Diagnosis of GHI. The combination of decreased serum concentrations of IGF-1, IGF-2, and IGFBP-3 plus increased serum concentrations of GH is highly suggestive of a diagnosis of GHI.[110] The possibility of GHRD is supported by a family history consistent with autosomal-recessive transmission. Savage and Rosenfeld[712] devised a scoring system for evaluating short children for the diagnosis of GHRD based on five parameters: basal serum GH greater than 5 ng/mL, serum IGF-1 less than or equal to 50 ng/mL, height SD scores less than –3, serum GHBP less than 10%, and a rise in serum IGF-1 concentrations after a week of GH stimulation of less than twofold the intra-assay variation (approximately 10%).

Blum and colleagues[713] proposed that these criteria could be strengthened by evaluating GH secretory profiles, rather than isolated basal levels; employing an age-dependent range for evaluation of serum IGF-1 concentrations and using the 0.1 percentile as the cutoff level; employing highly sensitive IGF-1 radioimmunoassays and defining a failed GH response as the inability to increase serum IGF-1 concentrations by at least 15 ng/mL; and employing basal and GH-stimulated IGFBP-3 concentrations. These criteria fit well with the population of GHRD patients studied in Ecuador, but that is a remarkably homogeneous population of patients who have severe GHI.[110,709] The universal applicability of these criteria remains to be evaluated. An important biochemical marker will be the IGF-1 (and possibly IGFBP-3) response to GH stimulation. Although such tests were first employed in the early 1980s, normal ranges and age-defined responses of serum IGF-1 concentrations have not yet been determined.[714]

Decreased serum concentrations of GHBP are obviously highly suggestive of a diagnosis of GHRD, but it is important to point out that cases of GHRD with normal serum concentrations of GHBP have already been identified.[642,715] Such cases may represent mutations in the site responsible for dimerization of the GHR, or potentially for abnormalities of the intracellular portion of the receptor or of the postreceptor signal transduction mechanism. On the other hand, polymorphisms of the GHR gene without resulting reductions in IGF-1 and IGFBP-3 concentrations should not be considered GHRD. At this point, definitive diagnosis requires the classic phenotype, decreased

serum concentrations of IGF-1 and IGFBP-3, and identification of an abnormality of the GHR gene.

Constitutional Delay of Growth and Maturation. The diagnosis of constitutional delay has had different meanings to different clinicians.[716,717] To some, it has consisted of delayed adolescent growth and maturation in the presence of decreased (even if only transiently) GH secretion.[717,718] More commonly, it has been considered a normal variant (characterized by short stature) but with relatively normal growth rates during childhood, delayed puberty, a delayed pubertal growth spurt, and attainment of normal adult height.

Most patients with constitutional delay begin to deviate from the normal growth curve during the early years of life and are typically by age 2 years at or slightly below the 5th percentile for height. Such children would be expected to have normal serum IGF-1 and IGFBP-3 concentrations, a normal result of a GH provocative test (if pretreated with sex steroids), and skeletal ages that were delayed (Box 10-7). By definition, children with pure constitutional delay should have bone ages sufficiently delayed to result in normal predicted adult heights (see Box 10-7). When constitutional delay is found in the context of familial short stature, however, children may experience a delayed adolescent growth spurt and a short final height. Such children should be considered to have elements of constitutional delay and familial short stature and should be classified as ISS and considered for GH therapy.

As stated previously, some have attributed constitutional delay to a transient GHD or to a "lazy" pituitary. It is likely that much of this experience can be attributed to the inadequacies of GH testing, especially to the failure to pretreat patients with a brief course of sex steroids.[690] Low serum concentrations of IGF-1 and IGFBP-3 or a poor GH response to provocative testing (after priming with sex steroids) should mandate an investigation for an underlying pathologic process, such as intracranial tumors.

BOX 10-7 Criteria for Presumptive Diagnosis of Constitutional Delay of Growth and Maturation

- No history of systemic illness
- Normal nutrition
- Normal physical examination, including body proportions
- Normal thyroid function test results
- Normal renal function test results
- Normal complete blood cell count, erythrocyte sedimentation rate, electrolytes
- Normal stimulated GH
- Height between −2.5 and −1.5 SDS
- Height velocity > −1 SDS
- Delayed puberty:
- Males: failure to achieve Tanner G2 stage by age 13.8 years or P2 by 15.6 years
- Females: failure to achieve Tanner B2 stage by age 13.3 years
- Delayed bone age (more than 1 year delayed)
- Normal predicted adult height:
- Males: >165 cm (65 inches)
- Females: >153 cm (60 inches)

Idiopathic Short Stature. ISS can be defined as a condition in which the height of an individual is more than 2 SD below the corresponding mean height for a given age, sex, and population group without evidence of systemic, endocrine, nutritional, or chromosomal abnormalities. Specifically, children with ISS have normal birth weight and are growth hormone sufficient. ISS describes a heterogeneous group of children consisting of many presently unidentified causes of short stature. It is estimated that approximately 60% to 80% of all short children at or below –2 SD fit the definition of ISS.

This definition of ISS includes short children labeled with "constitutional delay of growth and puberty" and "familial short stature." The frequency of referral of these children is dependent on the socioeconomic environment. Furthermore, there is a greater perceived disability of short stature in boys compared to girls irrespective of social class. ISS should be subcategorized, principally based on auxologic criteria. The main distinction is between children with a familial history of short stature whose heights are within the expected range for parental target height and those children who are short for their parents. The corrected target height standard deviation score (SDS) is calculated as 0.72 multiplied by the average of the father's and mother's height SD scores and the lower limit of the target height range as corrected target height –1.6 SD.

It is generally accepted that on average adult height achieved in children with ISS is below the parental target height. ISS should also be classified by the presence or absence of bone age delay, indicating the probability of delayed growth and puberty. Subcategorization may help to predict adult height, which would be expected to be greater in a child with delayed maturation. Individuals with no family history of short stature generally have a lower adult height in comparison to target height. In situations in which a specific genetic diagnosis associated with short stature is expected (such as Noonan syndrome or GH insensitivity), the gene(s) of interest should be examined. Online resources exist, such as Genetest (www.genetests.org), which identify laboratories capable of performing these tests.

Although routine analysis of SHOX should not be undertaken in all patients with ISS, SHOX gene analysis should be considered for any patient with clinical findings compatible with SHOX haploinsufficiency. With currently available data it is difficult to generalize the impact of short stature on psychosocial adaptation. Short stature may be a risk factor for psychosocial problems, such as social immaturity, infantilization, low self-esteem, and being bullied—especially for those referred for evaluation. The large interindividual differences in adaptation to short stature and in the impact of being short may be a function of several risk and protective factors, including parental attitudes and prevailing cultural opinions. Stress experiences may be frequent, but true psychopathology is rare.[719]

TREATMENT OF GROWTH DISORDERS

When growth failure is the result of a chronic underlying disease (such as renal failure, cystic fibrosis, or malabsorption syndromes), therapy must be directed at treatment of the underlying condition. Although growth acceleration may be observed with GH or IGF-1 therapy, complete catch-up requires correction of the primary medical problem. If treatment of the underlying condition involves glucocorticoids, growth failure may be profound and is unlikely to be correctable until the patient is weaned from steroids.

Correction of growth failure associated with chronic hypothyroidism requires appropriate thyroid replacement. As discussed previously, thyroid therapy results in dramatic catch-up growth but also markedly accelerates skeletal maturation—potentially limiting adult height. More gradual thyroid replacement, especially in the beginning of the treatment, the use of gonadotropin inhibitors to delay puberty, or the use of aromatase inhibitors to slow skeletal age maturation may be necessary to maximize final adult height.

