alcohol in the household suggests ingestion or injection.

Clinical Examination

Physical findings are only occasionally useful, typically in infants. Hepatomegaly suggests a GSD or an FAO disorder. Short stature or failure to thrive often occurs in a GSD, Fanconi-Bickel syndrome, and hypopituitarism. Neuromuscular signs may occur in association with FAO disorders and adrenoleukodystrophy. Midline defects such as central cleft lip and palate, single central incisor, optic nerve hypoplasia, or micropenis are often associated with pituitary hormonal deficiencies.

Critical Sample

Finally, the third stage revolves around the critical sample (see Figure 21-5). The key feature to assess is the presence or absence of acidosis. This can be determined from basic studies before the results of the intermediary metabolites. A chemistry panel with measurement of bicarbonate levels and a urine dip for ketones will be immediately available in most centers. In addition, a lactate level should be easily available.

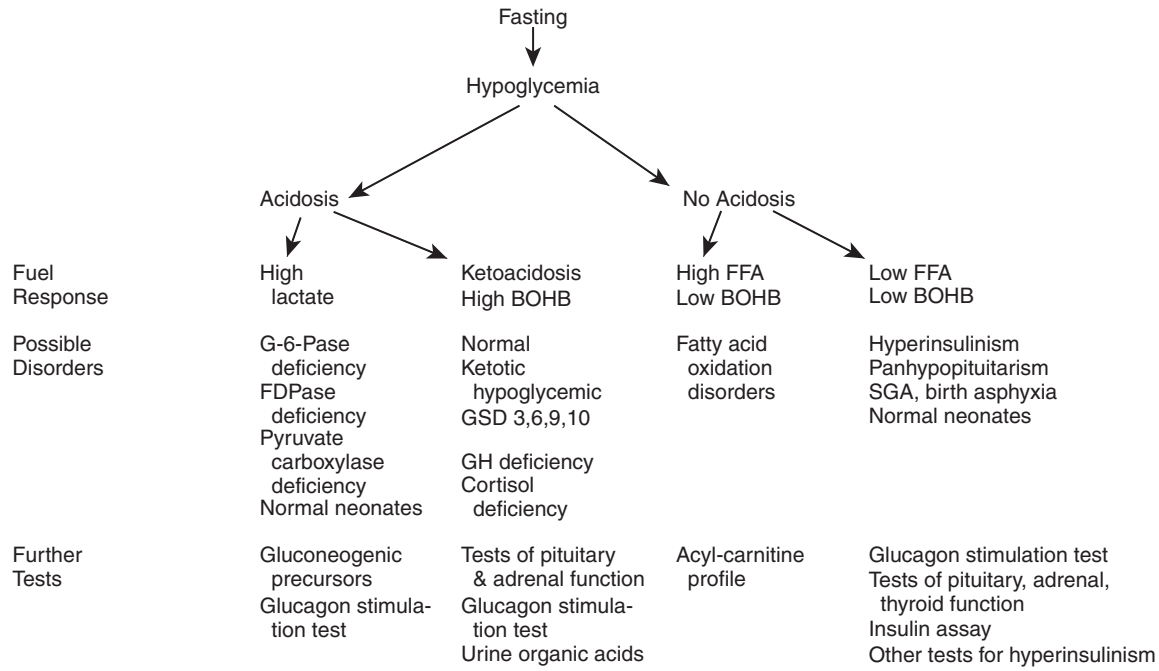

FIGURE 21-5 ■ An algorithmic approach to hypoglycemia. *FDPase,* fructose 1,6-diphosphatase; *FFA,* free fatty acids; *G-6-Pase,* glucose 6-phosphatase; *GH,* growth hormone; *GSD,* glycogen storage disorder; and *SGA,* small for gestational age.

Acidosis with elevated lactate and absent ketones suggests disorders of glycogenolysis or gluconeogenesis. GSD type 1 and a fructose 1,6-diphosphatase (FDPase) deficiency may be difficult to differentiate, and a fed glucagon stimulation test may help. There will be a rise in lactate and no rise in glucose in GSD type 1, with a rise in glucose in FDPase deficiency. An intravenous fructose tolerance test may be required. In the older child, lactic acidosis and hypoglycemia may suggest alcohol ingestion.

Acidosis with ketones occurs in normal fasting children, idiopathic ketotic hypoglycemia, and GSD types 3, 6, 9, and glycogen synthetase deficiency. Ketones also may be present in deficiencies of GH and cortisol. Disorders of FAO may sometimes present as small to moderate ketones in the urine, particularly when the patient is dehydrated. Some forms (such as the short-chain length disorders, the disorders of electron transport, and HMG-CoA lyase deficiency) may also have mild ketosis.

No acidosis or ketones in the urine is strongly suggestive of hyperinsulinism caused by genetic defects, insulinoma, accidentally administered excess insulin, deliberately administered insulin with intent to harm, or oral hypoglycemic agents. FAO defects will often be hypoketotic, but patients with some forms may have trace or small ketones in the urine. Those with hyperinsulinism will have neither elevated free fatty acids nor elevated ketones, whereas those with FAO will have elevated free fatty acids and low ketones. FAO may be diagnosed by acyl-carnitine profile or by urine organic acid measurement. Hyperinsulinism owing to genetic defects and insulinoma can be differentiated from insulin administration by the presence of C peptide in the plasma at the time of hypoglycemia. Oral hypoglycemic agents will have elevated insulin and C peptide, and the diagnosis will be missed unless suspected and unless a urine toxicology with a request for the specific drug to be sought is performed.

EMERGENCY TREATMENT OF HYPOGLYCEMIA

Once the critical sample has been obtained, a minibolus of 0.2 g/kg of dextrose should be administered by intravenous infusion over 1 minute (2 mL/kg of 10% dextrose; see Table 21-4). This should be followed by a continuous intravenous infusion of 8 mg/kg/min using dextrose 10% solution. This rate of glucose administration may be rapidly and conveniently calculated by using the simple formula that 5 mL/kg/hr of a 10% dextrose solution provides approximately 8 mg/kg/min of glucose. Glucose levels should be determined 15 minutes after the bolus has been given and while the maintenance glucose infusion is running. If hypoglycemia recurs, a bolus of 0.5 g/kg may be given (5 mL/kg of dextrose 10%) and the glucose infusion increased by 25% to 50%. For details of specific treatments of individual disorders, see the sections on each condition.

QUESTIONS

A 30-month-old boy was too lethargic to be fed after his mother tried to awaken him in the morning. He was rushed to the local emergency department where he was still obtunded and lab glucose was 37 mg/dL. He improved with intravenous dextrose. An analysis of bagged urine shows a large amount of ketones. No other diagnostic tests have been done when you are called for advice 2 hours later, around noon.

1. Which history may be most relevant to the cause of his hypoglycemia?
   a. His grandmother, who lives with him, takes glyburide,
   b. His mother had gestational diabetes requiring insulin,
   c. His length is small compared to family heights,
   d. He has been taking both inhaled and nasal fluticasone for asthma and rhinitis,
   e. Both c and d

Answer: e. The ketonuria makes it unlikely that his hypoglycemia is due to injected insulin or sulfonylurea ingestion. However, both growth hormone deficiency and adrenal insufficiency due to suppression can cause morning hypoglycemia with ketosis.

2. Tests that will be of most value if obtained in the next hour include which of the following?
   a. Basic chemistry panel
   b. Insulin and C-peptide
   c. Cortisol and growth hormone
   d. Acylcarnitine profile and urine organic acids
   e. Both a and d

Answer: e. It is important to see if he is acidotic, and both the acylcarnitine profile and the urine organic acid will remain abnormal even after immediate correction of hypoglycemia for most organic acidoses and some of the disorders of fatty acid oxidation. Insulin and c-peptide will have already risen from the dextrose, and single GH and cortisol levels at noon would be of limited value for excluding adrenal or pituitary deficiency.

A 15-year-old girl complained to her family doctor of "almost passing out" on three occasions late in the morning at school. Her doctor ordered a fasting chemistry panel that was unremarkable except for a glucose level of 62. Her doctor then ordered a 5-hour oral glucose tolerance test that produced the following glucose levels without symptoms: 88, 123, 78, 61, 69, and 75. Which of the following statements are true?

3. A low fasting glucose in a routinely ordered chemistry panel drawn when this patient was asymptomatic is more likely to be an artifact of delayed specimen processing than hypoglycemia. True or false?

Answer: True. Routine chemistry panels are often subject to delayed separation of serum.

4. The OGTT is abnormal, as less than 10% of healthy young women reach glucose levels below 60 mg/dL in the latter half of an extended oral glucose tolerance test, and the glucose level at 2 to 3 hours should not fall below the baseline fasting value. True or false?

Answer: False. More than 10% of healthy young women will fall below 50 mg/dL during an extended OGTT. Later glucose levels during an OGTT are often lower than the baseline in healthy people.

5. An insulinoma is excluded by these test results. True or false?

Answer: False. Insulinomas are uncommon, but neither a random fasting glucose nor an OGTT changes the small probability that the patient has one.

6. An insulinoma is excluded because her symptoms did not occur while fasting. True or false?

Answer: False. Hypoglycemia from insulinomas may occur at any time in relation to meals.

7. The next step to exclude an insulinoma would be to obtain a glucose reading during symptoms, either by comparing a meter glucose obtained during symptoms with some glucoses without symptoms, or by conducting an extended diagnostic fast. True or false?

Answer: True. An insulinoma is a rare cause of such spells in adolescents, but this is a possible presentation and the next step is to try to demonstrate hypoglycemia during symptoms.

CHAPTER 22

Obesity, Metabolic Syndrome, and Disorders of Energy Balance

Ram Weiss, MD, PhD • Robert H. Lustig, MD, MSL

CHAPTER OUTLINE

INTRODUCTION

Energy balance is the "final frontier" of endocrinology. Prior to 1994, with the discovery of leptin, disorders of energy balance were not even considered to be endocrine diseases. Today, obesity can account for up to 25% of pediatric endocrine practice referrals, and type 2 diabetes accounts for up to 33% of the new referrals for pediatric diabetes, the majority of whom are also obese. Since the discovery of leptin, the negative feedback pathway of energy balance has been elucidated, and endocrinologists have embraced disorders of energy balance as part of their management portfolio. Thus, the study of energy balance has become a matter of continuing education for pediatric endocrinologists. The whole field is a work in progress, which is problematic because our diagnostic armamentarium and our treatment options for the most part do not target the multiple hormonal feedback loops that govern energy balance. This chapter conveys a clear and up-to-date basic understanding of the energy balance pathway and provides a clinical rationale and formulation for evaluating and treating these patients.

NEUROENDOCRINE REGULATION OF ENERGY BALANCE

The negative feedback axis of energy balance and its function during homeostasis has been largely delineated through studies in animal models; human data are presented where available. The axis is composed of three arms (Figure 22-1). The first is the afferent arm, which conveys peripheral information on hunger and peripheral metabolism, in the form of hormonal and neural inputs, to the hypothalamus. The second is a central processing unit, consisting of various areas within the hypothalamus. The ventromedial hypothalamus (VMH; consisting of the ventromedial [VMN] and arcuate [ARC] nuclei), integrates the afferent peripheral signals, along with other central stimuli; the paraventricular nuclei (PVN) and lateral hypothalamic area (LHA) serve as a gated neurotransmitter system to alter neural signals for changes in feeding and energy expenditure. The third component is the efferent arm and consists of a complex network of autonomic effectors, which regulate energy intake, and energy expenditure versus storage.[1,2] Anatomic disruptions or genetic or metabolic alterations of the afferent, central processing, or efferent arms can alter energy intake or expenditure in stereotyped ways, which can lead to either obesity or cachexia.

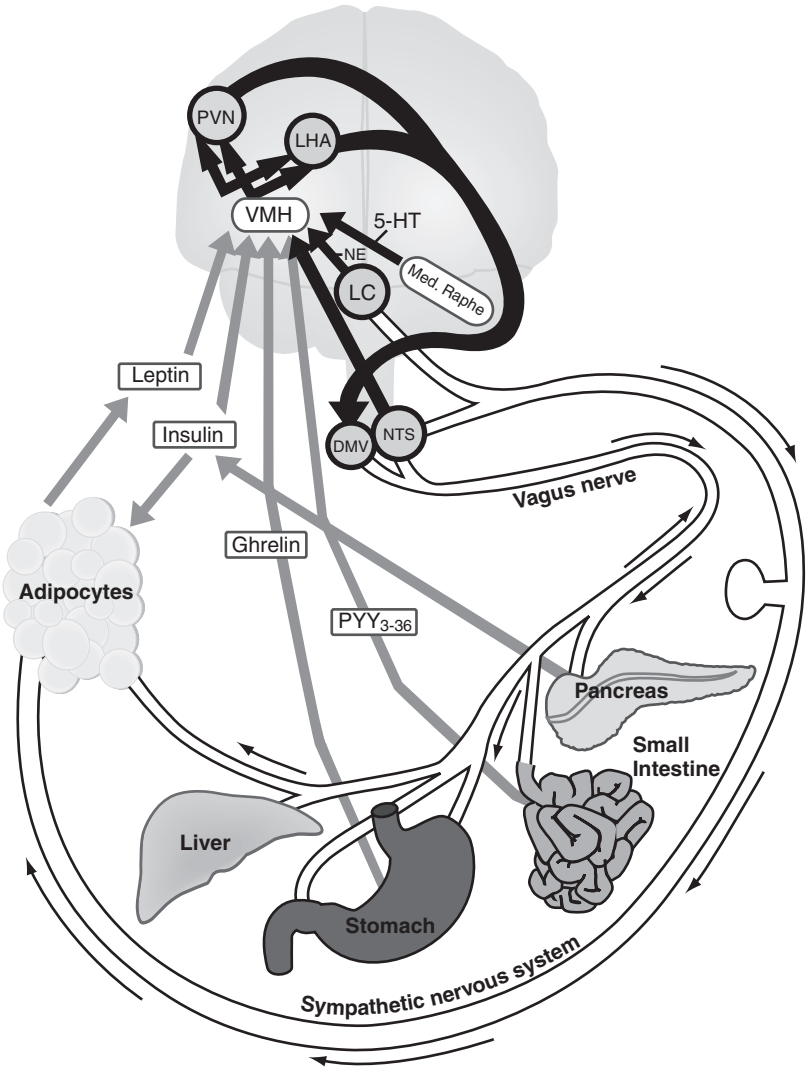

FIGURE 22-1 ■ The homeostatic pathway of energy balance. Afferent (gray), central (black), and efferent (white) pathways are delineated. The hormones insulin, leptin, ghrelin, and peptide $YY_{(3\text{-}36)}$ ($PYY_{3\text{–}36}$) provide afferent information to the ventromedial hypothalamus regarding short-term energy metabolism and energy sufficiency. From there, the ventromedial hypothalamus elicits anorexigenic (α-melanocyte stimulating hormone, cocaine-amphetamine regulated transcript) and orexigenic (neuropeptide Y, agouti-related protein) signals to the melanocortin-4 receptor in the paraventricular nucleus and lateral hypothalamic area. These lead to efferent output via the locus coeruleus, via the nucleus tractus solitarius, which activates the sympathetic nervous system, causing the adipocyte to undergo lipolysis, or via the dorsal motor nucleus of the vagus, which activates the vagus nerve to store energy, both by increasing pancreatic insulin secretion, and (in rodents) by increasing adipose tissue sensitivity to insulin. 5-HT, serotonin (5-hydroxytryptamine); DMV, dorsal motor nucleus of the vagus; LC, locus coeruleus; LHA, lateral hypothalamic area; NE, norepinephrine; NTS, nucleus tractus solitarius; PVN, paraventricular nucleus; VMH, ventromedial hypothalamus. (From Lustig, R. H. (2006). Childhood obesity: behavioral aberration or biochemical drive? Reinterpreting the First Law of Thermodynamics. *Nature Clin Pract Endo Metab, 2*, 447–458. Courtesy of Nature Publishing Group, with permission.)

The Afferent System

Alimentary Afferents

Hunger

The Afferent Vagus. The vagus nerve is the primary neural connection between the brain and the gut. The afferent vagus nerve conveys sensory information regarding the mechanical stretch of the stomach and duodenum and sensations of gastric fullness to the nucleus tractus solitarius (NTS).[3] Of note is that each of the following alimentary neuropeptide effects on hunger and satiety is obviated by concomitant vagotomy, implicating the afferent vagus as the primary mediator of alimentary energy balance signals.[4-6]

Ghrelin. Ghrelin, an octanoylated 28-amino-acid peptide, was discovered serendipitously while looking for the endogenous ligand of the growth hormone secretagogue receptor (GHS-R).[7] Ghrelin induces the release of growth hormone (GH) through stimulation of the pituitary GHS-R. The endogenous secretion of ghrelin from the fasting stomach is high, but the administration of nutrients decreases it; volumetric stretching of the stomach wall has no effect. However, ghrelin also binds to the GHS-R in the VMH, which increases hunger, food intake, and fat deposition.[8,9] Ghrelin also increases the respiratory quotient (RQ) in rats, suggesting a reduction of fat oxidation and promotion of fat storage. Ghrelin appears to tie the lipolytic effect of GH with the hunger signal and is probably important in the acute response to fasting. In humans, ghrelin levels rise with increasing subjective hunger and peak at the time of voluntary food consumption,[10] suggesting that ghrelin acts on the VMH to trigger meal initiation. Ghrelin infusion increases food intake in humans.[11] However, plasma ghrelin levels are low in obese individuals and increase with fasting,[12] suggesting that ghrelin is a response to, rather than a cause of, obesity.

Satiety

Peptide YY $_{3\text{-}36}$ ($PYY_{3\text{-}36}$). A hormonal signal to control meal volume is $PYY_{3\text{-}36}$.[13] This peptide fragment is secreted by intestinal L cells in response to the exposure to nutrient, crosses the blood-brain barrier, and binds to the Y_2 receptor in the VMH. Activation of this receptor causes a decrease in neuropeptide Y (NPY) mRNA in neurons of the orexigenic arm of the central processing system (discussed later). In nonobese humans, infusion of $PYY_{3\text{-}36}$ during a 12-hour period decreased the total amount of food ingested from 2200 to 1500 kcal, but without an effect on food ingested during the next 12-hour interval.[13] Although the pharmacology of this peptide is being elucidated, its specific role in obesity is not yet known.

Glucagon-Like Peptide-1 (GLP-1). Those same intestinal L cells produce GLP-1 through the posttranslational processing of preproglucagon. Two equipotent forms of GLP-1 are generated: a glycine-extended form GLP-1 (7–37) and the amidated peptide GLP-1(7–36)amide.[14] GLP-1 acts on the stomach to inhibit gastric emptying; this prolongs the time it takes to absorb a meal. GLP-1 also activates its receptor on pancreatic β cells to stimulate cAMP production, protein kinase A activation, and insulin secretion (Figure 22-2), thereby improving glucose tolerance, a mechanism of the "incretin" effect. GLP-1 also acts on rodent β cells to stimulate neogenesis, thereby increasing β-cell mass.[15] Lastly, GLP-1 also exerts potent effects on reduction of appetite, both through reduction in gastric emptying and through direct decreases of corticotropin-releasing hormone (CRH) signaling in the PVN and increasing leptin signaling in the VMH.[16]

Cholecystokinin (CCK). CCK is an 8-amino-acid gut peptide released in response to a caloric load. It circulates and binds to CCK_A receptors in the pylorus, vagus nerve, NTS, and area postrema to promote satiety.[3]

Metabolic Afferents

Leptin. Energy intake versus expenditure is normally regulated very tightly (within 0.15% per year) by the hormone leptin. Leptin is a 167-amino-acid hormone, produced by adipocytes, which transmits the primary long-term signal of energy depletion/repletion to the VMH.[17,18] Leptin's primary neuroendocrine role is to mediate information about the size of peripheral adipocyte energy stores to the VMH. Leptin is a prerequisite signal to the VMH for the initiation of high-energy processes, such as puberty and pregnancy.[19,20] Leptin reduces food intake and increases the activity of the sympathetic nervous system (SNS).[21] Conversely, low circulating levels of leptin infer diminished energy stores, which signal via the VMH to reduce energy expenditure, inhibit metabolic processes, and increase appetite. Serum leptin concentrations drop precipitously and in excess of body fat loss during periods of short-term fasting,[22,23] and it seems likely that leptin functions primarily as a peripheral signal to the hypothalamus of inadequate caloric intake rather than specifically as a satiety signal.[24]

In the fed state, circulating levels of leptin correlate with the percentage of body fat.[25,26] Leptin production by adipocytes is stimulated by insulin and glucocorticoids[27,28] and is inhibited by β-adrenergic stimulation.[24] Programming of relative leptin concentrations by early caloric intake may be one mechanism that links early overnutrition with later obesity.[29]

Leptin binds to its receptor (a member of the cytokine receptor superfamily) on target VMH neurons. Four receptor isoforms are formed by differential mRNA splicing: ObRa, an isoform with a shortened intracellular domain, which may function as a transporter; ObRb, the intact full-length receptor; ObRc, also with a short intracellular domain; and ObRe, without an intracellular domain, but which may function as a soluble receptor.[30] As leptin binds to its VMH receptor, three neuronal signals are transduced. The first is the opening of an adenosine triphosphate (ATP)–sensitive potassium channel, which hyperpolarizes the neuron and decreases its firing rate.[31] The second is the activation of a cytoplasmic janus kinase 2 (JAK2), which phosphorylates a tyrosine moiety on proteins of a family called signal transducers and activators of transcription (STAT-3).[32] The phosphorylated STAT-3 translocates to the nucleus, where it promotes leptin-dependent gene transcription.[33] However, leptin also activates the insulin receptor substrate 2/phosphatidyl inositol-3-kinase (IRS2/PI3K) second messenger system in VMH neurons, which increases neurotransmission of the central anorexigenic signaling pathway.[34]

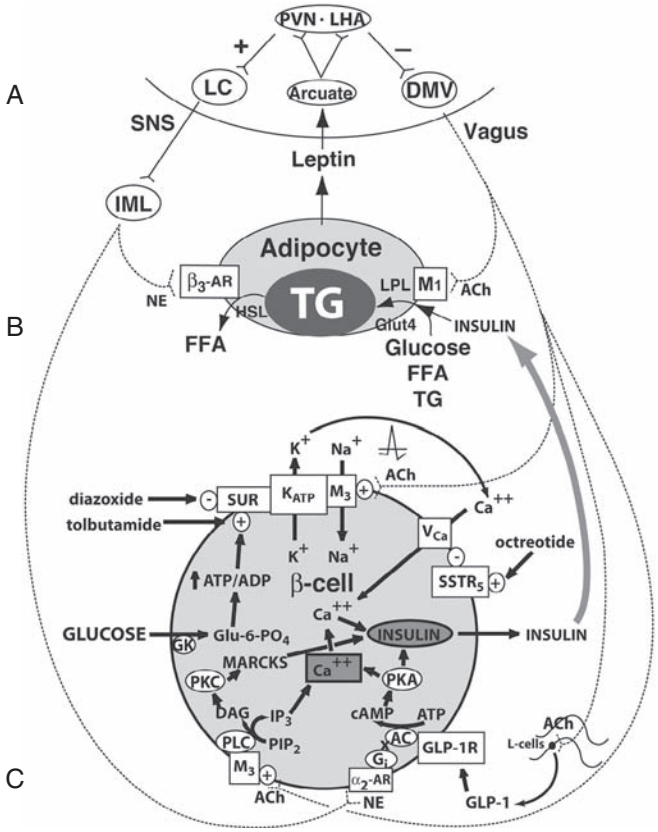

FIGURE 22-2 ■ Central regulation of leptin signaling, autonomic innervation of the adipocyte and β cell, and the starvation response. **A,** The arcuate nucleus transduces the peripheral leptin signal as one of sufficiency or deficiency. In leptin sufficiency, efferents from the hypothalamus synapse in the locus coeruleus, which stimulates the sympathetic nervous system. In leptin deficiency or resistance, efferents from the hypothalamus stimulate the dorsal motor nucleus of the vagus. **B,** Autonomic innervation and hormonal stimulation of white adipose tissue. In leptin sufficiency, norepinephrine binds to the β_3-adrenergic receptor, which stimulates hormone-sensitive lipase, promoting lipolysis of stored triglyceride into free fatty acids. In leptin deficiency or resistance, vagal acetylcholine increases adipose tissue insulin sensitivity (documented only in rats to date), promotes uptake of glucose and free fatty acids for lipogenesis, and promotes triglyceride uptake through activation of lipoprotein lipase. **C,** Autonomic innervation and hormonal stimulation of the β cell. Glucose entering the cell is converted to glucose-6-phosphate by the enzyme glucokinase, generating ATP, which closes an ATP-dependent potassium channel, resulting in cell depolarization. A voltage-gated calcium channel opens, allowing for intracellular calcium influx, which activates neurosecretory mechanisms leading to insulin vesicular exocytosis. In leptin sufficiency, norepinephrine binds to α_2-adrenoceptors on the β-cell membrane to stimulate inhibitory G proteins, decrease adenyl cyclase and its product cAMP, and thereby reduce protein kinase A levels and insulin release. In leptin deficiency or resistance, the vagus stimulates insulin secretion through three mechanisms.[99] First, acetylcholine binds to a M_3 muscarinic receptor, opening a sodium channel, which augments the ATP-dependent cell depolarization, increasing the calcium influx, and insulin exocytosis. Second, acetylcholine activates a pathway that increases protein kinase C, which also promotes insulin secretion. Third, the vagus innervates L cells of the small intestine, which secrete glucagon-like peptide-1, which activates protein kinase A, contributing to insulin exocytosis. Octreotide binds to a somatostatin receptor on the β cell, which is coupled to the voltage-gated calcium channel, limiting calcium influx and the amount of insulin released in response to glucose (reprinted with kind permission of Springer Science and Business media). α_2-AR, α_2-adrenergic receptor; β_3-AR, β_3-adrenergic receptor; AC, adenyl cyclase; ACh, acetylcholine; DAG, diacylglycerol; DMV, dorsal motor nucleus of the vagus; FFA, free fatty acids; G_i, inhibitory G protein; GK, glucokinase; GLP-1, glucagon-like peptide-1; GLP-1R, GLP-1 receptor; Glu-6-PO_4, glucose-6-phosphate; Glut4, glucose transporter-4; HSL, hormone-sensitive lipase; IML, intermediolateral cell column; IP_3, inositol triphosphate; LC, locus coeruleus; LHA, lateral hypothalamic area; LPL, lipoprotein lipase; MARCKS, myristoylated alanine-rich protein kinase C substrate; NE, norepinephrine; PIP_2, phosphatidylinositol pyrophosphate; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C; PVN, paraventricular nucleus; $SSTR_5$, somatostatin-5 receptor; TG, triglyceride; V_{Ca}, voltage-gated calcium channel; VMH, ventromedial hypothalamus; SUR, sulfonylurea receptor. (From Lustig, R. H. (2006). Childhood obesity: behavioral aberration or biochemical drive? Reinterpreting the first law of thermodynamics. *Nature Clin Pract Endo Metab, 2*, 447–458. Courtesy of Nature Publishing Group, with permission.)

Insulin. Insulin plays an extremely important role in energy balance,[35] as it is part of both the afferent and efferent systems. On the afferent side, there is a significant insulin receptor density in a subpopulation of VMH neurons,[36] and there is coordinated transport of insulin across the blood-brain barrier,[37] suggesting a central role for this hormone. In animals, acute and chronic intracerebroventricular (ICV) infusions of insulin decrease feeding behavior and induce satiety.[38-40] The data on acute and chronic peripheral insulin infusions are less clear. Studies of overinsulinized diabetic rats demonstrate increased caloric intake (to prevent subacute hypoglycemia) and the development of peripheral insulin resistance.[41,42] Chronic experimental peripheral insulin infusions decrease hepatic and skeletal muscle glucose uptake by decreasing Glut4 expression, but they do not alter

adipose tissue glucose uptake.[43,44] One study on humans showed that injecting short-term insulin peripherally during meals did not have an effect on satiety.[45]

Insulin normally activates the insulin receptor substrate 2/phosphatidyl inositol-3-kinase (IRS2/PI3K) second messenger system in VMH neurons,[46] which increases neurotransmission of the central anorexigenic signaling pathway (discussed later). The importance of central nervous system (CNS) insulin action was underscored by the development of a brain/neuron–specific insulin receptor knockout (NIRKO) mouse, which cannot transduce a CNS insulin signal.[47] Such mice become hyperphagic, obese, and infertile, with high peripheral insulin levels. These data suggest that peripheral insulin mediates a satiety signal in the VMH to help control energy balance.[48] Various knockouts of the insulin signal transduction pathway that reduce insulin signaling lead to an obese phenotype,[49,50] whereas those that improve insulin signaling lead to a lean phenotype.[51,52]

Central Processing

The peripheral afferent signals outlined earlier reach neurons in the VMH, where they are integrated by a gated neural circuit, designed to promote or diminish both energy intake and expenditure (see Figure 22-2). This circuit consists of two arms: the anorexigenic arm, which contains neurons expressing the colocalized peptides proopiomelanocortin (POMC) and cocaine/amphetamine-regulated transcript (CART); and the orexigenic arm, which contains neurons with the colocalized peptides neuropeptide Y (NPY) and agouti-related protein (AgRP). Ghrelin receptor-immunoreactivity colocalizes with NPY and AgRP neurons, whereas insulin and leptin receptors are located on both POMC/CART and NPY/AgRP neurons in the VMH,[53] suggesting divergent regulation of each arm. These two arms compete for occupancy of melanocortin receptors (MCRs; either MC_3R or MC_4R) in the PVN and LHA.

Anorexigenesis, POMC/α-MSH, and CART

POMC is differentially cleaved in different tissues and neurons. The ligand α-melanocyte stimulating hormone (α-MSH) is the primary product involved in anorexigenesis. Both overfeeding and peripheral leptin infusion induce the synthesis of POMC and α-MSH within the ARC.[54] α-MSH induces anorexia by binding to melanocortin receptors within the PVN or LHA. CART is a hypothalamic neuropeptide induced by leptin and reduced by fasting. Intrahypothalamic infusion blocks appetite, whereas antagonism of endogenous CART increases caloric intake.[55]

Orexigenesis, NPY, and AgRP

NPY and AgRP colocalize to a different set of neurons within the ARC, immediately adjacent to those expressing POMC/CART.[56] NPY has numerous functions within the hypothalamus, including initiation of feeding, puberty, regulation of gonadotropin secretion, and adrenal responsiveness.[57,58] NPY is the primary orexigenic peptide. ICV infusion of NPY in rats rapidly leads to hyperphagia, energy storage, and obesity,[59,60] mediated through Y_1 and Y_5 receptors. Fasting and weight loss increase NPY expression in the ARC, accounting for increased hunger, whereas $PYY_{3\text{-}36}$ (through Y_2 receptors) and leptin decrease NPY mRNA[13,61] AgRP is the human homolog of the protein agouti, which is present in abundance in the yellow (A^y-a) mouse.[62] This protein is an endogenous competitive antagonist of all melanocortin receptors (MCRs), accounting for the yellow color in these mice. In the presence of large amounts of AgRP at the synaptic cleft in the PVN, α-MSH cannot bind to the MC_4R to induce satiety.[63]

Other Neuroendocrine Modulators of Energy Balance

Norepinephrine (NE). NE neurons in the locus coeruleus synapse on VMH neurons to regulate food intake.[64] The actions of NE on food intake seem paradoxical, as intrahypothalamic NE infusions stimulate food intake through effects on central α_2- and β-adrenergic receptors,[65] whereas central infusion of α_1-agonists markedly reduces food intake.[66]

Serotonin (5-HT). 5-HT has been implicated in the perception of satiety based on many lines of evidence: (1) injection of 5-HT into the hypothalamus increases satiety, particularly with respect to carbohydrate[67]; (2) central administration of 5-HT_{2c} receptor agonists increase satiety, whereas antagonists induce feeding[68]; (3) administration of selective 5-HT reuptake inhibitors induce early satiety[69]; (4) leptin increases 5-HT turnover[70]; and (5) the 5-HT_{2c}R-KO mouse exhibits increased food intake and body weight.[71] The role of 5-HT in the transduction of the satiety signal may have both central and peripheral components, as intestinal 5-HT is secreted into the bloodstream during a meal, where it may have an impact on gastrointestinal (GI) neuronal function and muscle tone, and may bind to 5-HT receptors in the NTS (discussed previously) to promote satiety.[72]

Melanin-Concentrating Hormone (MCH). MCH is a 17-amino-acid peptide expressed in the zona incerta and LHA. MCH neurons synapse on neurons in the forebrain and the locus coeruleus. MCH appears to be important in conditions such as anxiety and aggression around food.[73] Expression of this peptide is up-regulated in *ob/ob* mice. MCH-knockout mice are hypophagic and lean,[74] whereas transgenic MCH-overexpressing mice develop obesity and insulin resistance.[75] ICV administration of MCH stimulates food intake, similar to that seen with NPY administration.[76]

Orexins A and B. These 33- and 28-amino-acid peptides, respectively, have been implicated in both energy balance and autonomic function in mice.[77] Orexin knockout mice demonstrate narcolepsy, hypophagia, and obesity,[78] suggesting that orexins bridge the gap between the afferent and efferent energy balance systems.[79] Orexins in the LHA stimulate neuropeptide

Y (NPY) release, which may account for their effects on orexigenesis, and also stimulate the corticotropin-releasing factor (CRF) and sympathetic nervous system (SNS) output to increase wakefulness and energy expenditure, learning and memory, and the hedonic reward system (discussed later).[80] Conversely, orexin neurons in the perifornical and dorsomedial hypothalamus regulate arousal and response to stress.

Endocannabinoids (EC). It has long been known that tetrahydrocannabinol stimulates food intake. This observation led to the identification of endogenous EC and their receptor, termed CB_1.[81] The CB_1 receptor is expressed in corticotropin-releasing factor (CRH) neurons in the PVN, in CART neurons in the VMN, and in MCH- and orexin-positive neurons in the LHA and perifornical region. Fasting and feeding are associated with high and low levels of ECs in the hypothalamus, respectively. For example, CB_1 receptor-knockout mice have increased CRH and reduced CART expression. In the *ob/ob* mouse, hypothalamic EC levels are increased, whereas leptin infused intravenously reduces these levels, indicating that a direct negative control is exerted by leptin on the EC system. Glucocorticoids increase food intake by stimulating EC synthesis and secretion, whereas leptin blocks this effect.[82] Finally, the presence of CB_1 receptors on afferent vagal neurons suggest that endocannabinoids may be involved in mediating satiety signals originating in the gut.

Melanocortin Receptors (MCR) and Central Neural Integration

The human MC_4R localizes to chromosome 2, and is a 7-transmembrane G-coupled receptor, encoded by an intron-less 1 kB gene. The binding of hypothalamic α-MSH to the MC_4R in the PVN and LHA results in a state of satiety, whereas ICV administration of MC_4R antagonists stimulates feeding, suggesting that MC_4R transduces satiety information on caloric sufficiency. A different phenotype is observed in the MC_3R knockout mouse. These animals are obese, but they are instead hypophagic and have increased body fat for their lean mass. They gain weight on either low- or high-fat chow and do not change substrate oxidation in response to changes in dietary fat content, suggesting a defect in energy expenditure.[83] Thus, these two hypothalamic MCRs appear to modulate different aspects of energy metabolism. One hypothesis is that the MC_4R modulates energy intake, whereas the MC_3R modulates energy expenditure.[84]

The Efferent System

The MCRs in the PVN and LHA transduce the anorexigenic and orexigenic information coming from the VMH, in order to modulate activity of the sympathetic nervous system (SNS), which promotes energy expenditure, and the efferent vagus, which promotes energy storage (see Figure 22-2). In this way, peripheral energy balance can be modulated acutely to provide requisite energy for metabolic needs, and store the rest.

The Sympathetic Nervous System (SNS) and Energy Expenditure

Anorexigenic pressure increases energy expenditure through activation of the SNS.[85] For instance, leptin administration to *ob/ob* mice promotes increased brown adipose tissue lipolysis, thermogenesis, renovascular activity, and increased movement, all associated with increased energy expenditure, which assists in weight loss.[86] Similarly, insulin administration acutely increases SNS activity in normal rats and in humans.[87,88] The magnitude of energy expenditure also has a salutary effect on quality of life; factors that reduce resting energy expenditure (REE) (e.g., hypothyroidism) reduce quality of life, whereas factors that increase REE (e.g., caffeine) increase quality of life (at least acutely).

The SNS increases energy expenditure in four ways: (1) by innervating the hypothalamus and appetite centers in the medulla to reduce appetite; (2) by increasing thyroid-stimulating hormone (TSH) secretion to increase thyroid hormone release and energy expenditure; (3) by innervating skeletal muscles to increase energy expenditure; and (4) by innervating β_3-adrenergic receptors in white adipose tissue to promote lipolysis.

Activation of the SNS increases energy expenditure by the skeletal muscle, by activating β_2-adrenergic receptors,[89] which in turn increase the expression of numerous genes in skeletal muscle,[90] especially those involved in carbohydrate metabolism. SNS activation stimulates glycogenolysis, incites myocardial energy expenditure, increases in glucose and fatty acid oxidation, and increases protein synthesis.[91]

Activation of the SNS in rodents stimulates the β_3-adrenergic receptor of brown adipose tissue to promote lipolysis.[92] In humans, activation of the β_3-adrenergic receptor increases cAMP, which activates protein kinase A. PKA acts in two separate molecular pathways to increase energy expenditure. First, PKA phosphorylates the cyclic AMP response element binding protein (CREB), which induces expression of PPARγ-coactivator-1α (PGC-1α). PGC-1α then binds to enhancer elements on the uncoupling protein-1 (UCP1) gene, which increases the expression and activity of uncoupling proteins (UCPs) 1 and 2.[93,94] Uncoupling proteins reduce the proton gradient across the inner membranes of mitochondria, thereby diverting protons from storage in the form of ATP to heat production. Originally, uncoupling proteins were discovered in brown adipose tissue and were found to be responsible for thermogenesis. UCP1 is an inner membrane mitochondrial protein that uncouples proton entry from ATP synthesis[95]; therefore, UCP1 expression dissipates energy as heat, thus reducing the energy efficiency of the adipose tissue. However, UCP2 has been found in most tissues and UCP3 in skeletal muscle. Second, PKA activation activates the enzyme hormone sensitive lipase (HSL), which is responsible for lipolysis of intracellular triglyceride to its component free fatty acids (FFAs). The FFAs also induce UCP1, further increasing energy expenditure. The FFAs released from the adipocyte also travel to the liver where they are utilized for energy by metabolizing into two-carbon fragments. Lipolysis reduces leptin

expression; thus, a negative feedback loop is achieved between leptin and the SNS (see Figure 22-2).

The Efferent Vagus and Energy Storage

In response to declining levels of leptin or persistent orexigenic pressure, the LHA and PVN send efferent projections residing in the medial longitudinal fasciculus to the dorsal motor nucleus of the vagus nerve (DMV), activating the efferent vagus.[96] The efferent vagus opposes the SNS by promoting energy storage in four ways: (1) by slowing the heart rate, myocardial oxygen consumption is reduced; (2) the vagus nerve promotes alimentary peristalsis, pyloric opening, and energy substrate absorption; (3) through direct effects on the adipocyte, the vagus nerve promotes insulin sensitivity to increase the clearance of energy substrate into adipose tissue; and (4) through effects on the β cells, the vagus increases postprandial insulin secretion, which promotes energy deposition into adipose tissue.[97-100]

Retrograde tracing of white adipose tissue reveals a wealth of efferents originating at the DMV.[100] These efferents synapse on the M_1 muscarinic receptor on the adipocyte, which increases insulin sensitivity of the adipocyte. Denervation of white adipose tissue results in a reduction of glucose and FFA uptake, and an induction of HSL, which promotes lipolysis—both of which reduce the efficiency of insulin-induced energy storage. Thus, vagal modulation of the adipocyte augments storage of both glucose and FFAs by improving adipose insulin sensitivity [101] (see Figure 22-2).