Treatment of Constitutional Delay

Constitutional delay is a normal variant with (by definition) potential for a normal (although delayed) pubertal maturation and a normal adult height. Most cases can be successfully managed by careful examination and evaluation to rule out other causes of delayed puberty or abnormal growth, combined with appropriate explanation, conservative follow-up, and psychological counseling. The skeletal age and Bayley-Pinneau table are often helpful in explaining the potential for normal growth. A family history of constitutional delay is also frequently a source of reassurance but may not always be elicited. On occasion, however, the stigmas of delayed maturation and short stature may be psychologically disabling for the adolescent.

Studies have demonstrated that some adolescents with constitutional delay have poor self-images and limited social involvement.[720] In such patients, there is a role for the judicious use of short-term sex steroids. In males, therapy should generally be limited to adolescents who meet the following criteria: a minimal age of 14 years; height below the third percentile; prepubertal or early Tanner G2 stage, with a serum testosterone level less than 100 ng/dL; evidence of poor self-image that does not respond to reassurance alone; and predicted adult height well within the normal range. The patients usually have a skeletal age delay that corrects their height to the midparental (target) height range. Therapy in males consists of depot testosterone (enanthate or cypionate), 50 to 100 mg every 3 to 4 weeks for a total of 4 to 6 injections.[721]

Patients will typically show early secondary sex characteristics by the fourth injection and grow an average of 10 cm in the ensuing year. This brief course of therapy has been shown to not cause overly rapid skeletal maturation, compromise adult height, or suppress pubertal maturation.[722] It is important to emphasize to the patient that he is normal, that therapy is short term and designed to provide him with some pubertal development earlier than he would experience on his own, and that treatment will not increase adult height. In such situations, the combination of short-term androgen therapy plus reassurance and counseling has been helpful in assisting the patient with constitutional delay cope with a difficult adolescence.

Patients must be reevaluated to ensure that they spontaneously enter "true" puberty. One year after testosterone treatment, patients should demonstrate testicular enlargement and a serum testosterone level in the pubertal or adult range. If this is not the case, the diagnoses of pituitary insufficiency or hypogonadotropic hypogonadism should be considered. Although a second course of testosterone may be warranted at this time, it is our experience that most such patients eventually prove to be gonadotropin deficient.

The availability of several new forms of testosterone supplementation, which are approved for adults with hypogonadism, has provided pediatricians with an opportunity to offer patients a choice among different androgen replacement therapies. Although these new therapies have not been published as efficacious in children with constitutional delay, we have personal experience with their successful use—with an equivalent response to that obtained with testosterone injections. Testosterone gel is painless and easy to apply, and it has proven popular since its release.[723] Testosterone patches also allow patients to avoid the need for injections but work best when applied to the scrotum and are often accompanied by complaints of itching.[724] The dosing of these alternative forms of therapy in children is not clearly established. Care must be taken, as these preparations increase the risk for administration of too large a dose of androgen, as most preparations are developed for adult androgen replacement.[725] Further experience will undoubtedly accumulate on their use in pediatrics in the coming years. The combined use of androgen therapy with aromatase inhibition is theoretically attractive in patients with constitutional growth delay who have a height prediction below their genetic target height range. Several prospective trials have shown that treatment with aromatase inhibitors delays skeletal maturation and increases predicted adult height. Data on long term follow-up of constitutionally delayed patients treated like this suggest that this may also result in taller adult height.[726] However, use of these agents still is considered experimental until the drug safety profile has been evaluated in more patients with longer follow-up, especially regarding the qualitative effects on skeletal development.

Referrals for constitutional delay are much more common in males than in females, undoubtedly reflecting our cultural values. When constitutional delay is a problem in girls, short-term estrogen therapy can be employed. The use of GH in patients with constitutional delay is discussed later in this chapter.

Treatment of Growth Hormone Deficiency

Patients with proven GHD should be treated with recombinant human GH (rhGH) as soon as possible after

the diagnosis is made. The primary objectives of the therapy for GHD are normalization of height during childhood and attainment of normal adult height. Normally growing patients with craniopharyngioma and GHD should be considered for therapy with GH for metabolic and body composition benefits and for enhancement of pubertal growth.

GH exhibits a high degree of species specificity in its actions. Unlike most other hormones, the only GH biologically active in humans is primate GH. For many years, the only practical source of primate GH for treatment of GHD was human cadaver pituitary glands—first employed in the late 1950s. Over the next 25 years, more than 27,000 children with GHD worldwide were treated. In 1985, distribution of pituitary-derived human growth hormone (hGH) in the United States and most of Europe was halted because of concern about a causal relationship with Creutzfeldt-Jakob disease—a rare and fatal spongiform encephalopathy that had been previously reported to be capable of iatrogenic transmission through human tissue.[727,728]

In North America and Europe, this disorder has an incidence of approximately 1 case per million. Noniatrogenic cases are exceedingly rare before the age of 50 years. To date, more than 20 young adults of about 8000 patients in the United States who had received human cadaver pituitary products have died of Creutzfeldt-Jakob disease. In France, there have been more than 60 cases of Creutzfeldt-Jakob disease among 1700 human cadaver GH recipients—and in England 32 cases among 1900 recipients of human cadaver GH have been reported.

Fortuitously, at the time that the risks of pituitary-derived hGH were discovered, recombinant DNA–derived hGH had already begun extensive testing for safety and efficacy.[312,729,730] The original form of rhGH included an N-terminal methionine, added for use as a start signal for transcription (met-hGH). This preparation was found to mimic pituitary-derived hGH in its anabolic and metabolic actions. Subsequent rhGH preparations were produced without the additional methionine. Over the next decade, rhGH universally replaced pituitary-derived hGH as the treatment of choice for children with GHD.

Dosing of GH

Despite continued variability and lack of consensus, considerable progress and improvement have been made in the standardization of GH dosage and administration. It is well established that GH administration should be initiated as early as possible in the GH-deficient child to optimize final height outcome.[731] Daily administration of GH is clearly more effective than giving the same total dose three times weekly.[732] GH injections are best administered in the evening, better mimicking natural physiology and achieving higher GH peaks.[733] The injected hGH should be administered subcutaneously.

The dosage of GH should be expressed in milligrams (or micrograms) per kilogram per day, although consideration should be given to dosing in micrograms per square meter of body surface per day in patients with obesity. GH is routinely used in the range of 25 to 50 μg/kg/day. A dose-response relationship in terms of height velocity in the first 2 years has been clearly demonstrated within this range (Figure 10-30).[734-736] On this regimen, the typical GH-deficient child accelerates growth from a pretreatment rate of 3 to 4 cm/year to 10 to 12 cm/year in year 1 of therapy and 7 to 9 cm/year in years 2 and 3. This progressive waning of GH efficacy has been observed universally and is still not fully understood. It can, however, be overcome at least in part by increasing the dosage of hGH. In the United States, at a dosage of 50 mcg/kg/day, the approximate current cost of hGH therapy for a 20-kg child is $15,000/year. The practice of individualizing treatment according to the specific needs of each GH-deficient child is gaining acceptance.

Consensus does not exist as to how to formulate individualized treatment plans. Emerging evidence suggests that mathematical prediction models of growth response may be useful for determination of the optimal individual dose.[710,737,738] Although these models will need further improvement in their predictive power (as well as further validation), their potential utility is considerable. GH doses can be calculated to achieve specific therapeutic aims (i.e., catch-up to target height within 2, 3, or 4 years). These models can also enable a comparison between observed and predicted growth, hastening identification of causes of suboptimal growth. Further application of these models to specific diseases and conditions in which GH responsiveness varies will allow disease-specific optimization.

Despite the availability of GH therapy, long-term studies have indicated that many patients fail to achieve normal adult heights—and only a few attain their genetic target heights. Although the development of rhGH has solved the problem of supply experienced in the pituitary GH era, delays in diagnosis and initiation of therapy have still compromised adult height. Data from the National Cooperative Growth Study evaluation of adult heights in 121 patients with childhood GHD indicate a mean adult

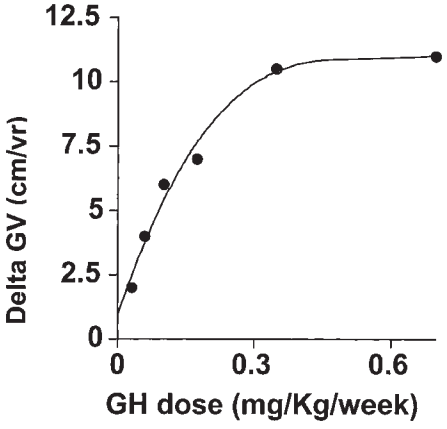

FIGURE 10-30 ■ Meta-analysis of the dose-response relationship between growth hormone (GH) and delta growth velocity (GV) in the first year of treatment of naive GH-deficient children. The lower three doses are from Frasier and colleagues,[501] and the higher three doses are from Cohen and coworkers.[502]

height in male and female patients of < 0.7 SD.[739] By multiple-regression analysis, factors found to correlate with enhanced adult height were baseline height, younger age at onset of treatment, longer treatment duration, and a greater growth velocity during the first year of treatment.

In an effort to increase final height of GHD patients, Mauras and associates[740] have evaluated the use of high-dose GH during puberty—with the rationale that GH secretion normally doubles during the pubertal growth spurt (as indicated by the dramatic rise in serum IGF-1 concentrations during puberty) and that the pubertal growth spurt normally accounts for approximately 17% of adult male height and 12% of adult female height. Earlier studies by Stanhope and associates[741] indicated that little difference in height gain could be observed when adolescent patients were treated with 30 versus 15 IU/m^2/wk of GH (approximately 0.04 versus 0.02 mg/kg/day).

Mauras and associates[740] evaluated higher doses of GH during puberty (100 versus 50 mcg/kg/day) and found that the higher dosage resulted in a 4.6-cm increase in near-final height (defined as height at a bone age of more than 16 years in males and more than 14 years in females). The mean height SD score at near-final height was higher for the 100-mcg/kg/day group. The higher GH dosage did not result in more rapid acceleration of skeletal maturation.

An alternative approach to maximizing height gain during adolescence is to combine GH treatment with suppression of the hypothalamic-pituitary-gonadal axis by GnRH analogues (or, but only in boys, the use of aromatase inhibitors). This combined therapy may lead to significant improvement of final height or predicted adult height of patients, as shown in some studies (but long-term results are still lacking). In addition, the effect of suppression of puberty on bone accretion during the critical pubertal phase (as well as on psychosocial function) has not yet been evaluated adequately. Similar concerns may exist for the combination of GH therapy with aromatase inhibitors, which are designed to prevent the effects of estrogen on epiphyseal fusion.

Novel Modalities for Treatment of GHD

Several novel treatment modalities have emerged (Box 10-8). These include oral secretagogues, GHRH, extended-action depot rhGH preparations, and liquid rhGH formulations. A number of GH-releasing peptides and nonpeptidyl GH secretagogues have been formulated since their discovery in the 1980s.[742] Although these oral agents would be an attractive potential treatment option for GHD secondary to hypothalamic GRF deficiency, their evaluation remains incomplete at this time.[743,744] GHRH has been demonstrated to be safe and more effective than placebo at increasing height velocity in some GHD children. However, further long-term studies are needed.[745,746]

BOX 10-8 New and Emerging Modalities for Treatment of GH Deficiency

- Liquid formulations
- Pen-type delivery devices
- Long-acting GH formulations
- Sustained-release GH formulations
- Dermal patch delivery of GH
- Oral ghrelin-mimetics

The development of sustained-release long-acting depot GH formulations may eventually provide a desirable alternative to daily subcutaneous rhGH injections for some patients. Currently, such formulations remain under study in ongoing clinical trials—and although efficacious they appear less effective than daily rhGH therapy. Further studies will be necessary, however, to ascertain whether such preparations can provide the same level of growth acceleration as is seen with daily GH—and whether side effects will not be increased. Liquid rhGH formulations, which eliminate the need for reconstitution, and new delivery devices such as pen systems have been introduced and appear to improve patient compliance.

Additional novel delivery GH strategies remain under active development, including orally inhaled and intranasally administered rhGH formulations. In time and with further experience, novel treatment approaches may emerge as useful alternatives to conventional rhGH therapy. The combination of GH along with IGF-I therapies may also prove to be a useful treatment of growth disorders.

Management of Multiple Pituitary Hormone Deficiency

In the patient with an initial diagnosis of isolated GHD, particularly those with an ectopic posterior pituitary or other developmental abnormalities, the clinician should be alert to the risk of the development of MPHD. This involves regular repeat biochemical testing and consideration of repeat pituitary imaging. If GHD is part of a multiple pituitary insufficiency, it is necessary to address each endocrine deficiency. TSH deficiency is often "unmasked" during the initial phase of hGH therapy, and thyroid tests should be performed both before the onset of therapy and during the first 3 months of hGH treatment.[747] Even if normal initially, thyroid function should be tested subsequently on at least an annual basis.

The pituitary-adrenal axis is customarily evaluated during the insulin stimulation test for GHD. If ACTH secretion is impaired, patients should be placed on the lowest safe maintenance dose of glucocorticoids—certainly no more than 10 mg/m^2/day of hydrocortisone. Higher doses may impair the growth response to hGH therapy but may be necessary during times of stress. An alternative approach is to avoid maintenance glucocorticoids and treat with steroids only during periods of physiologic stress.

Gonadotropin deficiency may be evident in infancy in the child with microphallus. This can usually be treated with three to four monthly injections of 25 to 50 mg of testosterone enanthate.[748] Management of puberty can be more complicated because the physical and psychological benefits of normalizing sexual maturation must be

balanced against the risk of epiphyseal fusion. When hGH therapy is initiated in childhood and the child's growth is normalized before adolescence, it is appropriate to begin sex steroid replacement at a normal age (e.g., 11 to 12 in females and 12 to 13 in males).

In males, this can be done by beginning with monthly injections of 100 mg of testosterone enanthate—gradually increasing to 200 mg/month, and eventually moving to the appropriate adult replacement regimen. In girls, therapy involves use of conjugated estrogens or ethinyl estradiol, and eventual cycling with estrogen and progesterone (as described elsewhere in this book). On the other hand, in patients in whom normal or precocious puberty may limit the statural response to hGH, it may be appropriate to delay puberty by the use of the GnRH analogue.

Monitoring GH Therapy

Careful monitoring of pediatric patients with GHD is critical. Important aspects of this process are outlined in Box 10-9. The routine follow-up of GHD children should be performed by a pediatric endocrinologist on a 3- to 6-month basis in partnership with the patient's primary care physician. Assessment of the growth response is perhaps the single most important parameter of monitoring. This consists of accurate determination of height velocity and interval height increase (best expressed in terms of the change in height Z score). Establishment of a target height (typically the midparental target height) against which the child's progress can be assessed is important. Careful attention must also be directed toward screening for possible adverse effects and toward assessing compliance.