The DMV also sends efferent projections to the β cells of the pancreas.[102] This pathway is responsible for the "cephalic" or preabsorptive phase of insulin secretion, which is glucose independent and can be blocked by atropine.[103] Overactive vagal neurotransmission increases insulin secretion from β cells in response to an oral glucose load through three distinct but overlapping mechanisms[104] (see Figure 22-2):

1. Vagal firing increases acetylcholine availability and binding to the M_3 muscarinic receptor on the β cell, which is coupled to a sodium channel within the pancreatic β-cell membrane.[105] As glucose enters the β cell after ingestion of a meal, the enzyme glucokinase phosphorylates glucose to form glucose-6-phosphate, increasing intracellular ATP, which induces closure of the ATP-dependent potassium channel. Upon channel closure, the β cell experiences an ATP concentration-dependent β cell depolarization[106,107] and the opening of a separate voltage-gated calcium channel within the membrane. Intracellular calcium influx increases acutely, which results in rapid insulin vesicular exocytosis. Concomitant opening of the sodium channel by vagally mediated acetylcholine augments β-cell depolarization, which in turn augments the intracellular calcium influx and results in insulin hypersecretion.[108-110]
2. Vagally mediated acetylcholine increases phospholipases A_2, C, and D within the β cell, which hydrolyze intracellular phosphatidylinositol to diacylglycerol (DAG) and inositol triphosphate (IP_3).[104] DAG is a potent stimulator of protein kinase C (PKC),[111] which phosphorylates myristoylated alanine-rich protein kinase C substrate (MARCKS), which then binds actin and calcium-calmodulin and induces insulin vesicular exocytosis.[112] IP_3 potentiates the release of calcium within β cells from intracellular stores, which also promotes insulin secretion.[113]
3. The vagus also stimulates the release of GLP-1 from intestinal L cells, which circulates and binds to a GLP-1 receptor within the β-cell membrane. Activation of this receptor induces a calcium-calmodulin-sensitive adenyl cyclase, with conversion of intracellular ATP to cAMP, which then activates protein kinase A. PKA causes both the release of intracellular calcium stores and the phosphorylation of vesicular proteins, each contributing to an increase in insulin exocytosis.[14,114]

In the efferent pathway, insulin is responsible for shunting blood-borne nutrients into adipose for storage. Indeed, the primary hormonal signal for adipogenesis is insulin.[115] Within the adipocyte, insulin increases (1) glut4 expression, (2) acetyl-CoA carboxylase, (3) fatty acid synthase, and (4) lipoprotein lipase.[116] Thus, the net effect of insulin on the adipocyte is the rapid clearance and storage of circulating glucose and lipid. Thus, insulin promotes energy storage.

CNS MODULATION OF FOOD INTAKE

The Hypothalamus and the Starvation Response

The regulation of the various components of the energy balance system is manifest during the starvation response. Everyone has a "personal leptin threshold," probably genetically set, above which the brain interprets a state of energy sufficiency.[117] Thus, the leptin-replete state is characterized by increased physical activity, decreased appetite, and increased feelings of well-being. However, in response to caloric restriction, leptin levels decline even before weight loss is manifest,[22,23] which the VMH interprets as starvation. Gastric secretion of ghrelin increases, which increases pituitary GH release, in order to stimulate lipolysis to provide energy substrate for catabolism. Ghrelin stimulates NPY/AgRP to antagonize α-MSH/CART. Decline of leptin reduces α-MSH/CART as well. This leads to decreased MC_4R occupancy so that the reduced anorexigenic pressure on the MC_4R increases feeding behavior and energy efficiency (with reduced fat oxidation) in order to store energy as fat. In response, the efferent pathway of energy balance coordinates efforts at improving energy efficiency and increasing energy storage. Total and resting energy expenditures decline in an attempt to conserve energy.[118] Specifically, UCP1 levels within adipose tissue decline[119] as a result of decreased SNS activity in response to starvation.[120] In spite of decreased SNS tone at the adipocyte, there is clearly an obligate lipolysis (due to insulin suppression and up-regulation of hormone-sensitive lipase), which is necessary to maintain energy delivery to the musculature and brain in the form of liver-derived ketone bodies. Additionally, in the starved state, vagal tone is increased in order to slow the heart rate and

myocardial oxygen consumption, increase β-cell insulin secretion in response to glucose, and increase adipose insulin sensitivity—all directed to increase energy storage.[120] These revert back to baseline once caloric sufficiency is reestablished, and leptin levels rise.

The Nucleus Accumbens and the Hedonic Pathway of Food Reward

The negative feedback pathway delineated beforehand is not the only site of central regulation of food intake. Complementary to insulin and leptin's ability to alter energy balance, these hormones also modify the "hedonic pathway," or the pleasurable and motivating responses to food. This is the same pathway that responds to drugs of abuse, such as nicotine and morphine. The hedonic pathway comprises the ventral tegmental area (VTA) and the nucleus accumbens (NA), with inputs from various components of the limbic system, including the striatum, amygdala, hypothalamus, and hippocampus. Food intake is a readout of the hedonic pathway; administration of morphine to the NA increases food intake in a dose-dependent fashion.[121] When functional, the hedonic pathway helps curtail food intake in situations where energy stores are replete; however, when dysfunctional, this pathway can increase food intake leading to obesity.

The VTA appears to mediate feeding on the basis of palatability rather than energy need. The dopaminergic projection from the VTA to the NA mediates the motivating, rewarding, and reinforcing properties of various stimuli, such as food and addictive drugs. Leptin and insulin receptors are expressed in the VTA, and both hormones have been implicated in modulating rewarding responses to food and other pleasurable stimuli.[122] For instance, fasting and food restriction (where insulin and leptin levels are low) increase the addictive properties of drugs of abuse, whereas ICV leptin can reverse these effects.[123] In rodent models of addiction, increased addictive behavior (and pleasurable response from a food reward), as measured by dopamine release and dopamine receptor signaling, is greater after food deprivation.[124] In humans with leptin deficiency, alterations in activity in the nucleus accumbens can be seen using functional MRI scanning, and these changes subside with administration of exogenous leptin.[125] Acutely, insulin increases expression and activity of the dopamine transporter, which clears and removes dopamine from the synapse; thus, acute insulin exposure blunts the reward of food.[126] Furthermore, insulin appears to inhibit the ability of VTA agonists (e.g., opioids) to increase intake of sucrose.[127] Finally, insulin blocks the ability of rats to form a conditioned place preference association to a palatable food.[128] However, insulin resistance of this pathway may lead to increased reward of food.

One question that has garnered increasing interest is whether any macronutrient has addictive properties. In animal studies, sugar has been shown to induce the four criteria for addiction: (1) bingeing, (2) withdrawal, (3) craving, and (4) cross-sensitization with other drugs of abuse.[129] Within fast food, sugar and caffeine satisfy the criteria presented in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-V) for dependence in humans.[130] However, the question of whether food addiction exists, and whether it can explain patients with obesity, remains hotly contested.[131]

The Amygdala and the Stress Response

The VMH and VTA-NA mediate satiety when energy stores are replete, but they appear to be easily overridden by amygdala activation and resultant stress, a state of physiologic insulin resistance. Numerous lines of evidence suggest that the stress glucocorticoid corticosterone (in the rat) or cortisol (in the human) is essential for the full expression of obesity, which helps to explain the disruptive role of stress in weight regulation.[132]

Stress and glucocorticoids are integral in promoting adiposity and the metabolic syndrome. Adrenalectomized rats maintained pharmacologically with high levels of corticosterone demonstrate that exogenous fat intake is directly proportional to circulating corticosterone concentrations,[133] whereas amygdala activation by stress is dampened by the ingestion of energy-dense food.[134] In intact rats, corticosterone stimulates eating, particularly of high-fat food, and in humans, cortisol administration increases food intake.[135] Human research shows increased caloric intake of "comfort foods" (i.e., those with high energy density) after acute stress,[136] and that the stress response contributes to leptin resistance (discussed later).[137] Several studies in children have observed relationships between stress and unhealthy dietary practices, including increased snacking, and an elevated risk for problems with weight during adolescence and adulthood.[138] In a controlled study of 9-year-olds, children who scored high on dietary restraint and who felt more stressed by lab challenges tended to eat more comfort food.[139]

Leptin Resistance

Most obese children have high leptin levels but do not have receptor mutations, manifesting what is commonly referred to as "functional leptin resistance." Leptin resistance prevents exogenous leptin administration from promoting weight loss.[140] The response to most weight-loss regimens plateaus rapidly due to the rapid fall of peripheral leptin levels below a personal "leptin threshold,"[141] which is likely genetically determined. Leptin decline causes the VMH to sense a reduction in peripheral energy stores, which modulates a decrease in REE to conserve energy, analogous to the starvation response (discussed earlier),[118] but occurring at elevated leptin levels.

The cause of leptin resistance is unknown, but it may have several etiologies. Leptin crosses the blood-brain barrier via a saturable transporter, which limits the amount of leptin reaching its receptor in the VMH [142,143]; this transporter operates more efficiently at lower levels of leptin, while preventing increased signaling at higher levels.[144] Activation of the leptin receptor induces the intraneuronal expression of suppressor of cytokine signaling-3 (SOCS-3), which limits leptin signal transduction in an autoregulatory fashion.[51]

The standard method for producing insulin resistance and obesity in rodents is a high-fat diet. Dietary

fat promotes leptin resistance through its effects on hypertriglyceridemia,[145] which limits access of peripheral leptin to the VMH, and also by interfering with leptin signal transduction upstream of STAT-3, its primary second messenger.[146] One likely modulator of this pathway is the enzyme phosphatidyl inositol-3-kinase (PI3K), which is the downstream effector of insulin action in POMC neurons[147] and which appears to account for the effects of dietary fat on leptin resistance and obesity.[148]

Two clinical paradigms have been shown to improve leptin sensitivity. After weight loss through caloric restriction, exogenous administration of leptin can then increase REE back to baseline and permit further weight loss,[149,150] suggesting that the weight loss itself improves leptin sensitivity. Second, suppression of insulin correlates with improvement in leptin sensitivity and promotes weight loss,[151] suggesting that hyperinsulinemia promotes leptin resistance by interfering with leptin signal transduction in the VMH and VTA.[152] Indeed, insulin reduction strategies can effectively promote weight loss in children with hyperinsulinemia by improving leptin sensitivity.[153] These clinical substantiations of the PI3K data in animals has led to the hypothesis that chronic hyperinsulinemia blocks leptin signal transduction at the VMH and VTA, which turns a negative feedback cycle into a vicious feed-forward cycle.

Based on the concept that hyperinsulinemia promotes weight gain at the adipocyte, yet blocks leptin signaling in the hypothalamus and nucleus accumbens, the role of starvation, reward, and stress on weight gain and adiposity via their effects on insulin are a reasonable hypothesis, termed the "limbic triangle" (Figure 22-3).[154] However, this hypothesis remains to be proven.

ENERGY EXCESS—OBESITY

The rise in the prevalence of obesity in children and adolescents is one of the most alarming public health issues facing the world today. Although the rise in the prevalence of obesity in children and adolescents seems to have leveled in some parts of the world,[155] many others, especially developing countries, are still experiencing a steady increase. Obesity is associated with significant health problems in children, is an early risk factor for a great

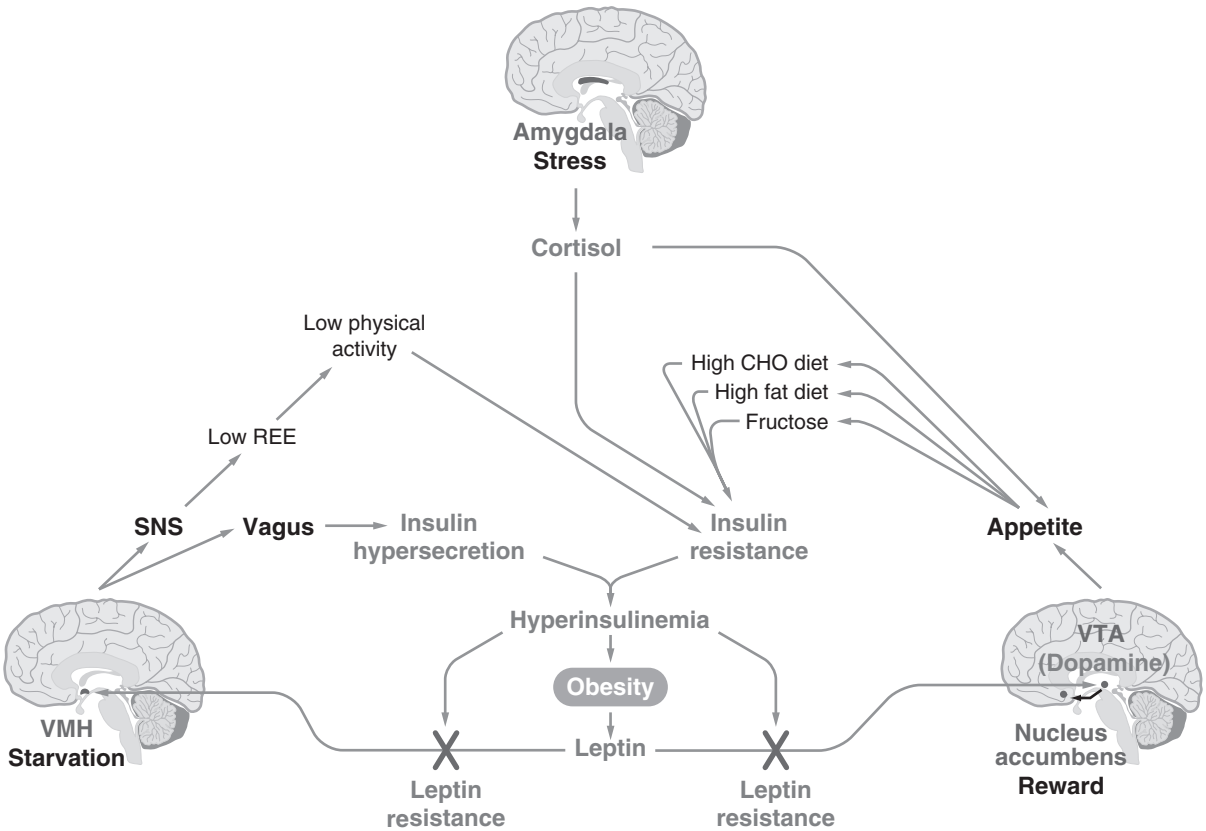

FIGURE 22-3 ■ The "limbic triangle." Three areas of the CNS conspire to drive food intake and reduce physical activity, resulting in persistent weight gain. The ventromedial hypothalamus (VMH) transduces the leptin signal from adipocytes to reduce energy intake and increase energy expenditure; however, hyperinsulinemia prevents leptin signaling, promoting the "starvation response." The ventral tegmental area (VTA) transduces the leptin signal to reduce dopamine neurotransmission to the nucleus accumbens (NA), reducing food intake; however, hyperinsulinemia prevents leptin signaling here as well, increasing dopamine and promoting the "reward" of food. The amygdala transduces fear and stress, which results in increased cortisol release from the adrenal cortex. The elevated cortisol also drives energy-rich food intake and promotes insulin resistance, further interfering with leptin signaling at the other two CNS sites. Thus, activation of any aspect of the limbic triangle turns on a positive feedback loop, promoting continued weight gain and obesity. (From Mietus-Snyder, M. L., & Lustig, R. H. (2008). Childhood obesity: adrift in the "limbic triangle." *Ann Rev Med, 59*, 119–134.)

many cases of adult morbidity and mortality,[156] and is an important factor in increasing health care expenditures.[157] Childhood obesity tends to track to adulthood,[158] and those who remain obese as adults have a significant risk for the development of type 2 diabetes, atherosclerosis, and dyslipidemia. In contrast, obese children who lost weight and became nonobese adults do not have an increased risk for such morbidity[159]; thus, early and effective intervention against obesity during childhood is crucial.

Definition

The theoretical definition of obesity is a degree of somatic overweight that affords detrimental health consequences.[160] Based on morbidity and mortality statistics, and with a desire to prevent future risk of morbidity, we practically define obesity as a statistical magnitude of overweight for a population, keeping in mind that morbidity and mortality vary with degree of overweight in different racial, ethnic, and socioeconomic groups,[161] and indeed for individuals as well. The World Health Organization[162] categorizes adult overweight into four subgroups based on body mass index (BMI; weight [kg] ÷ height [m]^2): BMI 25 to 30 (overweight); BMI 30 to 35, grade 1 (moderately obese); BMI 35 to 40, grade 2 (severely obese); and BMI > 40, grade 3 (morbidly obese). Some make a further delineation at BMI > 60, denoting this as "superobesity," as even surgical therapies are less effective in this range.

Most obesity in adulthood has its origins in childhood,[163,164] making obesity a pediatric concern and the prevention and treatment of obesity a pediatric goal. BMI is also the accepted marker in children.[165] In childhood, a comparison of BMI to normal curves for age[166] allows for categorization of BMI above the 85th percentile as overweight and that above the 95th percentile as obese (Figure 22-4A and B).

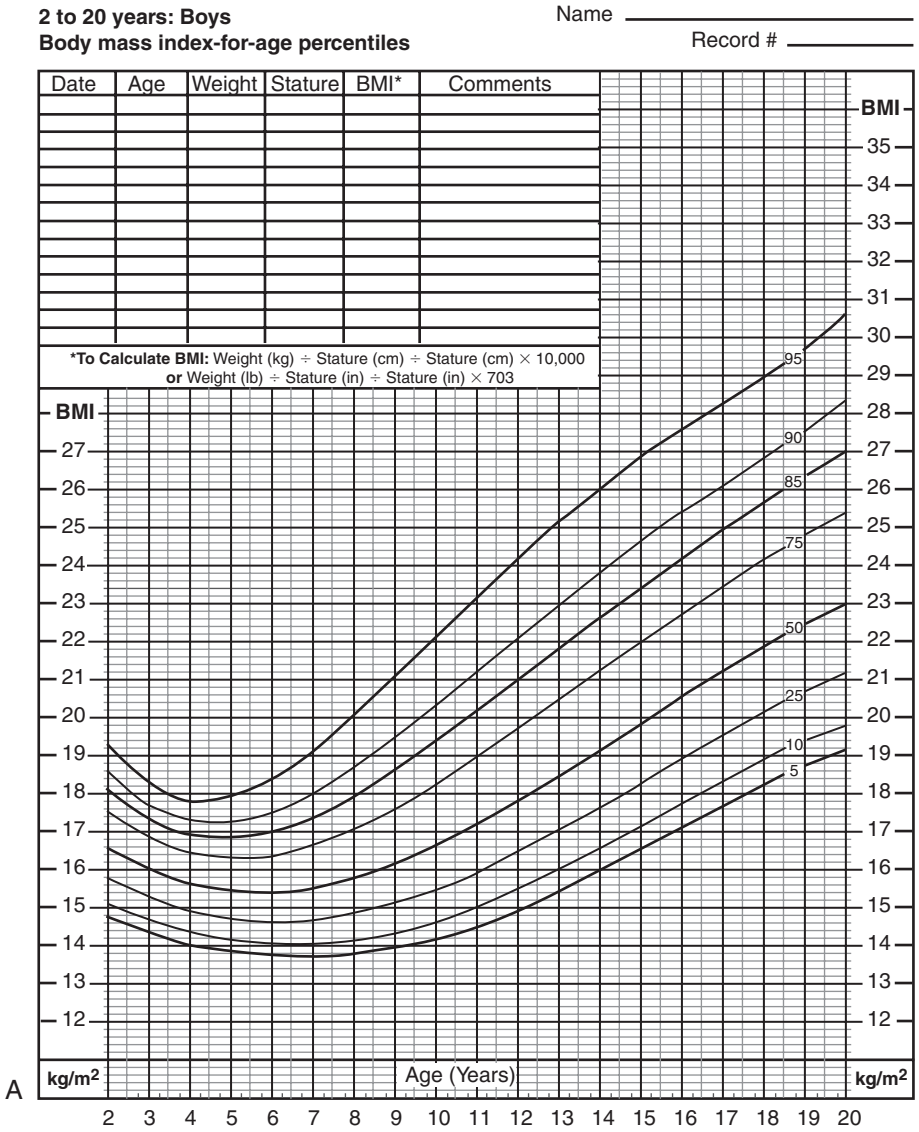

FIGURE 22-4 ■ Body mass index (BMI)-for-age percentiles for U.S. boys (**A**) and U.S. girls (**B**), 2 to 20 years of age. Note that the 95th percentile signifies obesity. The adiposity rebound occurs at approximately 5 years of age in both sexes; the earlier the adiposity rebound occurs, the more likely an organic etiology for the weight gain can be inferred. (From www.cdc.gov/growthcharts [National Center of Health Statistics, 2000].)

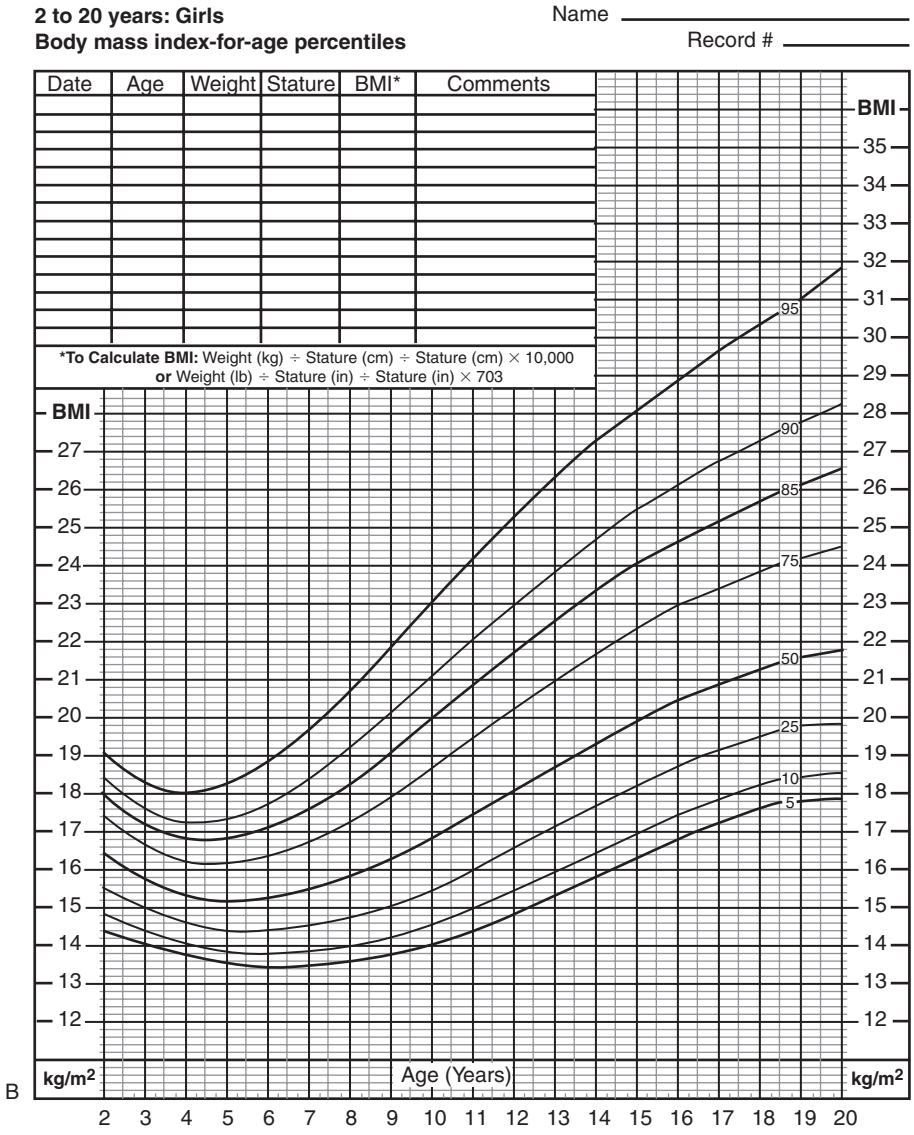

FIGURE 22-4, cont'd

Although BMI is the standard for obesity for statistical purposes and within populations, it should be noted that BMI takes into account muscle and bone, as well as both subcutaneous and visceral fat. Furthermore, BMI in children is age and puberty dependent, thus the BMI z-score is a more accurate assessment of childhood adiposity. Lastly, waist circumference (an indirect measure of visceral fat) has emerged as a more accurate indicator of metabolic disturbance in children.[167]

Prevalence and Epidemiology

The prevalence of childhood obesity in the United States has increased dramatically since the 1980s[168,169] and continues to do so, although the comparison of longitudinal and cross-sectional data is difficult due to different definitions and measurement parameters between epidemiologic studies. Estimates of obesity prevalence in the United States based on data from the 2009-2010 National Health and Nutrition Examination Survey (NHANES IV)[155] demonstrate that the epidemic of childhood obesity is occurring at earlier ages: In 2009 to 2010, 9.7% (95% CI, 7.6% to 12.3%) of infants and toddlers had a high weight-for-recumbent length and 16.9% (95% CI, 15.4% to 18.4%) of children and adolescents from 2 through 19 years of age were obese. Trend analyses over a 12-year period indicated a significant increase in obesity prevalence between 1999-2000 and 2009-2010 in males ages 2 through 19 years (odds ratio, 1.05; 95% CI, 1.01 to 1.10) but not in females (odds ratio, 1.02; 95% CI, 0.98 to 1.07) per 2-year survey cycle. There was a significant increase in BMI among adolescent males ages 12 through 19 years ($P = .04$) but not among any other age group or among females. Thus, in 2009-2010, the prevalence of obesity in children and adolescents was 16.9%; this was not changed compared with 2007-2008. Importantly, whereas the prevalence of obesity in Caucasian children declined slightly, the prevalence of African-American and Latino obesity

continued to climb. Furthermore, the prevalence of severe obesity (BMI > the 97th percentile) is still on the rise.[170] Lastly, projections argue that by 2030, 42% of American adults will be obese.[157]

Global Prevalence

Obesity has overtaken AIDS and malnutrition as the number one public health problem in the world.[171] The global prevalence of childhood obesity has been increasing worldwide at an alarming rate since the 1990s. Rates have increased 2.7-fold to 3.8-fold over 29 years in the United States,[169] 2-fold to 2.8-fold over 10 years in England, 3.4-fold to 4.6-fold over 10 years in Australia, and 3.4-fold to 3.6-fold over 23 years in Brazil. In Asia, the prevalence has increased 1.1-fold to 1.4-fold over 6 years in China and 2.3-fold to 2.5-fold over 26 years in Japan. In Africa, the prevalence has increased 3.9-fold over 18 years in Egypt, 3.8-fold over 6 years in Ghana, and 2.5-fold over 5 years in Morocco.[172] Based on data from 2008, nearly 20% of Indian boys and 18% of Indian girls from 2 to 17 years of age are considered overweight. Even higher prevalence rates are reported from New Zealand and Taiwan, making the Far East and Oceania regions the current hub of the obesity epidemic.[170]

In developed countries, the urban poor are more susceptible for developing obesity, presumably due to poor dietary practices and limited opportunity for physical activity.[173,174] In contrast, obesity is more frequent in upper socioeconomic classes of developing countries, probably due to transition to a more Western lifestyle with a more energy-dense diet consisting of higher fats and sugar, which tend to be more palatable at a lower cost.[175,176] This may be due to specific properties of processed food, which promote leptin resistance.[152]

Racial and Ethnic Considerations

The NHANES surveys only list prevalence among Caucasians, African Americans, and Hispanics, despite the fact that Native Americans, Pacific Islanders, Asians, and other racial/ethnic groups are experiencing rapid increases in prevalence as well. Across racial groups, there is a marked dichotomy in the prevalence and in the rate of increase of childhood obesity.[170,177] For instance, the prevalence among African-American (24.4%), Hispanic (21.7%), and Mexican-American adolescents (22.2%) is significantly higher than that among white adolescents (15.6%). Importantly, the prevalence of severe obesity (BMI > the 97th percentile) among African-American (18.5%), Hispanic (15.2%), and Mexican-American adolescents (15.2%) by far exceeds that of non-Hispanic white adolescents (10.5%). The rate of increase in the prevalence of obesity among African-American and Hispanic adolescents almost doubled between 1988-1994 and 1999-2000, from 13.4% to 23.6% in African Americans and from 13.8% to 23.4% in Hispanics. In the National Heart, Lung and Blood Institute (NHLBI) Growth and Health Study,[178] the prevalence of obesity in 9-year-old African-American girls was 17.7%, in Caucasian girls 7.7%, and both of these prevalences doubled over the 10 years of study. These differences in prevalence hold true at younger ages as well. The 1994 Pediatric Nutrition Surveillance System (PedNSS) indicated that 12% of 2- to 4-year-old Native American children were overweight, which is similar to Hispanic children at the same age (12%) but much higher than white children (6%). The prevalence of overweight at 5 to 6 years in Native Americans is twice that in U.S. youth in general, and the prevalence of obesity is even three times higher.[179] Among infants and toddlers younger than 2 years of age, the prevalence of obesity is highest in African Americans (18.5%), as compared to 10.1% in Caucasians and 13.7% in Hispanics. It is possible that different dietary practices may account for some of these differences. For instance, a study of 2-year-old Latino children in California correlated obesity with early consumption of sugar-sweetened beverages.[180]

Within racial populations, ethnic variability in the prevalence of childhood obesity has also been noted. The United States National Longitudinal Study of Adolescent Health (Add Health) indicated that the BMI ≥ the 85th percentile in adolescent Hispanics was more common among Mexican Americans (32.1%) and Puerto Ricans (30.3%), as compared with Cuban Americans (27.1%) and Central South Americans (26.2%).[174] Only 25% of first-generation Hispanic adolescents were overweight based on a BMI ≥ the 85th percentile, as compared with 32% of second- and third-generation Hispanics. The prevalence of overweight in Asian-American adolescents in this study was 20.6%, with comparable prevalence among Filipinos (18.5%) and Chinese (15.3%). Again, only 12% of first-generation Asian Americans were overweight, compared with 27% and 28% of those from the second and third generations, respectively. In Native Americans, there is great variation in the prevalence of obesity from 12% to 77%, based on tribes, age groups, measurement tools, and cutoff values, among the studies performed between 1990 and 2000.[179] These studies indicate that obesity in Native Americans begins very early in childhood.

Predictive Factors

The higher the BMI during childhood, the more likely adult obesity will manifest. In general, children with a BMI ≥ the 95th percentile have a very high risk for adult obesity.[181] Obesity in adolescence is a primary risk factor for obesity in adulthood, with an increased odds ratio from 1.3 for obesity at 1 to 2 years of age to 17.5 for obesity at 15 to 17 years of age.[182] The change of BMI during and after adolescence is the most important predictive variable for adult obesity.[183] Children and adolescents with BMI ≥ the 95th percentile have a 62% to 98% chance of being obese at 35 years of age, with a 50% chance in males age ≥ 13 years and 66% chance in girls age ≥ 13 years.[184] Importantly, an elevated BMI in adolescence—one that is well within the range currently considered to be normal—constitutes a substantial risk factor for obesity-related disorders in midlife. Although the risk of diabetes is mainly associated with increased BMI close to the time of diagnosis, the risk of coronary heart disease is associated with an elevated BMI both in adolescence and in adulthood.[185]

The age of adiposity rebound, the point of the BMI nadir before the body fatness begins to rise (between 5 and 6 years of age) (see Figure 22-4A and B), is also an important predictor for adult obesity.[186] Girls tend to have a slightly earlier adiposity rebound than do boys. Children with an early adiposity rebound have a fivefold greater chance of becoming obese as adults, compared to those with a late adiposity rebound. At the age of adiposity rebound, children already overweight have a sixfold greater risk for adult obesity, as compared to lean children. Therefore, the earlier the onset of childhood obesity, the greater is the risk for adult obesity.

Infant overnutrition plays an extremely important role in the future development of obesity. Numerous studies have implicated bottle feeding as a specific risk factor.[187] The prevalence of obesity in children who were never breastfed was 4.5%, as compared with 2.8% in breastfed children, and a clear time-response effect was identified for the duration of breastfeeding on the decline in the prevalence of obesity as well.[188] Early overnutrition has been correlated with elevated leptin concentrations in later life.[29] Differences in both volume and composition of commercial formula versus breast milk have been proposed as etiologic factors.

Parental obesity is also an important predictor of childhood obesity. Children with at least one overweight parent at the age of adiposity rebound have a four- to fivefold greater chance of becoming obese adults. Lean children 5 years old or younger have a 13-fold risk of adult obesity if both parents are obese. Excessive BMI gains of parents during childhood and adulthood are also associated with a higher BMI and risk of obesity in the offspring.[189] Conversely, older obese children (10 to 14 years of age) have a 22.3-fold increased risk of adult obesity regardless of parental weight,[164] suggesting that parental obesity is important in early childhood weight gain.[190] Parental obesity is also related to early adiposity rebound, although it is unclear whether the relation between parental and childhood obesity is genetic, epigenetic, or environmental.

METABOLIC IMPACT OF CHILDHOOD OBESITY

Many of the metabolic and cardiovascular (CV) complications of obesity are already evident during childhood and are closely related to the development of insulin resistance causes of hyperinsulinemia, the most common biochemical abnormality seen in obesity.[191] The obesity-related comorbidities that emerge early in childhood are alterations in glucose metabolism, dyslipidemia, and hypertension. Although an accelerated atherogenic process is present in obese children, thrombotic CV events do not usually appear until adulthood. The clustering of these manifestations is termed the *metabolic syndrome* or *the insulin resistance syndrome*, suggesting that peripheral insulin resistance may be the driving force behind most cases of related morbidity.

Insulin Resistance

Insulin resistance is defined as the decreased tissue response to insulin-mediated cellular actions and is the inverse of insulin sensitivity. The term *insulin resistance*, as generally applied, refers to whole-body reduced glucose uptake in response to physiologic insulin levels and its consequent effects on glucose and insulin metabolism. However, it is now clear that not all tissues are equally insulin resistant. Generalized insulin resistance would result in global metabolic dysfunction, such as leprechaunism or Rabson-Mendenhall syndrome. Thus, the insulin resistance of obesity must, of necessity, affect different tissues quantitatively (see Chapter 19 on diabetes mellitus and insulin receptor mutations).

Hepatic Insulin Resistance

The liver plays a major role in substrate metabolism and is the primary target of insulin action. After insulin's release from the β cell following a glucose load, it travels directly to the liver via the portal vein, where it binds to the insulin receptor and elicits two key actions at the level of gene transcription. First, insulin stimulates the phosphorylation of FoxO1, which prevents it from entering the nucleus,[192,193] and thus diminishes the expression of genes required for gluconeogenesis, mainly phosphoenolpyruvate carboxykinase and glucose 6-phosphatase. The net effect is diminished hepatic glucose output. Second, insulin activates the transcription factor sterol regulatory element-binding protein (SREBP)-1c, which in turn increases the transcription of genes required for fatty acid and triglyceride (TG) biosynthesis, most notably ATP-citrate lyase, acetyl-coenzyme A carboxylase, and fatty acid synthase, which together constitute the process of *de novo* lipogenesis (DNL). TGs synthesized by DNL are then packaged with apoliprotein B (apoB) into very low-density lipoproteins (VLDL) for export to the periphery for storage or utilization by reciprocal activation of lipoprotein lipase (LPL) on the surfaces of endothelial cells in adipose or muscle tissues.[194]

For reasons that remain unclear, insulin-resistant subjects typically have "selective" or "dissociated" hepatic insulin resistance—that is, they have impaired glucose homeostasis (mediated by the FoxO1 pathway) but enhanced insulin-mediated hepatic DNL (mediated by the SREBP-1c pathway).[195] The increase in free fatty acid (FFA) flux within the liver, either by DNL or FFA delivery via the portal vein, impairs hepatic insulin action,[196] leading to increases in hepatic glucose output, the synthesis of proinflammatory cytokines, excess triglyceride secretion by the liver, low HDL cholesterol levels, and an increase of relatively cholesterol-depleted LDL particles.[197] Furthermore, the intrahepatic accumulation of FFA and lipid is also detrimental to liver insulin sensitivity, as this leads to the generation of toxic lipid-derived metabolites such as diacylglycerol (DAG), fatty acyl CoA, and ceramides. These in turn trigger the activation of protein kinase C-ε (PKCε) and serine/threonine phosphorylation of IRS-1, which attenuates hepatic insulin signal transduction.[198]

Adipose Tissue Insulin Resistance

The expanded adipose tissue mass that accompanies obesity often leads to increased lipolysis and FFA turnover.

Normally, insulin inhibits adipose tissue lipolysis; however, in the insulin-resistant state, the process is accelerated, leading to increased FFA release into the circulation. Moreover, visceral adipocytes are more sensitive to catecholamine-stimulated lipolysis than subcutaneous adipocytes, further increasing FFA flux.[199] Macrophages also infiltrate into adipose tissue and contribute to both adipocyte hypertrophy and cytokine release.[200-202] These circulating cytokines also affect insulin action in other tissues, such as liver and muscle.

Muscle Insulin Resistance

Downstream of an insulin-resistant liver, increased plasma FFA levels disrupt the glucose-fatty acid or "Randle" cycle and insulin-mediated glucose transport in skeletal muscle,[203,204] facilitating the development of hyperglycemia. The ectopic deposition in skeletal muscle of fat as intramyocellular lipid may also play a direct role in the pathogenesis of insulin resistance and metabolic syndrome via the lipid metabolite-induced activation of PKCϵ with the subsequent impairment of insulin signaling.[198]

Assessment of Insulin Resistance

The euglycemic hyperinsulinemic clamp is the gold standard for measuring insulin sensitivity; the frequently sampled intravenous (IV) glucose tolerance test (FSIVGTT) and steady-state plasma glucose (SSPG) methods are also valid measurements. Euglycemic hyperinsulinemic clamp studies have shown that insulin resistance is determined primarily by the response of skeletal muscle, with over 75% of infused glucose taken up by muscle and only 2% to 3% by adipose tissue.[205] All three methods are generally time consuming, require IV infusions and frequent blood sampling, are burdensome for participants, are costly, and require a research setting. In an attempt to simplify the measurement of insulin sensitivity, a number of methods using single simultaneously obtained samples of fasting insulin and glucose have been developed, such as the homeostatic model assessment of insulin resistance (HOMA-IR). Each of these methods uses a mathematical formula that adjusts for individual variability in insulin and glucose secretion and clearance. Although the goal for these methods was to improve the accuracy of fasting insulin alone by the addition of fasting glucose, it is now agreed that they yield similar results to fasting insulin. When correlated with gold standard methods in children, fasting insulin is a poor measure of whole body insulin sensitivity in an individual child. Although the primary interest has been in insulin resistance, the adverse effects related to insulin resistance are more likely mediated via compensatory hyperinsulinemia.

The two most important biologic conditions associated with insulin resistance in childhood are ethnicity and puberty. Studies show that African-American, Hispanic, Pima Indian, and Asian children are less insulin sensitive compared with Caucasian children.[206] The insulin resistance in minority ethnic groups is manifested as lower insulin-stimulated glucose uptake, concomitant with hyperinsulinemia, evidence of increased insulin secretion from the β cell, and decreased insulin clearance. During puberty there is ~25% to 50% decline in insulin sensitivity with recovery when pubertal development is complete. The compensatory increase in insulin secretion during puberty may be blunted in African-American and Hispanic youth, thus increasing their risk for T2DM around the time of puberty. The development of T2DM is covered in depth in Chapter 9, yet it is worth noting that impaired glucose tolerance (IGT), known as prediabetes, is a relatively common condition in obese children and adolescents. IGT in obese youth is typically characterized by obesity with an unfavorable pattern of lipid partitioning, with an increased deposition of fat in the visceral and intramyocellular lipid (IMCL) compartments.[207]

Lipid Partitioning

The term *lipid partitioning* refers to the distribution of body fat in various organs and compartments. The majority of excess fat is stored in its conventional subcutaneous depot, yet other potential storage sites exist as well, such as the intra-abdominal (visceral) fat compartment and insulin-responsive tissues such as muscle and liver. One hypothesis to explain the relation between obesity and insulin resistance is the "portal-visceral" paradigm.[208] This hypothesis claims that increased adiposity causes an accumulation of fat in the visceral depot, leading to an increased portal and systemic free fatty acid (FFA) flux[209] (Figure 22-5). Associations between visceral adiposity, insulin resistance, and comorbidities have been demonstrated across most age groups and ethnicities.[210] Of note, studies of *in vivo* free fatty acid fluxes from the visceral and subcutaneous truncal and abdominal depots have failed to demonstrate a substantial difference in net fluxes between these depots.

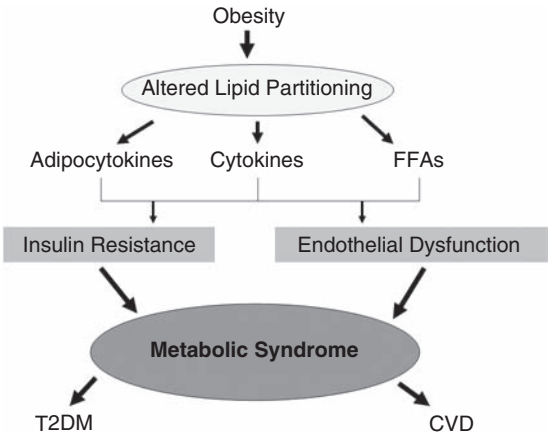

FIGURE 22-5 ■ A hypothesis on the relation between obesity and the metabolic syndrome. The metabolic impact of obesity is determined by the pattern of lipid partitioning. Lipid storage in insulin-sensitive tissues such as liver or muscle and in the visceral compartment is associated with a typical metabolic profile characterized by elevated free fatty acids and inflammatory cytokines alongside reduced levels of adiponectin. This combination can independently lead to peripheral insulin resistance and to endothelial dysfunction. The combination of insulin resistance and early atherogenesis (manifested as endothelial dysfunction) drives the development of altered glucose metabolism and of cardiovascular disease.

Subcutaneous fat, which does not drain into the portal system, is strongly related to insulin resistance in healthy obese and diabetic men.[211] Similarly, truncal subcutaneous fat mass has been demonstrated to independently predict insulin resistance in obese women. Visceral and subcutaneous fat differ in their biologic responses,[212] as visceral fat is more resistant to insulin and has increased sensitivity to catecholamines. These observations emphasize that both visceral and subcutaneous abdominal fat can contribute to insulin resistance, possibly by different mechanisms.[213]

Studies performed in obese adolescents highlight the fact that the ratio of visceral to subcutaneous fat may be the determinant of their metabolic impact rather than their absolute quantity. Indeed, obese adolescents with a high ratio, which are not necessarily more obese than others, demonstrate a markedly adverse metabolic phenotype of severe insulin resistance and alterations in glucose and lipid metabolism.[214] Moreover, intrahepatic fat, though strongly associated with high levels of visceral fat, is also associated with the insulin-resistant state in obese adolescents, independent of all other fat depots.[215]

An alternative theory to explain the relation between obesity and insulin resistance is the "ectopic lipid deposition" paradigm.[216] This theory is based on the observations that lipid content in liver or muscle is increased in obesity and in T2DM and is a strong predictor of insulin resistance.[217,218] Moreover, in conditions such as lipodystrophies, all fat is stored in liver and muscle due to lack of subcutaneous fat tissue, causing severe insulin resistance and diabetes.[219] In obese adults (BMI $>$ 30), muscle attenuation on computed tomography (CT) (representing lipid content) is a stronger predictor of insulin resistance than is visceral fat.[220] Studies performed *in vivo* using ^{1}H-NMR spectroscopy demonstrated increased IMCL content to be a strong determinant of insulin resistance in adults[221] and in obese adolescents.[222] Alternatively, lipid deposition in hepatocytes to produce intrahepatocellular lipid (IHCL) is highly predictive of insulin resistance, even more so than visceral fat.[223] Thus, obesity-driven morbidity may begin when the subcutaneous fat reaches its capacity to store excess fat and begins to shunt lipid to ectopic tissues, such as liver and muscle, leading to peripheral insulin resistance,[224] or possibly when liver or muscle accumulates lipid produced *de novo* in response to dietary manipulation (discussed later). Another postulated cause of IMCL and IHCL accumulation is a reduction of fat β oxidation,[225] related to low aerobic capacity, a reduced number or malfunction of mitochondria, or reduced SNS tone. The effect of IMCL or IHCL accumulation on peripheral sensitivity is postulated to be due to an alteration of the insulin signal transduction pathway in muscle, caused by derivates of fat such as long chain fatty acyl-CoA and diacylglycerol within the hepatocyte or myocyte. These derivates activate the serine/threonine kinase cascade and cause serine phosphorylation of IRS-1, which inhibits insulin signaling.[226] A comparable mechanism has been demonstrated in the liver, where the accumulation of lipids, in particular diacylglycerol, activates the inflammatory cascade by inducing *c-jun* N-terminal kinase (JNK-1), which causes serine rather than tyrosine phosphorylation of IRS-1, leading to an inhibition of hepatic insulin signaling.[227,228]

Vascular Changes

Early stages of the atherosclerotic process may be detected in obese children. It has become clear that endothelial dysfunction represents a key early step in the development of atherosclerosis.[229] The hallmark and cause of endothelial dysfunction is impairment in nitric oxide (NO)-mediated vasodilatation.[230] This is due to decreased NO production by endothelial nitric oxide synthase (eNOS), which has been postulated to result from high levels of free fatty acids and inflammatory cytokines (IL-6, TNF-α) in insulin-resistant obese individuals, increased reactive oxygen species, or increased uric acid, which inhibits eNOS activity.[231] Decreased NO bioavailability leads to an imbalance between vasodilating and vasoconstricting factors (such as endothelin), which leads to impaired vascular smooth muscle relaxation, increased adhesion of inflammatory cells to the endothelium, increased expression of plasminogen activator inhibitor–1 (PAI-1; a pro-thrombotic molecule), and increased vascular smooth muscle cell proliferation. Thus, decreased NO bioavailability is thought to create a proinflammatory, prothrombotic environment, which promotes atherosclerosis.[232] Endothelial function represents an integrated index of the overall CV risk burden in any given individual. Since the early 2000s, noninvasive techniques for the assessment of endothelial function, including high-resolution external vascular ultrasound to measure flow-mediated endothelium-dependent dilatation (FMD) of the brachial artery during hyperemia, have been developed.[233,234] Impaired FMD correlates with arterial wall stiffness, coronary dilatation, and endothelial dysfunction in obese children.[235] Similarly, anatomic changes in peripheral arterial vessels such as increased intimal medial thickness (IMT) have also been demonstrated in obese children and adolescents,[236] which mimics early coronary pathology and predicts adverse CV outcomes.

There are no studies that directly measure *in vivo* insulin sensitivity and its relationship to atherosclerotic abnormalities in children. Very limited observations suggest a relationship between HOMA-IR and arterial stiffness and fasting insulin levels in youth. However, a role for insulin resistance in the early abnormalities of vascular smooth muscles is proposed based on the observation that circulating biomarkers of endothelial dysfunction (intercellular adhesion molecule and E-selectin) are highest, whereas adiponectin, the anti-atherogenic adipocytokine, is lowest among the most insulin-resistant youth. The landmark Bogalusa heart study demonstrated that CV risk factors present in childhood are predictive of coronary artery disease in adulthood.[191,237] Among these risk factors, LDL-cholesterol and body mass index (BMI) measured in childhood were found to predict intima-media thickness (IMT) in young adults.[238] There is now substantial evidence that the insulin resistance of childhood obesity creates the metabolic platform for adult CV disease.[239-241] Moreover, the constellation of peripheral insulin resistance, an unfavorable adipocytokine profile, subacute inflammation, and

endothelial dysfunction work in parallel to promote the pathologic processes of aging.

Adipocytokines

Leptin

The discovery of leptin in 1994 has dramatically changed the view of adipose tissue in the regulation of energy balance.[17] Adipocytes secrete several proteins that act as regulators of glucose and lipid homeostasis.[242] These proteins have been collectively referred to as adipocytokines because of their structural similarity with cytokines. Circulating leptin levels correlate with the degree of obesity. As stated earlier, the primary role of leptin is to serve as an adiposity sensor to protect against starvation. Leptin probably has a permissive role in high-energy metabolic processes such as puberty, ovulation, and pregnancy, but its role in states of energy excess is less known. In obesity, the development of leptin resistance may result in a breakdown of the normal partitioning of surplus lipids in the adipocyte compartment.[243]

Adiponectin

The cytokine adiponectin is peculiar in obesity because, in contrast to the other adipocytokines, its level is reduced in obesity.[244] The adiponectin gene is expressed exclusively in adipose tissue and codes a protein with a carboxyl terminal globular head domain and an amino terminal collagen domain, which is structurally reminiscent of the complement factor 1q.[245] The gene is located on chromosome 3q27, a location previously linked to the development of type 2 diabetes and the metabolic syndrome. Several single nucleotide polymorphisms (SNPs) in the adiponectin gene have been reported to be associated with the development of T2DM in populations around the world, suggesting that adiponectin plays a major role in glucose metabolism.[246] Adiponectin circulates in plasma in three major forms: a low-molecular-weight trimer, a middle-molecular-weight hexamer, and a high-molecular-weight 12 to 18-mer.[247] Circulating plasma adiponectin concentrations demonstrate a sexual dimorphism (females have greater concentrations), suggesting a role for sex hormones in the regulation of adiponectin production or clearance. Dietary factors such as linoleic acid or fish oil versus a high-carbohydrate diet or increased oxidative stress have been shown to increase or decrease adiponectin concentrations, respectively. These observations suggest that the circulating levels of adiponectin are regulated by complex interactions between genetic and environmental factors.[248]

The receptors for adiponectin have been characterized in rodent models and cloned. Two receptors, named ADIPOR1 and ADIPOR2, have been characterized. ADIPOR1 is expressed in numerous tissues including muscle, whereas ADIPOR2 is mostly restricted to the liver. Both receptors are bound to the cell membrane yet are unique in comparison to other G protein–coupled receptors in the fact that the C terminal is external whereas the N terminal is intracellular.[249] Both ADIPOR1 and ADIPOR2 are receptors for the globular head of adiponectin and serve as initiators of signal transduction pathways that lead to increased PPARα and increased AMP kinase activities, which promote glucose uptake and increased fatty acid oxidation. Adiponectin has been shown to have potent anti-atherogenic functions, as it accumulates in the subendothelial space of injured vascular walls to reduce the expression of adhesion molecules and the recruitment of macrophages.[250]

Studies in obese children and adolescents have shown that adiponectin is inversely related with the degree of obesity, insulin sensitivity, visceral adiposity, IHCL, and IMCL, whereas weight loss increases adiponectin. A fall in adiponectin has been shown to coincide with the onset of insulin resistance[251] and the development of diabetes in monkeys.[252] All of these observations along with human clinical data support a pivotal role for adiponectin in the prevention of the comorbidities of the metabolic syndrome.

Family studies using parent-offspring regressions revealed that most adipocytokines show evidence for significant inheritance. A principal component (PC) analysis of standardized hormone levels demonstrates surprising heritability of the three most common axes of variation. The main axis, which explained 21% of the variation, was most strongly loaded on levels of leptin, TNFα, insulin, and PAI-1, and inversely with adiponectin. It was significantly associated with body mass index (BMI), phenotypically stronger in children, and showed a heritability of 50%, after adjustment for age, gender, and generational effects. Thus, adipocytokines are highly heritable and their pattern of covariation significantly influences BMI as early as the preteen years.[253]

Myokines and Natriuretic Peptides. Skeletal and heart muscle may serve as an endocrine organ as well. Some of the effects of exercise on skeletal muscle are mediated by the transcriptional coactivator PPAR-γ coactivator 1α (PGC-1α). In the mouse, PGC-1α expression in muscle stimulates an increase in expression of FNDC5, a membrane protein that is cleaved and secreted as a newly identified hormone, named irisin. Irisin acts on white adipose cells in culture and in vivo to stimulate UCP1 expression and a broad program of brown fatlike development. Irisin is induced with exercise in mice and humans, and mildly increased irisin levels in the blood cause an increase in energy expenditure in mice with no changes in movement or food intake. This results in improvements in obesity and glucose homeostasis. This novel myokine is actually the first hormonal link between exercise and the adipose tissue changes it may induce.[254] Atrial natriuretic peptides (ANPs) also have been implicated in fat metabolism. These natriuretic peptides are produced with exercise, cardiac wall stress, weight loss, and cold exposure, and they are inhibited by obesity and insulin resistance. The ANP binds to its natriuretic receptor, facilitating the formation of cGMP from GTP. In turn, cGMP phosphorylates cGMP-dependent protein kinase, which activates lipolysis and phosphorylates p38 mitogen-activated protein kinase to enhance mitochondrial biogenesis with increased energy expenditure and increased heat generation, as part of the brown-fat thermogenic program. Thus, both skeletal

and cardiac muscle may respond to exercise by inducing changes in fat metabolism to enhance caloric expenditure and limit obesity. These new findings are likely to open new avenues of clinical research to limit the consequences of the "obesity epidemic."[255,256]

Inflammatory Cytokines. Accumulating evidence indicates that obesity is associated with subclinical chronic inflammation.[257] The adipose tissue serves not merely a simple reservoir of energy stored as triglycerides, but serves as an active secretory organ releasing many peptides, including inflammatory cytokines, into the circulation. In obesity, the balance between these numerous peptides is altered, such that larger adipocytes and macrophages embedded within them produce more inflammatory cytokines (i.e., TNF-α, IL-6) and fewer anti-inflammatory peptides such as adiponectin.[258] One theory posits that as energy accumulates in adipocytes, the perilipin border of the fat vacuole breaks down, causing the adipocyte to die.[259] Cell death recruits macrophages in the adipose tissue, especially the visceral compartment, which in the process of clearing debris also elaborate inflammatory cytokines, initiating a pro-inflammatory milieu that predates and possibly drives the development of systemic insulin resistance, diabetes, and endothelial dysfunction.[260,261] Systemic concentrations of C-reactive protein (CRP) and IL-6, two major markers and participants of the inflammatory process, are increased in obese children and adolescents. CRP levels within the "high-normal" range have been shown to predict CV disease[262] and development of T2DM[263] in adults. Elevated levels of CRP correlate with other components of the metabolic syndrome in obese children.[264,265] Thus, inflammation may be one of the links between obesity and insulin resistance and may also promote endothelial dysfunction and early atherogenesis.

Reactive Oxygen Species (ROS). The "free radical theory" holds that an imbalance between ROS generation and antioxidant defenses is a major factor in the determination of lipid peroxidation and protein misfolding, with resultant DNA and cellular damage.[266] Excessive intracellular ROS formation occurs via three pathways: (1) inflammatory cytokines derived from visceral fat accumulation,[267] (2) dysfunctional mitochondrial energetics,[268] and (3) glycation (discussed later). Excessive nutrient processing by mitochondria can result in uncoupling of oxidative phosphorylation and increased generation of ROS; this, in turn, leads to altered mitochondrial function and further ROS generation.[269] ROS accumulation can also impair endoplasmic reticulum (ER) function, causing ER stress and the compensatory unfolded protein response (UPR). The UPR can itself be overwhelmed by persistent excessive nutrient processing and ROS generation, leading to cellular shutdown, defective insulin secretion, and T2DM[270 271] (Figure 22-6).

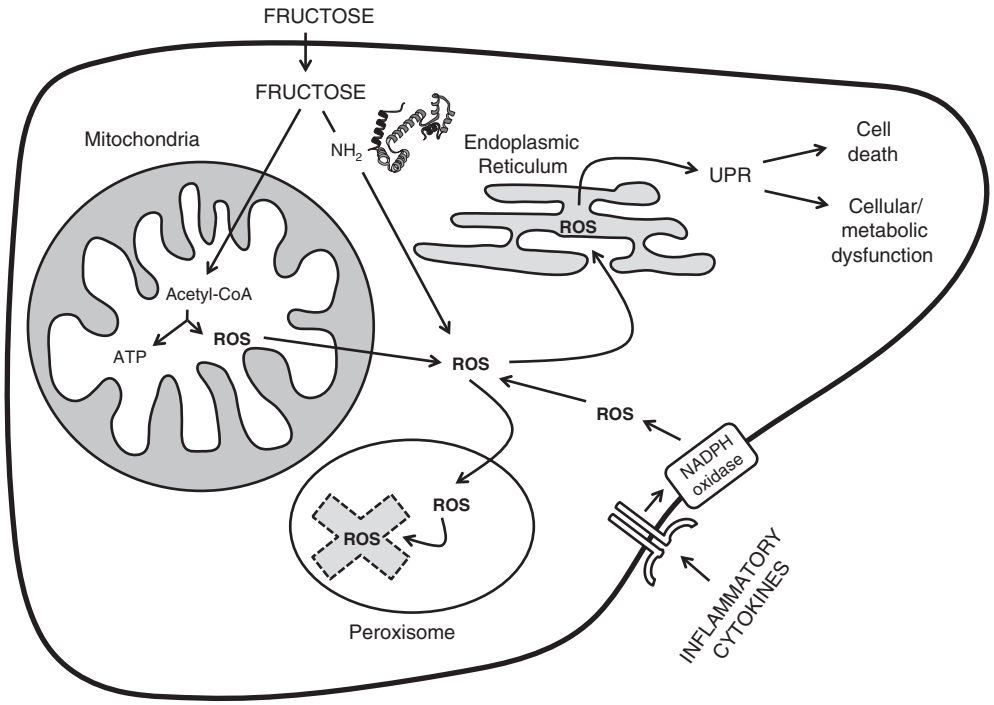

FIGURE 22-6 ■ Mechanisms of subcellular metabolic dysfunction, using fructose as an example. The formation of acetyl-CoA leads to lipid deposition and activation of inflammatory pathways, which serine phosphorylate IRS-1, leading to insulin resistance. Furthermore, metabolic processing in the mitochondria, the glycation of protein ϵ-amino groups via the Maillard reaction, and circulating inflammatory cytokines, due to their receptor-mediated activation of NADPH oxidase, all increase intracellular levels of reactive oxygen species (ROS). In the absence of sufficient peroxisomal quenching and degradation, the ROS moieties lead to endoplasmic reticulum (ER) stress, promoting the unfolded response (UPR), and cause either cell death (apoptosis) or cellular/metabolic dysfunction. ATP, adenosine triphosphate; CoA, coenzyme A; JNK-1, *c-jun* N-terminal kinase 1; NADPH, nicotinamide adenine dinucleotide phosphate; PKCϵ, protein kinase C−ϵ; pSer-IRS-1, serine phosphorylated IRS-1; ROS, reactive oxygen species; UPR, uncoupled protein response. (From Bremer, A. A., Mietus-Snyder, M. L., & Lustig, R. H. (2012). Toward a unifying hypothesis of metabolic syndrome. *Pediatrics*, *129*, 557–570.)

As ROSs are inherent by-products of cellular metabolism, endogenous cellular antioxidants (e.g., catalase and glutathione) quench the ROS before they have a chance to promote peroxidation. These antioxidants are found primarily in peroxisomes, which abut the mitochondria and act as "support staff" for ROS processing. Reduction in peroxisomal activity results in mitochondrial dysfunction and endoplasmic reticulum stress. Furthermore, cytokines such as TNF-α can reduce peroxisomal number and function, rendering cells even more vulnerable.[272,273]

Others. Several other novel adipocytokines have been identified, but their clinical significance in humans is still unclear. For instance, resistin, a 12.5-kDa polypeptide hormone, is produced by adipocytes in rodents and by immunocompetent cells in humans. In rodents, resistin appears to have an important role in the development of hepatic insulin resistance, yet its role in humans is less clear but may be related to involvement in the regulation of inflammatory processes, rather than tissue-specific insulin sensitivity.

Comorbidities Related to Insulin Resistance

The Metabolic Syndrome

The association and clustering of T2DM, hypertension, dyslipidemia, and CV disease in adults has led to the hypothesis that they may arise from a common antecedent. The World Health Organization (WHO) argues that this antecedent is insulin resistance and defines this association as the "metabolic syndrome."[274-277] A consensus definition of the metabolic syndrome for the pediatric age group has been published[278] and declares that children younger than 10 years of age should not be defined as having this condition. For children older than 10 years of age, the obesity component of the definition is waist circumference and not BMI, indicating the clinical importance of intra-abdominal fat. The metabolic syndrome affects approximately 25% of the U.S. adult population.[279] Because of its wide prevalence, the metabolic syndrome is of enormous clinical and public health importance, even at its earliest stages. Although still debated, one scheme of the pathophysiology of the metabolic syndrome is shown in Figure 22-5. According to this paradigm, the impact of obesity is determined by the pattern of lipid partitioning (i.e., the specific depots in which excess fat is stored). This pattern of lipid storage determines the adipocytokine secretion profile, on circulating concentrations of inflammatory cytokines and on the flux of FFA. The combined effect of these factors determines the sensitivity of insulin target organs (such as muscle and liver) to insulin and impacts the vascular system by affecting endothelial function. Peripheral insulin resistance and endothelial dysfunction are the early promoters of overt pathology, culminating in T2DM and cardiovascular disease. Regardless of the definition of *metabolic syndrome* used, insulin resistance and high insulin levels are associated with the clustering of cardiometabolic risks associated with metabolic syndrome in a variety of ethnic groups.

Nonalcoholic Fatty Liver Disease (NAFLD)

NAFLD represents fatty infiltration of the liver in the absence of alcohol consumption.[280] The spectrum of NAFLD ranges from pure fatty infiltration (steatosis) to inflammation (nonalcoholic steatohepatitis, or NASH), to fibrosis and even cirrhosis.[281] NAFLD was found in the NHANES III survey to be more prevalent in obese African-American and Hispanic males, with T2DM, hypertension, and hyperlipidemia.[282] These associations have led to the hypothesis that NAFLD may precede the onset of T2DM in some individuals. NAFLD is now the most common liver disease among children in North America.[283,284] NAFLD in children is associated with increased visceral fat deposition[285] and may progress to cirrhosis and related complications.[286] The association between abdominal obesity and fatty liver may be partially explained by sustained exposure of the liver to an increased flux of FFA from the visceral depot.[213] NAFLD may represent an early manifestation of ectopic lipid deposition in the liver and represents a challenge to the clinician due to the contrast of its minimal early manifestations and its potential serious outcomes. Studies using the clamp methodology demonstrate that NAFLD is associated with hepatic and peripheral insulin resistance. The relation between insulin sensitivity and NAFLD seems to be, in part, driven by abdominal fat content.

Insulin plays a key role in regulating transcription factors such as sterol response element binding protein-1c (SREBP-1c), which are abundantly expressed in the liver.[287] SREBP-1c is pivotal in the control of hepatic lipogenesis and is increased in proportion to circulating insulin levels.[288] These data raise the possibility that fasting hyperinsulinemia may contribute to hepatic steatosis, rather than vice versa. Alternatively, inflammatory cytokines released by visceral fat or by the hepatic immunoreactive cells may contribute to altered hepatic lipid metabolism.[280] The majority of patients probably experience NAFLD without progressing on to NASH. It is likely that subsequent inflammation from increased ROS formation without appropriate quenching is necessary to promote progression to NASH (the so-called second hit theory).[286,289] As hepatic imaging modalities improve, noninvasive quantification of hepatic lipid deposition may enable us to use it as a target for intervention. For the time being, NAFLD can be surmised by an elevated ALT. However, ALT does not have to be very elevated; the 95th percentile for ALT in children is 25.8 U/mL for boys and 22.1 for girls.[290]

Polycystic Ovarian Syndrome (PCOS)

The association of hyperandrogenism and oligomenorrhea or amenorrhea in females, termed PCOS, is a frequent comorbidity of obesity, which can extend down to childhood. This disorder is covered in detail in Chapter 15. A 2003 consensus statement[291] defined the diagnostic criteria for PCOS as two out of the following three (after exclusion of other hyperandrogenic disorders): oligo/anovulation, clinical or biochemical manifestations of hyperandrogenism, and polycystic ovaries by ultrasound. PCOS is the most common cause of infertility due to anovulation and a

major risk factor for development of the metabolic syndrome and altered glucose metabolism in females. The antecedents of PCOS have been identified in prepubertal girls, suggesting a developmental lesion.[292]

Adolescent girls with PCOS can have moderate to severe insulin resistance with increased risk for altered glucose metabolism, and the impairment in insulin sensitivity is more pronounced in obese rather than lean PCOS girls. In some ethnic groups, girls with premature pubarche, a potential antecedent of PCOS, have relatively increased insulin levels, thus a causal link between hyperinsulinemia and androgen hypersecretion (of adrenal or ovarian origin) has been hypothesized. Population studies of normal girls have shown that rapid weight gain is associated with higher adrenal androgens and body fatness, and that hyperinsulinemia is related to early menarche. Thus, the association of higher insulin levels with premature pubarche and subsequent PCOS may be driven, at least in part, by obesity. Obesity characterizes about 50% of women with classic PCOS,[293] although it is even more common among adolescents. Increased peripheral insulin resistance occurs in approximately 50% of patients with PCOS and almost certainly plays a role in the pathogenesis of this condition. On the other hand, almost all forms of severe insulin resistance, such as T2DM or rare lipodystrophy syndromes, are also associated with PCOS. Of note, insulin resistance has not been included as a diagnostic criterion for PCOS mainly because of the difficulty of its measurement. Fasting hyperinsulinemia and an increased insulin secretory response to an oral glucose load have been demonstrated in girls with PCOS.[294] Indeed, obese adolescent girls with PCOS have been shown to be 50% more insulin resistant than weight-matched controls without PCOS.[295] The constellation of metabolic abnormalities typically seen in insulin-resistant individuals is commonly encountered in obese adolescents with PCOS, including NAFLD[296] and T2DM.[297] The increased prevalence of the metabolic syndrome may be related to the hyperandrogenism independent of obesity-related insulin resistance.[298] Early markers of accelerated atherogenesis are already present in young females with PCOS,[299] indicating that early intervention aimed at reducing CV risk may be beneficial.

Metabolic examination of patients with PCOS demonstrates hepatic and muscle resistance, but not ovarian insulin resistance, possibly accounting for insulin stimulation of theca cell androgen production.[300] The correlation between insulin resistance and hyperandrogenism begs a unifying hypothesis as to their pathogenesis, which is proffered by the "serine phosphorylation hypothesis," which suggests that both P450c17 and the insulin receptor are aberrantly serine phosphorylated; in the case of P450c17, this leads to excess activity and increased androgen production,[301] and in the case of the insulin receptor, this leads to tissue-specific insulin resistance.[302] However, this hypothesis remains to be proven.

Other Endocrine Comorbidities

Obesity causes changes in other hormonal systems, some of which confer specific morbidities. The age of pubertal initiation has been creeping earlier, particularly in African Americans. This advancement is explained in part by the increasing overnutrition and BMI seen in this population.[303] Infertility in older adolescents and adult women may occur either as a manifestation of PCOS due to excessive ovarian androgen production in females or due to excessive aromatization of androgen to estrogen by peripheral adipose tissue with suppression of the hypothalamic-pituitary gonadal axis in both sexes.[304] The hyperestrogenemia may also promote gynecomastia in males.[305] In addition, the hypercapnia associated with obstructive sleep apnea can suppress hypothalamic GnRH function, leading to a syndrome of delayed puberty.[306]

Obesity is associated with decreased growth hormone (GH) secretion, and indeed most obese subjects, despite normal or excessive statural growth, fail GH stimulation testing. However, caloric restriction for 24 hours can restore normal GH responsivity.[307] Despite the functional GH inadequacy, statural growth is accelerated, bone age is advanced, and peripheral total and free IGF-1 levels are normal or elevated in obesity, suggesting normal or accentuated GH sensitivity,[308] or possibly due to the suppression of IGFBP-1 and the effects of hyperinsulinemia on activation of the growth plate IGF-1 receptor.[309] Free thyroxine levels tend to be lower and TSH higher in obese children, although mostly within the normal range along with some TSH levels within the subclinical hypothyroidism category; the mechanism is unknown. The elevated TSH levels in obesity seem a consequence rather than a cause of obesity. Therefore, treatment of hyperthyrotropinemia with thyroxine is unnecessary in obese children. Lastly, obesity can be associated with increased cortisol exposure, possibly due to conversion of circulating cortisone to cortisol by the enzyme 11β-hydroxysteroid dehydrogenase-1 (11β−HSD1) located within adipocytes.[310]

Other Nonendocrine Comorbidities

Childhood obesity is associated with numerous other comorbidities. Pseudotumor cerebri[311] is a rare and poorly understood condition leading to intracranial hypertension, whose manifestations include papilledema and headache. Treatment includes serial lumbar puncture, acetazolamide to reduce CSF production; in severe cases there is a need for a ventriculoperitoneal shunt, and occasionally optic nerve sheath fenestration is necessary to save eyesight. Obstructive sleep apnea occurs frequently in morbidly obese children; presumably due to the large amount of retropharyngeal fat that compresses the upper airway during sleep.[312] Affected patients snore, often stop breathing for more than 20 seconds during sleep, and wake up during the night with headache. Treatment includes nocturnal positive airway pressure and, when appropriate, tonsilloadenoidectomy; however, symptoms often recur. Obese children manifest numerous orthopedic difficulties, including fractures, knee pain, anatomic lower limb malalignment, and impairment in mobility.[313] Cholelithiasis occurs in approximately 2.5% of obese adolescents, especially in females, but is not usually seen in prepubertal obese children.[314] Lastly, psychological distress, including clinical depression, is clearly manifested in obese children[315] and specifically in

the severely obese. These various comorbidities all appear to be associated with a BMI z-score in a curvilinear fashion[316]; thus, the more obese a patient is, the more likely he or she will manifest comorbidity.

FACTORS ASSOCIATED WITH THE CURRENT EPIDEMIC OF OBESITY

Genetics

The association between obesity and genetics owes to two separate lines of investigation: (1) the discoveries of monogenic disorders of the energy balance pathway (discussed later) and (2) studies of specific racial and ethnic groups, in which obesity seems to segregate, such as the Pimas and Hispanics in the Southwest United States.[317,318] These observations are combined with an attractive theory on the natural selection of individuals in response to drastic environmental/ecologic pressure (i.e., famine), termed the *thrifty gene hypothesis*,[319] to yield a very strong driving force for the elucidation of specific genetic loci in the pathogenesis of obesity.[320] However, the rapid timescale of the increased prevalence of childhood obesity cannot possibly reflect a population genetic change. Therefore, the current model is that obesity is a result of gene-environment interactions; an ancient genetic selection to deposit fat efficiently may have provided a survival advantage in old times but is maladaptive with our current food overabundance. In the common forms of obesity, relating single nucleotide polymorphisms with associated risks for obesity is difficult, as the effects are uncertain and the results not always confirmed. Several single nucleotide polymorphisms in specific genes have been identified, such as the fat mass and obesity associated (FTO) gene. Variation in the FTO gene has provided the most robust associations with common obesity to date, yet the FTO variant that confers a predisposition to obesity does not appear to be involved in the regulation of energy expenditure but may have a role in the control of food intake and food choice, suggesting a link to a hyperphagic phenotype or a preference for energy-dense foods.[321] The large genome wide association studies (GWAS) have yielded to date 34 loci that may be relevant to the development of adult obesity, yet they explain less than 5% of the phenotype.[322] However, an analysis done specifically in children reveals two more loci that may provide more genetic susceptibility.[323]

Epigenetics and Developmental Programming

Follow-up studies of newborns who were small for their gestational age (SGA), large for gestational age (LGA), and premature have noted markedly increased risks for obesity and the metabolic syndrome. The "fetal origins hypothesis"[324] states that some aspect of the *in utero* environment contributes to the development of obesity and chronic disease in later life. The specific developmental aberration that promotes obesity remains unknown. However, each of these three antenatal conditions is associated with insulin resistance. The "developmental model" of chronic diseases postulates that early-life events affect individual differences in vulnerability to lifestyle and environment. This concept is supported by studies of *in utero* or at-birth conditions on future diseases by the fact that differences in adult lifestyles only partially explain the development of diseases. One possible mechanism for such developmental programming includes epigenetic changes, which may contribute to alterations in gene expression. For instance, the pattern of DNA methylation noted in cord blood predicted the degree of adiposity at age 9 years.[325]

Documentation of the relationship of SGA with adult obesity and CV disease started with studies of the Dutch famine during World War II and its aftermath.[326] Several studies of SGA newborns demonstrate that they are hyperinsulinemic and insulin resistant at birth, exhibit rapid catch-up growth in the early postnatal period, and develop obesity in childhood, which remains and promotes persistent insulin resistance and the metabolic syndrome. An analysis of Indian newborns born in India versus the United Kingdom.[327] demonstrate that even though those born in India weigh 700 g less at birth, their glucose and insulin levels are markedly elevated. After adjustment for birth weight, the India-born babies demonstrate increased adiposity, four times higher insulin levels, and two times higher leptin levels than babies born in the U.K. Thus, these babies are insulin resistant even at birth, which translates into increased adiposity. Following such babies into childhood, numerous studies document insulin resistance during early childhood.[328-330]

Babies born LGA are hyperinsulinemic at birth.[331] Although most LGA babies are due to gestational diabetes mellitus (GDM) and exposure to hyperglycemia throughout the pregnancy, this is not always the cause. A follow-up of LGA babies without GDM demonstrates a doubling of prevalence of insulin resistance and metabolic syndrome, whereas LGA babies resulting from GDM manifest a threefold increase.[332,333] Indeed, the "vertical" transmission of maternal diabetes to the offspring in the form of later obesity and diabetes has been documented in studies of Pima Indians.[334,335] Lastly, weight gain during pregnancy increases birthweight, the risk for LGA, and obesity in the offspring[336,337] (Figure 22-7).[661]

Although there are no studies documenting hyperinsulinemia at birth in premature infants due to technical reasons, follow-up of these babies into early childhood also demonstrates increased weight gain and insulin resistance and compensatory insulin secretion that is inappropriately high for their degree of weight gain.[338]

The protective effect of breastfeeding against the development of future obesity has long been known,[188] and there appears to be a dose response; the longer the breastfeeding, the more protective.[339] However, this may be complicated by confounding factors, such as socioeconomic status, maternal smoking during pregnancy, and maternal BMI.[340] The mechanism of breastfeeding's antiobesity effect is also unclear. Some think infant feeding self-regulation is most relevant, whereas one study suggests that leptin in breast milk may contribute to this protection,[341] and finally the concern about the fructose/sucrose content in infant formula has also received attention.

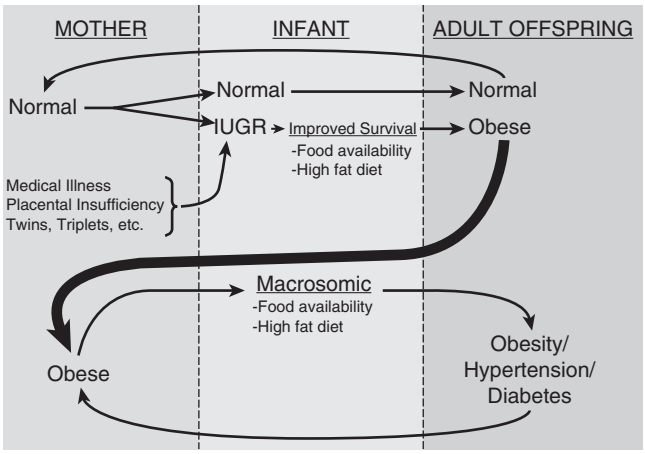

FIGURE 22-7 ■ Postulated mechanisms by which developmental programming (either intrauterine growth retardation or neonatal macrosomia) can lead to adult obesity in the offspring. (From Ross, M. G., Huber, I., & Desai, M. (2010). Intrauterine growth restriction, small for gestational age, and experimental obesity. In R. H. Lustig (Ed.), *Obesity before birth: maternal and prenatal effects on the offspring* (pp. 215–239) New York: Springer.)

Environmental Factors

Numerous environmental factors have also been associated with the obesity epidemic, particularly in children. However, most of these associations are derived from cross-sectional rather than longitudinal studies, and in many instances, the mechanism remains lacking.[342] Several longitudinal studies in adults have clearly demonstrated that specific dietary and other lifestyle behaviors are independently associated with long-term weight gain, with a substantial aggregate effect. For instance, on the basis of increased daily servings of individual dietary components, 4-year weight change was most strongly associated with the intake of potato chips (0.767 kg), potatoes (0.58 kg), sugar-sweetened beverages (0.45 kg), unprocessed red meats (0.43 kg), and processed meats (0.42 kg) and was inversely associated with the intake of vegetables (−0.1 kg), whole grains (−0.168 kg), fruits (−0.224 kg), nuts (−0.25 kg), and yogurt (−0.37 kg) ($P \leq .005$ for each comparison).[343] Similarly, the sociodemographic environment has been shown to affect the chance of being obese in adults. Indeed, the opportunity to move from a neighborhood with a high prevalence of poverty to one with lesser poverty was associated with modest but potentially important reductions in the prevalence of extreme obesity and diabetes.[344] Similar relationships are likely, but not proven, for children and adolescents.

Stress and Cortisol

In humans, elevated cortisol or markers of HPA axis dysregulation correlate with abdominal fat distribution and the metabolic syndrome.[345] Although circulating cortisol is clearly important in determining visceral adiposity, the identification of a reduction of circulating cortisone to cortisol within visceral fat tissue by the enzyme 11β-hydroxysteroid dehydrogenase-1 (11β−HSD1) has also been linked to the metabolic syndrome.[310,346] These data suggest that cortisol is important for both increasing visceral adiposity and promoting the metabolic syndrome.

In adults, job stress and depression stress with increased cortisol secretion[347] lead to insulin resistance and the metabolic syndrome. Psychosocial stresses correlate with the risk of myocardial infarction in adults[348]; it is assumed that such patients exhibit increased HPA axis activation.[349] Even exogenous glucocorticoid administration is a risk factor for CV events.[350] Evidence of associations between elevated cortisol and psychological distress with abdominal fat distribution in adults is compelling. For instance, urinary glucocorticoid excretion is linked to aspects of the metabolic syndrome, including blood pressure, fasting glucose, insulin, and waist circumference.[345] Some individuals seem to be "high-responders" to a stress stimulus and demonstrate higher cortisol secretion. These individuals seem more prone for an alteration in satiety recognition and consume larger amounts of calories following the stress exposure (see Figure 22-3). However, the role of stress and cortisol in childhood obesity is currently undefined.

Sleep Deprivation

Americans get significantly less sleep than they did in the 1980s. Adults in the United State currently average less than 7 hours of sleep per night—almost 2 hours less than in 1980—and about one third of them get less than 6 hours per night.[352] Analyses of data from the first National Health and Nutrition Examination Survey (NHANES I) revealed that adults (ages 32 to 49 years old) who got less than 7 hours of sleep were more likely to be obese 5 to 8 years later than those who got 7 or more hours of sleep.[353] Similarly, a 13-year prospective cohort study in which participants were interviewed at ages 27, 29, 34, and 40 years of age found that sleep duration correlated negatively with obesity.[354] The link between short sleep duration and obesity has also been observed among children.[355] Like adults, increasing numbers of children are chronically sleep deprived. This is especially true of obese children, who have been found to get less sleep than children of normal weight. In addition to its other effects, sleep is one of the most powerful cross-sectional[356] and longitudinal[357] predictors of childhood obesity in prepubertal children. Although relatively little is known about the mechanism for the sleep-obesity relationship, especially among children, there are reasons to assume increased stress (discussed earlier) and altered activity of various hormones, such as leptin, ghrelin, and cortisol.