Monitoring Serum IGF-1 Levels

The consensus is that annual monitoring of serum IGF-1 and IGFBP-3 levels should be an aspect of routine care of the GHD child receiving rhGH therapy.[749] Titration of rhGH dose to maintain these growth factors within age-dependent normal limits is physiologically sound and is standard practice in the treatment of adults with GHD. It is well recognized that IGF-1 and IGFBP-3 levels are low in children with GHD and increase with rhGH injections.[750]

BOX 10-9 Elements of Monitoring GH Therapy

- Close follow-up with a pediatric endocrinologist every 3 to 6 months
- Determination of growth response (change in height Z score)
- Monitoring serum IGF-1 and IGFBP-3 levels
- Screening for potential adverse effects
- Evaluation of compliance
- Consideration of dose adjustment based on IGF values, growth response, and comparison to growth prediction models

IGF, insulin-like growth factor; IGFBP-3, insulin-like growth factor-binding protein-3.

The relationship between the rise in IGF-1 levels and the growth response during therapy has been demonstrated in a study that used a GH-dose titration to achieve target IGF-I levels.[751] In that study, it was demonstrated that at least over the first 2 years of treatment there is a substantial correlation between the level of the IGF-I achieved and the height gain—and that this correlation was valid for both GHD and ISS patients. Growth factor monitoring certainly has important utility in assessment of compliance issues as well as in the assurance of safety. Several epidemiologic studies have linked serum IGF-1 levels and lower IGFBP-3 levels to increased risk of prostate, breast, and colorectal cancer in otherwise healthy subjects.[222,749,752] Although a causal relationship between serum IGF-1 levels and cancer is not proven, monitoring lifetime exposure to IGF-1, and ensuring that IGF-1 and IGFBP-3 levels in the GH-deficient patient are within age-defined normal limits certainly seem prudent at this time.

Role of Serial Bone Age Assessment

Although a well-established diagnostic tool in the initial evaluation of a GH-deficient patient, bone age assessment no longer has a role in the ongoing management of childhood GHD. Previously, many clinicians have included serial bone age assessment as part of their monitoring of a GH-deficient child's progress on rhGH therapy by comparing the observed to predicted heights and by following the Bailey-Pinneau predicted height calculations.[753,754]

When the wide SDs applied to such measures and the lack of clinical evidence that management is enhanced by their use are considered, they have no sound role in the monitoring of GH therapy.[755] It also appears that although GH therapy accelerates bone maturation, there may be an initial delay before this is apparent radiographically and height predictions may be skewed as a result.[755] At this time, the role of bone age assessment during GH therapy lies only in determining remaining growth potential in the patient with GHD approaching final height and in assessing children with concerns about rapid progression of puberty.

Assessment of Treatment Efficacy and Optimizing Growth Response

Clearly defined individual treatment goals need to be established for each patient with GHD. During the initial 2 years of therapy, catch-up growth at a rate twofold to fourfold above pretreatment growth velocity and a gain of 1 to 2 SDs in height should be expected in the majority of patients.[756] This will be influenced by age at diagnosis and severity of GHD. The dose may need to be increased if catch-up growth is inadequate. After the initial catch-up phase, growth velocity should be maintained at a rate at or above the 50th percentile for age.

Mathematical prediction models may be used not only to predict growth response to a specific dose but also to guide the pediatric endocrinologist in modifying therapy when the observed growth falls short of predicted growth.[738] Prediction models have considerable promise

but need to be improved and studied further in a prospective manner before any recommendations regarding their use can be formulated. In instances in which an inadequate response is encountered, it is also important to consider all possible causes—including poor compliance, technical difficulties, underlying hypothyroidism, incorrect diagnosis, poor nutrition, neutralizing antibodies, and intercurrent illness.

It is critical to maximize height with GH therapy before the onset of puberty. If this is not achieved, modulation of the GH dose during puberty may be considered. As stated previously, the growth response to hGH typically attenuates after the first year—but it should continue to be equal to or greater than the normal height velocity for age throughout treatment. In situations in which the clinical response to hGH is suboptimal, the following possibilities must be considered: poor compliance, improper preparation of hGH for administration or incorrect injection techniques, subclinical hypothyroidism, chronic disease, glucocorticoid therapy, history of irradiation of the spine, epiphyseal fusion, anti-GH antibodies,[757] and incorrect diagnosis of GHD as explanation for growth retardation. Some recipients of rhGH have developed detectable anti-GH antibodies, but growth failure resulting from such antibodies has been exceedingly rare.

Maximal growth response to hGH can be obtained by early diagnosis and initiation of therapy and by careful attention to compliance and psychological support. Thus, although some studies have indicated that as many as 50% of males and 85% of females with idiopathic GHD do not achieve adult heights above the third percentile,[739,758] it is our belief that normalization of height (i.e., achieving target height) should be achievable in most cases. Despite the efficacy of hGH in accelerating growth in children with GHD and the ability of such therapy to normalize adult height if treatment is begun sufficiently early, several studies have indicated that the long-term prognosis for such patients is guarded.[759] The educational, vocational, and social outlook for adults with GHD dating from childhood is frequently suboptimal. Whether this suboptimal psychosocial outlook reflects subtle intellectual deficits or the consequences of lower expectations of patients, families, or teachers remains to be determined. In any case, patients with GHD clearly require careful and thorough follow-up throughout childhood and adolescence—and possibly adulthood.

Studies have focused on the clinical consequences of GHD in adults and on the potential benefits of hGH therapy in such patients.[760,761] Signs and symptoms of adult GHD have included reduced lean body mass and musculature, increased body fat, reduced bone mineral density, reduced exercise performance, and increased plasma cholesterol. Adults with GHD have been found to have a significantly increased risk of death from cardiovascular causes, a finding potentially linked to the increase in adiposity and in serum cholesterol.[762]

Adults with GHD have been found to have "impaired psychological well-being and quality of life" characterized by depression, anxiety, reduced energy and vitality, and social isolation. Several placebo-controlled studies have demonstrated that hGH therapy for adults with GHD results in marked alterations in body composition, fat distribution, bone density, and sense of well-being.[763,764] Whether these effects of hGH therapy will be sustained (and if so, what the optimal hGH regimen will be) remains to be determined.

Because of the potential metabolic benefits of treatment of adult GHD, it is necessary to discuss the need for lifelong GH therapy with patients and families at the time of diagnosis. Given the studies that have demonstrated that many (perhaps the majority) of the children diagnosed with childhood GHD demonstrate normal GH levels on repeat provocative testing, it is recommended that on completion of skeletal growth GH therapy be halted for a period of 1 to 3 months and the patient then retested. Toogood and colleagues[765] have reported that the likelihood of GHD persisting in adult life increases with the number of pituitary hormone deficiencies. Approximately 90% of patients with two or three additional pituitary hormone deficiencies had provocative GH levels less than 5 ng/mL. Similarly, patients with documented structural abnormalities of the hypothalamus-pituitary (such as pituitary hypoplasia, pituitary stalk agenesis, posterior pituitary ectopia, or septo-optic dysplasia) have a very high likelihood of retesting as GHD.

A conservative approach would suggest that all children diagnosed as having GHD should be retested by insulin-provocative tests on completion of skeletal growth and before a commitment is made for long-term adult treatment. An argument can be made, however, that patients with multiple pituitary hormone deficiencies, documented structural abnormalities, or documented hypothalamic-pituitary molecular defects do not necessarily require retesting—or at most should have IGF-1 and IGFBP-3 concentrations determined. On the other hand, the child who has carried a diagnosis of idiopathic isolated GHD should always be retested.

Transition to Adult Management

A suggested algorithm to guide the transition to adult management is displayed in Figure 10-31. After attainment of final height, the pediatric endocrinologist should retest the GH-IGF axis using the adult GHD diagnostic criteria as defined by the Growth Hormone Research Society (GRS) Consensus Workshop on Adult GHD.