Television Viewing and "Screen Time"

Television watching is considered one of the most modifiable causes of childhood obesity.[358] There are four possible mechanisms linking television watching and obesity. First, television watching may increase stress levels and cortisol (discussed earlier), thereby increasing food intake and promoting obesity.[359] Second, television watching displaces physical activity. Most, but not all studies find inverse correlations between television watching and

physical activity and fitness.[360,361] Third, television watching increases calorie consumption because people eat while viewing or are affected by food advertising. Television viewing is also associated with increased high-fat food intake, decreased fruit and vegetable consumption, and increased soft drink intake.[362] "Junk food" is the most frequently advertised product category on children's television. Lastly, REE and nonexercise-associated thermogenesis (NEAT) seem to decrease during television watching.[363] According to NHANES III (1988-1994), the prevalence of childhood obesity is lowest among children who watch television ≤ 1 hour/day and highest among those who watch ≥ 4 hours/day.[364] The relationship between television watching and obesity has been examined in a large number of cross-sectional epidemiologic studies but in few longitudinal studies.[358] Several experimental studies have been conducted on the impact of reduced television watching, and their results support the suggestion that reduced television watching may help to reduce the obesity risk or promote weight loss in obese children.[365] These studies represent the strongest direct evidence that altering television watching alone is a promising strategy for preventing childhood obesity. Other forms of "screen time," such as playing videogames and using cell phones, are also implicated in the obesity pathogenesis.

Dietary Factors

Although the primary focus in terms of obesity has been on total calories ingested, an emerging body of evidence suggests that the quality of those calories play an important role in the pathogenesis of metabolic syndrome, by increasing hepatic insulin resistance or increasing ROS formation.

Dietary Fat versus Carbohydrate

Fat is generally considered more obesogenic than other macronutrients, because it is more energy dense, highly palatable, and more effectively converted to body fat.[366] A high-fat meal induces less thermogenesis and a higher positive fat balance than an isocaloric and isoprotein-containing low-fat meal.[367] Excessive fat intake is believed to cause weight gain,[368] but the relationships between dietary fat intake and childhood adiposity remain controversial.[369]

The prevalence of overweight in the United States has increased despite a decreased percentage of dietary energy derived from fat. A meta-analysis of 12 studies in overweight or obese adults who were given dietary advice on low-fat diet and followed for 6 to 18 months suggested that low-fat diets are no better than calorie-restricted diets for long-term weight loss.[370] Similarly, in children, total fat consumption expressed as a percentage of energy intake has decreased.[371] This decrease in fat consumption is largely due to increased total energy intake in the form of carbohydrates. Much of this imbalance is attributed to changing beverage consumption patterns, characterized by declining milk intakes and substantial increases in soft-drink consumption,[372] which may have its own etiopathogenesis (discussed later). Most interventions with a low-fat, "heart-healthy" diet have not been successful in childhood overweight prevention.[373]

The reduction in carbohydrate intake is taken to the extreme in the Atkins diet, which restricts adult subjects to less than 25 g/day of ingested carbohydrate. Adult evaluations of the diet have been disappointing long term,[374,375] and the popular diet has been abandoned. There are currently no data on the effects of this diet on children or adolescents. However, it should be noted that the ketogenic diet used to control seizures is similar in composition to the Atkins diet. A 2-year study of the ketogenic diet demonstrated persistent decreases in weight z-scores in children who were above average when the diet was initiated, without a significant compromise in general nutrition or height.[376]

Trans-unsaturated Fatty Acids (Trans Fats)

Trans-unsaturated fats in processed foods have been a staple in the Western diet since the early 20th century. This is because the trans-isomerization of the double bond prevents fatty acid breakdown by bacteria, prolonging the shelf life of foods. Like its bacterial predecessors, human mitochondria cannot subject trans fats to β oxidation in the liver,[377] contributing to ectopic intrahepatic lipid accumulation. Fortunately, due to the recognized association between trans fat consumption and cardiovascular disease in the mid-1980s and more stringent labeling requirements since 2006, the percentage of calories from trans fats consumed in the "Western diet" has gradually declined.[378] Trans fats have no health benefit and cause hepatic steatosis and insulin resistance[379]; however, their current consumption trends are temporally disparate with the current increasing prevalence of metabolic syndrome, suggesting that other factors are involved.

Glycemic Index and Fiber

Not all sugars exert the same insulinogenic response. Complex carbohydrates can be taken in two forms: either a combination of α1-4 linkages and α1-6 linkages, which gives the starch a globular structure called amylopectin, as seen in bread, rice, pasta, potatoes, and glycogen; or a linear polymer of α1-4 linkages called amylose, as seen in beans, lentils, and other legumes. Digestion and absorption of the former in the intestine is rapid due to the simultaneous actions of both α1-4 and α1-6 glucosidases, whereas that of the latter is much slower, because the α1-4 glucosidase can only cleave single glucose moieties on either side of the polymer. This phenomenon constitutes the basis of the glycemic index (GI),[380] which refers to the glucose area under the curve after consumption. High-GI foods lead to an accentuated insulin response, which can shunt energy substrate to adipose tissue.[381] Controlled studies on children with a high-GI diet demonstrate that energy intake is 53% higher than it is for children on a low-GI diet.[382] One study on adolescents demonstrated that an *ad libitum* low-GI diet was more effective in promoting weight loss than an energy-restricted low-fat diet.[383] Therefore, the GI may be a simple concept to

institute, although the "toxic environment" of American foodstuffs may make it difficult to maintain.

Dietary fiber consists of the nonstarch, polysaccharide portion of plant foods, including cellulose, hemicellulose, pectins, β-glucans, fructans, gums, mucilages, and algal polysaccharides. Major sources of dietary fiber include whole grains, fruits, vegetables, legumes, and nuts. Fiber content accounts for 50% of the variability in glycemic load (GL; GI × volume) between foods. Cohort studies of adults demonstrate that fiber intake is inversely associated with weight gain, fasting insulin levels, and risk of T2DM.[384,385] Fiber may influence the regulation of body weight by several mechanisms involving intrinsic, hormonal, and colonic effects, which eventually decrease food intake by promoting satiation (lower meal energy content), satiety (longer duration between meals), or by increasing fat oxidation and decreasing fat storage.[386] A fiber-rich meal is processed more slowly, has less caloric density, and is lower in fat and added sugars. Fiber-containing foods engender slower glucose absorption, which lessens the postprandial insulin surge and decreases lipogenesis.[387] In addition, high-fiber meals allow undigested triglyceride to be delivered to the colon, where fermentation to short-chain fatty acids and their absorption improve lipids and insulin sensitivity.[388] Archeologists surmise that our ancestors consumed approximately 100 grams of fiber/day.[389] However, the dietary fiber intake throughout childhood and adolescence currently averages approximately 12 g/day and has not changed since the 1980s.[390] Therefore, parents and school food service personnel should strive to offer fiber-rich foods to children so that their acceptance and consumption of these foods will increase.[391]

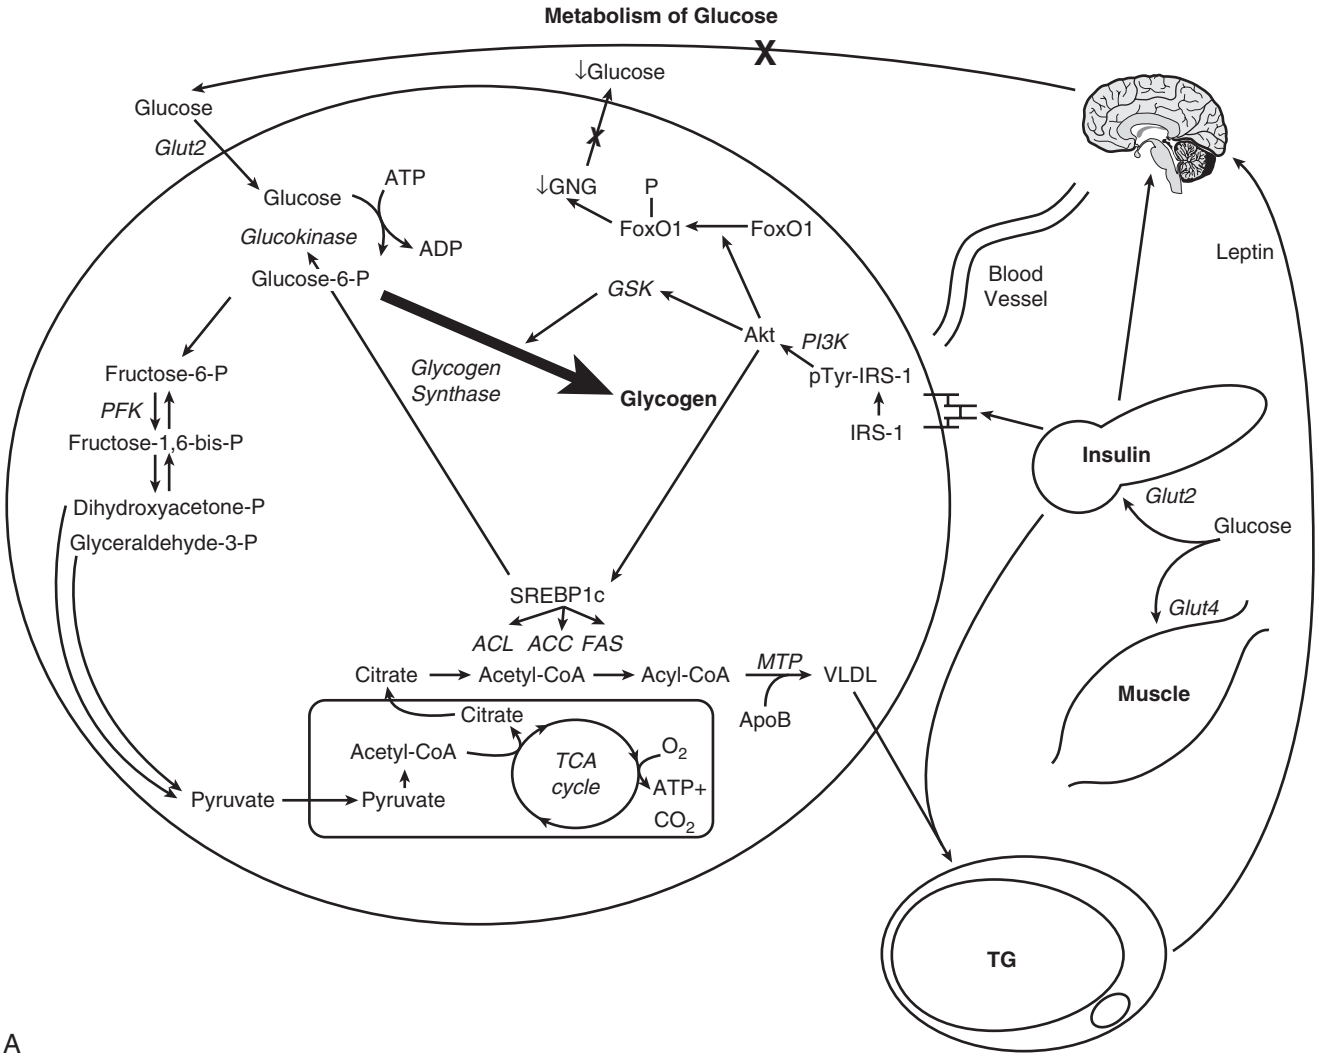
Fructose

The most commonly used sweetener in the U.S. diet is the disaccharide sucrose (e.g., table sugar), which contains 50% fructose and 50% glucose. However, in North America and many other countries, nondiet soft drinks are sweetened with high-fructose corn syrup (HFCS), which contains up to 55% of the monosaccharide fructose. Thanks to its abundance, sweetness, and low price, HFCS has become the most common sweetener used in processed foods. The issue is not that HFCS is biologically more ominous than sucrose, it is that its low cost has made it available to everyone, especially low socioeconomic groups. HFCS is found in processed foods ranging from soft drinks and candy bars to crackers, hot dog buns, and ketchup. Average daily fructose consumption has increased by over 25% since the 1980s. The growing dependence on fructose in the Western diet may be fueling the obesity and T2DM epidemics.[392] The highest fructose loads are soda (1.7 g/30 mL) and juice (1.8 g/30 mL). Although soda has received most of the attention,[180,393] high fruit juice intake is also associated with childhood obesity, especially among lower-income families.[394] The American Academy of Pediatrics has altered its recommendations, suggesting that fruit juice consumption be limited to 120 to 150 mL/day for 1- to 6-year-old children and 240 to 360 mL/day for 7- to 18-year-old children.[395]

Animal models demonstrate that high-fructose diets lead to increased energy intake, decreased resting energy expenditure, excess fat deposition, and insulin resistance[396]; these outcomes suggest that fructose consumption is playing a role in the epidemics of insulin resistance and obesity and T2DM in humans.[397,398]

Fructose in the gut is transported into the enterocyte via the fructose transporter Glut5, independent of ATP hydrolysis and sodium absorption. Once inside in the enterocyte, a small portion of the fructose load is converted to lactic acid and released in the portal circulation; another small portion may also be converted to glucose. However, the majority of ingested fructose is secreted into the portal circulation and delivered to the liver. There, fructose is rapidly metabolized to fructose-1-phosphate (F1P) via fructokinase, an insulin-independent process that also bypasses the negative feedback regulation of phosphofructokinase in the glycolytic pathway. Thus, fructose metabolism generates lipogenic substrates (e.g., glyceraldehyde-3-phosphate and acetyl-CoA) in an unregulated fashion, which are delivered straight to the mitochondria. This excessive mitochondrial substrate then drives hepatic DNL, which can then overwhelm apoB and the lipid export machinery, leading to intrahepatic lipid deposition and steatosis.[289] Hepatic DNL also limits further fatty acid oxidation in the liver via excess production of malonyl-CoA, which reduces the entry of fatty acids into the mitochondria by inhibiting carnitine palmitoyl transferase-1 (CPT-1). F1P also stimulates sterol regulatory binding protein-1c (SREBP-1c) via peroxisome proliferator-activated receptor gamma coactivator (PGC)-1β[399] independently of insulin, which activates the genes involved in DNL; moreover, fructose has been shown to induce activation of carbohydrate-response element binding protein (ChREBP), which also increases the expression of all the enzymes of DNL. Furthermore, F1P activates dual-specificity mitogen-activated protein kinase 7 (MKK7), which subsequently stimulates Janus kinase-1 (JNK-1), a hepatic enzyme considered to act as a bridge between hepatic metabolism and inflammation.[400] In addition, the lipogenic intermediate diacyl glycerol (DAG) (formed during fructose metabolism in the liver) activates protein kinase C epsilon (PKCε), which phosphorylates serine residues on insulin receptor substrate-1(IRS-1), inactivating it, and leading to hepatic insulin resistance.[289] This impairs insulin-mediated phosphorylation of FoxO1, leading to increased expression of the genes required for gluconeogenesis and promoting increased hepatic glucose output, also contributing to hyperglycemia and the development of T2DM. The excess TGs secreted from the liver into the circulation as fat-laden VLDL particles following the ingestion of fructose, coupled with a fructose-induced reduction in LPL activity, cause sustained postprandial dyslipidemia, thereby augmenting the risk for cardiovascular disease[401,402] (Figure 22-8).[662]

Fructose also does not suppress secretion of the so-called hunger hormone ghrelin, levels of which correlate with perceived hunger. In sum, fructose consumption has metabolic and hormonal consequences that facilitate the development of obesity and the metabolic syndrome.[398]



A

FIGURE 22-8 ■ Hepatic (**A**) glucose and (**B**) fructose metabolism. Of an ingested glucose load, 20% is metabolized by the liver; thus, in a 120-calorie glucose load (two slices of white bread), 24 calories are hepatically metabolized. Under the action of insulin, glycogen synthase is increased, and the majority of the glucose load is stored as glycogen. While insulin activation of sterol response element binding protein-1c (SREBP-1c) activates the lipogenic pathway, there is little citrate formed to act as substrate for lipogenesis. In addition, insulin action on the liver phosphorylates forkhead protein-O1 (FoxO1), excluding it from the nucleus, and suppressing the enzymes involved in gluconeogenesis (GNG). In comparison, virtually 100% of a fructose load is hepatically metabolized; thus, in a 120-calorie sucrose load (an 8-ounce glass of orange juice), a bolus of 72 calories reach the liver. In contrast to glucose, fructose induces (1) substrate-dependent hepatocellular phosphate depletion, which increases uric acid and contributes to hypertension through inhibition of endothelial nitric oxide synthase and reduction of nitric oxide (NO); (2) stimulation of *de novo* lipogenesis and excess production of VLDL and serum triglyceride, promoting dyslipidemia; (3) accumulation of intrahepatic lipid droplets, promoting hepatic steatosis; (4) production of FFA, which promotes muscle insulin resistance; (5) *c-jun* N-terminal kinase (JNK-1) activation, which serine phosphorylates and the hepatic insulin receptor, rendering it inactive, and contributing to hepatic insulin resistance, which promotes hyperinsulinemia and influences substrate deposition into fat; and (6) CNS hyperinsulinemia, which antagonizes leptin signaling (see Figure 22-3) and promotes continued energy intake. Glut2, glucose transporter 2; Glut4, glucose transporter 4; Glut 5, glucose transporter 5; SREBP-1c, sterol regulatory element binding protein-1c; PGC-1β, peroxisome proliferator-activated receptor-γ coactivator-1β; MKK7, MAP kinase kinase 7; PKCε, protein kinase C-ε; IRS-1, insulin receptor substrate-1; ChREBP, carbohydrate response element binding protein; PI3K, phosphatidyl inositol-3-kinase; CPT-1, carnitine palmitoyl transferase-1; GSK, glycogen synthase kinase; PFK, phosphofructokinase; PP2A, protein phosphatase 2a; ACL, ATP citrate lyase; ACC, acetyl CoA carboxylase; FAS, fatty acid synthase; ApoB, apolipoprotein B; MTP, microsomal transfer protein; VLDL, very low density lipoprotein; FFA, free fatty acids; LPL, lipoprotein lipase; IR, insulin resistance; ACSS2, acyl-CoA synthetase short-chain family member 2. Continued

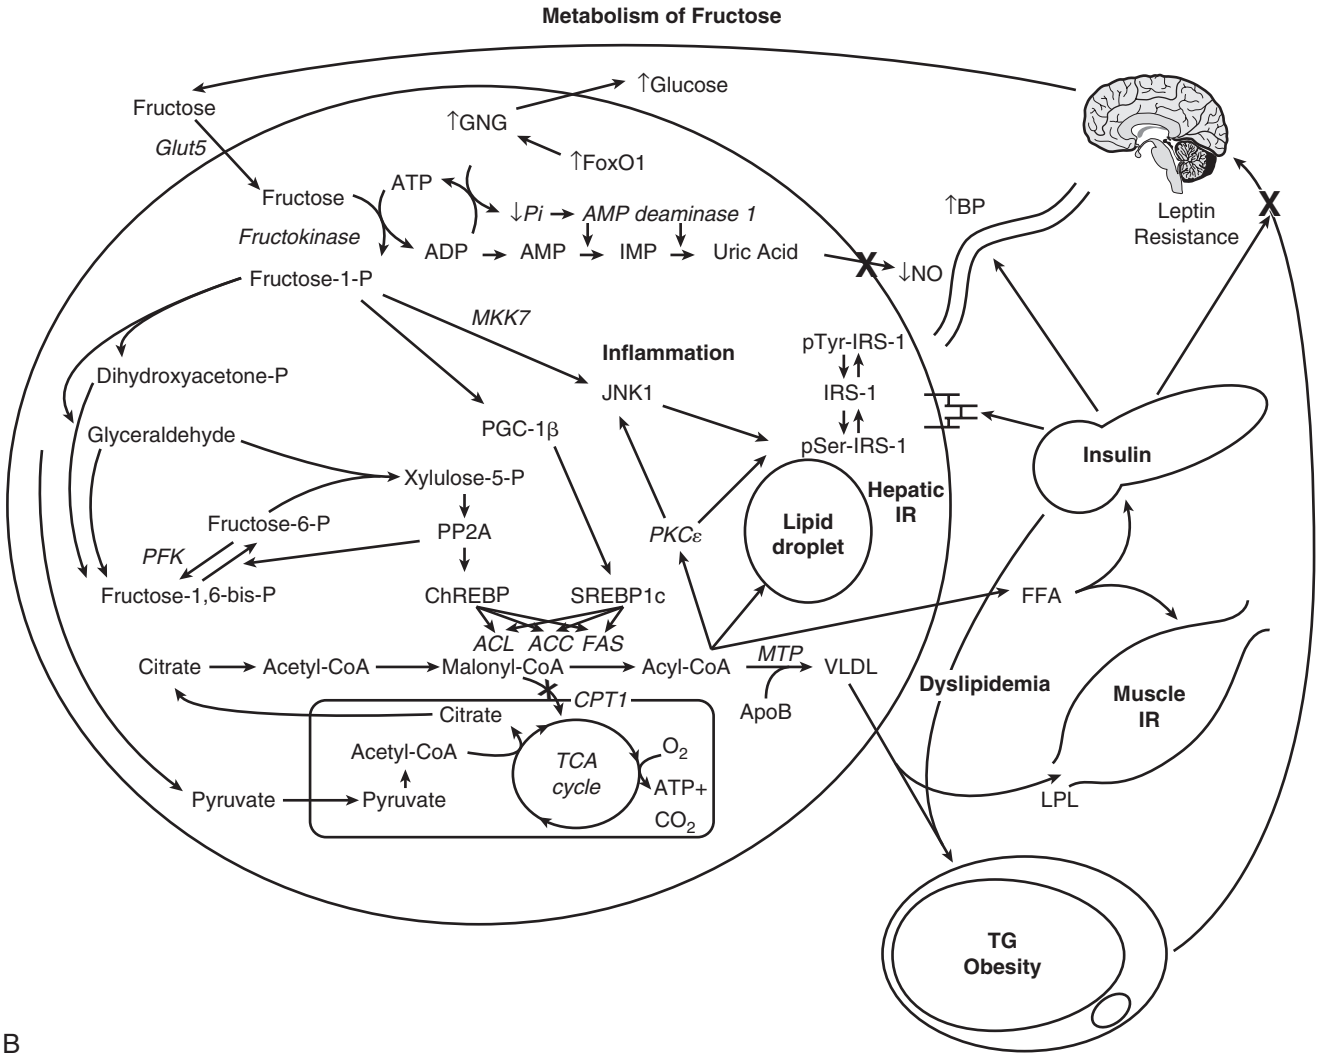

FIGURE 22-8, cont'd

Due to its unique stereochemistry, the ring form of fructose (a five-membered furan with axial hydroxymethyl groups) is under a great deal of ionic strain, which favors the linear form of the molecule, exposing the reactive 2-keto group, which can readily engage in the nonenzymatic fructosylation of exposed amino moieties of proteins via the Maillard reaction, in the same way that the 1-aldehyde position of glucose is reactive.[289] Each Maillard reaction generates one ROS, which must be quenched by an antioxidant or risk cellular damage. In an *in vitro* study, incubation of hepatocytes with fructose yielded no direct damage; however, when these hepatocytes were preincubated with sublethal doses of hydrogen peroxide to reduce their peroxisomal ROS-quenching ability, fructose then became as hepatotoxic as other organic aldehydes.[403] Furthermore, an *in vivo* study in antioxidant-deficient mice demonstrated that intrahepatic lipid toxicity and hepatocellular death occurred following sucrose administration.[404] These data thus suggest that excessive ROS, in combination with micronutrient insufficiencies that impair antioxidant reserves, can lead to cellular damage and promote the metabolic syndrome.

Branched-Chain Amino Acids

Branched-chain amino acids (BCAAs: valine, leucine, and isoleucine) are essential amino acids that account for > 20% of the amino acids in the typical "Western diet."[405] Although normally utilized for protein biosynthesis and cell growth, when provided in excess they are diverted away from protein synthesis and toward energy utilization.[406]

In the liver, BCAAs increase the transcription of carbohydrate regulatory element-binding protein (ChREBP) and SREBP-1c,[407] facilitating DNL. Furthermore, BCAAs limit insulin-induced PI3-K signaling and stimulate the activation of the mammalian target of rapamycin (mTOR), promoting the serine phosphorylation of IRS-1 and impairment of insulin signaling. In addition, just as there are obesity-related changes in adipokines and cardiovascular risk markers, there also appear to be obesity-associated changes in BCAA metabolism and subsequent serum levels. In particular, valine and leucine/isoleucine

levels have been reported to be 20% and 14% higher, respectively, in obese compared to lean subjects.[406] Mechanistically, this appears to be accounted for by a high rate of flux through the BCAA catabolic pathway, resulting in the increased production of alanine. Since alanine is a highly gluconeogenic amino acid, increased BCAA catabolism may thus contribute to increased hepatic glucose output.[408] Furthermore, the increased α-ketoacids generated by increased flux of the BCAAs through their catabolic pathways also potentially suppress mitochondrial β-oxidation.

Furthermore, chronic BCAA elevation impairs the transport of aromatic amino acids into the brain; the reduced production of serotonin (derived from tryptophan) and catecholamines (derived from phenylalanine and tyrosine) may drive hunger.[406] The "BCAA overload" hypothesis suggests that in the context of a dietary pattern that includes high fat consumption, BCAAs may make an independent contribution to the development of insulin resistance, a hypothesis supported by metabolomics studies demonstrating high BCAA levels in normoglycemic individuals who subsequently develop insulin resistance and diabetes.[409,410]

Ethanol

Although adult epidemiologic studies associate light to moderate ethanol consumption with improved insulin sensitivity and wine consumption with reduced cardiovascular risk, other cross-sectional and prospective studies implicate a dose-dependent effect of alcohol in the metabolic syndrome and suggest that chronic consumption of large amounts of ethanol worsen insulin sensitivity. Ethanol bypasses glycolysis by being converted by alcohol dehydrogenase-1B to form acetaldehyde, which promotes ROS formation and must also be quenched by hepatic antioxidants such as glutathione or ascorbic acid. Acetaldehyde is then metabolized by the enzyme aldehyde dehydrogenase-2 to acetic acid, which in turn is metabolized by the enzyme acyl-CoA synthetase short-chain family member 2 to form acetyl-CoA. The acetyl-CoA can then enter the mitochondria; or, in the presence of other caloric substrates, it is preferentially used for the synthesis of fatty acids through DNL. The excess malonyl-CoA produced from ethanol metabolism inhibits CPT-1, limiting mitochondrial fatty acid β-oxidation. Ethanol also blocks fatty acid β-oxidation by inhibiting both peroxisome proliferator-activated receptor (PPAR)-α, which suppresses microsomal triglyceride transfer protein, thereby altering the liver's lipid export machinery.[411-413] Buildup of intrahepatic lipid metabolites leads to subsequent activation of the enzyme *c-jun* N-terminal kinase-1 (JNK-1) and serine-phosphorylation of IRS 1, driving further hepatic insulin resistance. Thus, ethanol metabolism results in intrahepatic lipid accumulation and liver injury,[414,415] driving hepatic insulin resistance and promoting the metabolic syndrome.[416] However, although clearly a concern in adults, it is unlikely that ethanol contributes significantly to metabolic syndrome in children.

Calcium and Dairy

There have been several reports of an inverse relationship between dietary calcium and obesity indices.[417,418] Dietary calcium plays an important role in regulating energy metabolism. Increased calcitriol (1,25-dihydroxyvitamin D) in response to low calcium diets stimulates Ca^{2+} influx in human adipocytes and may lead to the stimulation of lipogenic gene expression and lipogenesis, as well as the inhibition of lipolysis.[418] This may result in an expansion of adipocyte triglyceride stores, which can promote adiposity. Increased dietary calcium reduces calcitriol levels and leads to a reduction of fat mass without caloric restriction in mice,[419] and this antiobesity effect of dietary calcium is supported by human clinical and epidemiologic studies.[420] Vitamin D deficiency correlates with increasing BMI, especially in African Americans[421]; however, it is not known if this is due to the substitution of soft drinks for dairy, lactose intolerance, or other factors. One adult study[422] revealed a consistent effect of higher calcium intake on lower body weight and body fat; however, pediatric studies are lacking.

Trace Minerals

Chromium and vanadium appear to be involved in the insulin signaling process. In diabetic animals, chromium or vanadium supplementation results in improvement in insulin sensitivity and glycemic control,[423,424] and there is a suggestion of decreased weight. It is not yet known whether the pathogenesis of insulin resistance in humans involves a deficiency of a trace mineral; however, inadequate dietary intakes of vitamins and minerals are widespread, most likely due to the excessive consumption of energy-rich, micronutrient-poor, refined food. Inadequate intake of micronutrients may result in chronic metabolic disruption, mitochondrial decay, DNA damage, oxidant leakage, and cellular aging associated with late onset diseases such as obesity and cancer.[425]

Infectious Causes

The pattern of increase in prevalence during the current obesity epidemic is reminiscent of an infectious transmission. Studies in animals implicate adenovirus-36 in the conversion from lean to obese.[426] Studies in adults thus far demonstrate a correlation between BMI and antibodies to this virus.[427] Adenovirus-36 appears to differentiate fat cells. Ad-36 antibody levels correlate with BMI in certain populations, particularly in children. In one study, 15% of obese children were Ad-36 positive, in contrast to 7% of normal-weight children. But *within* the obese population, those who were Ad-36 positive weighed, on average, ~16 kg more than those who were not. Presently, all human data on Ad-36 and obesity are based on correlations. Bacteria also are implicated in obesity. The predominance of certain human intestinal flora species (Firmicutes versus bacteroides) may predispose both animals and humans to obesity,[428] possibly by increasing efficiency of energy absorption[429]; however, factors that determine their predominance are unknown.

Medications

Numerous medications promote excessive weight gain in children. The most commonly prescribed are pharmacologic doses of glucocorticoids (e.g., prednisone, methylprednisolone, dexamethasone), used for their anti-inflammatory and antineoplastic activities. Patients so treated frequently become obese[430,431] and develop many of the features of Cushing syndrome (e.g., visceral adiposity, hyperlipidemia, hypertension, glucose intolerance), which typify the metabolic syndrome.[350] Sex hormone administration also promotes excessive weight gain, presumably by inducing insulin resistance.[432] In patients with type 1 diabetes, strict glycemic control is usually accompanied by slight overinsulinization of the patient, leading to a greater occurrence of mild hypoglycemic episodes requiring nonhunger-driven calorie consumption and potentially to excessive weight gain.[433] Lastly, more and more children are being placed on the atypical antipsychotics risperidone, olanzapine, quetiapine, clozapine, aripiprazole, and ziprasidone to affect mood and behavior.[434] These medications induce insulin resistance, which foments persistent hyperphagia and weight gain and increases the risk for the metabolic syndrome specifically during the first months following their initiation.[435]

DISORDERS OF OBESITY

The concept that obesity is a phenotype of numerous pathologies is evident from the examination of specific endocrine disorders leading to obesity in early childhood (Box 22-1). Some involve neural mechanisms, others involve classic hormonal mechanisms, whereas others involve dysregulation of increased energy intake, decreased energy expenditure, or increased energy storage at the adipocyte. It is important to remember that even in referral centers for obese children, children with an "organic" cause of their obesity represent less than 2% of the population; the majority represents the classic genetic-environmental complex interaction.

BOX 22-1 Classification of Childhood Obesity Disorders

Monogenetic Disorders of the Energy Balance Pathway

- Leptin deficiency
- Leptin receptor deficiency
- POMC mutation ("red" hair, adrenal insufficiency)
- Prohormone convertase-1 deficiency
- MC_3R mutation
- MC_4R mutation
- SIM-1 mutation
- Brain-derived neurotrophic factor (BDNF) deficiency

Syndromic Disorders (Mental Retardation Prominent)

- Prader-Willi syndrome
  - Short stature
  - Hypogonadism
  - Hypotonia
  - Ghrelin overproduction
- Bardet-Biedl syndrome
  - Retinitis pigmentosa
  - Polydactyly
  - Hypogonadism
- *Trk*B mutation
  - Hypotonia
  - Impaired short-term memory
  - Decreased nociception
- Borjeson-Forssman-Lehmann syndrome
  - Microcephaly
  - Large ears
  - Hypogonadism
- Carpenter syndrome
  - Variable craniosynostosis
  - Brachydactyly, polydactyly, syndactyly
  - Congenital heart disease
  - Hypogonadism
- Cohen syndrome
  - Persistent hypotonia
  - Microcephaly
  - Maxillary hypoplasia
  - Prominent incisors
- Alstrom syndrome
  - Hypogonadism
  - Short stature
  - Neurosensory deficits

"Classic" Endocrine Disorders (Short Stature/Growth Failure Prominent)

- Hypothyroidism
  - Primary
  - Central
- Cushing syndrome (adrenal hypercorticism)
  - Adrenal adenoma/carcinoma
  - Adrenal micronodular hyperplasia
  - Pituitary ACTH-secreting tumor
  - Ectopic ACTH-secreting tumor
  - Exogenous glucocorticoid administration
- Growth hormone deficiency
- Pseudohypoparathyroidism 1a
  - Maternal transmission (AHO + multihormone resistance)
  - Paternal transmission (pseudopseudohypoparathyroidism, AHO only)

Insulin Dynamic Disorders

- Hypothalamic obesity (insulin hypersecretion)
- Insulin resistance
- Leptin resistance

Other Disorders

- Rapid-onset obesity with hypoventilation, hypothalamic, autonomic dysregulation, often with neural crest tumor syndrome (ROHHAD)

"Classic" Endocrine Disorders with an Obesity Phenotype

In children, linear or statural growth accounts for up to 20% of ingested calories. Endocrine states that allow for normal energy intake for age, but inhibit linear growth, will of necessity lead to excessive energy storage. This is the case for the four "classic" endocrine disorders associated with obesity. These can be distinguished from other causes of pediatric obesity on the basis of their suboptimal growth rate, as opposed to overnutrition, which tends to increase the rate of both growth and skeletal maturation, probably due to excess insulin cross-reacting with the IGF-1 receptor.[309]

Hypothyroidism results in a lower REE due to insufficient circulating T_3, along with decreased voluntary energy expenditure (VEE) due to fatigue. The decrease in total energy expenditure, despite a relatively low caloric intake, promotes persistent energy storage and increases adiposity. Thyroid hormone replacement is sufficient to increase growth, REE, and VEE to resolve the obesity over time.

Cushing syndrome arrests growth and results in cortisol-induced hyperphagia,[135] along with a decrease in REE and VEE due to muscle wasting. A reduction of circulating glucocorticoid through medical or surgical means usually reverses the obesity to some degree. Exogenous glucocorticoid therapy can result in the same obesity phenotype. Hypercortisolism may be more related to obesity than previously realized, due to the transgenic model of 11βHSD1 overexpression in visceral adipose tissue, which converts inactive circulating cortisone to cortisol.[310] However, its role in human obesity is not clear, as correlations between 11βHSD1 polymorphisms and BMI or waist:hip ratio were weak at best,[436] and enzyme activity was not elevated in one human study.[437]

GH deficiency prevents lipolysis and promotes visceral adiposity, although obesity is usually not severe. The disorder should be diagnosed long before the obesity phenotype develops. GH deficiency is also associated with fatigue and decreased VEE. GH deficiency is often accompanied by other pituitary hormone deficiencies (e.g., central hypothyroidism), which can also decrease REE. GH therapy is able to reverse these defects, increase muscle mass, and promote weight loss.

Pseudohypoparathyroidism type 1a (PHP1a) is an autosomal dominant mutation of *GNAS1*, which codes for the $G_{s\alpha}$ subunit, necessary for peptide hormone signal transduction. Maternal transmission leads to PHP1a (multihormone resistance) along with Albright hereditary osteodystrophy (AHO), of which a cardinal feature is obesity, probably due to the inability to stimulate cAMP in response to β-adrenergic stimulation within adipocytes, due to defective G-protein signal transduction.[438] Paternal transmission leads to AHO without multihormone resistance, also known as pseudopseudohypoparathyroidism. This form of obesity is not responsive to current medications.

Monogenetic Disorders of the Negative Feedback Pathway

The elucidation of the regulation of the energy balance pathway is exemplified by the discovery of specific defects within that pathway leading to early-onset obesity. Numerous obesity syndromes within the pathway have been described and are reviewed in detail elsewhere.[439,440]

Leptin Deficiency

Mutations of the leptin gene in humans recapitulate the phenotype of the *ob/ob* leptin-deficient mouse.[441] Only a few such patients have been described, primarily of Pakistani and Turkish descent, and for the most part they were born to consanguineous parents. These patients manifest hyperphagia from birth, with obesity documented as early as 6 months of age. The lack of leptin induces the starvation response in the form of reduced thyroid hormone concentrations, lack of sympathetic tone, lack of pubertal progression, and defective immunity.[442] Despite the modest hypothyroidism, the concomitant hyperinsulinemia allows excess insulin to cross-react with the IGF-1 receptor in order to maintain growth rate and bone age until the usual time of puberty. However, because of the important role of leptin in initiating and maintaining puberty, untreated patients with leptin deficiency are short, due to the lack of a pubertal growth spurt. The diagnosis is made by demonstrating extremely low or unmeasurable serum concentrations of leptin. However, treatment with recombinant leptin effectively restores leptin signaling, thereby reducing hyperphagia, resolving obesity, inducing puberty, and regulating immunity.[442] Heterozygotes for leptin deficiency assume an intermediate phenotype.[443]

Leptin Receptor (LEPR) Deficiency

Three family members in France of Algerian ancestry were originally found to have a mutation truncating the leptin receptor prior to its insertion in the membrane.[444] This family had symptoms and signs similar to those with leptin deficiency; they also had growth retardation, low thyroid, and low IGF-1 and IGFBP-3 concentrations. The reason for this dichotomy is not known. When testing a large cohort of subjects with severe, early-onset obesity, the prevalence of pathogenic LEPR mutations was 3%. Affected subjects were characterized by hyperphagia, severe obesity, alterations in immune function, and delayed puberty due to hypogonadotropic hypogonadism. Serum leptin levels were within the range predicted by the elevated fat mass in these subjects (thus, serum leptin cannot be used as a marker for leptin-receptor deficiency). Their clinical features were less severe than those of subjects with congenital leptin deficiency.[445]

POMC Splicing Mutation

The inability to synthesize POMC due to missense or truncation mutations results in the inability to splice out α-MSH in the brain, leading to defective anorexigenesis at the MC_4R and early-onset obesity; in the periphery, this defect leads to "red" hair resulting from a lack of α-MSH action at the skin MC_1R; and in the pituitary the defect results in an inability to splice out ACTH, leading to secondary adrenal insufficiency.[446] A Turkish patient with this mutation was reported to have dark hair, indicating that

pigmentation of the hair is not entirely explained by the mutation's effect on MC_1R.[447] The diagnosis is easily established due to the unusual phenotype, ACTH levels, and hypocortisolemia. There is currently no treatment for the obesity.

Prohormone Convertase-1 (PC-1) Deficiency

Defects in this enzyme lead to the inability to process various preprohormones to their active ligands, such as POMC to ACTH and α-MSH, proinsulin to insulin, and various gut propeptides to active hormones.[448] Affected patients manifest severe early-onset obesity, ACTH deficiency, hypogonadism, hyperproinsulinemia, and small intestinal dysfunction due to inability to cleave intestinal propeptides to their mature form. The diagnosis can be made by finding extremely high levels of proinsulin, and molecular diagnostics may be required to confirm the gene defect. Treatment currently does not exist for the obesity.

Melanocortin-3 Receptor (MC_3R) Mutation

Two family members in Singapore with mutations of the MC_3R manifested with early-onset obesity.[449] This receptor appears to have a slightly different function from the MC_4R, as it seems to be involved in regulating energy expenditure as opposed to energy intake.[84] Diagnosis can only be made by gene sequencing. No treatment currently exists.

Melanocortin-4 Receptor (MC_4R) Mutation

Mutations in the MC_4R appear to account for up to 5% of morbid obesity cases, especially those beginning in childhood.[450,451] This mutation is transmitted as a codominant inheritance. Mutation carriers have severe obesity, increased lean mass, increased linear growth, hyperphagia, and severe hyperinsulinemia; homozygotes are more severely affected than heterozygotes. Subjects with mutations retaining residual signaling capacity have a less severe phenotype. Thus, mutations in MC4R result in a distinct obesity syndrome that is inherited in a codominant manner.[451] As the melanocortin system has been shown to directly control lipid metabolism as well as systemic blood pressure, mutation carriers usually manifest the typical elements of the insulin-resistance syndrome.[452] The diagnosis is made by gene sequencing. There is currently no treatment for this disorder.

SIM-1 Mutation

SIM-1 stands for *single minded*, a Drosophila gene involved in neurogenesis, particularly the PVN, which expresses the MC_4R. SIM-1 appears to act as a signal transduction mechanism integrating information downstream from MC_4R activation.[453] Heterozygous null mice for SIM-1 are obese. The human homolog is on chromosome 6q. A girl with hyperphagia, obesity, and developmental delay with a balanced translocation between 1p22.1 and 6q16.2 was found to have a mutation of SIM-1.[454] Only a few polymorphisms of SIM-1 in obesity have been reported, and their significance is not yet established.[455]

Chromosome 16p11.2

Large deletions of chromosome 16p11.2 have been shown to account for 0.7% of a large cohort of morbidly obese patients.[456]

Brain-Derived Neurotrophic Factor Deletion

The brain-derived neurotrophic factor (BDNF) inhibits food intake, and rodent models of BDNF disruption all exhibit increased food intake and obesity, as well as hyperactivity. Serum concentration of BDNF protein was significantly reduced by 50% in obese patients with the WAGR syndrome compared to those who were not obese and compared with age- and BMI-matched subjects. The WAGR syndrome (*W*ilms tumor, *a*niridia, *g*enital abnormality, *m*ental *r*etardation) is caused by heterozygous gene deletions on chromosome 11p13, which result in the haploinsufficiency of WT1 and PAX6 genes that are in close relation to the BDNF gene at 11p14.1. Haploinsufficiency for BDNF was associated with increased ad libitum food intake, severe early-onset obesity, hyperactivity, and cognitive impairment.[457]

Pleiotropic Obesity/Mental Retardation Disorders

Approximately 30 obesity syndromes have been described, and most if not all are associated with mental retardation.[458] Each has some other distinguishing phenotype, which makes the diagnosis obvious on clinical grounds. Various genetic linkages have been noted, but the etiologies for the obesity in these disorders remain obscure.

Prader-Willi Syndrome (PWS)

PWS is a defect in the paternal allele of chromosome 15q11-13,[459] either from deletion, mutation, defective imprinting, or uniparental disomy of the paternal chromosome 15. Subjects affected with PWS present with hypotonia and failure to thrive in the neonatal period, and they develop the classic findings of hypogonadism, short stature, mental retardation, and severe obesity as they get older. PWS patients are classically described as voracious eaters, although they can be easily dissuaded from food if they are removed from behavioral signals for food intake. REE is approximately 60% of normal in PWS, promoting adiposity.[460] In addition, ghrelin levels are massively elevated in PWS,[461] which may be one etiology for their persistent hyperphagia. Others have suggested that the obesity in PWS is a function of growth hormone (GH) deficiency, with defective lipolysis.[462]

Bardet-Biedl Syndrome

This syndrome is characterized by obesity, mild mental retardation, dysmorphic extremities (including polydactyly), retinitis pigmentosa, hypogonadism, and renal malformations. The inheritance of Bardet-Biedl is complex, but it is

usually described as autosomal recessive. Eight different genetic loci have been implicated,[463] although their functions continue to remain elusive. The cause of the obesity remains unknown, but it is postulated to be due to the failed development of ciliated hypothalamic neurons.[464,465] Cilia are conserved sensory organelles that protrude from the apical membrane of cells and play vital developmental and physiologic roles in all vertebrates. Moreover, mouse genetic models and *in vitro* experiments suggest a positive role for cilia in leptin signaling in the hypothalamus and a negative role for cilia in the formation of adipocytes in peripheral tissues—offering two potential explanations on how ciliary lesions lead to obesity. Diagnosis usually rests on clinical grounds. Although no specific treatment is available, anecdotal instances of the efficacy of metformin exist.

TrkB Mutation

The NTRK2 gene codes for the ligand-specific subunit for the receptor *Trk*B, which has brain-derived growth factor (BDNF) as its ligand. *Trk*B is important for neural development. An 8-year-old boy with early hypotonia, developmental delay, impaired short-term memory, decreased responsiveness to nociception, and severe hyperphagia starting at 6 months culminating in morbid obesity was reported.[466] Examination of the NTRK2 gene demonstrated an A to G transition in codon 722, substituting cysteine for tyrosine, which inhibited the phosphorylation of *Trk*B. A second patient with obesity, impaired cognitive function, and hyperactivity was found to have an isocentric inversion at the BDNF locus.[467] The etiology of the hyperphagia and obesity remain unclear.

Carpenter Syndrome

This syndrome consists of obesity plus variable craniosynostosis, brachydactyly, polydactyly, syndactyly, congenital heart disease, and hypogonadism. Its etiology remains obscure.

Cohen Syndrome

This disorder presents with persistent hypotonia, microcephaly, maxillary hypoplasia, and prominent incisors. The gene for Cohen syndrome has been mapped to chromosome 8q,[468] and it codes for a transmembrane protein of unknown function.

Alstrom Syndrome

This syndrome presents with neurosensory deficits, such as deafness, with various other endocrinopathies, which cause early-onset type 2 diabetes. The ALMS1 gene has been identified[469]; it appears to be important in cilia function[465] and may account for abnormal neuronal migration or leptin signaling.

Börjeson-Forssman-Lehmann Syndrome

This syndrome is characterized by microcephaly, seizures, large ears, and hypogonadism. The defective gene is a zinc-finger protein of unknown function.[470]

Rapid Onset Obesity, Hypoventilation, Hypothalamic, Autonomic and Thermal Dysregulation, with and without Neural Tumor (ROHHAD)

A recently identified syndrome includes hyperphagia and rapidly evolving obesity, combined with various forms of hypothalamic dysfunction (including GH deficiency, hypogonadotropic hypogonadism, central hypothyroidism, and ACTH abnormalities), central hypoventilation or altered respiratory control, thermal dysregulation, and risk for the development of tumors of neural crest origin.[471] The cause and treatment of this syndrome remain unknown.

Insulin Dynamic Disorders

Hypothalamic Obesity and Insulin Hypersecretion

It is well known that bilateral electrolytic lesions or deafferentation of the VMH in rats leads to intractable weight gain,[109,110,472-474] even upon food restriction.[475] Originally, the obesity was considered to be due to damage to a "satiety" center, which promoted hyperphagia and increased energy storage.[476] However, we now understand that a dysfunction of leptin signal transduction in the VMH due to hypothalamic damage— secondary to CNS tumor, surgery, radiation, or trauma—can alter both the afferent and efferent pathway of energy balance and lead to severe and intractable weight gain.[477,478] In this syndrome of "hypothalamic obesity," hypothalamic insult prevents the integration of peripheral afferent signals; the VMH cannot transduce these signals into a sense of energy sufficiency and a subjective state of satiety.[54,473] Patients with hypothalamic obesity exhibit weight gain, even in response to forced caloric restriction.[477] This seems paradoxical, as one would expect that if hyperphagia were the reason for the obesity, then caloric restriction would be effective. The reason for this paradox is similar to that for the *db/db* mouse, which is that these subjects exhibit "organic leptin resistance"—that is, the inability to respond to their own leptin due to the VMH damage.

Numerous assessments of weight gain following cancer therapy in children have been performed. Most of these evaluations have been retrospective and performed in the acute lymphoblastic leukemia (ALL) survivor population.[479] An extremely high frequency of hypothalamic obesity of 30% to 77% has been documented after craniopharyngioma treatment.[480] In each of these cancer types, hypothalamic damage is the primary risk factor for development of this syndrome.[481] However, the syndrome has also been reported in cases of pseudotumor cerebri, trauma, and infiltrative or inflammatory diseases of the hypothalamus.[477] Aside from the symptoms of tumor-induced increased intracranial pressure, patients with hypothalamic obesity classically exhibit signs of limbic system involvement, such as hypogonadism, somnolence, rage, and hyperphagia[482]; however, such classic presentations are actually rare.[474]

Hypothalamic obesity is the result of "organic" leptin resistance due to death of VMH neurons, leading to

defective autonomic neurotransmission.[99] This is akin to the starvation response, in that it manifests (1) defective activation of the SNS, which retards lipolysis and energy expenditure[483,484] (indeed, such patients demonstrate significantly reduced resting energy expenditure)[485] and (2) overactivation of the vagus,[486] which promotes an obligate insulin hypersecretion and energy storage.[487] In both animals and humans, vagal hyperreactivity can be prevented by pancreatic vagotomy.[110,488-490] Therapy for this disorder remains extremely problematic, as the brain seems to be "locked" in an orexigenic balance favoring energy consumption and storage. As the crucial period of weight gain is within the first year following the brain insult, it is crucial to focus on preventive measures during this narrow window of opportunity.

Primary Insulin Resistance

Insulin resistance is a primary entity in some pediatric populations. It is associated with the development of the metabolic syndrome, especially in certain racial and ethnic groups.[491] For example, the Pima Indians of Arizona exhibit a 50% incidence of obesity and type 2 diabetes.[492] In studies of adult twins, approximately half of the variance in insulin sensitivity and secretion can be attributed to genetic factors. Healthy children with a family history of T2DM are more insulin resistant, with an impaired balance between insulin sensitivity and secretion. Insulin resistance correlates with abdominal adiposity and CV morbidity.[493,494] The presence of acanthosis nigricans, a hyperpigmented and hypertrophic patch of skin at extensor surfaces such as the nape of the neck, is a clinical marker of hyperinsulinemia,[495] due to cross-reactivity between insulin and the epidermal growth factor receptor of the skin.[496] Fasting hyperinsulinemia, an indicator of inherent insulin resistance in children, is an important predictor of adult obesity.[497,498] This is further exacerbated by sex hormones (especially estrogen), contributing to the increased incidence of insulin resistance and obesity in teenage girls. The cause is unknown, but primary insulin resistance may be a manifestation of all three inciting factors: genetic, epigenetic, and environmental (discussed previously). There may be specific genetic predispositions,[317] which have been enriched by natural selection. In addition, the high incidence of gestational DM in Pima mothers promotes obesity and T2DM in the offspring.[335] Lastly, the consumption of low-quality processed food[152] made available by government subsidies promote continued obesity. It should be noted that in primary insulin resistance, dietary and exercise interventions have been notoriously ineffective at reducing the obesity.[499,500] The locus of the resistance to insulin is not defined; reduced numbers and function of insulin receptors may in part be secondary to the hyperinsulinemia itself, rather than due to a primary defect.

EVALUATION AND TREATMENT OF THE OBESE CHILD

Diagnostic Approach

The key to successful obesity therapy is accurate diagnosis. Our diagnostic armamentarium is not yet fully developed, so matching treatment to diagnosis is still uncertain. Specific points in the evaluation and their rationale are listed in Table 22-1. In eliciting the history, birth weight, parent's BMIs, gestational diabetes, prematurity, history of breastfeeding, and neonatal complications (especially CNS injury) are all relevant. The younger the patient's obesity is noted (i.e., early adiposity rebound), the more likely an organic reason will be identified. Neurodevelopmental abnormalities and signs of dysmorphism may signify the need for a genetic referral. The medication list must be reviewed, especially for atypical antipsychotics. Orthopedic pain, headache, and snoring must be assessed. Dietary history must include skipping breakfast, daily ingestion of sodas and juices, and frequency and type of snacking. The degree of perceived stress by the patient is also likely a major contributor to visceral adiposity. A corollary is the number of caretakers the child has, as a higher number increases stress, family chaos, and lack of child supervision.

On physical examination, linear growth is key, as a classic endocrine evaluation (e.g., hypothyroidism, Cushing's, GH deficiency, pseudohypoparathyroidism [PHP]) is not necessary if linear growth is not attenuated. However, hyperinsulinemia and insulin resistance may cause accelerated growth, due to cross-reactivity of insulin with the IGF-1 receptor.[309] Important physical features to assess include acanthosis nigricans and waist circumference (both of which are associated with insulin resistance and the metabolic syndrome), funduscopic examination to rule out pseudotumor cerebri, liver enlargement to suggest hepatic steatosis, hirsutism to suggest PCOS, and muscle tone to evaluate hypotonia and myopathy, which reduce energy expenditure.

Laboratory evaluation includes tests of obesity-related morbidity (e.g., AST, ALT, lipids, fasting glucose and HbA1c, knee and hip x-rays [in cases of suspected Blount deformity]). Specific diagnostic studies must be tailored to the individual patient. For instance, growth attenuation requires endocrine evaluation, including thyroid function tests, IGF-1 and IGFBP-3, 24-hour urinary cortisol or midnight serum cortisol, and possibly magnetic resonance imaging (MRI) of the hypothalamus and pituitary. Luteinizing hormone (LH), follicle stimulating hormone (FSH), and testosterone levels may be appropriate when evaluating for delayed puberty in males or PCOS in females. Patients with developmental delay will require karyotype and MRI. Severe obesity in a toddler may require a leptin level and genetic testing for a MC_4R mutation. Evaluating patients for insulin resistance remains controversial. A proper identification of risk factors by family history and a prudent physical examination is certainly appropriate. At this point in time, obtaining a fasting insulin level remains controversial. In the clinical setting, fasting insulin is an unreliable measure of insulin sensitivity. Testing of aliquots of a common sample assayed in different laboratories has shown disparate results; however, there is a current effort to standardize insulin assays nationwide in the United States. Even if a uniformly reliable insulin assay became available, separate standards would need to be developed by genders, ethnic groups, and pubertal stages. Also, the correlation between fasting insulin and euglycemic-hyperinsulinemic clamp-derived whole-body insulin sensitivity in children

TABLE 22-1 **Diagnostic Evaluation of Childhood Obesity and Its Comorbidities**

	History
Genetic etiology	Parent BMI, race, mental retardation
Epigenetic etiology	Birth weight, gestational difficulties, prematurity
CNS etiology	CNS insult, mental retardation or developmental delay
Endocrine etiology	Slowdown in linear growth, red hair
Medication etiology	Medication history, esp. atypical antipsychotics
Dietary etiology	Calorie recall, esp. sugar-containing liquids, breastfeeding Hx
Physical activity etiology	Exercise history, television, computer, and cell phone recall
Stress etiology	Socioeconomic status, number of caregivers, television recall, sleep status, atypical depression
Sleep apnea	History of snoring, headache, waking up with headache
PCOS	Hirsutism, oligomenorrhea, amenorrhea
Type 2 diabetes	Polyuria, polydipsia, nocturia, recent weight loss
Orthopedic morbidity	Knee or hip pain, limitation of motion
Depression	Affect, activity level, school performance
	Physical
Insulin resistance	Acanthosis nigricans, skin tags, waist circumference
Hypertension	SBP or DBP > the 90th percentile for age
Pseudotumor cerebri	Papilledema
Hepatic steatosis	Hepatomegaly
PCOS	Hirsutism
Precocious/delayed puberty	Gonadal and pubic hair status
Sleep apnea	Tonsillar hypertrophy
Myopathy	Decreased muscle tone, hyporeflexia
Syndromic obesity	Specific neurocutaneous stigmata (see Box 22-1), retardation
	Laboratory
Hepatic steatosis	ALT, hepatic ultrasound
Glucose intolerance	Fasting glucose > 100 or 2-hour glucose > 140
Type 2 diabetes mellitus	Fasting glucose > 125 or 2-hour glucose > 200; HbA1c > 6.5%
Dyslipidemia	Lipid profile with increased VLDL, TG:HDL > 2.5
Insulin resistance	Fasting insulin, glucose
Insulin hypersecretion	3-hour OGTT with insulin levels
CNS lesion	MRI, especially with hypothalamic coned-down views

is relatively poor, with an r value of 0.42,[501] and other surrogate measures of insulin resistance do not exhibit superior correlation. This may have to do with the fact that fasting insulin levels likely reflect hepatic rather than total body insulin resistance.[271] Lastly, there is currently no recommended pharmacologic treatment for isolated insulin resistance. The mere presence of obesity should call for intervention to lower weight and consequently improve insulin sensitivity. An OGTT may become necessary in an obese child, to evaluate for type 2 diabetes in cases where a suggestive history and familial risk factors are present.

Lifestyle Modification

Lifestyle modification is and remains the cornerstone of obesity therapy, especially in children. This approach is common sense and based on a handful of early studies demonstrating the efficacy of lifestyle in a select hand-picked group of children with intensive follow-up.[502] Indeed, the Diabetes Prevention Trial for T2DM demonstrated the efficacy of lifestyle on weight loss in adults; however, the cost per patient of administering such an intervention was prohibitive.[503] Data supporting the long-term efficacy of lifestyle modification in the "real world" is not particularly persuasive. An analysis of numerous methodologies concluded that although there are limited quality data to recommend one treatment program over another, combined behavioral lifestyle interventions compared to standard care or self-help can produce a significant and clinically meaningful reduction in overweight in children and adolescents.[504] Importantly follow-up studies of numerous large-scale interventions often find a rapidly diminishing effect once the study has been completed. Finally, a meta-analysis of 39 published intervention studies designed to prevent childhood obesity showed that 40% of the 33,852 participating children had a reduction in BMI, whereas the remaining 60% exhibited no effect.[505] Of note, it has been shown that a year after initial weight reduction, levels of the circulating mediators of appetite that encourage weight regain after diet-induced weight loss do not revert to the levels recorded before weight loss. This emphasizes the problem of maintaining long-term weight loss and the difficulties facing those who wish to lose weight and maintain it.[506] Optimistically, the effectiveness of interventions to prevent, rather than reverse, obesity in childhood (particularly for programs targeted to children ages 6 to 12 years) seems to be much more effective.[507]

Although weight loss is the conventional goal for intervention among adults, weight maintenance is recommended for the majority of children. The prevention of weight gain is easier, less expensive, and more effective than treating obesity itself,[508] and the prevention of overweight

among children prior to the presence of risk-related behaviors is crucial to stem the obesity epidemic. The primary goal of obesity prevention should be to promote physical activity and healthy diet with an emphasis on improving overall health, rather than weight loss.[509] There are at least four reasons to promote interventions to improve nutrition and physical activity in children.[510] First, the child may receive immediate benefits such as better fitness, energy, or micronutrient intake. Second, intervention at critical periods may improve adult health. Third, modifying chronic disease risks in childhood may lead to lower rates and risk factors in adults. Lastly, modifying children's behaviors may lead to improved behaviors in adulthood that would protect against chronic diseases.

Behavioral-cognitive therapy is designed to deal with both parent and patient, with behavior restructuring and reinforcement. Behavior changes include counseling sessions, teaching parenting skills, praise and contracts, self-monitoring tools, stimulus control within the home, role-modeling of behaviors by parents, and vigorous and long-term exercise programs. These programs have been successful in small studies with handpicked subjects by specific investigators,[511,512] but they have not yet been successful when attempted in clinic populations. One new clinical approach involves motivational interviewing,[513] a method for helping patients work through their ambivalence about behavior change. This method has been shown to be effective for substance abuse and in cases of adult diabetes; whether it will be successful in treating pediatric obesity remains to be seen.[514]

Dietary Intervention

Dietary intervention is essential in order to reduce not just caloric intake but the insulin response that promotes excessive energy deposition into adipose tissue. A myriad of studies demonstrate an association between the consumption of high-calorie, high-fat, high-carbohydrate, low-fiber foods and the development of pediatric obesity.[373] Specific maneuvers that have been successful in reducing the insulin response and promoting weight loss or stability in children include (1) the elimination of sugar-containing beverages (including both soda and juice)[515,516] and (2) a shift to a low-glycemic-load diet.[383] Not only does dietary modification to reduce the insulin response promote weight loss,[517] but it also promotes increased energy expenditure during the weight maintenance phase,[518] presumably by improving leptin sensitivity, which would help prevent weight regain. Other commonsense approaches in adults (although pediatric efficacy data are lacking) include (3) eating breakfast, (4) reducing portion sizes, (5) increasing fruit and vegetable consumption, (6) reducing between-meal snacking, and (7) reducing fast-food consumption.[519,520] However, dietary intervention alone is not a successful strategy for reducing pediatric overweight, unless the treatment is very intensive,[521] in which case the majority drop out. Furthermore, studies of nonsupervised dieting have demonstrated the opposite effect—that is, increased attempts in female adolescents predict a greater increase in weight and risk for obesity.[522]

Importantly, diets are a crucial part of weight maintenance and not only aimed at weight loss. Specifically, following a successful weight loss a weight maintenance diet is crucial to prevent weight regain due to the metabolic "starvation response" mentioned earlier in the text. Comparison of dietary approaches to weight maintenance following weight loss in children has shown that among overweight and obese young adults compared with pre–weight loss energy expenditure, isocaloric feeding following 10% to 15% weight loss resulted in decreases in REE and TEE that were greatest with a low-fat diet, intermediate with the low-glycemic index diet, and least with the very low-carbohydrate diet. This suggests that a low-carbohydrate diet may attenuate the "starvation response" induced by weight loss and help sustain the new weight achieved.[518]

Physical Activity Intervention

In adults, exercise is not an effective means of inducing weight loss unless combined with a reduction of caloric intake. The role of exercise may have a greater impact on weight maintenance rather than weight loss.[523] Similarly, there is question as to whether physical activity regimens for children can stabilize or reduce BMI.[524,525] Short-term studies show that vigorous exercise can result in short-term reductions in adiposity[526] and improved insulin sensitivity.[527] This amounts to a minimum of 30 minutes of vigorous exercise, 5 days per week, as proposed activity guidelines from the Institute of Medicine.[528] However, the effectiveness of these interventions eventually plateaus, and even short-term cessation rapidly reverses any accrued benefit.[529] To succeed, physical activity interventions must be long-term, sustained, and incorporated into behavioral modifications aimed at the individual, at the family, at the school, and within the community in general.[526,529] In other words, in order to make physical activity work, it must become a priority.

Lifestyle programs including supervised exercise can improve fasting insulin levels as quickly as 2 weeks before measurable weight loss occurs. Furthermore, lifestyle intervention has improved body composition without a change in body weight. Available studies suggest that fitness may play a more important role than body mass index reduction on an improvement in insulin sensitivity in obese adolescents. Appropriate interventions include (1) making school-based physical education mandatory for every child and school, (2) increasing access to after-school recreation, (3) increasing culturally appropriate activities, (4) reducing the competitive nature of sports so that more children will participate, (5) increasing the incorporation of physical activity into daily life (e.g., stairs, walking to school as appropriate), and (6) increasing the participation of parents in physical recreation, for their own weight management and as role models for their children. Lastly, the effects of reducing sedentary behavior by restricting television viewing has been efficacious in both small and large studies, and in diverse ethnic groups,[358] although fitness is not improved. Restriction of television also has the secondary effect of reducing caloric intake while watching television.

Results using either dietary or exercise intervention alone are not encouraging. Those studies that use behavioral, dietary, and exercise components together appear to be more successful,[373,530] although long-term efficacy is lacking.

School Intervention

Numerous school-based interventions have focused on reducing obesity rates, most of which have not been successful, in part because school cafeteria fare in most districts remains problematic. However, interventions that increased time spent in vigorous physical activity (20 minutes in elementary schools and 30 minutes in middle schools) were more successful.[531] One approach is to improve the self-esteem and self-efficacy of students, as opposed to simply educating them about eating disorders, as this increases physical activity.[532] Schools can model health-promoting environments and provide appropriate health education. Doing so may increase self-efficacy, reduce coping stress, and empower children to make healthy lifestyle choices.

Family Intervention

Invariably, the patient is not the only obese member of the family. There is frequently family chaos, which promotes obesity in other family members. Various caretakers (grandmothers, babysitters, etc.) will feed children and allow unrestricted television as a method of confining their activities indoors, particularly in dangerous neighborhoods. Some parents will not alter their shopping for "junk" food because they believe siblings should not be deprived; usually it is those same parents who will not be deprived. Divorced parents often use food as reward in order to buy the child's love and loyalty. Thus, the family itself must be the target of lifestyle intervention. Parental involvement is critical, and the concept of "food is not love" must be emphasized. Families need training to modify behavior and thereby make healthy dietary choices, increase activity, and reduce perceived stress. A meta-analysis of randomized trials of combined lifestyle interventions for treating pediatric obesity yielded a significant although underwhelming decrease in BMI of 1.5 kg/m^2 with targeted family intervention, and a nonsignificant decrease in BMI of 0.4 kg/m^2 in those that targeted the patient alone.[533]

Pharmacotherapy

Indications for Pharmacotherapy

Pharmacologic therapies in children must be considered adjuncts to standard lifestyle modification. The main problem is that presently only one drug has been approved for use in obese children, though a new medication (lorcaserin) and a combination of approved medications (phentermine-topiramate) are now approved for adults, and studies are starting in children. In addition, several limitations preclude physicians from the early implementation of drug therapies for the treatment of childhood obesity—for example, (1) the youngest age for which the U.S. Food and Drug Administration (FDA) has approved any obesity pharmacotherapy is 10 years; (2) the long-term use of pharmacologic intervention has not always proven to be more efficacious than behavior modification; (3) there exists a limited number of well-controlled studies of safe and effective pharmacologic intervention in obese children; (4) the relative risk for the development of adverse events in children must be weighed against the long-term potential for improvement of morbidity and mortality, which is difficult to estimate in children; and (5) targeting the pathology is still in its infancy. Also, we must not forget that many drugs used to treat adult obesity led to unforeseen complications, which resulted either in their restriction (thyroid hormone, amphetamine) or recall (e.g., sibutramine, rimonabant, dinitrophenol, fenfluramine, dexfenfluramine, phenylpropanolamine, ephedra).[534-539] Despite these concerns, the negative health impact of childhood obesity may justify long-term medication to control its progression.

In the current pharmacopoeia of childhood obesity (Table 22-2), only a nonspecific fat absorption reduction approach is available for obesity per se. Targeting obesity-related insulin resistance adds further agents, yet their effect in regard to weight reduction is disappointing.

Reduction of Energy Absorption: Orlistat

Orlistat is a modified bacterial drug that specifically inhibits intestinal lipase and can reduce fat and cholesterol absorption by approximately 30% in subjects eating a 30% fat diet.[540] Orlistat irreversibly binds to the active site of the lipase, preventing the intraluminal deacylation of triglycerides and resulting in a 16 gram/day increase in fecal fat excretion.[541] Orlistat does not inhibit other intestinal enzymes. It has minimal absorption and exerts no effect on systemic lipases.[542,543]

Although there have been several open-label trials of orlistat in adolescents, only two randomized control trials (RCTs) have been published.[544,545] The side effects with orlistat are predictable from its mechanism of action on intestinal lipase.[534] Orlistat appears to be well tolerated in adults, with the principal complaints being borborygmi, flatus, and abdominal cramps. The most troubling side effects are fecal incontinence, oily spotting, and flatus with discharge, which are highly aversive in the pediatric population. Orlistat does not affect the pharmacokinetic properties of most other pharmaceutical agents. Absorption of vitamins A and E and β-carotene may be slightly reduced, and this may require vitamin therapy in a small number of patients. In one study,[546] vitamin D supplementation was required in 18% of subjects despite the prescription of a daily multivitamin containing vitamin D, although in the company-sponsored study, effects on vitamin levels were minor.[545] Orlistat must be taken with each meal, which reduces its attractiveness for children, who are in school during lunchtime. Orlistat is currently approved for the treatment of children as young as 12 years. An over-the-counter lower-dose preparation has obtained FDA approval and should be available soon.

TABLE 22-2 **Medications for the Treatment of Pediatric Obesity**

Drug	Dosage	Efficacy	Side Effects	Monitoring and Contraindications
Orlistat Not FDA approved for < 12 years of age	120 mg PO tid	Open-label: Wt—5.4 kg, BMI—2 kg/m^2 at 6 months RCT: Wt—2.6 kg, BMI—0.85, WC—2.7 cm over placebo at 12 months	Borborygmi, flatus, abdominal cramps, fecal incontinence, oily spotting, vitamin malabsorption	Monitor 25OHD$_3$ levels. MVI supplementation is strongly recommended. A lower dose preparation has been approved for over-the-counter sale.
Metformin Not FDA approved for treatment of obesity. Approved for ≥ 10 years of age for type 2 diabetes mellitus	250-1000 mg PO bid	RCT: BMI Z score—0.35 SD versus placebo at 6 months RCT: Wt—2.7% versus placebo at 6 months Post-hoc analysis: efficacy dependent on degree of insulin resistance; BMI Z score—0.23 SD in first 4 months,—0.12 SD in next year	Nausea, flatulence, bloating, diarrhea; usually resolves; lactic acidosis not yet reported in children	Do not use in renal failure or with intravenous contrast. MVI supplementation is strongly recommended.
Octreotide Not FDA approved for treatment of obesity, otherwise ≥ 18 years of age	5-15 μg/kg/day SQ ÷ tid	Open-label: Wt—4.8 kg, BMI—2 kg/m^2 in 6 months RCT:—7.6 kg, BMI—2.5 kg/m^2 over placebo at 6 months Post-hoc analysis: BMI Z score—0.70 SD in 6 months, dependent on insulin secretion and sensitivity	Gallstones, diarrhea, edema, abdominal cramps, nausea, bloating, reduction in thyroxine concentrations	Monitor fasting glucose, FT$_4$, HbA$_{1c}$. *Useful only for hypothalamic obesity.* Ursodiol coadministration strongly recommended.
Leptin Not approved by FDA	Titration of dose to serum levels, SQ	Anecdotal: BMI—19 kg/m^2 over 4 years	Local reactions	Useful *only* in leptin deficiency.
Topiramate Not FDA approved for treatment of obesity	96-256 mg PO qd	RCT: Wt—8% over placebo at 6 months	Paresthesias, difficulty with concentration/attention, depression, difficulty with memory, language problems, nervousness, psychomotor slowing	No pediatric data
Growth hormone Not FDA approved for treatment of obesity	1-3 mg/m^2 SQ qd	Decreases in percentage body fat, with increases in absolute lean body mass	Edema, carpal tunnel syndrome, death in patients with preexisting obstructive sleep apnea	*Recommended only in Prader-Willi syndrome primarily to increase height velocity.* It also decreases fat mass but should only be used after screening to rule out obstructive sleep apnea. Must closely monitor pulmonary function, glucose, HbA$_{1c}$.

Should be considered only after an unsuccessful 6-month trial of lifestyle intervention. All drugs effective only when combined with appropriate lifestyle intervention.
RCT, randomized controlled trial, MVI, multivitamin.

Improvement of Insulin Resistance: Metformin

Metformin is a bisubstituted, short-chain hydrophilic guanidine derivative used to treat children and adults with type 2 diabetes mellitus (T2DM).[547-550] Metformin also decreases fasting hyperinsulinemia, prevents T2DM,[551] and promotes weight loss in some obese individuals[552,553] by improving hepatic and muscle insulin sensitivity. Metformin has little effect on energy expenditure.[548] Although some believe that metformin promotes weight loss though a primary anorectic effect (as initial side effects of nausea and gastrointestinal distress limit caloric intake acutely),[554] most believe that the decline in caloric intake observed with metformin is related to its enhancement of glucose clearance, through a reduction of hepatic glucose output, and reduction in fasting hyperinsulinemia.[555,556] Metformin improves hepatic insulin resistance by inducing hepatic AMP kinase,[557] which reduces hepatic gluconeogenesis; therefore, pancreatic insulin secretion and peripheral insulin levels fall. Metformin also restores PI3-kinase and MAP kinase activity in muscle cells, improving muscle insulin sensitivity.[558] Another possible mechanism of metformin action is through stimulation of glucagon-like peptide-1 (GLP-1),[14,559] which may inhibit food intake through central actions on the VMH.[15]

Thus far, results of two RCTs in children and adolescents have been reported.[560,561] Examination of the open-label responses to metformin in a multivariate analysis demonstrated two predictors for efficacy: race (Caucasian > African American) and the degree of insulin resistance prior to therapy.[153] Metformin has also been used "off-label" for the treatment of polycystic ovarian syndrome and nonalcoholic steatohepatitis, with varying degrees of success.[562-567] One particular use for metformin may be to combat the weight gain associated with atypical antipsychotics.[568] However, the cessation of metformin therapy leads to a rebound hyperinsulinemia and rapid weight gain, which may negate any beneficial effects seen during the medication window.

Side effects with metformin include nausea, flatulence, bloating, and diarrhea upon the initiation of therapy, which appears to be self-limited and resolves within 3 to 4 weeks of initiation. Approximately 5% of pediatric patients discontinue metformin therapy because of its severe side effects. The most feared complication of metformin in adults is lactic acidosis, which is estimated to occur at a rate of 3 per 100,000 patient-exposure years, primarily in patients with contraindications to the use of metformin; however, no documented cases in children have been reported. Metformin increases the urinary excretion of vitamins B_1 and B_6, which are important in the tricarboxylic acid cycle and which may hasten the lactic acidosis.[569] Vitamin B_{12} deficiency also has been reported in as many as 9% of adult subjects using metformin. Therefore, prophylactic multivitamin supplementation is recommended with metformin use. Contraindications to metformin use include renal insufficiency, congestive heart failure or pulmonary insufficiency, acute liver disease, and alcohol use sufficient to cause acute hepatic toxicity. Metformin also should be withheld when patients are hospitalized with any condition that may decrease systemic perfusion or when the use of contrast agents is anticipated.[555] It should be noted that metformin has been FDA-approved for the treatment of T2DM in children, but it is unlikely to be approved for childhood obesity or insulin resistance.

Suppression of Insulin Hypersecretion: Octreotide

It is well known that bilateral electrolytic lesions or deafferentation of the VMH in rats leads to intractable weight gain,[109,110,472-474] even upon food restriction.[475] In humans, hypothalamic damage due to CNS tumor, surgery, radiation or trauma can alter both the afferent and efferent pathways of energy balance and lead to severe and intractable weight gain.[477,478] In this syndrome of "hypothalamic obesity," hypothalamic insult confers an "organic leptin resistance" as the VMH senses starvation[54,473]; therefore, energy intake is high, and expenditure is low.[480] Children with hypothalamic obesity exhibit weight gain, even in response to forced caloric restriction,[570] secondary to (1) overactivation of the vagus, which promotes an obligate insulin hypersecretion and energy storage, and (2) defective activation of the SNS, which retards lipolysis and energy expenditure.[99,479] Insulin hypersecretion with normal insulin sensitivity is noted on oral glucose tolerance testing in these children.[487] This same phenomenon of insulin hypersecretion has also been documented in a subset of obese adults without CNS damage.[571]

The voltage-gated calcium channel of the β-cell is coupled to a somatostatin ($SSTR_5$) receptor.[572,573] Octreotide binds to this receptor, which limits the opening of this calcium channel, reduces the influx of calcium into the β cells, and in turn reduces calmodulin activation and vesicle exocytosis, thereby acutely decreasing the magnitude of insulin response to glucose[574] (see Figure 22-2), which results in weight loss or stabilization. Two RCTs and an observational prediction study using octreotide for obesity have been performed.[502,503] An examination of BMI responses to octreotide in pediatric hypothalamic obesity in a multivariate analysis demonstrated that insulin hypersecretion with a concomitant retention of insulin sensitivity prior to therapy augured for success.[153] A larger-scale study of patients following a brain insult showed limited efficacy, probably due to the timing of the intervention—most weight gain in cases of hypothalamic obesity occurs early following the insult. Pharmacotherapy that begins too late may fail to reverse this condition, whereas early an initiation of treatment may prevent excessive weight gain.

Octreotide is usually well tolerated. The most common side effects include diarrhea, abdominal cramps, nausea, and bloating, which are self-limited and usually resolve in 3 to 4 weeks.[575,576] Other adverse events include gallstones (which are preventable by coadministration of ursodiol), edema, development of sterile abscess at the injection sites, B_{12} deficiency, suppression of growth hormone and TSH secretion, and mild hyperglycemia, especially in those with severe insulin resistance.[577] At present octreotide offers a promising approach for the treatment of insulin hypersecretion as seen in

hypothalamic obesity, but it is not FDA approved. The use of octreotide in obese children with acute glucose-stimulated insulin hypersecretion without cranial pathology has not yet been evaluated.

Other Targeted Therapies

Leptin. Mutations of the leptin gene in humans recapitulate the phenotype of the *ob/ob* leptin-deficient mouse.[441] Approximately 11 such patients have been described; they manifest hyperphagia from birth, with obesity documentable as early as 6 months of age. Leptin deficiency induces the starvation response,[442] with increased energy intake and decreased REE. The diagnosis is made by extremely low or unmeasurable serum leptin levels. In children with leptin deficiency, leptin therapy results in an extraordinary loss of weight and fat mass,[578,579] along with reduced hyperphagia, a resolution of obesity, induced puberty, and improved immunity.[442] Although leptin administration in adults did not prove effective by itself due to leptin resistance,[140] leptin may serve as an adjunct in combination with other medications after leptin sensitivity is ameliorated through weight loss.[149,580]

Growth Hormone (GH). GH fosters anabolism and lipolysis. GH therapy has been shown to increase REE, promote linear growth, increase muscle mass, and decrease the percentage of body fat in subjects with Prader-Willi syndrome.[462,581] It has also been shown to decrease the percentage of body fat in children with GH deficiency[582] due to its effect on lipoprotein lipase.[583] However, it is not clear whether these reductions in the percentage of body fat are primary effects on the adipose tissue compartment or rather due to the increase in lean body mass. Obesity results in a state of functional GH insufficiency, which can be ameliorated through weight loss.[584] GH therapy also improves the lipid profile in GH-deficient adults.[585] Currently, the role of GH therapy in the treatment of nonsyndromic childhood obesity is unclear and not approved.

GLP-1 Analogs. Several long-acting GLP-1 analogs have been introduced, some with an antiobesity indication. GLP-1 is a gut-derived incretin that also serves a satiety signal, as described earlier. As its half-life in the circulation is brief (~2 minutes) due to degradation by the enzyme DPP-4, stable analogs have been designed aiming initially at β-cell enhancement but also showing some significant weight loss effects.[586] None of these agents have thus far been approved for use in children, yet studies are under way to test their efficacy in this population.

The Future of Pediatric Obesity Pharmacotherapy

In response to the relative lack of efficacy of lifestyle interventions, the ever-expanding knowledge of the physiology of energy balance, and particularly as a business decision of potential financial reward, many pharmaceutical companies have launched obesity research programs. The following agents are currently in human study; however, use of any of these new agents in children will depend on proof of safety and efficacy based on experience in adults. *Topiramate* is a novel anticonvulsant, which blocks voltage-dependent sodium channels, enhances the activity of the $GABA_A$ receptor, and antagonizes a glutamate receptor other than the N-methyl-D-aspartate (NMDA) receptor.[587] Topiramate promotes weight loss in a dose-dependent fashion.[588] An RCT in adults demonstrated a 9.1% weight loss in subjects taking topiramate 192 mg/day along with significant improvements in blood pressure, waist circumference, and fasting glucose and insulin.[589] However, almost 33% of the subjects dropped out due to adverse events, which included paresthesias, somnolence, anorexia, fatigue, nervousness, decreased concentration, difficulty with memory, and aggression. There are currently no studies of topiramate use to address childhood obesity. *Oxyntomodulin* is an analog of $PYY_{(3-36)}$, which has been shown in a 4-week RCT to reduce energy intake and weight in adults.[590] There are no studies in children. Two new formulations have been approved for adults, including combination phentermine-topiramate (QSymia) and Lorcaserin, a serotonin 2c-agonist (Belviq). There are no studies in children as of yet.