Standard GH stimulation tests can be performed after an interval of 1 to 3 months of GH therapy.[766] In places where an insulin tolerance test is mandatory for the patient to qualify for further GH therapy, this test should be performed. At the time of retesting, other pituitary hormones and serum IGF-1 and IGFBP-3 levels should be measured.[704] As recommended by the GRS, the opportunity should be taken to assess body composition, bone mineral density, fasting lipids, insulin, and quality of life before and after discontinuation of GH therapy. Patients with severe long-standing MPHD, those with genetic defects, and those with severe organic GHD can probably be excluded from GH retesting.[627]

When the diagnosis of adult GHD is established, continuation of GH therapy is strongly recommended. Caution should be exercised when considering the decision

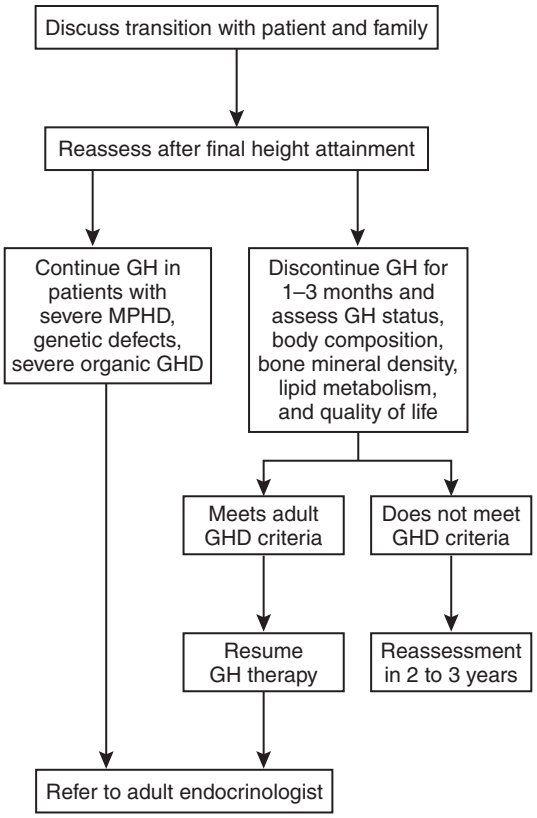

FIGURE 10-31 ■ Algorithm for transition to adult treatment of growth hormone (GH) deficiency. MPHD, multiple pituitary hormone deficiency.

of continuing GH therapy in conditions where there is a known risk of diabetes or malignancy. Although large patient registries have not seen an increase in the incidence of malignancy in pediatric GH recipients, patients with certain high-risk states (such as Bloom syndrome) may be at an increased risk as a result of long-term GH therapy and such patients should be monitored carefully. The transition to adult GH replacement should be arranged as a close collaboration between the pediatric and adult endocrinologists, who should discuss the reinitiation of treatment with the patient.

Growth Hormone Treatment of Other Forms of Short Stature

The development of rhGH has provided the capability for a theoretically unlimited supply of hGH. Although treatment of GHD is the one unequivocal indication for "replacement" therapy, the potential use of hGH for treatment of other forms of short stature has been actively explored. Theoretically, any child with open epiphyses should be capable of accelerating growth and achieving heights greater than indicated by genetic potential—as indicated by experience with cases of pituitary gigantism. Whether such therapy can be done safely and whether it justifies the cost and potential risks of hGH are more complicated issues. In addition, questions have been raised about the appropriateness of "cosmetic" hormonal therapy. Table 10-10 summarizes the different medical indications that the FDA has approved for treatment with rhGH as of September 2012.

TABLE 10-10 Key Indications for the Use of GH Therapy in the United States (USFDA-Approved Indications)

Children	Adults
Growth hormone deficiency	Growth hormone deficiency
Chronic kidney disease	HIV/AIDS wasting syndrome
Turner syndrome	Short bowel syndrome
SGA and lack of catch-up growth	
Prader-Willi syndrome	
Idiopathic short stature	
SHOX gene haploinsufficiency	
Noonan syndrome	

SGA, smallness for gestational age; USFDA, United States Food and Drug Administration.

Chronic Renal Failure

Several studies have now convincingly demonstrated the ability of hGH to accelerate growth over at least several years of therapy.[767,768] These findings have also been confirmed by several double-blind placebo-controlled investigations. Using an hGH dosage of 0.05 mg/kg/day, Fine and coworkers[769] showed a mean first-year growth rate of 10.7 cm in GH recipients and 6.5 cm in the placebo group. In the second year, GH-treated patients had a mean growth rate of 7.8 cm/year versus 5.5 cm/year in placebo recipients. No deleterious effects on renal function were observed. Additional evaluation of the effect of GH treatment on adult height in chronic renal failure patients has been compromised by small sample sizes and restriction to only prepubertal patients treated. However, the impact of GH therapy on final adult height in these patients has been evaluated through the Pfizer International Growth Database (KIGS), which showed long-term catch-up growth and increased near-adult height.[770] Mean height SD scores at near-adult height improved by 1.2 and 1.6 in boys and girls, respectively. The overall treatment response was diminished in patients who were concurrently on dialysis or had severely delayed puberty.

Turner Syndrome

Before the availability of rhGH, a number of uncontrolled studies had produced conflicting data concerning the efficacy of GH therapy in Turner syndrome.[771,772] In 1983, a randomized controlled study of rhGH was initiated.[230,347] First-year results indicated a growth rate of 3.8 cm/year in the control group, 6.6 cm/year in hGH recipients, 7.9 cm/year in oxandrolone recipients, and 9.8 cm/year in subjects receiving hGH plus oxandrolone. At the end of 6 years, heights for 30 subjects who had completed therapy were compared with their projected

adult heights[773] based on the growth curves of Lyon and colleagues.[11]

Mean height achieved after 2 to 6 years of treatment was 151.9 cm, compared to a mean projected adult height of only 143.8 cm. Near-adult heights in these subjects showed that girls receiving GH alone had a final height 8.4 cm greater than their projected adult heights. Girls receiving GH plus oxandrolone had a 10.3-cm increase.[348] Sixteen of 17 girls receiving GH alone achieved adult heights above the 50th percentile for Turner syndrome, and 10 of 17 attained heights above the 90th percentile. All 45 girls receiving combination treatment attained heights above the 50th percentile for Turner syndrome, and 23 of 45 had heights above the 90th percentile.

In a subsequent study, GH was employed in combination with estrogen replacement at either 12 or 15 years of age.[774] Earlier initiation of estrogen therapy resulted in accelerated epiphyseal fusion and a compromise in final height attained, a not surprising observation given the critical role of estrogen in skeletal maturation. Girls who began GH therapy before 11 years of age and estrogen at age 15 had the greatest increase in adult height. These data are in line with the results from the only randomized, controlled trial to adult height. After an average of 5.7 years of therapy plus induction of puberty at near-physiologic age (13 years), the mean height gain due to GH was +7.2 cm.[775]

Even more dramatic results have been observed in Dutch studies, in which the GH dosage was progressively increased to 0.09 mg/kg/day.[349] At the highest GH dosage, increases in adult height over projected heights averaged 16 cm. Estrogen therapy was withheld until subjects had received at least 4 years of GH treatment and reached a minimum age of 12 years. With this regimen, the majority of girls with Turner syndrome attained adult heights within the normal range. A follow-up study further established that GH therapy in Turner syndrome girls allows for height normalization in most patients: 83% reached a normal adult height (final height SD score > -2), and 63% ended up growing into their target height range.[776]

In light of the detailed historical data that exist on natural growth in Turner syndrome, the results to date provide convincing data that hGH can accelerate growth and increase adult height. Furthermore, early initiation of GH treatment should allow for normalization of growth in childhood—as well as the potential to begin estrogen replacement at a physiologically appropriate age. This subject is discussed in detail in Chapter 16.