Bariatric Surgery

In comparison to the criteria used for adults, stricter and more conservative criteria must be applied to adolescents due to the fact that only 85% of obese adolescents will become obese adults, the slightly improved rate of lifestyle and pharmacotherapeutic efficacy versus adults, a longer time interval before comorbidities become life threatening, and their inability to give legal consent. For all these reasons, an expert panel with representation from the American Pediatric Surgical Association and the American Academy of Pediatrics has suggested that bariatric surgery for adolescents should be done only in institutions committed to long-term management of these patients[591] and is justified in situations when obesity-related comorbid conditions (like obstructive sleep apnea) threaten the child's health. The panel provided stringent recommendations that bariatric surgery be limited to adolescents with a BMI > 40 with the presence of severe comorbidity or those with a BMI > 50 with a less severe comorbidity. Very few long-term studies on obese adolescents who have undergone bariatric surgery have been published, and none has identified predictors of success. It is not clear what should be the procedure of choice and what fashion of preparation and follow-up will optimize long-term results.

Bariatric procedures in children are still in their infancy. Gastric bypass has only been performed in children and adolescents since the beginning of the 21st century. This procedure appears to be safe and effective when candidates are carefully selected and the bariatric surgeon has advanced laparoscopic skills. Thus far, we have limited data on long-term complications, including those that might be associated with pregnancy. As physicians, we are confident in saying that this procedure will add years to the lives of the children who are morbidly obese and receiving treatment. But the degree to which it should be used as a solution cannot be determined until we have further data.

Indications for Bariatric Surgery

Conventional treatment of childhood obesity has proven to be time consuming, difficult, frustrating, and expensive. Although numerous short-term successes have been noted, long-term weight reductions are modest, and recidivism is the rule. In adolescents with extreme and morbid obesity that may be life-threatening, surgical therapy may be indicated in extreme and defined circumstances.[592,593] However, in comparison to the criteria used for adults, stricter and more conservative criteria must be applied to adolescents for the following reasons:

1. Not all obese adolescents will become obese adults.[594]
2. The rate of lifestyle and pharmacotherapeutic efficacy has modestly improved.
3. The time interval before comorbidities become life threatening has lengthened.
4. Adolescents are not able to give legal consent.

Therefore, it is virtually impossible to perform RCT surgical studies on children. The efficacy of any given approach will continue to be suspect, and different procedures cannot be compared. For all these reasons, an expert panel with representation from the American Pediatric Surgical Association and the American Academy of Pediatrics[593] suggested that bariatric surgery in adolescents could be justified in situations when obesity-related comorbid conditions threaten the child's health. The panel provided stringent recommendations that bariatric surgery be limited to adolescents with a BMI > 40 kg/m^2 with presence of severe comorbidity or those with a BMI > 50 kg/m^2 with a less severe comorbidity. However, these stringent criteria are undergoing careful scrutiny in an attempt to liberalize them.[595]

Special consideration should be taken to avoid bariatric surgery at very late stages of obesity, when the presence of obesity-related comorbidities and the inaccessibility of imaging (most magnetic resonance imaging [MRI] scanners have a weight limit of 450 pounds) may affect surgical outcome. Indeed, a review of eight retrospective studies in adolescents found that bariatric surgery in adolescents can promote durable weight loss in most patients, but there appears to be a significant complication and mortality rate.[596] Therefore, guidance is needed to determine the ideal circumstances at which the balance of risk versus benefit favors health preservation and reversal of complications with the lowest risk of morbidity and mortality from the procedure.

Bariatric procedures for weight loss can be divided into purely restrictive, those that bypass a segment of the foregut, and combination procedures. Purely malabsorptive procedures aim to decrease the functional length or efficiency of the intestinal mucosa through anatomic rearrangement of the intestine. These procedures include the jejunoileal bypass and the biliopancreatic diversion with duodenal switch. Due to the high morbidity and mortality of these procedures, they cannot be recommended for children and will not be discussed further. The restrictive procedures reduce stomach volume to decrease the volume of food ingested. They include the bariatric intragastric balloon (no data are available concerning this treatment on children) and the laparoscopic adjustable gastric band (LAGB). The Roux-en-Y gastric bypass (RYGB) is a combination procedure.[597] The sleeve gastrectomy seems to be a restrictive procedure, yet it probably shares some of the hormonal effects of the RYGB and is gaining popularity.

Restrictive: Laparoscopic Adjustable Gastric Banding (LAGB)

LAGB utilizes a prosthetic band to encircle and compartmentalize the proximal stomach into a small pouch and a large remnant.[597] The theoretical advantage of this technique is a decreased risk of staple line dehiscence. The introduction of a new laparoscopic approach and the use of an adjustable band (allowing the stomach size to change) make this procedure more attractive. Finally, this procedure is reversible (at least theoretically, although some surgeons scoff at this notion) or can be modified into the RYGB at a later date. Results vary widely in adults. A single RCT comparing LAGB to conservative obesity management in obese children has shown superior weight loss that was maintained over 2 years. Among obese adolescent participants, the use of gastric banding compared with lifestyle intervention resulted in a greater percentage achieving a loss of 50% of excess weight, corrected for age. There were associated benefits to health and quality of life.[598]

Combination: Roux-en-Y Gastric Bypass (RYGB)

RYGB involves dividing the stomach to create a small (15 to 30 mL) stomach pouch into which a segment of jejunum approximately 15 to 60 cm inferior to the ligament of Treitz is inserted, while the proximal portion of the jejunum that drains the bypassed lower stomach and duodenum is reanastomosed 75 to 150 cm inferior to the gastrojejunostomy.[597] This procedure combines the restrictive nature of gastrectomy with the consequences of dumping physiology as a negative conditioning response when high-calorie liquid meals are ingested. In addition, RYGB is associated with a decline in the circulating level of ghrelin, which may be in part responsible for the decrease in hunger associated with this procedure.[12] The procedure not only leads to extraordinary weight loss, but it can reverse type 2 diabetes as well.[599]

RYGB appears to result in significant early weight reduction in adults[597,600]; however, long-term studies demonstrate weight regain in many patients.[601] Limited data are available regarding the efficacy of these surgical procedures to induce weight loss in severely obese children and adolescents, and most of these are case series from individual surgeons or institutions.[602] In a case review, 10 severely obese adolescents (BMI 52.5 ± 10 kg/m^2) who underwent RYGB were followed for a mean 69 months (but ranging from 8 to 144 months).[603] In this series, weight loss was significant in 9 of 10 adolescents and was maintained as long as 10 years. The average weight loss was 53.6 ± 25.6 kg, which represents approximately 59% excess weight lost. Weight loss was also associated with an improvement of associated comorbidities including sleep apnea and hypertension. Finally, a large retrospective series focused on 33 obese adolescents[604] age 16 ± 1 year with a BMI of

52 ± 11 (ranging from 38 to 91) and obesity comorbidities. Researchers followed these subjects for up to 14 years after bariatric surgery, mostly RYGB. Adolescents participating in a multicenter study reported by the Pediatric Bariatric Study Group experienced excellent weight loss after laparoscopic RYGB with mean BMI change from 58 kg/m^2 to 35.8 kg/m^2 at 1 year.[605] Gastrojejunostomy stenosis (21 patients) requiring endoscopic balloon dilation and internal hernia (14 patients) requiring either laparoscopic or open reduction were the most common complications. This procedure appears to be safe and effective when candidates are carefully selected and the bariatric surgeon has advanced laparoscopic skills.

RYGB seems to provide complete remission of T2DM in obese adolescents. Importantly, when performed in superobese adolescents, the nadir BMI achieved is typically ~37% from baseline. If one performs the procedure on a patient with a BMI in the low 40s, the result may be a BMI that is within an acceptable healthy range. In contrast, performing the procedure in patients with a BMI > 50 leaves them, even after an optimal result, in the obese BMI range without further reductions.[606]

The most commonly reported complications of RYGB include iron-deficiency anemia (50%), transient folate deficiency (30%), and events requiring surgical intervention (40%: cholecystectomy in 20%, small bowel obstruction in 10%, and incisional hernia in 10%).[597] Because most of the stomach and duodenum is bypassed in this procedure, there is an increased risk for deficiencies in vitamin B_{12}, iron, calcium, and thiamine. Although beriberi has been reported in teenagers after RYGB,[607] compliance with daily supplementation and regular monitoring of patients can prevent such nutritional deficiencies.

Laparoscopic Sleeve Gastrectomy (LSG)

This procedure is becoming more widely used. It reduces gastric capacity by cutting out the greater curvature of the stomach (in other words, turning the stomach into a tube). The death rate is halfway between that for LAGB and the RYGB, and the efficacy is halfway between the two as well.[608]

Who Should Perform Bariatric Surgery in Children?

Surgical outcomes in adults vary widely among surgeons and institutions.[609-611] Furthermore, there is a clear learning curve, as the morbidity of bariatric surgery varies inversely with the number of procedures performed.[612] Also, because RCTs in adolescents are unlikely, the only method to validate and refine the use of these procedures will come from following patients carefully and long term. Lastly, the increased risk of readmission after bariatric surgery in adults[613] argues for close and careful follow-up and monitoring in adolescents. Therefore, it is essential that bariatric surgery in adolescents be performed in regional pediatric academic centers with programs equipped to handle the data acquisition, long-term follow-up, and the multidisciplinary nature of these difficult patients.[593]

A multidisciplinary team with medical, surgical, nutritional, and psychological expertise should carefully select adolescents who are well informed and motivated to become potential candidates for LAGB or RYGB. Attention to the principles of growth, development, and compliance is essential to avoid adverse physical, cognitive, and psychosocial outcomes following bariatric surgery.[593] It must be clear to the subject and the parent that bariatric surgery is in fact an adjunct to a sincere commitment to lifestyle, rather than a magic bullet. Indeed, evidence of relapse in adults after RYGB is now commonplace.

Subjects and families must be well informed as to the risks and complications of such surgery. The medical team will require endocrine, GI, cardiology, pulmonary, and otolaryngologic support. Prophylactic tracheostomy is rarely required to maintain airway patency and to allow for the resolution of the hypercapnia prior to surgery.[614] Adolescents undergoing bariatric surgery require lifelong medical and nutritional surveillance postoperatively.[592] Extensive counseling, education, and support are required both before and after bariatric surgery; patients left to their own recognizance tend to regain weight over time. Indeed, studies in adults document an increased risk of hospitalization after RYGB, due to difficulties from the procedure.[613] Monitoring of long-term weight maintenance, improvements in CV morbidity, and longevity are all necessary to determine the cost-effectiveness of bariatric surgery in the pediatric population.

ENERGY INADEQUACY

Starvation versus Cachexia

Although both are weight loss syndromes, understanding the neuroendocrine mechanisms that distinguish starvation from cachexia is integral to both understanding and treating these disorders properly. In starvation, the negative feedback energy balance pathway is intact. The signal of leptin inadequacy from the weight loss is transduced by the VMH neuron into reduced sympathetic activity (to conserve energy) and increased vagal activity (to store energy). However, in cachexia, this pathway is short circuited by cytokine action on the hypothalamus. The VMH POMC neuron expresses receptors for various cytokines, including IL-1 and TNF-α.[615] In response to cytokine exposure, POMC neurons are activated, resulting in anorexigenesis, increased sympathetic activity, decreased vagal activity, and energy wastage.[616,617] Proinflammatory cytokines increase epinephrine, growth hormone, and cortisol, and they reduce insulin. These long-term hormonal changes accelerate muscle proteolysis (cortisol), increase resting energy expenditure (SNS), contribute to insulin resistance (both epinephrine and cortisol-glucagon), increase catabolism (cortisol), and suppress appetite and intestinal transit (vagus). This is clearly adaptive in the short term during times of infection (in order to generate body heat to eradicate the organism), but it is maladaptive in the long term, when chronic cytokine signaling can lead to cachexia. Thus, even in the situations of leptin decline or inadequacy, cytokine activation of POMC neurons promotes continued cachexia and weight loss through persistent SNS activation.

Failure to Thrive

Failure to thrive (FTT) is not a disease per se but rather a sign of multiple organic and nonorganic conditions and the interactions between them leading to compromised growth at a young age. FTT still represents a common pediatric medical problem mostly managed in the outpatient setting. Although FTT can rarely be a manifestation of critical illness, the majority of cases are the result of undernutrition due to the combination of biologic, environmental, and psychological factors. The diagnosis of FTT requires a thorough, prudent, and oriented history taking by the caregiver and is not always simple to establish. Moreover, this diagnosis may carry several legal implications that are not within the scope of this text.

Definition

There is no consensus on a single definition for FTT. The condition reflects inadequate physical growth recorded over time using standard growth charts. The commonly used definitions in clinical practice include length or weight below the fifth percentile for age and gender, a downward cross of two major percentile lines of the growth chart over time, or a weight per height below the 10th percentile of expected. The practicality of usually using weight and not length curves evolves from the fact that undernutrition and chronic disease tend to primarily affect weight gain while preserving linear growth. Ultimately, linear growth is also affected if these conditions persist. It is important to emphasize that single measurements without longitudinal follow-up growth points are inadequate to make the diagnosis of FTT, and a wrongful diagnosis may be established in infants who were born small for gestational age or prematurely, and in some healthy growing infants growing along the lower percentiles.

Classification and Etiology

The traditional classification of FTT is to segregate between organic and nonorganic causes. The nonorganic causes refer to environmental and psychological factors such as sensory deprivation, parental and emotional deprivation, and feeding difficulties of no organic source that occur in infancy. This traditional classification seems to lack the insight that the majority of cases suffer from a combination of the two, reflecting a mixed etiology.[618] A different approach is to classify the disorder based on its pathophysiology (i.e., inadequate caloric intake, inadequate absorption, excess metabolic requirements, defective utilization of intake, and reduced growth potential).[619] Common causes of FTT based on this classification scheme are shown in Box 22-2.

Of note, normal growth variation can confound the diagnosis of FTT, as some infants may be born large for gestational age as a result of intrauterine causes (such as gestational diabetes) and later experience a "catch down" pattern of growth during infancy toward the actual growth potential curves. Another cause of such negative crossing of percentiles can be constitutional growth delay. It is estimated that up to 25% of children can cross curves by more than 25 percentile lines (representing a cross of two major growth percentile lines), for the previously mentioned reasons.[620] These infants reach a new point from which they display a normal growth rate and weight gain pattern, yet they do not have FTT.

Endocrine causes of FTT are uncommon, as typical hormonal deficiencies such as growth hormone deficiency or hypothyroidism present as growth failure but with

BOX 22-2 Differential Diagnosis of Failure to Thrive

1. Inadequate caloric intake
   - Poverty and low food resources
   - Mechanical feeding difficulties (altered swallowing ability, congenital anomalies, central nervous system damage, severe gastroesophageal reflux)
   - Wrongful preparation of infant formula (too diluted, too concentrated)
   - Unsuitable feeding habits by parent
   - Behavioral problems affecting eating
   - Child neglect
   - Poor parent-child interaction
2. Inadequate absorption of caloric intake
   - Reduced absorption surface area (short bowel syndrome, s/p necrotizing enterocolitis)
   - Chronic liver disease, biliary atresia
   - Celiac disease
   - Cystic fibrosis
   - Cow's milk allergy
   - Chronic diarrhea
   - Vitamin or mineral deficiencies (acrodermatitis enteropathica)
   - Vomiting due to CNS abnormalities (tumor, raised ICP)
3. Increased metabolism
   - Hyperthyroidism
   - Chronic infection (due to immune deficiency)
   - Occult malignancy
   - Congenital heart defects or acquired heart disease (mainly right to left shunts and heart failure)
   - Chronic lung disease with hypoxemia (bronchopulmonary dysplasia)
   - Burns
4. Defective utilization of calories
   - Renal failure, renal tubular acidosis
   - Inborn errors of metabolism (storage diseases, amino acid disorders)
5. Reduced growth potential
   - Genetic disorders (trisomies, skeletal dysplasias, Russell-Silver syndrome)
   - Specific genetic syndromes
   - Primordial dwarfism

preserved or increased weight gain. Hyperthyroidism (representing a state of increased metabolic demands and characteristically manifested by increased linear growth) and disorders of salt metabolism, such as hypoaldosteronism and pseudohypoaldosteronism, may have FTT as part of their clinical manifestations.[621] Hypophosphatemic rickets may also present as FTT.

Diagnosis and Evaluation

The key to making the diagnosis of FTT is in plotting anthropometric data (weight and length) during a reasonable follow-up period. Although a prudent and focused history and physical examination are the keys to diagnosis, often the correct diagnosis is made in retrospect. The lack of an organic etiology to explain the findings is not enough to establish a diagnosis of nonorganic FTT. A response to an active intervention, manifested at least as a limited period of adequate growth while altering a behavioral element by the caregiver or child, can help establish a diagnosis of nonorganic FTT.

History should focus on the dietary and feeding history, past and present medical history, social environment, and family history. The dietary history is aimed at assessing, as accurately as possible, the actual caloric intake of the patient. An important tool for this assessment can be the use of food logs of several days. The important details concern the actual amounts of food, the way the food is prepared (specifically relevant for the dilution technique of infant formulas and to cereals added to the formula), and beverages consumed, with a specific emphasis on sweetened juices and formula. These details should allow the practitioner to estimate the caloric intake.

The important details regarding feeding begin with the location of the meals and their timing throughout the day. Who feeds the patient or supervises the feeding process is of major importance. The feeding technique should be appropriate for the child's developmental stage. The timing is relevant in regard to frequent snacking in between meals that may cause early satiety during mealtimes.

A standard pediatric medical history should be taken from all patients, yet it should be focused on details that may be relevant to the diagnosis of FTT. The pregnancy and birth history are important for differentiating infants who were born small for gestational age from those who suffer from FTT. The timing at which poor weight gain began, especially in relation to changes in feeding, is critical for the diagnosis. Chronic medical conditions such as congenital heart disease, asthma, multiple recurrent infections, and anemia can all be causes of organic FTT. Multiple hospitalizations and a history of injuries can raise the suspicion of parental neglect. Gastrointestinal manifestations of relevant medical conditions such as frequent vomiting (in cases of milk allergy or gastroesophageal reflux) and stool frequency and consistency (in order to rule out malabsorption, celiac, inflammatory bowel disease, or cystic fibrosis) should be elicited in detail.

The social history should focus on identifying the patient's primary caregivers and determining whether there are economical issues that may affect the ability to nourish the patient adequately. Potential external and intrafamilial stressors that may affect the supply of food to the child should be sought (any stressor or life event that can affect the functioning of the caregiver in a way that could compromise the well being of the child). The family history should focus on the body habitus of parents and siblings in order to obtain clues regarding the genetic potential for height and weight. Medical conditions in siblings and relatives can suggest a predisposition to genetic disorders. The caregivers should be asked about mental illnesses, such as depression, that may hamper their ability to provide adequate care for the child. A family history of previous children who suffered from FTT should be investigated as well. A call to the local Department of Family Services may be warranted.

The physical examination begins with plotting the child's' length, weight and head circumference on standard growth charts, along with previous measurements (if available). The severity of the FTT can be estimated by assessing the present weight in comparison to the expected weight for age. If the weight is less than 60% of expected by the 50th percentile for age and length, the condition is severe, whereas a weight between the 60th and 75th percentile of expected is considered moderate FTT. Microcephaly accompanied by neurologic signs may suggest a CNS lesion. It should be remembered that head circumference is the last parameter to change in FTT, and only in the severest cases. The detection of dysmorphism may suggest a genetic cause for impaired growth and development. Measures of nutritional status (such as thickness of skin folds and body fat distribution) can be examined. It is important to carefully observe the interaction of the caregiver, and the child during feeding. Impaired parental-child interactions can have a major impact on feeding habits, and their identification is critical to the design of effective behavioral interventions tailored for the patient and family.

The majority of children with FTT have no laboratory abnormalities and no hormonal alterations. Minimal literature is available about comprehensive laboratory workups in children with FTT, although a classic manuscript about the workup of more than 180 infants in an inpatient setting found laboratory abnormalities in less than 1.4% of tests taken.[622] The choice of tests that may be beneficial should be based on the history and physical examination and usually is focused on the assessment of malnutrition in severe cases. A minimal workup, although not cost effective, may include a blood count, chemistry panel (including liver and renal function tests, electrolytes, serum protein, and albumin concentrations as well as blood acid-base status), and a urinalysis with pH. Additional tests should be oriented at specific findings from the history and physical examination. No hormonal tests are warranted initially unless a clinical suspicion of a specific disorder arises. In children older than 6 months, screening for iron deficiency and lead poisoning is warranted. Hospitalization and inpatient workup does not add any yield to the workup,[623] unless the degree of FTT is severe, or if there are concerns about child safety and neglect.

Management

The management of FTT is based on identifying the underlying cause and correcting it. The majority of cases are handled by a combination of nutritional and behavioral intervention. Importantly, the intervention should begin before the workup is complete (i.e., less than from the first evaluation). All medical problems are treated independently of nutritional and behavioral interventions and should not delay or hamper them. The mainstay of treatment of all infants with FTT is a calorie-rich diet accompanied by frequent and close monitoring of weight response. An effective intervention will document a catch-up weight and height gain that is maintained over time.

Feeding and eating behaviors should be addressed by walking the fine line between encouragement and pressure to promote eating. Timing meals and snacks and eating as a family in a pleasant environment of low stress may be important for improving eating and feeding practices. The feeding intervention is dependent on the infant's age at presentation. For breastfeeding infants, it is beneficial to attempt to increase breast milk supply[624] by pumping milk, treatment with metoclopramide to induce oxytocin secretion,[625] improving maternal nutrition and fluid intake, and making adaptations at the home and workplace that can promote and simplify the breastfeeding process. Suckling problems in neurologically impaired infants can be solved by providing expressed human milk via bottle feeding. Bottle-fed and older infants allow more interventions to increase the caloric content of the diet. Infants with FTT should receive ~150% of the recommended daily caloric intake based on their expected weight (rather than their actual weight).[626] Formula may be enriched by adding cereals, and toddlers may benefit from the addition of palatable high energy density foods (such as cheese and peanut butter) to their diet. High-calorie milk-based drinks (such as PediaSure, which provides 30 calories per ounce, compared to whole milk, which provides 19 calories ounce) can be added along with vitamin supplements. Zinc supplements have been shown to increase IGF-1 levels without affecting IGFBP-3 in infants with nonorganic FTT, yet this effect did not actually promote growth.[627]

Prognosis

The majority of infants and children with FTT show improvement with intervention. Others may even show progress when they achieve a more independent stage of development where they can attain their own food. Those who require gastrostomy feeding due to neurologic dysfunction may require assisted enteral nutrition for life. The cognitive and intellectual function outcomes of those who suffered from FTT seem worse than their peers, although this association has only been well established in cases of iron deficiency anemia.[628] It seems conceivable that deficiencies of other elements critical for brain development during infancy may have a similar adverse impact on intellectual properties at later ages, although this has not been studied systematically. The effects of nonorganic factors (such as emotional deprivation) on intellectual development, often coexisting with organic factors, may also contribute to decreased cognitive ability at later ages.

Cancer Cachexia

Cancer activates a complex set of CNS metabolic pathways, which result in cachexia (Box 22-3).[629] Peripheral cytokines gain access to the CNS through the central circumventricular organs, which bypass the blood-brain barrier, or by stimulation and amplification of CNS microglial cytokine or eicosanoid production. For instance, TNF-α stimulates VMH POMC neurons, which stimulates the SNS, which increases resting energy expenditure, increases cortisol and glucagon levels, and contributes to insulin resistance. IL-1 decreases neuropeptide Y within the VMH and thus decreases appetite. IL-1 also increases CRF, which indirectly inhibits appetite. IL-6 bears a striking similarity to ciliary neurotrophic factor (CNTF), which has been shown to reduce weight by activating VMH POMC neurons through a leptin-independent mechanism.[630] Conversely, due to a reduction in vagal activity, gastrointestinal motility is impaired in cancer cachexia and is clinically manifest by early and inappropriate satiety, which occurs in 40% to 60% of cancer patients.

In addition, cytokines have adverse peripheral effects. Uncoupling proteins are up-regulated by cytokines and contribute to increased energy expenditure. Cancer cachexia leads to the overexpression of UCP1 in brown adipose tissue; UCP2 in brain, skeletal muscle, and liver; and UCP3 in skeletal muscle. Levels of UCP2 and UCP3 in the liver and muscle are regulated by prostaglandins,

BOX 22-3 Metabolic Changes in Cachexia

Expression of Cytokines

- Increased production of acute phase proteins (APP)
- Up-regulation of transcription factor NFκB and AP-1
- Increased interleukin-1, IL-6, and tumor necrosis factor-α and interferon-γ
- Increased expression of tumor-specific cachexins (proteolysis inducing factor, lipid mobilizing factor, and anemia inducing substance)
- Increased expression of ubiquitin, E_1, E_2, E_3, and proteasome components (cell death and removal)

Increased SNS Tone

- Increased expression of hormone sensitive lipase in adipose tissue
- Up-regulation of uncoupling proteins (UCP2 and UCP3) in muscle and adipose tissue
- Increased hepatic gluconeogenesis

Reduced Vagal Tone

- Reduced lipoprotein lipase expression in adipose tissue
- Reduced intestinal transit
- Reduced hunger

and UCP3 is also regulated by triglycerides, all of which are increased in cancer.[631]

Cytokines cause insulin resistance in skeletal muscle, liver, and adipose tissue. TNF-α decreases insulin receptor and PPAR activity. In addition, there is an inverse correlation between interleukin-6 levels and insulin sensitivity.[632] Adipose tissue insulin resistance increases fat oxidation and decreases lipoprotein lipase activity, resulting in continued lipolysis.[633] The insulin resistance of cancer is not related to defective insulin clearance and therefore differs from other forms of primary insulin resistance.[634]

Cancers are uniformly anaerobic and depend on glucose for survival; thus, the glucose manufactured from gluconeogenesis secondary to hepatic insulin resistance is essential for tumor growth. Cancers release large amounts of lactate, which is converted in the liver back to glucose. Such gluconeogenesis consumes ATP, which also increases energy expenditure.[635] Additional raw materials for gluconeogenesis are alanine derived from skeletal muscle proteolysis and glycerol from lipolysis.

Treatment is difficult. Many methods have been tried (SNS antagonists, prostaglandin inhibitors, omega-3 fatty acids, melatonin, thalidomide, interleukins, anticytokine monoclonal antibodies, IL-1 receptor antagonists, and chemotherapy), but all are lacking. One promising new avenue is that of melanocortin antagonists,[615] but this is still in preclinical evaluation.

Diencephalic Syndrome

Originally described by Russell in 1951,[636] this rare disorder presents in infants younger than 1 year old and is an indication of a hypothalamic lesion, usually an anterior hypothalamic glioma, or other neoplasm affecting hypothalamic function. Although the clinical spectrum is variable, emaciation with paucity of subcutaneous fat but with normal linear growth and head circumference is inviolate. Other frequent features include hyperalertness, hyperkinesis, nystagmus, and vomiting.[637,638]

Although numerous patients have been anecdotally reported and characterized, the cause of the emaciation remains unclear. Subjects with diencephalic syndrome have extremely elevated baseline GH levels but normal IGF-1 levels, suggesting a modicum of GH resistance.[637] It has been suggested that the high GH leads to lipolysis and accounts for the emaciation, but this finding is not consistent in all patients. Only one evaluation of energy balance has been performed, which demonstrated 30% to 50% greater REE in comparison to normal babies, and 13% greater energy expenditure compared to intake.[639]

The recommended treatment is surgical extirpation of the lesion whenever feasible. Radiation is usually contraindicated for the very young patient. Frequently, these patients postoperatively manifest hypopituitarism and ultimately develop hypothalamic obesity.[638]

Anorexia Nervosa (AN)

Definition

Anorexia nervosa (AN) is an eating disorder that typically begins during adolescence and consists of persistent dieting and intense physical activity, usually accompanied by compulsive behavioral traits and sometimes purging behavior and binge eating. Most subjects manifest a disturbed body image and a persistent fear of fatness, both of which promote further weight loss. The result of this behavior is a pathologic weight loss, with pathophysiologic consequences. The risk of developing AN among females in Western societies is estimated to be between 0.5% and 1%.[640] There are two subtypes of anorexia: the food restrictive type, characterized by very low caloric intake plus excessive exercise, and the purging type, characterized by varying levels of food purging, usually by way of self-induced vomiting and laxative abuse. Alongside the obvious mental elements, the definition in the DSM-IV includes anthropometric as well as metabolic components: a significantly low weight (defined as a sustained weight below the 85th percentile of the expected weight per height due to weight loss or failure to gain weight during growth and development) and secondary amenorrhea in pubertal girls and women (defined as no menses in 3 months).

Medical complications driven by the chronically reduced caloric intake, purging behavior, and excessive exercise may affect several organ systems. Typically, patients develop a marked loss of subcutaneous fat tissue, impaired menstrual function, bradycardia and orthostatic hypotension, hypothermia, and increased hair loss. Importantly, anorexia nervosa that develops during adolescence may create adverse clinical effects that persist into adulthood,[641] including osteopenia and osteoporosis,[642] higher rates of miscarriage, and reduced offspring birth weight.[643] Anorexia may also alter cognitive abilities as during extreme weight loss, and a reduction of both gray and white matter occurs; conversely, during weight restoration white matter returns to premorbid levels, but gray matter does not.[644] Anorexia carries an increased mortality risk, specifically for suicide yet also from medical causes such as starvation per se and purging-induced arrhythmias. Full recovery of body habitus and of growth and development occurs in 50% to 70% of treated adolescents, yet achieving a full physiologic and psychological recovery may require a comprehensive treatment intervention that may last as long as 5 to 7 years.[645] Greater weight loss, lower sustained weight, and the coexistence of other psychiatric disorders adversely affect the probability of recovery. The outcomes for adults with anorexia nervosa are poorer than they are for those who are diagnosed and treated during adolescence.

Endocrine Associations

Obesity and malnutrition usually result in opposing effects on normal physiology and are both associated with changes in the hormonal profile. The majority of these changes represent an adaptive response yet should be considered as part of the differential diagnosis of specific hormonal excess or deficiency disorders. Figure 22-9 demonstrates the typical hormonal profile of patients with AN, aimed at energy preservation and the cessation of energetically costly and nonvital processes.

Hypothalamic-Pituitary-Thyroid Axis. The starvation status of AN may resemble the sick euthyroid syndrome.

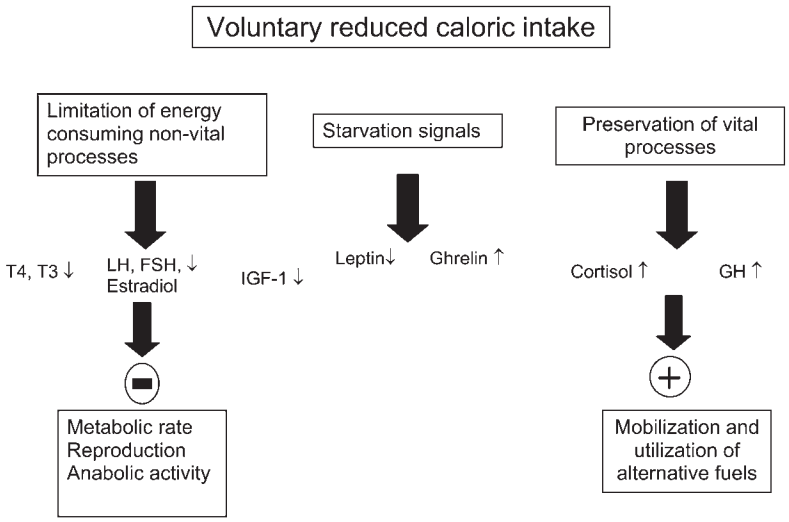

FIGURE 22-9 ■ Hormonal changes in anorexia nervosa. The hormonal profile of the patient with anorexia nervosa represents an adaptive response aimed at conserving energy. Processes that require significant energy such as reproduction and growth are limited by a complete suppression of the gonadotropic axis and by reduced IGF-1 levels, respectively. A seemingly chronic stress response characterized by increased growth hormone and cortisol is aimed at efficient utilization of the limited energetic sources present. Reduced leptin serves as a signal for down-regulating the hypothalamic-pituitary-gonadal axis. Reduced leptin also serves as a starvation signal, although this signal appears to be circumvented in this disorder.

In patients with AN, serum total and free T_4, total and free T_3, TSH, and TBG are significantly lower than normal, whereas rT_3 levels are significantly greater than they are in healthy controls.[646] Most AN patients have a hyporesponsiveness or delayed responsiveness of TSH to TRH stimulation. Of note, weight regain reverses the effects of AN on the hypothalamic-pituitary-thyroid axis back to normal; thus, the reduction in thyroxinemia may actually be a normal adaptive physiologic response to starvation. The differential diagnosis of hypothyroidism should be considered in patients with AN, as both disorders are characterized by low T_4 and T_3 levels. In primary hypothyroidism, TSH levels are greater than those observed in patients with AN, although in mild secondary hypothyroidism this distinction may be difficult. Obtaining a serum reverse T_3 (rT_3) level may be helpful in distinguishing a true thyroid disorder from the euthyroid sick syndrome associated with systemic illness.

Growth Hormone-IGF-1 Axis. Patients with AN typically have GH hypersecretion accompanied by low IGF-1 levels. Whether this profile is due to a primary hypothalamic dysfunction, a peripheral target organ resistance to GH, or an impaired negative IGF-1 central feedback mechanism is unclear. An increased GH response to GHRH has been demonstrated in AN, possibly reflecting an impairment of beta-adrenergic suppression of GH secretion.[647] The clinical presentation of weight loss, cessation of menses, and cold intolerance alongside low levels of pituitary-derived hormones may resemble panhypopituitarism, yet patients with AN present with GH hypersecretion.

Hypothalamic-Pituitary-Adrenal Axis. Patients with AN typically present with elevated cortisol levels in the presence of normal ACTH levels.[648] The elevated cortisol levels are apparently due to increased cortisol secretion alongside a reduction in cortisol clearance. Elevated CRH levels found in the cerebrospinal fluid of patients with AN suggest that AN represents an overall state of activation of the hypothalamic stress response, manifested peripherally by hypercortisolemia. An abnormal response in the dexamethasone suppression test, mainly of reduced suppression, suggests that an element of decreased feedback sensitivity occurs in this disorder.

Bone Metabolism. Adolescence represents a critical period for the accumulation of bone mineral, thus building bone strength and density for later years. The achievement of peak bone mass depends several hormonal effects characteristic of puberty (such as estradiol and IGF-1) as well as on adequate nutrition, all of which are compromised in patients with AN. Adolescents and adults with AN have a low bone mineral density. In adults this condition is due to increased bone resorption and reduced bone formation, but in adolescents it is characterized by an overall reduced bone turnover.[649] The reduced bone density is caused by the typical hormonal profile of AN (i.e., reduced estrogens and androgens, low IGF-1, and relative hypercortisolemia). Moreover, the reduced lean body mass and lower mechanical forces acting on long bones may also contribute to the overall reduced bone mineral density. Some publications also suggest that elevated levels of gut-derived hormones $PYY_{(3\text{-}36)}$ and ghrelin may also contribute to impaired bone metabolism in AN.[650] Importantly, resolving AN with weight gain often does not bring full recovery of the bone mineral density status. Osteopenia resulting from undernutrition and the typical hormonal dynamics of AN is one of several long-term complications of AN during adolescence, and thus is a major treatment target.

Hypothalamic-Pituitary-Gonadal Axis. Amenorrhea is one of the hallmarks of AN, yet it is not always

explained by the severe weight loss; thus, hypothalamic amenorrhea in AN often precedes weight loss and may persist after refeeding and achievement of normal weight. Gonadotropin levels are reduced in patients with AN, and GnRH stimulation testing in patients with AN demonstrates a blunted LH response with a preserved FSH response and very low levels of estradiol. LH pulsatility may revert to prepubertal patterns in adolescents who have previously achieved pubertal status. The amenorrhea of AN is also marked by strikingly reduced leptin levels. Leptin serves as a metabolic signal of energy status and nutritional reserve and thus may have a permissive role for the initiation of the complex hormonal dynamics necessary for normal reproductive function.[651] Teleologically, conserving energy for immediate and necessary metabolic demands while suppressing energetically expensive processes such as reproduction can serve as a protective measure in severely malnourished individuals, as seen in AN. The rise in leptin upon weight gain is associated with increases in gonadotropin secretion, suggesting that leptin serves a permissive role for the activation of the hypothalamic-pituitary-gonadal axis.

Fat-Derived Hormones. Adipocytes secrete a wide array of adipocytokines, the normal profile of which is altered in AN. Patients with AN typically have very low plasma leptin concentrations alongside a marked disturbance of the leptin diurnal secretion profile.[652] The concentration of leptin-binding protein (the soluble isoform of leptin receptor) has been reported to be increased in patients with AN, contributing to a further reduction in the concentration of free leptin.[653] Leptin has a major role in the neuroendocrine adaptations to the chronic starvation and undernutrition typical of AN, such as a reduction in gonadotropins, a reduction in thyroid hormone in order to conserve energy, a modified stress response manifested by hypercortisolemia, and elevated GH aimed at mobilizing and utilizing alternative energy sources.[654] Weight gain in AN patients can induce relative hyperleptinemia in comparison to controls matched for body mass index; circulating leptin concentrations in AN patients thus traverse from subnormal to supranormal levels within a few weeks.

Adiponectin is the only adipocytokine whose plasma concentrations are inversely related to fat mass. Conflicting results regarding adiponectin concentration in AN, ranging from hyperadiponectinemia[655] to hypoadiponectinemia,[656] have been reported. Interestingly, weight gain in AN is not necessarily associated with reciprocal changes in adiponectin concentration.[657]

Treatment

Indications for hospitalization and inpatient treatment of AN include dehydration, electrolyte disturbances (mainly hypokalemia), arrhythmias, CV instability (significant bradycardia, hypotension, and orthostatic changes), hypothermia, acute food refusal, acute complications of malnutrition (seizures, pancreatitis, cardiac failure), and psychiatric emergencies.

Along with psychological interventions that may consist of psychotherapy or pharmacotherapy (based on the spectrum of psychiatric pathology), an increase in caloric intake must be part of the treatment protocol. A protocol of starting with 1200 to 1500 kcal per day and increasing by 500 kcal is aimed at a gain of 0.5 to 1 kg per week.[658] There is no superior feeding regimen as long as adequate caloric intake is supplied. Extreme cases may be handled through hospitalization in dedicated inpatient units, and caloric intake in this setting may initially be provided by nasogastric and in extreme cases parenteral feeding.

One major treatment decision facing the caregiver of patients diagnosed with AN is whether to utilize estrogen replacement therapy to treat amenorrhea and protect the skeleton from osteopenia. There is a lack of a proven efficacious beneficial effect of estrogen replacement therapy in regard to improved bone mass in AN in comparison to placebo,[659] although this treatment modality is still commonly used.[660] This treatment approach may have several adverse effects on the treatment of adolescents, as it masks the beneficial effect of weight gain on the resumption of menses and may provide an erroneous sense of security in patients who are still at a critically low weight status. Increased calcium intake alongside 400 IU of vitamin D to accelerate absorption should be encouraged in all patients with AN as another potential protective measure of bone status.

CONCLUSIONS

The overwhelming majority of childhood obesity cases are not due to a documentable genetic or neuroanatomic lesion. Indeed, although classic endocrinopathies account for less than 2% of childhood obesity, every obese patient does manifest an endocrine disturbance (i.e., insulin resistance and/or leptin resistance). We must get past the obvious—that the child eats too much and exercises too little. The question that physicians must internally pose when seeing an obese patient is, "Where in the negative feedback energy balance pathway is this patient's dysfunction?" Only then can appropriate treatment be proffered. Similarly, in cachexia, we must go beyond the lack of appetite to understand the reasons for the wasting and illness. These are endocrine paradigms that may permit modulation, especially with endocrine therapies. Understanding the energy balance pathway, and where these various disorders impair its regulation, is the key to further research, and successful prevention and treatment.

QUESTIONS

1. Which correlates best with metabolic dysfunction?
   a. Visceral fat
   b. Intrahepatic fat
   c. Body mass index
   d. Subcutaneous fat

Answer: b

Fabbrini, E., Magkos, F., Mohammed, B. S., et al. (2009). Intrahepatic fat, not visceral fat, is linked with metabolic complications of obesity. *Proc Natl Acad Sci USA*, *106*, 15430–15435.

2. As caloric intake has increased since the 1980s, how has dietary fat intake been affected?
   a. Increased proportionately (i.e., percentage remained the same)
   b. Increased disproportionately (i.e., percentage increased)
   c. Increased because trans-fat intake increased
   d. Remained the same

Answer: d

Chanmugam, P., Guthrie, J. F., Cecilio, S., et al. (2003). Did fat intake in the United States really decline between 1989-1991 and 1994-1996? *J Am Diet Assoc*, *103*, 867–872.

3. Hypothalamic obesity occurs due to defective hypothalamic leptin signaling, resulting in which of the following?
   a. Autonomic dysfunction
   b. Increased caloric intake
   c. Decreased physical activity
   d. Decreased resting energy expenditure

Answer: a

Lustig, R. H. (2008). Hypothalamic obesity: causes, consequences, treatment. *Ped Endocr Rev*, *6*, 220–227.

4. It what way does hepatic fructose metabolism differ from hepatic glucose metabolism?
   a. Increases glycogen formation
   b. Promotes de novo lipogenesis
   c. Decreases forkhead protein (Foxo1) phosphorylation
   d. Increases mitochondrial β oxidation

Answer: b

Faeh, D., Minehira, K., Schwarz, J. M., et al. (2005). Effect of fructose overfeeding and fish oil administration on hepatic de novo lipogenesis and insulin sensitivity in healthy men. *Diabetes*, *54*, 1907–1913.

5. A 5-year-old is seen for obesity. Which feature suggests a classic endocrinopathy?
   a. Mental retardation
   b. Early adiposity rebound
   c. Family history
   d. Growth attenuation

Answer: d

6. A 7-year-old obese male is referred for evaluation. Which of the following suggest an epigenetic cause for the obesity?
   a. Acanthosis nigricans
   b. Normal weight parents
   c. Low Apgar scores
   d. Small for gestational age

Answer: d

Cutfield, W. S., Hofman, P. L., Mitchell, M., & Morison, I. M. (2007). Could epigenetics play a role in the developmental origins of health and disease? *Pediatr Res*, *61*(5 Pt. 2), 68R–75R.

7. A proven effective lifestyle strategy for stabilizing weight in children includes which of the following?
   a. Bringing lunch to school
   b. Reducing television time
   c. Increasing sleep duration
   d. Participating in physical education at school

Answer: b

Robinson, T. N. (1999). Reducing children's television viewing to prevent obesity: a randomized controlled trial. *JAMA*, *282*, 1561–1567.

8. Aside from liver biopsy, what is the most accurate for diagnosing nonalcoholic fatty liver disease?
   a. ALT
   b. Liver ultrasound
   c. MRI
   d. MRS

Answer: c

Mazhar, S. M., Shiehmorteza, M., & Sirlin, C. B. (2009). Noninvasive assessment of hepatic steatosis. *Clin Gastroenterol Hepatol*, 7, 135–140; Schwenzer, N. F., Springer, F., Schraml, C., et al. (2009). Non-invasive assessment and quantification of liver steatosis by ultrasound, computed tomography and magnetic resonance. *J Hepatol*, *51*, 433–445.

9. What is the current mean daily fiber intake?
   a. 6 g/day
   b. 12 g/day
   c. 18 g/day
   d. 24 g/day

Answer: b

Martlett, J. A., McBurney, M. I., & Slavin, J. L. (2002). Position of the American Dietetic Association: health implications of dietary fiber. *J Am Diet Assoc*, *102*, 993–1000.

10. Which subcellular organelle is thought to be responsible for most forms of obesity with mental retardation?
    a. Cilia
    b. Mitochondria
    c. Endoplasmic reticulum
    d. Peroxisomes

Answer: a

Sen Gupta, P., Prodromou, N., & Chapple, J. (2009). Can faulty antennae increase adiposity? The link between cilia proteins and obesity. *J Endocrinol*, *203*, 327–336.

CHAPTER 23

Lipid Disorders in Children and Adolescents

Stephen R. Daniels, MD, PhD • Sarah C. Couch, PhD, RD

CHAPTER OUTLINE

INTRODUCTION

Cardiovascular disease (CVD) is a major cause of morbidity and mortality among adults in industrialized countries. Dyslipidemia (specifically elevated low-density lipoprotein [LDL] cholesterol, low high-density lipoprotein [HDL] cholesterol, high non-HDL cholesterol, and triglycerides) has been identified as an independent risk factor in the development of CVD. There is strong evidence that lipoprotein levels track from childhood into adulthood and that abnormal levels of LDL cholesterol and perhaps other lipoproteins are associated with atherosclerosis and therefore with related adverse outcomes.

This chapter reviews the evidence for the role of cholesterol abnormalities in the early natural history of atherosclerosis. In addition, a general overview of lipoprotein metabolism is provided—followed by a review of genetic disorders in the metabolism of lipoproteins. Secondary causes of high cholesterol are explained, including the increasing prevalence of obesity and metabolic syndrome as a cause of cholesterol abnormalities in the pediatric population. Standards and approaches to screening for hyperlipidemia in children are reviewed, as well as current approaches to the dietary and pharmacologic management of pediatric lipid disorders.

METABOLISM

Lipid disorders in children and adolescents can result from defects in the production, transport, or degradation of lipoproteins. To understand the diverse causes of lipoprotein abnormalities, a brief review of lipoprotein structure, function, and metabolism is provided. Table 23-1 summarizes the lipoprotein subclasses, the source of each one, and the constituent lipids and apolipoproteins associated with each particle.

Triglycerides, cholesterol esters, phospholipids, and plant sterols within food postingestion are digested to fatty acids, 2-monoglycerides, lysophospholipids, unesterified cholesterol, and plant sterols. Absorption of these digestive end products occurs through two mechanisms: passive diffusion and carrier-mediated transport. In passive diffusion, nonpolar lipids are solubilized with the aid of bile acids and lysophospholipids into mixed micelles that can diffuse through the apical surface of the enteric membrane. Carrier-mediated transport involves several different transport proteins for fatty acids and sterols. CD 36, a fatty acid translocase, promotes long chain fatty acid and cholesterol absorption in the proximal small intestine.[1] At least two additional transporters, Niemann-Pick C1-like 1 protein (NPC1L1) and scavenger receptor B1 (SR-B1),

TABLE 23-1 **Lipoprotein Subclasses and Associated Apolipoproteins and Lipid Constituents**

Lipoprotein	Apolipoprotein	Source	Lipid Constituents
Chylomicrons	ApoB-48, apoC-II,* apoC-III, apoE*	Intestine	Dietary triglycerides
VLDL	ApoB-100, C-II,* C-III, apoE*	Liver	Endogenous cholesterol and triglyceride
IDL	ApoB-100, apoE	VLDL metabolism	Cholesterol and triglyceride
LDL	ApoB-100	VLDL metabolism	Cholesterol
HDL	ApoA-I, apoA-II, apoC-II, apoE	Liver and intestine	Cholesterol and phospholipid

*Transferred from HDL.
VLDL, very low density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein.

play a role in sterol uptake.[2,3] As such, NPC1L1 and SR-B1 are targets for the cholesterol-lowering medication ezetimibe, a potent inhibitor of cholesterol and plant sterol absorption.

Most of the plant sterol ingested and about half of the absorbed cholesterol are excreted from the intestinal cell back into the lumen by two adenosine triphosphate (ATP)-binding cassette (ABC) half-transporters, G5 and G8, thus limiting the amount of these sterols that is absorbed.[4,5] A rare mutation of either ABCG5 or ABCG8, known as sitosterolemia, results in abnormally high plant sterol levels in plasma and tissues and deposition of sterols in the skin and arteries. Individuals with this disorder are at an increased risk of premature atherosclerosis.[6]

Within the enterocyte, lipids are aggregated into lipoproteins through the action of a microsomal triglyceride transfer protein (MTP). MTP conjugates triglycerides and cholesterol ester with apolipoprotein B-48 (apoB-48) on the luminal side of the endoplasmic reticulum (ER) membrane to create a mature chylomicron.[7,8] A similar process is used to aggregate triglyceride and cholesterol with apoB-100 in the liver to form very low density lipoprotein (VLDL) particles. In the genetic disorder abetalipoproteinemia, mutations in the gene encoding MTP result in an inability to produce chylomicrons and VLDL, suggesting the essential nature of MTP in chylomicron and VLDL biogenesis.[8]

Chylomicrons once formed are too large to penetrate the capillary membrane. Consequently, they are secreted into the lymphatic system and enter the venous plasma compartment through the thoracic lymph duct. As the nascent particles are released into the plasma, several apolipoproteins (including apoC-II, C-III, and apoE) are preferentially transferred to the chylomicrons from circulating high-density lipoproteins (HDLs).[9] Figure 23-1 depicts chylomicron metabolism.

Chylomicrons transport dietary triglyceride and cholesterol to sites of storage or metabolism.[10] They are rapidly cleared from the circulation through the action of lipoprotein lipase (LPL). LPL is a triglyceride hydrolase found on the capillary endothelium of various tissues, with its highest concentration in muscle and adipose tissues.[11] LPL is activated by apoC-II and inhibited by apoC-III on the chylomicron. As the triglyceride contained within the chylomicron is hydrolyzed, the particle decreases in size. When approximately 80% of the initial triglyceride has been removed, apoC-II dissociates from its surface.[11] The triglyceride-depleted chylomicrons, now considered chylomicron remnants, are taken up by the liver through the LDL receptor (LDLR), a receptor that recognizes apoE on the chylomicron surface and apoB100 on the surface of liver-derived lipoproteins.[9] A smaller fraction of remnants may also be internalized via an LDLR-related protein-1 (LRP1)-mediated endocytosis.[12,13]

Very low density lipoproteins (VLDLs) originate from the liver, and like chylomicrons they are triglyceride-rich particles (Figure 23-2). In contrast to the intestinally

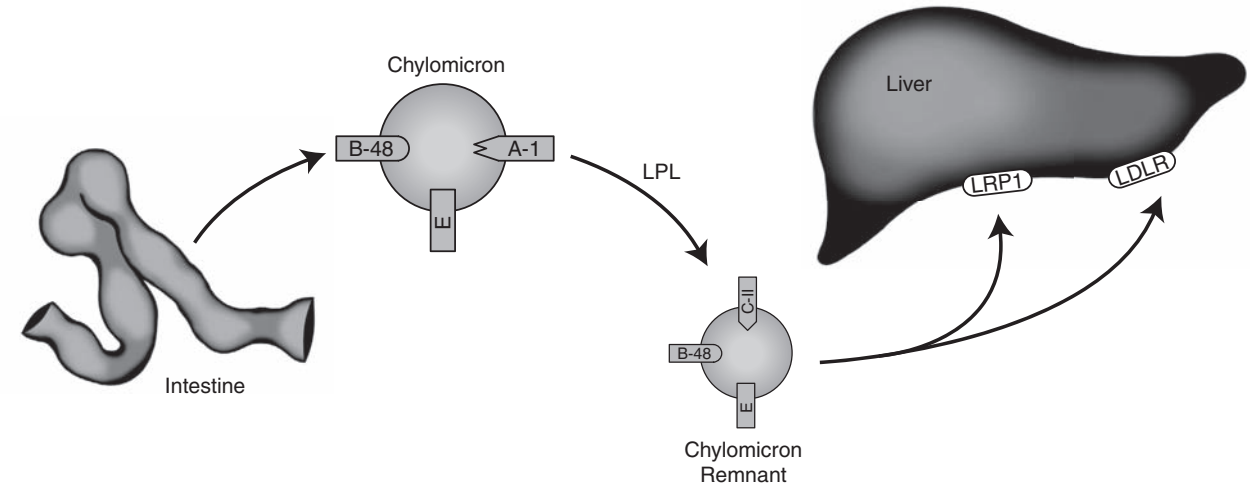

FIGURE 23-1 ■ Endogenous lipoprotein metabolism. See text for details. (Courtesy of Emilie Graham, University of Cincinnati.)

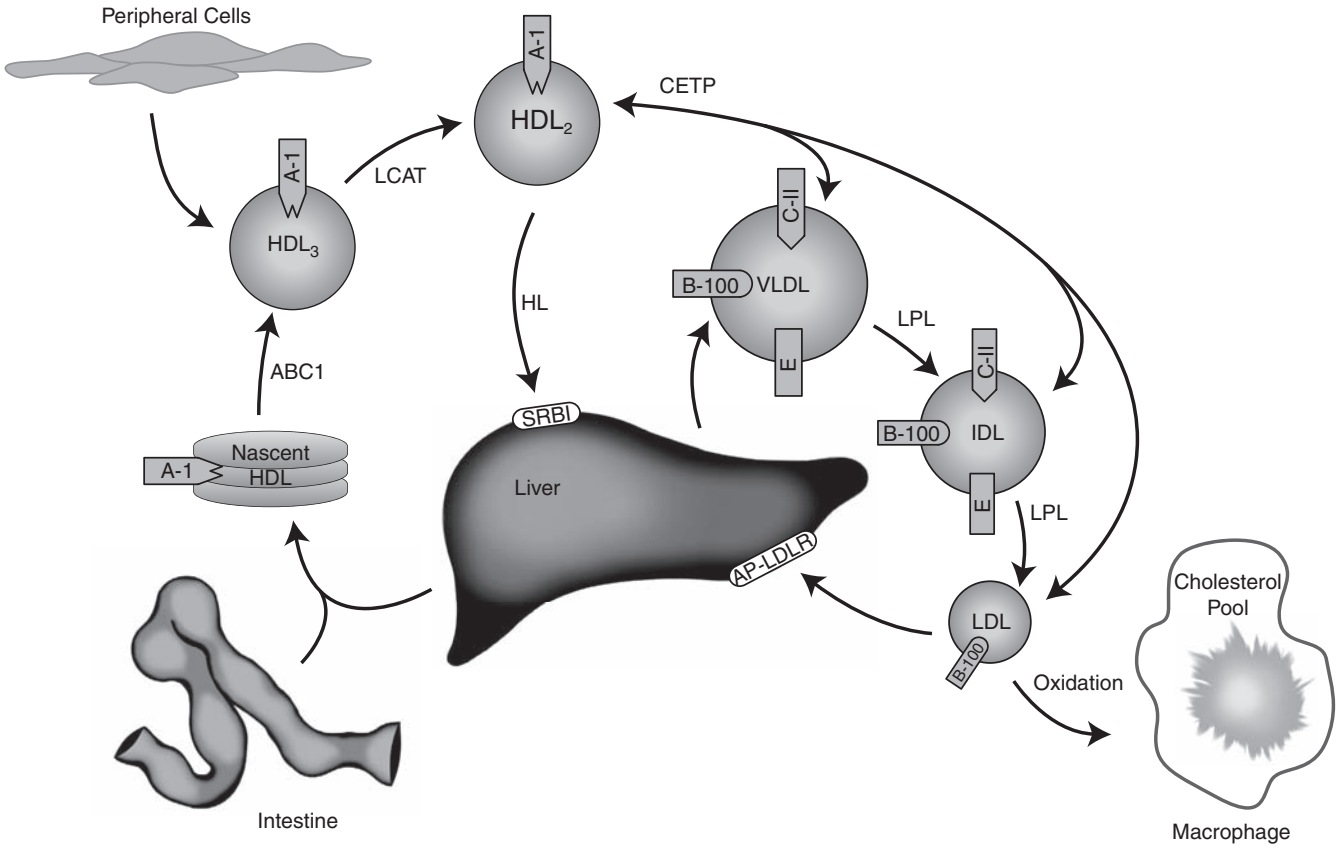

FIGURE 23-2 ■ Exogenous lipoprotein metabolism. See text for details. (Courtesy of Emilie Graham, University of Cincinnati.)

derived chylomicrons, the fatty acids contained within the VLDL triglyceride come from de novo synthesis from dietary carbohydrate, lipoprotein remnants, or circulating fatty acids internalized by the liver from plasma.[9] Within the hepatocyte, triglyceride and cholesterol ester are assembled by an MTP and surrounded with a phospholipid membrane associated with apoB-100.[8] The mature VLDL particles are released into the lymph and ultimately into the vascular space, where other apolipoproteins (including apoC-II, apoC-III, and apoE) adsorb to the VLDL surface. The metabolism of the VLDL particle follows a route similar to that of the chylomicron: apoC-II on its surface activates LPL, LPL hydrolyzes the VLDL triglyceride, the particle decreases in size (after an 80% loss of triglyceride), and ultimately apoC-II dissociates—resulting in the formation of VLDL remnants (also known as intermediate-density lipoproteins [IDLs]). Approximately half of the IDL is then removed from plasma through the interaction of apoB with the LDLR on the surface of liver cells.[9] The rest of the IDL is converted to LDL through further hydrolysis of core triglycerides by hepatic triglyceride lipase (HL).[14] ApoE is transferred from IDL to HDL during the transition of the remnant to LDL.[15]

LDL, the major carrier of cholesterol in plasma, is taken up into peripheral tissues and liver cells by the LDLR assisted by an adaptor protein (AP). The AP binds to the LDLR and clathrin, suggesting a role for AP in the recruitment and retention of LDLR in clathrin-coated pits.[16] Upon receptor binding, the LDL particle bound to LDLR/AP is rapidly internalized into clathrin-coated pits by endocytosis. Within the cell, the newly formed endosome becomes acidified through the action of an ATP-dependent proton pump.[17] Acidification causes degradation of the clathrin coat, dissociation of the LDLR from LDL, and subdivision of the endosomal membranes. The endosome containing the LDLR recirculates back to the cell membrane for additional LDL uptake. Alternatively, proprotein convertase subtilisin/kexin type 9 (PCSK9), binds LDLR, and short-circuits recycling of LDLR from the endosome, leading to its degradation.[18] The remaining LDL-containing endosome fuses with a lysosome, where hydrolytic enzymes digest the lipoprotein into its component parts: unesterified cholesterol, fatty acids, and free amino acids.[17]

The amount of cholesterol released from endosomal uptake regulates hepatic synthesis of LDLR and cholesterol. When cellular concentration of cholesterol is low, sterol receptor binding protein (SREBP) is released from the Golgi. SREBP translocates to the nucleus, where it serves as a nuclear factor that enhances the transcription of LDLR and hydroxymethylglutaryl (HMG) CoA reductase, the rate-limiting enzyme of cholesterol biosynthesis.[19] In this way, intracellular hepatic cholesterol concentration regulates the amount of cholesterol internalized and synthesized by the cell.

When excess LDL and other small apoB-containing lipoproteins (chylomicron remnants and IDL) are present in the plasma, the capacity of the LDLR to remove them is exceeded and these particles become more susceptible to oxidation. Oxidized apoB-containing lipoproteins can be taken up by scavenger receptors on macrophages in

the subendothelium of arteries and may contribute to the formation of atherosclerotic lesions.[20]

HDL transfers cholesterol and other lipids from peripheral tissues (including arterial atheroma) back to the liver. The particles are synthesized predominantly in the liver (and to a lesser extent in the intestine) as lipid-poor precursor particles (prebeta HDL) containing apoA-I (Figure 23-2).[9] Nascent HDL interacts with the plasma membrane of cells, collecting lipid through an ATP-binding cassette transporter-A1 (ABCA1) mechanism.[3,4] The cholesterol and phospholipids transferred through this process adsorb to the HDL, forming a disk-shaped particle referred to as HDL3. Within the plasma, HDL3 interacts with the enzyme lecithin cholesterol acyl transferase (LCAT)—which catalyzes the esterification of particle-associated cholesterol. ApoA-I on the HDL surface activates LCAT. Once formed, the cholesterol ester is more hydrophobic and moves to the interior of the particle—creating a sphere-shaped HDL particle known as HDL2.[21]

As HDL2 increases in size, the particle becomes substrate for cholesterol ester transfer protein (CETP). This enzyme promotes the exchange of esterified cholesterol within HDL2 for triglyceride contained within apoB-100–associated lipoproteins.[22] This lipid exchange is the primary mechanism whereby HDL participates in reverse cholesterol transport from tissues back to the liver. The rest of the cholesterol ester is selectively taken up from HDL by hepatocytes via a SRB1, without concomitant uptake of the entire HDL particle. This latter process may require the action of HL.[23] The lipid-poor prebeta HDL resulting from this process is released for recycling.[16]

PRIMARY DYSLIPIDEMIAS

Lipoprotein synthesis, transport, and metabolism occur in many steps and involve many specialized proteins. A number of genetic defects have been identified in these processes and are referred to as primary dyslipidemias. Most of these genetic defects present in childhood. Table 23-2 summarizes pediatric lipoprotein disorders with reference to the characteristic lipoprotein profile of each one. The genetic and metabolic etiologies of these disorders are detailed in the following material.

Disorders of Cholesterol Metabolism

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is the most common single gene disorder of lipoprotein metabolism. FH is inherited as an autosomal-dominant trait with relatively low prevalence in Western countries. The prevalence has been reported to be 10 times higher in certain populations with a presumed founder effect, such as the Lebanese, the French Canadians, and the South Afrikaners.[24] The heterozygous form is found in 1 in 500 persons, and the homozygous form is found in 1 in 1 million persons. The disorder is caused by a mutation in the LDLR gene.[25] More than 1100 mutations in this gene have been identified, including those that affect receptor synthesis, intracellular transport, ligand binding, internalization, and recycling.[26] In the heterozygous form, inheritance of one defective LDLR gene results in plasma LDL cholesterol levels two to three times higher than normal.[25]

Individuals with heterozygous FH are at an increased risk of developing early-onset coronary artery disease (CAD), usually between the ages of 30 and 60 years.[24] In the homozygous form, individuals inherit a mutant allele for FH from both parents, resulting in plasma LDL cholesterol concentrations that are four to six times higher than normal.[27] A more severe phenotype is found in individuals with receptor-negative mutations (those with <5% residual LDL receptor activity) compared to those with receptor-defective mutations (5% to 30% of normal LDL receptor activity).[28] Due to the excessively high plasma cholesterol levels in individuals with homozygous FH, cholesterol deposits are common in

TABLE 23-2 **Pediatric Lipoprotein Disorders***

Lipoprotein Disorder	Lipoprotein Analysis	Blood Lipids	Genetic Defect
Familial hypercholesterolemia	↑↑LDL	↑↑Cholesterol	LDL receptor (LDLR)

the tendons (xanthomas) and eyelids (xanthelasmas)—generally by the age of 5 years.[29] In the heterozygous form, xanthomas occur less frequently and generally not until one reaches older adulthood. Children with homozygous FH have early-onset atherosclerosis and often have myocardial infarction in the first decade of life, and death from CAD in the second decade. [29]

Autosomal Dominant and Autosomal-Recessive Hypercholesterolemia

Autosomal-dominant hypercholesterolemia (ADH) is another inherited disorder resulting in a phenotype that is expressed as marked elevations or low levels of LDL cholesterol. ADH is caused by mutations in proprotein convertase subtilisin/kexin type 9 (PCSK9).[30] This protein binds and favors degradation of the LDLR and thereby modulates the plasma levels of LDL cholesterol. Some of the naturally occurring PCSK9 mutations favor an increase in the function of the protein and cause hypercholesterolemia, whereas some favor a loss of function and are associated with low LDL cholesterol. The latter mutations appear to confer protection from developing CAD.

Autosomal recessive hypercholesterolemia (ARH) is caused by mutations in the ARH gene, which encodes the adaptor protein required for normal LDLR-mediated endocytosis in hepatocytes.[31] Several different mutations in this protein have been identified, all leading to a lack of or suboptimal internalization of the LDLR.[32] Cholesterol levels in individuals with ARH are five to six times higher than normal. Children with this disorder are clinically similar to those with homozygous FH. However, their parents usually have normal lipoprotein profiles. [31]

Familial Ligand-Defective ApoB-100

Familial ligand-defective apoB-100 (FDB) is a monogenic disorder that clinically resembles heterozygous FH. The disease is characterized by moderate to markedly high plasma LDL cholesterol levels, normal triglycerides, and tendon xanthomas. The disorder is caused by poor binding of the LDL particle to the LDLR due to a mutation in apoB-100.[33] Deficient LDLR binding results in a decreased clearance of LDL from plasma. The disorder is most common in individuals of European descent (1 per 1000).[9] Patients with FDB are at moderate to high risk of developing CAD.[34]

Sitosterolemia

Sitosterolemia is a rare autosomal-recessive disease caused by a mutation in either of two genes (ABCG5 or ABCG8) encoding the ABC half-transporters.[35] These genes are expressed in enterocytes and hepatocytes. The ABC half-transporters limit the absorption of cholesterol and plant sterols (and possibly shellfish sterols) in the gut. They also promote biliary and fecal excretion of cholesterol and phytosterols.[36,37] Defective proteins result in an abnormally high absorption of plant sterols (and, to a lesser extent, cholesterol) into the enterocyte and decreased excretion of these sterols from the liver into the bile. Plasma cholesterol can be mildly, moderately, or markedly elevated, whereas plant sterol concentrations in the plasma are markedly increased. Patients with sitosterolemia develop premature CAD and xanthomas in childhood, and may develop aortic stenosis.[35]

Disorders of Overproduction of VLDL

Familial combined hyperlipidemia (FCHL) is an autosomal-dominant disorder with a prevalence of 1% to 2% in Western populations.[38] Individuals with FCHL generally share the same metabolic defect, which is overproduction of hepatic VLDL. Families with FCHL have multiple patterns of hyperlipidemia, including hypercholesterolemia, hypertriglyceridemia, and elevated apoB levels. A diagnosis of FCHL is based on the presence of increased levels of cholesterol, triglyceride, or apoB in patients and their first-degree relatives.[38] Veerkamp and colleagues have developed a nomogram to calculate the probability that a person is likely to be affected by FCHL.[39] A classic feature of FCHL is that the lipoprotein profile is variable in the same individual over time and may depend on factors such as diet, exercise, and weight. FCHL can manifest in childhood but is usually not fully expressed until adulthood.[38] Patients with FCHL often have concurrent problems with insulin resistance, central obesity, and hypertension and are at an increased risk of premature CAD. [40]

Syndromes with a similar phenotype are hyperapobetalipoproteinemia, LDL subclass pattern B, and the clustering of CVD risk factors known as metabolic syndrome in adults.[38] Of the three, the latter syndrome is much more prevalent in children. Rates of metabolic syndrome are continuing to rise with the prevalence of obesity in the pediatric population.[41] There appears to be a mechanistic link between central obesity, insulin resistance, and dyslipidemia—with central obesity generally preceding both glucose and lipid abnormalities.

Disorders of Marked Hypertriglyceridemia

Familial Hypertriglyceridemia

Familial hypertriglyceridemia (FHTG) follows an autosomal-dominant inheritance pattern expressed predominantly in adulthood, with a population prevalence of ~5% to 10%.[38] The prevalence in children is increasing. Obesity is an important factor that can expedite the expression of FHTG, and patients often have concurrent glucose intolerance. The phenotype for FHTG is moderate to markedly high serum triglycerides (200 to 500 mg/dL range) and low to normal LDL and HDL cholesterol levels. The metabolic cause of the disorder is hepatic secretion of large triglyceride-rich VLDL particles that are catabolized slowly.[42] The fundamental genetic defect for FHTG has not been identified.

Familial Chylomicronemia Syndrome

Chylomicronemia syndrome is a compilation of rare monogenetic disorders that cause marked impairment of

lipoprotein lipase (LPL) activity. These disorders are phenotypically expressed as hypertriglyceridemia (usually triglycerides [TGs] > 1000 mg/dL) due to diminished or absent hydrolysis of chylomicron and VLDL-associated triglycerides by LPL.[43] Impairment of LPL activity may be related to LPL deficiency, apoC-II (cofactor for LPL) deficiency, or the more recently described apoA5 and glycosylphosphatidylinositol-anchored HDL-binding protein 1 (GPIHBP1) loss-of-function mutations that result in poor hydrolysis of chylomicron and VLDL-associated triglycerides.[44]

In homozygous chylomicronemia, fasting plasma has a viscous, creamy appearance due to the presence of large numbers of chylomicron particles. Risks for pancreatitis and hepatosplenomegaly are increased due to the markedly elevated serum triglycerides.[43] In addition, eruptive xanthomas and neurologic symptoms may be apparent. Individuals heterozygous for the syndrome may have a mild to moderate elevation in plasma triglycerides. Environmental factors such as weight gain may exacerbate hypertriglyceridemia. Premature CAD is generally not a feature of chylomicronemia, but cases have been reported.[44]

HYPOLIPIDEMIAS

Low HDL Cholesterol

In clinical practice, patients with low HDL cholesterol levels commonly have concurrent high triglycerides, with or without elevations in small dense LDL cholesterol.[38] These patients are usually obese, and the mechanistic explanation for this dyslipidemic triad is VLDL overproduction. Less common are familial disorders of HDL, including familial hypoalphalipoproteinemia, mutations of the apoA-1 protein, Tangier disease, and LCAT deficiency.[45] These disorders are characterized by a low HDL cholesterol level with no other lipid abnormality. Familial hypoalphalipoproteinemia follows an autosomal-dominant inheritance pattern.[46] ApoA-1 levels are also often low due to decreased production of HDL.

A number of mutations have been described in the apoA-1 gene and are associated with low HDL cholesterol and low apoA-1.[45,47] Tangier disease is due to mutations in the ABCA1 gene.[47] Patients affected by this disease are not able to actively withdraw cholesterol from cells onto nascent HDL particles, causing rapid degradation of the nascent HDL. ApoA-1 is rapidly cleared before it is able to acquire cholesterol. In Tangier disease, HDL cholesterol levels are close to zero and the apoA-1 levels are less than 5 mg/dL. The risk of premature CAD in these patients is mild to moderate.[46,47] LCAT deficiency is a very rare autosomal recessive disorder cause by mutations in LCAT, an enzyme synthesized by the liver and secreted into the plasma, where it associates with lipoproteins.[48] LCAT esterifies free cholesterol on the surface of HDL and enables the accumulation of cholesteryl esters in the core of HDL. In LCAT deficiency, lack of normal cholesterol esterification impairs formation of mature HDL particles, which are readily catabolized along with apoA-1. Remarkably, despite the extremely low levels of plasma HDL cholesterol (usually < 10 mg/dL) and apoA-1, premature CAD is not a consistent feature of this disorder.

Abetalipoproteinemia

Abetalipoproteinemia is associated with low serum cholesterol (< 50 mg/dL) and triglycerides (~2 to 45 mg/dL). Patients with this disorder present with steatorrhea and fatty liver. Without treatment, ataxia follows (with acanthocytosis and retinitis pigmentosa). Abetalipoproteinemia is caused by a defect in MTP.[49] Without MTP, no chylomicrons, VLDL, or LDL appear in the plasma. In these patients, HDL takes over as the primary cholesterol carrier. Thus, the defect is not fatal. Because of significant fat malabsorption, fat-soluble vitamin status is impaired.

In particular, because vitamin E absorption and cellular uptake require chylomicron and LDL transport, high doses of vitamin E are required to prevent retinal and sensory neuron degeneration. Additional dietary considerations include restricting long-chain dietary triglycerides to less than 15 g/day to alleviate the steatorrhea. Medium-chain triglycerides (MCT oils) can be used as an alternative source of energy.[44]

Hypobetalipoproteinemia

Hypobetalipoproteinemia is an autosomal-dominant disorder resulting from a defect in the apoB gene that produces a truncated apolipoprotein B.[50] Cholesterol levels in patients with heterozygous hypobetalipoproteinemia are usually 50% of those of an unaffected family member. The heterozygous form of this condition is benign. However, homozygous hypobetalipoproteinemia is associated with severe hypocholesterolemia, significant steatorrhea, fatty liver, acanthocytosis retinopathy, and peripheral neuropathy.[51]

Disorders with Lipoprotein Clearance via ApoE Pathways

Dysbetalipoproteinemia is characterized by elevated cholesterol and triglyceride levels.[38] The disorder results from the presence of a polymorphism of the apoE allele (apoE2, rather than the more common apoE3 or less common apoE4).[52] Metabolically, this defect results in a poor uptake of remnant particles and abnormal remnant catabolism because of the abnormal apoE. Increased remnants, VLDL, chylomicrons, and apoE are all present. Xanthomas may occur, and premature CAD has been reported. This lipoprotein disorder is rare in children and often presents in young adulthood.[38]

SECONDARY CAUSES

Secondary dyslipidemias can result from a variety of diseases and conditions (see Box 23-1). In the United States, the most prevalent cause of secondary dyslipidemia is overweight and obesity.[53] The dyslipidemic triad (namely, elevated triglycerides and small dense LDL and low HDL cholesterol) is commonly associated with overweight (in particular, with central adiposity).[53,54] In addition to dyslipidemia, insulin resistance and elevated blood pressure may be present. This cluster of abnormalities is

known in adults as the metabolic syndrome. Empirical evidence in children also indicates that obesity during childhood is associated with the same risk factor clustering seen in adults, that it continues into adult life, and that it is associated with an increased risk for accelerated early atherosclerosis.[55] The primary approach to treating this disorder in both adults and children is weight management. Improvement in weight status and a decrease in body fatness have been shown to be associated with improvements in the dyslipidemia and other comorbidities associated with obesity.[56]

Metabolic lipid perturbations in adult patients with types 1 and 2 diabetes mellitus are similar to those found in patients with the metabolic syndrome, but often are more severe.[57] Generally in adults with diabetes, triglycerides are elevated and HDL cholesterol is low—and LDL cholesterol can be normal or mildly or moderately elevated. Diabetes in adults is considered a CAD risk equivalent according to the National Cholesterol Education Program (NCEP). This means that the risk for developing CAD in patients with poorly controlled diabetes is equivalent to those with established CAD.[58] For this reason, the NCEP recommends aggressive treatment of dyslipidemia in adult patients with diabetes.

Although type 1 diabetes is currently the main form of diabetes seen in children, in the United States a growing number of patients with type 2 diabetes are under the age of 18 years.[59] Change in the prevalence of type 2 diabetes in youth is likely related to the growing obesity epidemic occurring in the pediatric population.[59,60] Data on lipid concentrations in children and adolescents with diabetes are few, particularly in those with type 2 diabetes.

The Search for Diabetes in Youth Study assessed the prevalence of serum lipid abnormalities among a representative sample of U.S. children and adolescents with type 1 and type 2 diabetes.[61] Findings from this study showed a substantial number of diabetic children over the age of 10 years with abnormal serum lipids: nearly 50% had an LDL cholesterol level above the optimal level of 100 mg/dL. For children with type 2 diabetes, 37% had elevated triglyceride levels and 44% had low HDL cholesterol. These data highlight the importance of serum lipid screening in children with diabetes. A growing body of literature also shows early vascular dysfunction in children with diabetes, regardless of type.[62] This is thought to be due to glycemic and lipid abnormalities associated with poorly managed diabetes. For this reason, new treatment guidelines recommend intensive glucose and lipid management for children with diabetes.[56] These guidelines are discussed later in the chapter.

Other causes of secondary dyslipidemia include hypothyroidism, nephrotic syndrome, other renal diseases, liver diseases, and infection.[63] The risk of development of atherosclerosis with these conditions is unknown but is likely proportionate to the length of exposure and extent of elevation in serum LDL cholesterol levels. Cardiovascular disease is common in patients with chronic renal insufficiency.[64] Dyslipidemias can also result from the ingestion of a variety of medications. These medications include progestins, estrogens, androgens, anabolic steroids, corticosteroids, cyclosporine, and retinoids. Secondary causes of dyslipidemias should be identified by patient historical data and a careful physical examination.[63] Laboratory tests (including thyroid, renal, and liver function panels) can confirm the diagnosis.

The treatment of dyslipidemia in patients with secondary causes is focused on managing the underlying disease. Diet and physical activity changes may also be recommended to reduce elevated LDL cholesterol and triglyceride levels.

VASCULAR CHANGES AND DYSLIPIDEMIA

It is well established that elevated concentrations of total cholesterol and LDL cholesterol in adult life are strong and reversible risk factors for CAD.[58] Whether dyslipidemia during childhood contributes to atherosclerotic lesions in coronary and other arteries has been a subject of debate, but accumulating evidence from pathology and in vivo imaging studies favors a relationship. Atherosclerotic lesions result from deposits of lipid and cholesterol in the intima of the arterial wall.[65] Early lesions, called fatty streaks, are formed from the accumulation of macrophages filled with lipid droplets (foam cells).

Fatty streaks do not disorganize the normal structure of the intima, do not deform or obstruct the artery, and are in and of themselves not considered harmful.[66] However, some continue to accumulate macrophage foam cells and extracellular lipid and smooth muscle cells—forming raised plaques. From these, more advanced lesions may develop—with further deposition of extracellular lipid, cholesterol crystals, collagen, and potentially calcium.[67] It is these raised lesions that result in a myocardial infarction because of their increasing size and obstruction of the arterial lumen or because of rupture of

the fibrous plaque, which results in the release of thrombogenic substances from the necrotic core.[67]

Pathobiologic studies of the coronary arteries of young individuals who died from causes unrelated to heart disease have been useful in documenting the progression of atherosclerosis by age and risk factor determinants. Stary and colleagues studied more than 500 postmortem samples of coronary arteries from persons younger than 30 years of age and found the presence of fatty streaks in the majority of children younger than 9 years of age, raised lesions in about half of adolescents, and more advanced lesions in about a third of the young adults studied.[68] In 93 autopsies of young adults for whom childhood risk factor data were available, Berenson and colleagues found that the extent of the surface of arteries covered with fatty streaks and fibrous plaques was positively associated with LDL cholesterol, triglycerides, blood pressure, and body mass index and negatively associated with HDL cholesterol levels in childhood.[69]

The Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study reached similar conclusions from examination of more than 3000 postmortem samples of coronary arteries of young adults who died from noncardiovascular events and who likewise had a variety of surrogates for antimortem risk factor measures available.[70] In general, pathology studies have made important contributions to the identification of risk factors for early aspects of the atherosclerotic process. In conjunction with findings from longitudinal studies such as the Framingham Heart Study (in which risk factor assessments of participants preceded the development of cardiovascular disease),[71] a group of risk factors, often referred to as the traditional risk factors for CAD, has been established. A complete list of pediatric risk factors for CAD is found in Box 23-2.

Advances in vascular imaging technology have provided a means of measuring early pathologic changes and functional abnormalities against coronary and other arteries in response to adverse changes in cardiovascular disease risk factors. The advantage in using this technology is that walls of superficial arteries can be imaged noninvasively in real time at high resolution, and changes to the arterial wall can be measured as a continuous variable from childhood to adulthood in patients with and without the presence of risk factors for CVD.[72] Computed tomography (CT) scanning is considered one of the most sensitive noninvasive tools for imaging the extent and location of coronary artery calcium present in atheroma.[73]

The presence of coronary artery calcium has been associated with adverse cardiovascular disease outcomes in adults.[74] In adolescents, small studies have shown associations among hypercholesterolemia, body mass index (BMI), and significant coronary artery calcium. In the Muscatine Study in which participants were assessed for CVD risk factors during their school-age years and later assessed for cardiovascular changes by CT scan, 31% of men and 10% of women aged 29 to 37 years had significant coronary artery calcification.[75] In this study, childhood risk factors associated with calcification were obesity, increased blood pressure, and low HDL cholesterol. Gidding and colleagues showed significant coronary calcium by electron bean CT in 7 of 29 young adults with heterozygous familial hypercholesterolemia.[76] Overweight was found to increase the likelihood of calcium being present in individuals already at high risk.