SHOX Deficiency

SHOX deficiency turns out to be a relatively common cause of short stature. In SHOX deficiency, short stature is mainly due to (mesomelic) shortening of the extremities. Heterozygote mutations, mainly deletions (approximately 80%), have been detected in 2% to 15% of subjects who initially were diagnosed as having idiopathic short stature. Fifty percent to 90% of patients carrying the clinical diagnosis of Leri-Weill dyschondrosteosis have SHOX deficiency, and almost 100% of girls with Turner syndrome have SHOX haploinsufficiency.[777] Several studies have shown that the improvement in statural growth with GH therapy in individuals with SHOX mutations is similar to the effect seen in Turner syndrome patients. In a 2-year prospective, open-label, parallel, multicenter study, GH-treated SHOX-deficient patients grew 3.5 cm and 1.9 cm more that an untreated control group during, respectively, the first and second years of therapy.[778] Final height was evaluated in a group of children with SHOX deficiency in a retrospective study taken after the children had received at least 2 years of GH treatment, and the results revealed an overall height gain of 7 cm, reminiscent of the height gain described in Turner syndrome patients.[779] The FDA has now approved growth hormone therapy for short stature resulting from SHOX deficiency; the recommended weekly dosage is 0.35 mg/kg/week.

Noonan Syndrome

Most of the data on the beneficial effect of GH on statural growth in Noonan syndrome are derived from observational studies using small numbers of patients, without randomization and without the use of controls. In addition, the effect of GH therapy on adult height has only been reported in a couple of studies. In one study, 18 children with Noonan syndrome were treated for a mean duration of 7.5 years until they reached final height. Their mean height SD score increased from −2.9 before GH treatment to −1.2 at the end of GH treatment, which represents a 10.3 cm height increment compared to their predicted adult height.[780] In a large cohort of Noonan syndrome patients from the international postmarketing KIGS database, more than 50% of 402 patients reached adult heights greater than −2 SD scores, whereas other studies yielded overall height gains in the range of 5 to 10 cm only.[781,782] A variety of factors likely influence the observed GH treatment responses. These include the timing of the onset of GH therapy and the duration of prepubertal GH exposure, the height achieved at puberty, and the reduced GH responsiveness seen in Noonan syndrome patients due to a PTPN11 mutation (about 50% of all patients). The FDA has approved GH treatment for short stature associated with Noonan syndrome at doses up to 0.066 mg/kg/day.

Down Syndrome

The encouraging results of hGH trials in Turner and Noonan syndromes have led to studies of hGH in other chromosomal disorders, such as Down syndrome. Several preliminary studies have confirmed the ability of hGH to accelerate growth in such patients, although ethical issues have been raised concerning the appropriateness of such therapy.[783,784] The mean height of children with Down syndrome increased significantly from −1.8 to −0.8 SD score during 3 years of GH therapy in a study from Sweden, whereas the mean height fell in a control group from −1.7 to −2.2 SD score. The study showed no effect on mental or gross-motor development, but some improvement in fine-motor development was reported in the GH-treated subjects.[785] Because no convincing study data exist to indicate that hGH improves neurologic or intellectual function in Down

syndrome patients, therapy with GH is not recommended in these children unless they also have GH deficiency.

Intrauterine Growth Retardation or Small for Gestational Age

A number of studies, employing pituitary-derived or recombinant DNA–derived hGH, have been performed in children with short stature resulting from IUGR/SGA.[786,787] These studies are hampered by the inherent heterogeneity of this group of patients, whose poor growth may reflect maternal factors, chromosomal disorders, dysmorphic syndromes, toxins, and so on. The interpretation of the results from these studies are frequently complicated by an accompanying diagnosis of GHD, often lacking stringency in diagnostic criteria.

Coutant and colleagues,[788] for example, compared children treated with GH for a diagnosis of IUGR associated with "idiopathic" GHD and children with IUGR not treated with GH and found no significant differences in adult height. Furthermore, almost 80% of the alleged GH-deficient IUGR children proved to have normal GH levels when reevaluated after cessation of growth. Two studies have examined the effects of two doses of continuous GH treatment administered over a 6-year period.[362,789,790] GH at doses of 0.033 and 0.067 mg/kg/day resulted in 2- and 2.7-SD increments in height, respectively.

In a prospective, randomized, double-blind, dose–response study, GH treatment for 6 years (with either 0.033 or 0.067 mg/kg/day) caused the majority of SGA patients to reach a height within the normal range.[362] The higher-dose group also had a greater height SD score increase than the lower-dose group, respectively, +2.5 and +2 SD score. After a mean treatment period of 7.8 years, 85% of patients had reached adult heights above −2 SD score and 98% reached adult heights within target height range (Figure 10-32).[791]

A meta-analysis of data from four different randomized controlled trials has been done (n = 391). Adult height of patients from the GH treated groups was significantly greater compared to the control groups: the mean difference was +0.9 SD score, yielding a 5.7 cm greater height ($p < 0.0001$).[792] Taken together, most studies have demonstrated taller final height, leading to approval in most countries of GH therapy for SGA children who lacked catch-up growth. The doses commonly used in SGA children are between 50 and 70 mcg/kg/day, and treatment is typically started at age 3 years.[789]

Prader-Willi Syndrome

One form of IUGR/short stature in which GH therapy has been studied fairly extensively is Prader-Willi syndrome. Early studies in a limited number of subjects demonstrated promising short-term results.[377] Lindgren and colleagues[793] demonstrated that patients with Prader-Willi syndrome had lower serum IGF-1 concentrations than did normal obese controls. Prader-Willi subjects treated with GH at a dosage of 0.033 mg/kg/day showed a 1-year increase in height velocity, whereas untreated

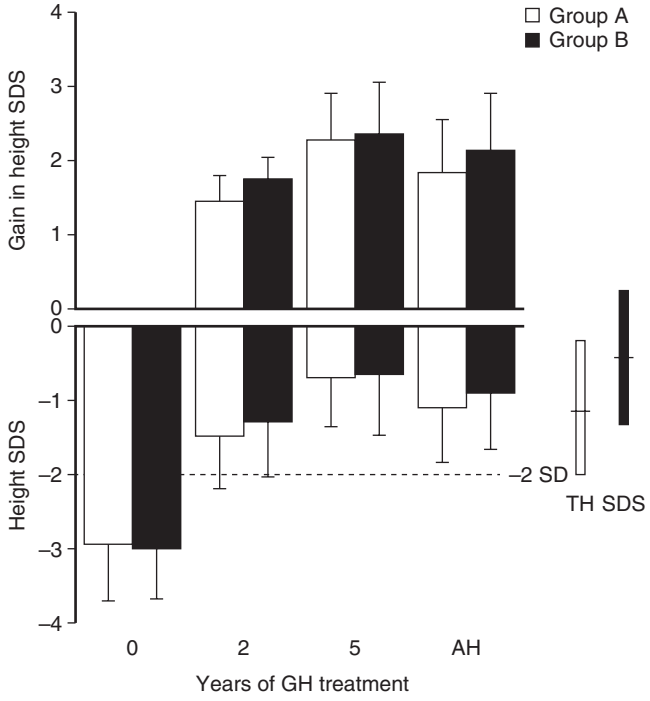

FIGURE 10-32 ■ Bottom panel: Height SD score (SD) during GH treatment and at adult height (AH) in relation to the target height (TH). Top panel: Gain in height SD score from the start until 2 years and until 5 years of GH treatment, and until AH. Group A: 0.033 mg/kg/day GH; group B: 0.067 mg/kg/day GH. (From Van Pareren, Y., Mulder, P., Houdijk, M., et al. (2003). Adult height after long-term, continuous growth hormone (GH) treatment in short children born small for gestational age: results of a randomized, double-blind, dose-response GH trial. *J Clin Endocrinol Metab, 88*, 3584–3590.)