Vascular ultrasound imaging has been utilized to assess alterations in brachial artery flow-mediated dilation, which is a measure of endothelial function, and carotid intima-media thickness (IMT).[73] In adults, both measures have been associated with adverse changes in traditional cardiovascular disease risk factors,[77] respond to normalization of risk factors,[78] and are considered important early markers for the progression of atherosclerotic disease.[77-80] Although few studies have used ultrasound technology to evaluate coronary arteries in the young, children with hypercholesterolemia have been assessed using measures of the carotid and brachial arteries and have been found to have abnormalities of carotid IMT and brachial artery vasodilation.[81-83]

Further, in young adults aged 33 to 42 years who had comprehensive risk factor assessments performed some 25 years prior, Davis and colleagues found an association between mean carotid IMT and elevations in total cholesterol and triglyceride concentrations during childhood.[84] Lavrencic and associates found that the mean carotid IMT was significantly greater in youth with FH compared with those in a control group—as well as being significantly greater in all subjects in regard to total cholesterol, LDL cholesterol, and systolic blood pressure.[85] Similar risk factors have been associated with impaired vasodilation, indicating endothelial dysfunction.[86-88]

In summary, these studies confirm the utility of vascular imaging for detecting early pathologic and functional changes to coronary vessels and associations with modifiable CVD risk factors in the young. Clinically, vascular imaging by ultrasound may be a valuable means of estimating the benefit of treating multiple CVD risk factors in children and adolescents. However, the collection of more normative data across age, race, and gender groups and longitudinal studies to determine age and puberty-related

BOX 23-2 Pediatric Risk Factors for Coronary Artery Disease

Positive Risk Factors

- Elevated LDL cholesterol (≥ 130 mg/dL)
- Family history of premature (aged > 55 years) coronary heart disease, CVD, or peripheral vascular disease
- Smoking
- Hypertension
- Obesity (≥ 95th percentile weight for height on National Center for Health Statistics [NCH] growth chart)
- Physical inactivity
- Diabetes

Negative Risk Factors

- High HDL cholesterol (> 60 mg/dL)

changes in these measures is needed before these methods could be adopted in clinical evaluation.[89] In general, CT scans may be less useful in younger patients because calcium depositions are uncommon before young adulthood.

SCREENING FOR LIPID DISORDERS

Routine Screening

The approach to pediatric screening for dyslipidemia has been controversial. Since the 1990s, pediatric guidelines established by the National Cholesterol Education Program (NCEP) have provided the standard of care with respect to lipid screening and treatment of dyslipidemia in children.[90] These guidelines recommend selective blood cholesterol screening in children based on a positive family history of premature CVD (prior to age 55 years), presence of dyslipidemia in a parent (total cholesterol > 240 mg/dL), or presence of additional CVD risk factors in the child such as hypertension, diabetes, and obesity. If family history is unknown, recommendations suggest that lipid screening of a child be done at the discretion of the primary care provider. These guidelines have served as the basis for related recommendations from the American Academy of Pediatrics,[91] the American Heart Association,[92] and the American Diabetes Association.[60]

The controversy regarding the NCEP targeted screening approach stems largely from studies showing that the NCEP family history–based approach compared to a universal or general approach to childhood screening for dyslipidemia missed many children with moderate dyslipidemia (as many as 30% to 60%) and failed to detect a substantial number who likely had genetic dyslipidemia who might require more intensive therapy.[93] Familial hypercholesterolemia (FH) is a relatively common problem, with the heterozygous form occurring in 1 in 500 individuals.[26,27] FH has been clearly associated with an increased lifetime risk of atherosclerotic CAD, and earlier treatment is associated with reduced subclinical evidence of atherosclerosis.[27] To increase the likelihood of detecting young patients with FH and other genetic dyslipidemias, the National Lipid Association[94] and more recently the National Heart, Lung, and Blood Institute (NHLBI) Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents[56] recommended universal lipid screening for children ages 9 to 10 years.

These newer recommendations recognized that there is considerable variation in LDL cholesterol with age during growth and development, especially during puberty.[95,96] Total and LDL cholesterol levels tend to decline during puberty, meaning that some adolescents will appear normal when in fact they will have elevated levels after puberty.[95] For this reason, 9 to 10 years of age was selected as a good age to screen, before the effect of puberty lowers LDL cholesterol levels, but closer to an age when drug therapy may be appropriate.[56] Additionally, the National Lipid Association (NLA)[94] and the expert panel[56] agreed that lipid screening should occur earlier (≥ 2 years of age) in the following conditions: presence of a positive family history for hypercholesterolemia or premature coronary heart disease (CHD) or the presence of major CHD risk factors such as hypertension, diabetes, and obesity.

The expert panel[56] also added nonfasting HDL cholesterol as a new screening tool for the identification of dyslipidemia in children. Non-HDL cholesterol is calculated by subtracting the HDL cholesterol from the total cholesterol. This measure reflects the amount of cholesterol carried by atherogenetic apolipoprotein B–containing lipoproteins (VLDL, IDL, and LDL). In both adults and children, non-HDL cholesterol has been determined to be more predictive of persistent dyslipidemia and therefore atherosclerosis and future CVD events than total cholesterol, LDL cholesterol, or HDL cholesterol alone.[97] A major advantage of non-HDL cholesterol is that it can be accurately calculated in a nonfasting state and is therefore practical to obtain in a primary care setting. Percentiles for non-HDL cholesterol have been established (Table 23-3) and are based on data from the Bogalusa Heart Study,[98] where non-HDL cholesterol ≥ the 95th percentile is

TABLE 23-3 **Normal Plasma Lipid and Lipoprotein Concentrations (mg/dL) for Children and Adolescents***

Category	Low	Acceptable	Borderline	High
Total cholesterol	—	< 170	170-199	≥ 200
LDL cholesterol	—	< 110	110-129	≥ 130
Non-HDL cholesterol	—	< 120	120-144	≥ 145
Apolipoprotein B	—	< 90	90-109	≥ 110

HDL cholesterol	< 40	> 45	40-45	
Apolipoprotein A-1	< 115	> 120	115-120	—

*Values for plasma lipids and lipoproteins are from the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents (2011). Summary report. Pediatrics 128:S1-S44.

LDL, low-density lipoprotein; HDL, high-density lipoprotein.

considered "abnormal/high" and between the 75th to 95th percentile is considered "borderline."

If a nonfasting non-HDL cholesterol is found to be abnormal, a fasting (12-hour) lipoprotein analysis is recommended[56] to allow quantification of total cholesterol, HDL cholesterol, triglycerides, and calculation of LDL cholesterol. The Friedewald equation—LDL cholesterol = total cholesterol − (HDL cholesterol + triglycerides/5)—can be used to calculate LDL cholesterol as long as the serum triglyceride level is < 400 mg/dL.[99] Direct measurement of LDL cholesterol concentration is available through some commercial laboratories and is indicated for individuals whose fasting triglyceride level is ≥ 400 mg/dL.

The lipid/lipoprotein cut points to be used in screening are presented in Table 23-3. Cut points for total cholesterol and LDL cholesterol in children are from the NCEP report.[90] The 75th and 95th percentiles for lipid values from this report were used to define "borderline" and "high" risk categories, respectively. If a lipoprotein analysis reveals LDL cholesterol to be borderline or high, there is consensus among guidelines that the test should be repeated and the average value of the two tests be considered for clinical decision making.[56]

Although the NCEP report provided population percentiles for triglyceride and HDL-C concentrations, recommended cut points for these variables were not established back in 1992.[90] Measurement of these variables has become more important because they are part of the clustering of risk factors associated with the growing epidemic of pediatric obesity in the United States.[54] Data from pathology and imaging studies show adverse changes in vascular structure and function in adulthood related to low HDL cholesterol and high triglyceride levels in childhood.[89] Therefore, the latest guideline[56] recommends cut points for triglycerides and HDL cholesterol based on percentiles provided by the NCEP.[90] The 75th and 95th percentiles for triglyceride values were used to define "borderline" and "high" risk categories, respectively, and the 25th and the 10th percentiles were used to define "borderline" and "high" risk groups for HDL cholesterol (see Table 23-3).

Although well-standardized immunochemical methods are available for the determination of apoB and apoA-1 measurements, guidelines suggest that measurements of apolipoproteins for universal screening provide no additional advantage over measuring non-HDL cholesterol, LDL cholesterol, and HDL cholesterol levels, except in youth with premature CVD in parents.[100,101] Cut points for apoB and apoA-1 from the National Health and Nutrition Examination Survey (NHANES) should be used in these cases[100] (see Table 23-3). Measurement of lipoprotein subclasses and their sizes in children and adolescents by advanced lipoprotein testing has been found to have no sufficient clinical utility to warrant routine use.[56]

Clinical evaluation of children and adolescents at high risk for CVD based on abnormal lipid levels should include a careful review of the patient's medical and family history and physical examination to identify additional risk factors and secondary causes of dyslipidemia. Assessment should include the following: review of past medical or family history for hypertension, diabetes mellitus, medication use, obesity, poor dietary habits (including excessive intake of saturated fat), sedentary behavior, and tobacco use; measurement of height, weight, and calculation of BMI; Tanner staging to assess pubertal growth; blood pressure measurement; physical inspection of skin, eyes, and tendons for lipid deposition and palpitation of the thyroid gland and liver for signs of enlargement; and laboratory tests (including thyroid, renal, and liver function panels). Glucose and insulin levels should be measured to assess for the presence of metabolic syndrome or diabetes.

Genetic Testing

Increasingly, DNA-based tests are being used to confirm the diagnosis of FH in patients with a family member who has a mutation or in a young patient with high LDL cholesterol with tendon xanthomas or atherosclerotic disease.[102] Currently, three genes (LDLR, apoB, and PCSK9) have been identified in association with mutations that cause this disorder.[103] In addition to LDLR, most laboratories test for the apolipoprotein B gene r500Q mutation. Rapid and relatively inexpensive methods have been developed to test a selected subset of the LDLR mutations. However, more expensive "complete gene scans" are needed for mutation-negative samples.[103] Once a mutation is identified, relatives can be tested rapidly and cheaply.

At present, it is unclear whether knowledge of specific mutations will lead to improved treatment. Several studies have shown that the degree of cholesterol lowering achieved by statins is influenced by the type of mutation (e.g., individuals with the APOB r3500Q mutation showed a strong positive response to statin therapy).[104,105] In addition, the diagnosis of FH based on genetic testing improved uptake and adherence to treatment in several studies.[106,107] Concerns remain about the long-term benefits and potential side effects from lifelong treatment with statins for identified children. As progress in this area continues, current treatment algorithms may need modification to describe the role of genetic testing in clinical practice.

DIET THERAPY IN MANAGING DYSLIPIDEMIA

New pediatric nutrition recommendations from the expert panel[56] support a two-pronged dietary approach to managing pediatric hypercholesterolemia: one geared to the population in general and the second focused on an individualized treatment of dyslipidemia, including an approach to elevated LDL-C and an approach to elevated triglycerides. On the population level for healthy infants, the expert panel[56] has recommended breastfeeding as optimal to 12 months of age if possible with supplementation of complementary foods when appropriate; the introduction of iron-fortified formula is recommended if breastfeeding is stopped or reduced before 1 year of age. Previous nutrition recommendations from the NCEP[90] did not include recommendations for

infants; however evidence in favor of the sustained cardiovascular benefits of breastfeeding, including lower total cholesterol, BMI, and carotid IMT into adulthood, is now strong.[108-110] These guidelines are in accordance with the Surgeon General's Office, the World Health Organization, the American Academy of Pediatrics, and the American Academy of Family Physicians.

The 2010 Dietary Guidelines for Americans (DGA)[111] provide optimal nutrition guidance for primary care providers to use in promoting nutrient adequacy and CVD risk reduction in children > 2 years of age. In keeping with the goal of reducing chronic disease risk among all Americans, the DGA support a dietary fat composition of 25% to 35% of calories, with less than 10% of calories from saturated fat, fewer than 300 mg of cholesterol per day, and no or minimal trans fats included. The DGA also emphasizes setting an appropriate daily calorie goal for healthy weight stability. This dietary pattern closely matches the former NCEP Step 1 diet[90] and is viewed as a primary preventive measure to optimize serum lipids, thereby reducing the risk of CVD in the pediatric population at large. Similar food-based dietary recommendations are available through the World Health Organization (www.fao.org/docrep/X0243E/x0243e00.htm).

Within appropriate gender- and age-specific requirements for growth and development in normal children and children with dyslipidemia, the expert panel[56] has recommended an early transition (between 1 and 2 years of age) to reduced fat, unflavored milk (from whole to 2%), and a dietary composition that matches that recommended by the DGA.[111] Advice to transition early to a low-fat diet (minimum of 30% of total calories to age 2 years) is supported by data from the ongoing Special Turku Risk Intervention Program (STRIP) study,[112-114] which showed that limiting total fat, saturated fat, and dietary cholesterol to DGA levels could be instituted safely after 6 months of age under medical supervision and lowered total cholesterol, LDL cholesterol, and BMI more than a usual higher-fat diet. The expert panel[56] has cautioned that any dietary changes initiated during childhood should be tailored to the child to ensure optimal growth and development and administered under the guidance of the child's primary care physician. Estimated calorie requirements based on age and gender at three levels of physical activity from the Institute of Medicine[115] are found in Table 23-4.

The expert panel's[56] population approach for youth ages 4 years and older encourages consumption of a plant-based diet comparable to the Dietary Approaches to Stop Hypertension (DASH)[116] dietary pattern. This dietary pattern recommends 7 to 10 servings/day of fruits and vegetables and 6 to 10 servings of breads, cereals, and grains. Whole fruits and vegetables rather than juice and whole grains rather than processed grains are encouraged. Key sources of saturated fat and cholesterol are moderated on the DASH dietary plan. For example, red meats are limited to modest amounts of lean cuts (e.g., 5 to 6 oz per day) and dairy products are limited to skim or low-fat varieties (24 to 32 oz/day). Plant-based foods should constitute the largest proportion of energy in children's diets. Most choices within these food groups are low in fat, cholesterol free, and high in fiber—and will help displace energy sources containing saturated fat.[117-118] The major health benefits of a DASH style of eating are lowered blood pressure, improved lipids, and improved weight status.[119,120] Box 23-3 highlights some practical dietary strategies for lowering saturated fat and cholesterol in the diets of the young.

For the individual child with identified dyslipidemia, a positive family history of premature CVD, obesity, or hypertension, the expert panel[56] has recommended initiating the same dietary approach recommended for the general population (as described previously). The expert panel has deemed this plan the Cardiovascular Health Integrated Lifestyle Diet (CHILD-1) and considers this the first line of therapy to remediate CVD risk factors with a primary target of lowering LDL cholesterol levels. If LDL cholesterol levels remain abnormal (LDL cholesterol ≥ 130 mg/dL) after 3 to 6 months of dietary adherence to the CHILD-1, further restriction of dietary saturated fat (< 7% of total calories) and cholesterol (< 200 mg/day), referred to as the CHILD-2 (LDL), is recommended. Repeated studies have shown that a stepwise dietary saturated fat reduction to 7% of total calories and cholesterol to 200 mg/day is safe and efficacious in lowering LDL cholesterol in children with hypercholesterolemia.[121-123]

TABLE 23-4 **Estimated Calorie Needs per Day by Age, Gender, and Physical Activity Level***

Gender	Age (Years)	Calorie Requirements (kcals) by Activity Level		
		SEDENTARY	MODERATELY ACTIVE	ACTIVE
Child	2-3	1000-1200	1000-1400	1000-1400
Female	4-8	1200-1400	1400-1600	1400-1800
	9-13	1400-1600	1600-2000	1800-2200
	14-18	1800	2000	2400
Males	4-8	1200-1400	1400-1600	1600-2000
	9-13	1600-2000	1800-2200	2000-2600
	14-18	2000-2400	2400-2800	2800-3200

*Estimated amounts of calories needed to maintain caloric balance for various age and gender groups at three different levels of physical activity are from the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents (2011). Summary report. Pediatrics 128:S1-S44.

BOX 23-3 Practical Dietary Strategies for Lowering Saturated Fat and Cholesterol

- Eat 7 to 10 servings of fresh, frozen, or canned fruits and vegetables daily.
- Use vegetable oils and soft margarines low in saturated fat and trans fatty acids instead of butter or most other animal fats in the diet.
- Eat whole-grain breads and cereals rather than processed grain products.
- Use nonfat (skim) or low-fat milk and dairy products daily.
- Eat more fish, especially oily fish (broiled or baked).
- Eat lean cuts of meat, and trim any obvious fat from red meat before cooking.
- Take the skin off chicken or turkey and eat only the white meat.
- Avoid processed meats such as hotdogs, sausage, and bologna.
- Avoid creams or sauces made with butter or whole-milk dairy products.
- Choose low-fat snacks such as ginger snaps, graham crackers, pretzels, plain popcorn, animal crackers, and vanilla wafers.
- Use recommended portion sizes on food labels when preparing and serving food.

Low-fat diets should be designed to be nutritionally adequate and consultation with a registered dietitian is particularly helpful in that regard. In some studies, lower intakes of calcium, zinc, vitamin E, and phosphorus on low-fat diets were reported for diets initiated without medical supervision.[123] To prevent overzealous implementation of a very low fat diet for children with dyslipidemia, which could lead to failure to thrive,[124] the expert panel[56] has recommended 25% as the lower end of the range for total fat calories, consistent with the acceptable macronutrient distribution range stipulated by the DGA[111] for children ≥ 2 years of age. In most cases, dietary compliance to the CHILD-2 diet should normalize borderline-high LDL cholesterol levels. The reported response to diets with this composition of total fat, saturated fat, and cholesterol in children with LDL cholesterol levels > 130 mg/dL has ranged from 3% to 10%.[125,126]

For children older than 2 years of age with persistently high LDL cholesterol levels, additional dietary adjuncts can be used. These may include margarines containing plant stanol/sterol esters or water-soluble fibers, such as psyllium. About three servings of stanol containing margarine daily (equivalent to approximately 2 g/day), consumed as part of a low-fat diet, can reduce LDL cholesterol by 5% to 15%.[127-129] Psyllium at a dose of 6 g/day added to a low-fat diet may provide an additional 5% to 10% reduction in LDL cholesterol.[129,130] The extent to which LDL cholesterol is lowered may depend on previous dietary intake and baseline LDL cholesterol levels. Dietary supplements are covered in more detail later in the chapter (dietary additives and supplements).

For children with elevated triglycerides or low HDL cholesterol, the expert panel[56] has recommended following the CHILD-2 (TG) dietary pattern, which includes reducing one's intake of simple sugars from processed desserts, snacks, and sugared-sweetened beverages. Foods that are high in simple sugar generally add excess calories to the diet, which may contribute to weight gain and elevate serum triglycerides.[131] Weight management should be a goal of diet therapy for children with a BMI ≥ the 85th percentile. Weight-reduction approaches should focus on decreasing the child's weight-for-height percentile while maintaining linear growth.[132] Although weight loss may temporarily lower HDL cholesterol, weight stabilization at a new lower level will lead to a gradual increase in HDL cholesterol over time.[133] Fish oils from fatty fish, such as salmon and tuna, contain omega 3 fatty acids, which may also help to lower serum triglycerides.[134] Increased physical activity should be encouraged with a goal of 1 hour per day of moderate to vigorous activity, and sedentary activities (such as watching television viewing and playing computer and video games) should be limited to no more than 2 hours per day.[56]

PHARMACOLOGIC MANAGEMENT

For many children with moderately or severely elevated LDL cholesterol, which usually results from a genetic dyslipidemia, diet alone will not lower their cholesterol levels to the acceptable or even borderline range. In these cases, lipid-lowering drug therapy will be required to achieve LDL cholesterol treatment goals in children age 10 years and older. Long-term drug therapy is associated with a decreased incidence of heart disease and overall mortality in adults.[58] Although no studies directly demonstrate the efficacy of administering lipid-lowering drug therapy in children to prevent CVD, there is evidence from vascular imaging studies that statins may delay the atherosclerotic disease process.[135-137]

The expert panel[56] has recommended using medication in patients who are at least 10 years of age and whose postdietary (e.g., CHILD-1 → CHILD-2 after 6 months) LDL cholesterol level is ≥ 190 mg/dL or whose LDL cholesterol level is ≥ 160 mg/dL and there is a family history of early CVD, with at least one high-level or at least two moderate-level risk factors for CVD. In children with FH who have substantially elevated LDL cholesterol, medication management may need to be started earlier than age 10.[137] A lipid specialist should be consulted in these cases. A follow-up LDL cholesterol assessment is recommended 6 weeks after starting drug therapy and every 3 months thereafter until LDL cholesterol goals are met. Thereafter, follow-up can be less frequent.

For children in general, the goal for LDL cholesterol is < 130 mg/dL. For children with diabetes, the goal for LDL cholesterol is < 100 mg/dL.[60,138] The lower LDL cholesterol goal for children with diabetes reflects a synthesis of pediatric guidelines and treatment recommendations for adults with diabetes that now consider the presence of diabetes a coronary heart disease risk equivalent.[58] Table 23-5 summarizes the recommendations of the expert panel[56] regarding lipid screening

TABLE 23-5 **Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents Recommendations for Lipid Management of Children and Adolescents with Diabetes***

	Type 1 and Type 2 Diabetes Mellitus
Screening	After glycemic control > 2 years at diagnosis if other CVD risk factors; otherwise at 10 years; if normal, rescreen every 5 years At diagnosis regardless of age; if normal, rescreen every 2 years
Lipid goals	LDL-C ≤ 100 mg/dL Non-HDL-C < 120 mg/dL Triglycerides < 90 mg/dL
Treatment strategies	Glycemic control Diet (CHILD-1→CHILD-2) Physical activity Weight reduction if appropriate Medication indications if initial management fails: • Age ≥ 10 years • If LDL > 160 mg/dL • If LDL 130-159 mg/dL consider based on CVD risk profile • Statins with or without resins • Fibrates if TG > 1000 mg/dL • Manage other CVD risk factors (see Table 23-4) if appropriate

*Recommendations are from the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents (2011). Summary report. Pediatrics 128:S1-S44.
CVD, cardiovascular disease; LDL, low-density lipoprotein; HDL, high-density lipoprotein.

and management of children and youth with diabetes. Medications used in the treatment of specific lipid abnormalities are summarized in Table 23-6 and are reviewed in the following material.

Bile Acid–Binding Agents

Bile acid–binding agents lower serum cholesterol indirectly by binding with bile acids in the gastrointestinal tract. This action prevents their reabsorption into the enterohepatic circulation, resulting in their loss from the body and removal from the cholesterol pool.[139] To compensate for this loss, the liver increases endogenous cholesterol synthesis and up-regulates LDL-receptor synthesis—thereby lowering LDL cholesterol levels in the blood. In bile-acid resin trials in children, a dose of 8 g/day while on a cholesterol-lowering diet resulted in a decrease in LDL cholesterol ranging from 10% to 20%.[140,141]

Bile-acid resins come in powder and tablet form. The powder is usually taken twice daily (4-g scoop) mixed with water or juice. Resins in this form tend to be gritty in texture and children complain that they are unpleasant to drink. Tablets are more palatable but are large and difficult for some children to swallow. Overall, studies report poor to fair compliance with the medication.[139,142] Side effects are few and are mainly gastrointestinal in nature, including constipation and gas. These can be minimized with increased intake of water and fiber. Resins may increase triglyceride levels and may interfere with the absorption of certain medications and fat-soluble vitamins.[143] Supplementation with a multivitamin and folate (1 mg daily) is usually recommended.[139]

HMG-CoA Reductase Inhibitors

HMG-CoA reductase inhibitors (also known as statins) lower LDL cholesterol in the blood by blocking hepatic HMG Co-A reductase, the rate-limiting enzyme in cholesterol biosynthesis.[137] This action depletes the intracellular cholesterol pool, leading to an up-regulation of LDL receptors and a decrease in serum cholesterol. Doses ranging from 5 to 40 mg/day in children with familial hypercholesterolemia have resulted in a 23% to 40% lowering of LDL cholesterol.[135-137] Statins may be taken in combination with bile acid–binding agents for patients who fail to meet LDL cholesterol targets with statin monotherapy. No adverse effects of the combined therapies were noted in a pediatric trial of the medications, and the efficacy of the two medications taken together was additive.[94]

In vivo imaging studies have demonstrated improvements in surrogate markers for atherosclerosis with statin therapy. Reversal of endothelial dysfunction and regression of carotid IMT have been reported in children treated with statins over a 2-year period.[136,137] This latter finding suggests that the initiation of lipid-lowering statins in childhood may inhibit progression or might even lead to a regression of atherosclerosis.

Adverse effects of the medication are few but have included gastrointestinal (GI) complaints, elevated liver transaminase and creatine kinase (CK) levels, and myositis.[139,143,144] For this reason, statins would not be recommended for patients with liver disease. Follow-up of patients treated with statins should include a laboratory assessment of liver transaminase and CK levels and identification of adverse physical symptoms such as muscle cramps.

TABLE 23-6 **Drugs Used in the Treatment of Pediatric Lipid Disorders**

Class of Medication	Common Name	Mechanism of Action	Change in Lipid Profile	Adverse Effects
Bile acid–binding agents	Cholestyramine Colestipol Colesevelam	Binds intestinal bile acids; more cholesterol converted into bile acids; decrease hepatic cholesterol pool	↓ LDL ↑ TG	Constipation Abdominal cramping
HMG Co-A reductase inhibitors	Atorvastatin Simvastatin Pravastatin Rosuvastatin Lovastatin Fluvastatin	Inhibits cholesterol synthesis in hepatic cells; decreases cholesterol pool resulting in up-regulation of LDLR	↓ LDL ↓ TG ↑ HDL	Dyspepsia ↑ Liver transaminases ↑ CK Myositis
Fibrates*	Fenofibrate	Increases degradation of VLDL cholesterol and TG; hepatic synthesis of VLDL may be decreased	↓ TG ↑ HDL	Constipation Myositis Anemia
	Gemfibrozil			
Niacin*	Niacin extended release	Inhibits release of free fatty acids from adipose tissue; decreases VLDL and LDL cholesterol production and HDL cholesterol degradation	↓ LDL ↓ TG ↑ HDL	Flushing Headache ↑ Liver transaminases
Cholesterol absorption blocker*	Ezetimibe	Inhibits intestinal absorption of cholesterol and plant sterols	↓ LDL	Not reported in children or adolescents

*Not FDA approved for youths (as of this writing).
CK, creatine kinase; LDLR, low-density lipoprotein receptor; VLDL, very low density lipoprotein; LDL, low-density lipoprotein; TG, triglycerides; HDL, high-density lipoproteins.

Because statins are potentially teratogenic, it is essential that physicians determine that adolescent girls are not pregnant or likely to become pregnant before initiating therapy.[139] The longest statin trials have been 2 years in length. Thus, whether statins adversely affect long-term growth and development and are safe for lifelong use has not been ascertained. Longer-term safety and efficacy studies are needed, particularly with a follow-up of vascular end points.

Inhibitors of Cholesterol Absorption

Ezetimibe is a cholesterol-lowering agent that prevents the absorption of cholesterol and plant sterols by inhibiting the passage of sterols across the intestinal wall.[145] The reduction in cholesterol absorption leads to a decrease in hepatic cholesterol uptake and availability. As a result, there is a compensatory increase in hepatic cholesterol biosynthesis, an up-regulation of LDL receptor expression, and an overall decrease in blood LDL cholesterol levels. In children and adolescents, a daily intake of 10 mg/day reduced LDL cholesterol by approximately 20%.[78] Currently ezetimibe has not been systematically studied, and the Food and Drug Administration (FDA) has not approved it for use in children.

Fibric Acid Derivatives

Fibric acid derivatives (also known as fibrates) lower blood triglyceride levels by increasing degradation and reducing the hepatic production of VLDL.[139,145] The drug also increases the production of apoA-I, resulting in higher HDL cholesterol levels. Side effects are similar to those for statins and include GI complaints, elevated liver transaminase activity, and myopathy.[139] For this reason, fibrates are not recommended for use with statins. These medications are not FDA approved for use with children and adolescents and should be used only in consultation with a lipid specialist for adolescents with genetic hypertriglyceridemia.[56]

Niacin

Niacin decreases hepatic VLDL production, leading to decreased production of LDL cholesterol.[139,145] Children with heterozygous FH treated with 1000 to 2250 mg of niacin daily over an average of 8 months showed a 23% to 30% reduction in LDL cholesterol.[146] However, 76% of the children had adverse effects from therapy (e.g., flushing, headache, nausea, glucose intolerance, myopathy, abnormal liver function) and 38% discontinued the drug. Niacin is not recommended for children younger than 2 years of age and is generally not used to treat children with FH unless LDL cholesterol is persistently elevated or unusual hypertriglyceridemia and low HDL cholesterol are present.[56] Niacin given in combination with statins has been used to treat homozygous FH. Niacin is available in immediate and slow-release forms (Niaspan, Slo-Niacin).

Dietary Additives and Supplements

Plant sterols and stanols consumed at levels of 2 g per day have been shown to reduce LDL cholesterol levels by 9% to 20% in adults.[58] Foods containing these additives (e.g., margarines and salad dressings) lower serum cholesterol

by preventing dietary cholesterol absorption in the gastrointestinal tract.[127] In children with familial hypercholesterolemia, use of 2 g/day of plant sterols decreased LDL cholesterol by 5% to 15% but did not improve endothelial function.[128] This suggests that LDL cholesterol must be reduced to a certain threshold level before improvement of endothelial function can occur.

More studies examining the long-term effects of plant sterols on the vascular endothelium are warranted. Concern has been raised about the potential for the malabsorption of fat and fat-soluble vitamins in children consuming plant sterols chronically.[58] The expert panel[56] recommends reserving the use of foods supplemented with plant sterols/stanols to children with moderate to severe elevation in cholesterol, and monitoring fat-soluble vitamin status.[123]

Dietary supplements containing soluble fiber, garlic, and fish oils have been used to treat pediatric dyslipidemia with limited to moderate efficacy. In a randomized controlled trial, Davidson and colleagues studied the effect of psyllium fiber versus placebo on change in blood cholesterol levels of 6- to 18-year-old children with hypercholesterolemia.[130] Psyllium fiber (6 g/day) and the placebo were added to a ready-to-eat cereal. Compliance to treatment was excellent; consumption of the enriched cereal resulted in a modest 7% reduction in LDL cholesterol concentrations compared to the control cereal.

Garlic extract therapy was studied in a randomized controlled trial for effects on serum lipoproteins in 8- to 18-year-old children with FH.[147] The extract was given in three daily doses of 300 mg versus a placebo for 8 weeks. No significant effects of garlic treatment versus placebo were noted on total, LDL, or HDL cholesterol.

Omega-3 fatty acids, as found in fish oils, are known to reduce serum triglyceride levels in adults.[58] In a randomized crossover study, children with FH and FCHL were supplemented with either 1.2 g/day of docosahexaenoic acid (DHA) or a placebo for 6 weeks.[134] All children were given dietary counseling to reduce saturated fat intake to $< 7\%$ of calories. Outcomes studied included triglycerides, LDL and HDL cholesterol, and endothelial function as measured by flow-mediated dilation (FMD) of the brachial artery. Findings showed that DHA supplementation was associated with increased levels of total, LDL, and HDL cholesterol but no change in triglycerides compared to the placebo group. FMD improved significantly after DHA supplementation compared to baseline in both groups, and the change was greater in the DHA-treated group versus the controls. This finding suggests that in children DHA may not be effective for positively modifying serum lipids. However, the endothelium may be a therapeutic target for DHA in hyperlipidemic children.

LDL Apheresis

For children with homozygous familial hypercholesterolemia and extremely elevated LDL cholesterol (> 500 mg/dL), where LDL cholesterol cannot be reduced through the combination of diet therapy and multiple medication management, biweekly LDL apheresis has been utilized successfully to achieve significant lipid lowering under the care of a lipid specialist. In this process, apoB-containing particles are selectively removed from the circulation through extracorporeal precipitation.[148] Apheresis reduced LDL concentrations up to 72% compared with maximal drug therapy in patients with homozygous FH. The procedure is FDA approved, and qualified medical sites that perform this procedure are listed on the National Lipid Association website (www.lipid.org).

CONCLUSIONS AND FUTURE DIRECTIONS

Increasing evidence indicates that extreme elevation in LDL cholesterol is associated with vascular pathology in youth. With new recommendations for universal screening of pediatric patients, more patients with significant hypercholesterolemia are likely to be identified. Fortunately, appropriate therapy is available to modify and potentially reverse vascular abnormalities. Pediatric clinical trials of lifestyle and drug therapy to treat dyslipidemia suggest similar effectiveness and safety to that observed in adults. Most studies, however, have been of short or medium term in design. Longer-term safety and efficacy studies are needed, particularly with follow-up of vascular end points. Also, few clinical data are available to document at what age drug therapy should be appropriately and safely started. More work is needed in this regard to support clinical judgments on what age and dosage should be used in children at high risk for CHD.

QUESTIONS

1. A 4-year-old child is diagnosed with the autosomal recessive disease sitosterolemia with a mutation in two genes encoding the ABC half-transporter. In assessing the patient, all of the following are likely to be present *except* which one?
   a. High plant sterol levels in plasma
   b. Tendon xanthomas
   c. Normal plasma cholesterol
   d. Aortic stenosis

Answer: c

2. Which of the following statements commonly describes individuals with heterozygous familial hypercholesterolemia (FH) of the receptor-defective type?
   a. Have plasma LDL-cholesterol that is two to three times higher than normal
   b. Experience early onset atherosclerosis
   c. Have xanthomas in the tendons
   d. Require treatment with LDL apheresis

Answer: a

3. A mutation in proprotein convertase subtilisin/kexin type 9 (PCSK9) of the increase in function type will generally result in which of the following?
   a. Marked elevations in LDL-cholesterol
   b. Low levels of LDL-cholesterol
   c. High levels of VLD particles
   d. Low levels of HDL-cholesterol

Answer: a

4. Which of the following statements is (are) true regarding familial combined hyperlipidemia (FCHL)?
   a. The metabolic defect is overproduction of VLDL.
   b. A diagnosis of the disorder is based on the presence of increased levels of cholesterol, triglyceride or apo B in patients and their first-degree relatives.
   c. The disorder can manifest in childhood but is usually not fully expressed until adulthood.
   d. All the statements above are true about FCHL.

Answer: d

5. All *except* which of the following could cause chylomicronemia syndrome?
   a. Lipoprotein lipase deficiency
   b. Apo CII deficiency
   c. Apo A5 loss of function mutations
   d. LDL receptor deficiency

Answer: d

6. The NHLBI Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents has recommended universal lipid screening for which of the following groups?
   a. All children
   b. Children ages 9 to 10 years
   c. Adolescents ages 12 years and above
   d. Adolescents ages 16 years and above

Answer: b

7. The expert panel added a nonfasting HDL cholesterol as a new screening tool for the identification of dyslipidemia in childhood. What is (are) the advantage(s) of this assessment tool over other methods?
   a. It reflects the amount of cholesterol carried by all atherogenic apolipoprotein B containing lipoproteins.
   b. Is more predictive of persistent dyslipidemia than total cholesterol, LDL-cholesterol or HDL cholesterol alone.
   c. It can be accurately calculated in a nonfasting state.
   d. All of the statements above are considered advantages of nonfasting HDL cholesterol measurement.

Answer: d

8. Which of the following is true of the Cardiovascular Health Integrated Lifestyle Diet (CHILD-1)?
   a. Emphasizes reducing dietary saturated fat to less than 7% of total calories
   b. Is considered the first line of therapy to lower LDL-cholesterol levels in children
   c. Recommends the use of plant sterols at a 2-gram dose per day
   d. Recommends a dietary cholesterol reduction to 200 mg/day

Answer: b

9. To lower triglycerides, all of the following are encouraged as part of the expert panel's CHILD-2 (TG) dietary pattern *except* which one?
   a. Reduced intake of simple sugars
   b. Weight management/reduction as necessary
   c. Reduced intake of dairy foods to no more than two servings per day.
   d. Increased fatty fish consumption (e.g., salmon and tuna) to increase intake of omega-3 fatty acids

Answer: c

10. Which of the following medications may be useful for a child with high triglycerides that cannot be lowered with the CHILD-2 (TG) diet in consultation with a lipid specialist?
    a. Ezetimibe
    b. Fibrates
    c. Statins
    d. Bile acid resins

Answer: b

Index

Note: Page numbers followed by a *b* indicates boxes; those followed by an *f* indicate figures; those followed by a *t* indicate tables.

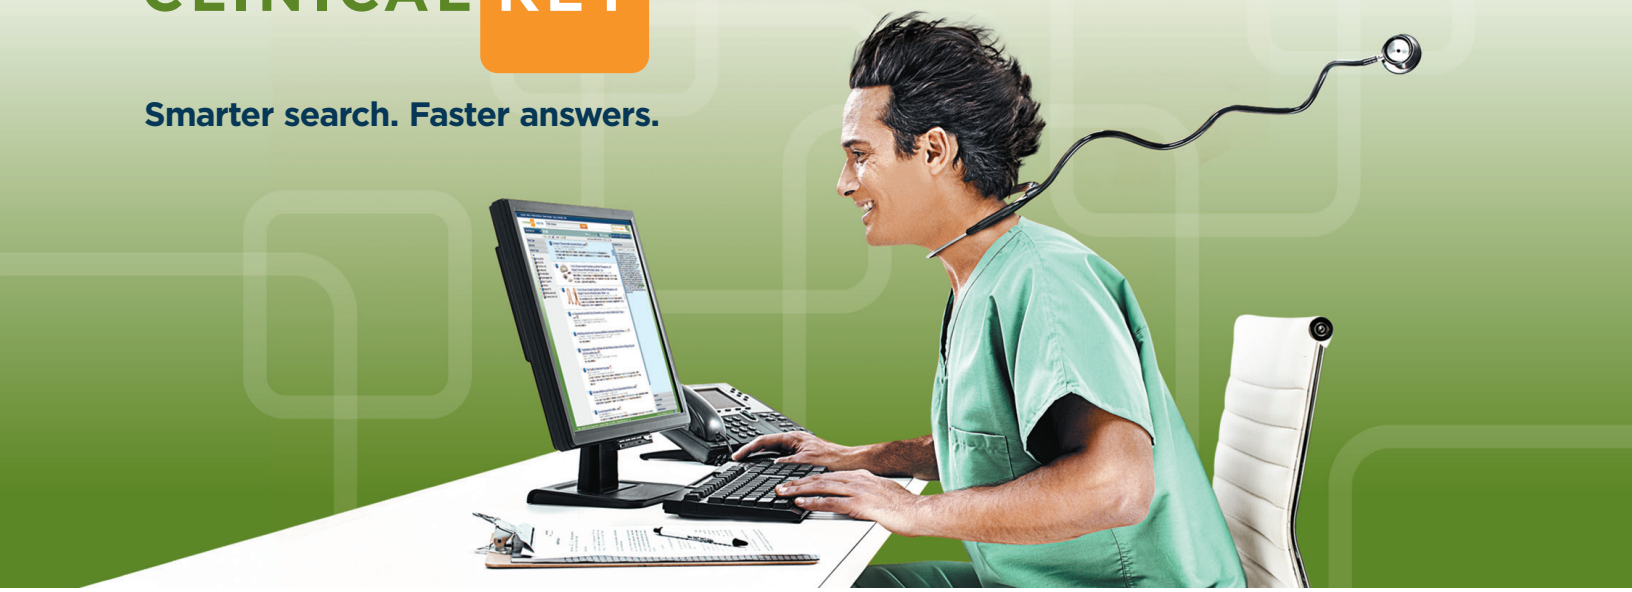
CLINICAL KEY™

Smarter search. Faster answers.



Smarter, Faster Search for Better Patient Care

Unlike a conventional search engine, ClinicalKey is specifically designed to serve doctors by providing three core components:

1 Comprehensive Content

The most current, evidence-based answers available for every medical and surgical specialty.

2 Trusted Answers

Content supplied by Elsevier, the world's leading provider of health and science information.

3 Unrivaled Speed to Answer

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!