Prader-Willi subjects experienced a decrease in height velocity.

GH treatment also resulted in a reduction of relative fat mass and an increase in fat-free mass. Carrel and coworkers[181] employed a similar dosage of GH in Prader-Willi patients with reduced clonidine-stimulated GH levels and low serum IGF-1 concentrations and demonstrated an increase in height velocity, whereas untreated controls showed no significant change in height velocity.

The FDA has recognized Prader-Willi syndrome to be an accepted diagnosis for GH therapy, even in the absence of demonstrable GHD. The GH treatment is effective in improving growth during childhood, final adult height, and body composition as well.

Randomized controlled studies using a GH dose of 1 mg/m^2/day showed a significant increase in height and height velocity during the first year of treatment, accompanied by reduction in total body fat and an increase in lean body mass, as demonstrated by dual-energy x-ray absorptiometry (DEXA), as well as an increase in muscle strength and agility, sustained in the second year of therapy. After the initial 2 years of GH therapy,[794] 2 additional years demonstrated continued beneficial effects on body composition with GH doses of 1 and 1.5 mg/m^2/day. Bone mineral density also improved.[795] Few studies, however, have reported data on adult height. In the KIGS database analysis, 33 patients were followed to

near-adult or adult height; in nearly two thirds of the patients, height fell above −2 SD score, and median adult height was −1 SD score after a mean of 8.4 years of GH therapy.[796]

The benefits of administering GH treatment as early as 2 years of age are well known, but there is also some evidence of additional benefit when starting GH between 6 and 12 months of age. This further benefit affects the Prader-Willi syndrome child's head growth, muscle function, motor development, and may even positively impact cognition.[797]

Since the 1990s, additional case reports have pointed to a possible GH-associated mortality in patients with Prader-Willi syndrome who have massive obesity. This may be related to a complication from a respiratory tract infection, worsening sleep apnea with or without hypoventillation, adenoid or tonsil hypertrophy, or aspiration associated with obesity.[549] A review that included 64 children (42 boys and 22 girls, 28 on GH treatment) suggested there may be a high-risk period for death during the first 9 months after GH was commenced. For this reason it has been advised that GH should be started at a relatively low dose (e.g., 0.25 to 0.30 mg/m^2/day or 0.009 to 0.012 mg/kg/day) with gradual increases during the first weeks and months toward a standard GH replacement dosage around 1 mg/m^2/day or 0.035 mg/kg·day. Clinicians should monitor clinical effects closely, particularly screening for the presence or worsening of sleep apnea.[798]

Osteochondrodysplasias

Therapy with hGH has been studied in several studies of skeletal dysplasias. The largest initial experience was in achondroplasia and published by Seino and coworkers,[799] who reported on hGH administration to 40 children. During the first year of treatment, the height velocity increased from 3.8 to 6.6 cm/year. In year 2, the height velocity decreased to approximately 5 cm/year. A modest improvement was seen in the ratio of lower limb length to height. Although hGH was well tolerated, it is of note that one patient with atlantoaxial dislocation during hGH therapy has been reported. In another 5-year trial, GH treatment was given to 35 children with achondroplasia to investigate height and body proportion responses (GH therapy was omitted for one of the study years). Mean height velocities improved during the first 2 years of GH therapy, but growth velocity decreased during the third year below baseline. Height SD score increased significantly (by +1.3 to +1.6, based on the GH dose used) during the 5 years of the study. Sitting height SD score also improved during the study. Body proportion did not show any significant change.[800] The effects of 3 years of GH treatment in patients with hypochondroplasia are better than in achondroplasia: respective increase in height SD score of +1.4 versus +0.3.[801] Further studies are needed to determine if continued treatment of hypochondroplasia patients improves adult height or has additional benefit on bone mineralization and quality of life. There has also been limited experience with GH treatment of other skeletal disorders, such as hereditary multiple exostoses, osteogenesis imperfecta, spondyloepiphyseal dysplasia congenita, Schmid type metaphyseal dysplasia, and Ellis-van Creveld syndrome.

Idiopathic Short Stature

Several countries, including the United States, have approved GH therapy of ISS. It is important to recognize that this is a heterogeneous group of patients, as emphasized by Kelnar and coworkers.[802] Even though they are grouped under the title "normal short children" or as having "idiopathic short stature," this group includes children who have passed provocative GH testing but are nevertheless IGF deficient—reflecting the inadequacies of GH testing.

There is abundant evidence that determination of provocative GH levels does not adequately discriminate between true GHD (IGF deficiency) and ISS. In addition, the group labeled "normal short children" will inevitably contain children with unidentified syndromes and possibly with unidentified chronic illnesses or endocrine disorders. These issues have made it difficult to properly evaluate existing clinical trials. Furthermore, published clinical trials have not contained long-term control groups and have indicated considerable variability in growth response.[803-805]

The majority of normal short children treated with hGH have shown growth acceleration that is generally sustained over the first several years of therapy (although attenuation of the response is seen, just as in all other instances of hGH treatment). Longer-term data are inadequate, however, to address the impact of therapy on adult height. Hintz and coworkers[806] treated 80 children with ISS (0.3 mg/kg/wk) for 2 to 10 years and compared results with those in untreated short retrospective control subjects. In children with ISS, GH therapy increased the mean height SDS scores from −2.7 at the start of treatment to −1.4 at final height. The mean increase in final height over the pretreatment predicted adult height was 5 cm for boys and 5.9 cm for girls. Concern has been raised that hGH therapy in normal short children may result in an earlier onset of puberty—and as a result, earlier fusion of the epiphyses—and thereby may offset the positive response observed during the early years of hGH treatment.[807]

Other important questions have been raised about the financial, ethical, and psychosocial impact of hGH therapy on normal short children.[808] Given the current cost of hGH, the financial implications of treating normal short children (whether it is the bottom 5, 3, 1, or 0.1%) is considerable and potentially diverts a limited pool of health care resources away from other needs. The point is well taken that 5% of the population will always be below the 5th percentile whether we treat them with hGH or not. Concern has been raised that focusing on a short child's stature potentially disables an otherwise normal child, handicapping that child psychologically or socially. No convincing data have been presented that hGH treatment of normal short children improves psychological, social, or educational function. Finally, the known and unknown treatment risks of hGH therapy must be considered when treatment of otherwise normal children is an issue.

On the other hand, given the current limitations in our ability to clinically or biochemically discriminate definitively between GHD and normal short stature, our inadequate understanding of neurosecretory defects of GH secretion, our inadequate definition of "partial" GHD, and the need to move to a more global concept of "IGF deficiency," it seems unfair to prevent hGH therapy of short children who do not meet a definition of GHD (i.e., provocative testing) we recognize as inadequate. Many of these children behave clinically and biochemically in a manner identical to those with classic GHD.

The mean improvement in adult height in children with ISS attributable to GH therapy (average duration of 4 to 7 years) is 3.5 to 7.5 cm compared to initial predicted adult height. Responses are highly variable and are dose dependent. Concern has been raised that in ISS, higher GH doses (> 50 ug/kg/day) may advance bone age (BA) and the onset of puberty, but this has not been seen in other studies.

Multiple factors affect the growth response to GH in ISS, most of which are unknown. The first-year response is influenced negatively by age at start (and positively by GH dose), weight at start, and difference from target height—and these factors account for approximately 40% of the variance. Adult height outcome is influenced negatively by age at start and positively by midparental height, height at start, bone age delay, and the first-year response to growth hormone.[807] The utility of baseline and treatment-related biochemical data including IGF-I has not been validated in long-term studies, but 2-year studies suggest that the rise in IGF-I correlates with short-term height gain.

Children treated with GH should be monitored for height, weight, pubertal development, and adverse effects at 3- to 6-month intervals. Periodic monitoring for scoliosis, tonsillar hypertrophy, papilledema, and slipped femoral capital epiphyses (SCFE) should be performed as part of the regular physical exam during follow-up visits. We recommend that after 1 year the response to therapy be assessed by calculating height velocity SDS as well as the change in height SDS. Bone age may be obtained periodically to reassess height prediction and for consideration of manipulation of the tempo of puberty. IGF-1 levels may be helpful in guiding GH dose adjustment, but the significance of abnormally elevated IGF-1 levels remains unknown. Thus far, no cases of elevated blood glucose in GH treated patients with ISS have been reported—but there is controversy regarding the need for routine monitoring of glucose metabolism.

Dosage is usually selected and adjusted by weight. If the growth response is considered inadequate, the dose may be increased. There are no definitive data concerning the long-term safety of doses exceeding 50 ug/kg/day in ISS. The upper limit of GH dosage used in ISS and other indications is approximately 70 ug/kg/day,[789,806] but the possibility of using such doses varies in terms of national health economics. In the future, growth prediction models may improve GH dosing strategies. IGF-1 levels may be helpful in assessing compliance and GH sensitivity. Levels that are consistently elevated (> 2.5 SDS) should prompt consideration of GH dose reduction. Studies on IGF-based dose adjustments in ISS have demonstrated increased short-term growth when higher IGF targets were selected, but this strategy has not been validated in long-term studies in terms of safety or final height effects.

If height prediction is below –2 SDS at the time of pubertal onset in either sex, the addition of GnRH analogues may be considered. Alternatively, in males aromatase inhibitors may also be an option. However, long-term efficacy and safety data are not available for either of these interventions. In addition, the impact of delayed puberty on somatic and psychological development is not known. We do not recommend aromatase inhibitors in girls.

There are two schools of thought about the duration of treatment. One is that treatment should stop when near-adult height is achieved, which is Ht velocity < 2 cm/year or bone age > 16 years (in boys) and > 14 years (in girls). Alternatively, therapy can be discontinued when height is in the "normal" adult range (above –2 SD) or has reached another cutoff for the reference adult population (for example, in Australia the 10th percentile; elsewhere, the 50th percentile). Stopping therapy is influenced by patient/family satisfaction with the result of therapy, ongoing cost-benefit analysis, and when the child wants to stop for other reasons.

Miscellaneous Causes of Growth Failure

In addition to the clinical conditions described previously, hGH has been employed in treatment of short stature associated with a variety of other conditions characterized by postnatal growth failure (e.g., neurofibromatosis or inflammatory bowel disease). In general, such trials have been uncontrolled and have not included sufficient numbers of subjects for adequate evaluation of efficacy. A review of a large database, however, indicates that many of these conditions might in fact be responsive to GH therapy.[809]

Although this database is uncontrolled, 4-year results of GH treatment of Russell-Silver syndrome dwarfism, neural tube defects, neurofibromatosis, and familial hypophosphatemic rickets were indistinguishable from those observed with GH treatment of "idiopathic GHD" using comparable dosages of GH. Furthermore, a variety of other conditions (such as Down syndrome, cystic fibrosis, fetal alcohol syndrome, Crohn's disease, sickle cell anemia, hypochondroplasia, and thalassemia) responded in a manner comparable to that observed with Turner syndrome.

Although management of such patients is often complex and important ethical issues may characterize the use of GH, one must conclude that, at least on auxologic grounds, it becomes difficult to discriminate among GHD (as currently diagnosed), Turner syndrome, and many other medical conditions characterized by growth failure. If, as proposed by Allen and Fost,[810] responsiveness to GH rather than GHD should be the most important criterion for GH treatment, these findings indicate that GH therapy for many of these "other" conditions warrants an open-minded appropriately controlled evaluation. From a practical perspective however, it has

become more difficult for the clinician to consider a GH trial in patients with the aforementioned conditions. Reasons for this include not only the paucity of long-term data from controlled studies but also the cost burden to society associated with the high expense of GH therapy itself. Finally, the lack of strong quality-of-life data warrants that consideration of a GH trial in these "other" patients is done via research protocols. Only with well-designed studies enrolling sufficient patient numbers and continuing until near-adult height has been attained will we determine if GH therapy is both efficacious and safe in these "other" conditions.

Normal Aging and Other Catabolic States

A lengthy discussion of the potential use of hGH in normal aging is beyond the scope of this chapter.[184] The rationale for therapy is based on the concept of the "somatopause," referring to the fact that GH secretion normally declines progressively after 30 years of age—reflected in decreasing serum concentrations of IGF-1. Aging can be viewed as a catabolic state, with the potential that hGH therapy will reverse or retard the loss of muscle mass and strength and the decrease in bone density characteristic of the older population.

It is also conceivable, however, that aging individuals may be more sensitive to the metabolic changes produced by hGH, resulting in fluid accumulation, carpal tunnel syndrome, and glucose intolerance. Clinical studies are currently in progress. hGH therapy is also being investigated in a variety of catabolic states,[185] such as burns, tumor cachexia, major abdominal surgery, AIDS, sepsis, and hyperalimentation. Although the frontiers of new indications of GH therapy are being explored in well-controlled trials, we believe that, outside of appropriate clinical studies, clinicians should not routinely treat aging, catabolic states, and other unapproved indications for GH therapy.

Side Effects of Growth Hormone

Pituitary-derived hGH, which for a quarter of a century had an enviable safety record, proved to be the agent for transmission of the fatal spongiform encephalopathy Creutzfeldt-Jakob disease.[727,805] Although this risk does not exist with recombinant DNA-derived hGH, the experience with pituitary hGH serves as a grim reminder of the potential toxicity that can reside in "normal" products and "physiologic replacement." Nevertheless, 20-plus years of extensive experience with rhGH has been encouraging. Concerns have been raised, however, about a number of potential complications that clearly required continued follow-up and assessment. This evaluation has been greatly facilitated by the extensive databases established by hGH manufacturers.

Development of Leukemia

In 1988, the development of leukemia as a complication of hGH therapy was reported in 5 cases from Japan.[392] Since then, more than 30 cases of leukemia in hGH-treated patients have been reported—a disproportionate number coming from Japan,[393] but with cases also reported in the United States.[394] One of the difficulties in assessing the role of hGH treatment in these cases was that many children with GHD have clinical conditions that may predispose them to the development of leukemia, such as histories of previous malignancies, histories of irradiation, and underlying syndromes known to predispose to the development of leukemia (Bloom syndrome, Down syndrome, Fanconi anemia).

Patients have included recipients of pituitary-derived and recombinant DNA–derived hGH, and leukemia has occurred both during treatment and after termination of therapy. Cases of leukemia have been also reported in GH-deficient individuals without any history of hGH therapy, suggesting that the GHD state by itself might be a predisposing factor. In a comprehensive set of large cohorts of patients from the United States, Europe, and (most recently) Japan, the concern of increased leukemia risk in patients with GHD without predisposing factors has been dispelled.

In a large series describing the entire Japanese experience, the same authors who first reported the increased incidence of leukemia in GHD reanalyzed their data—together with a much larger number of patients treated since the original report—and showed that the risk for leukemia is the same for GH recipients and controls.[811] Consequently, most authorities now agree that hGH treatment is not a causative agent in the development of leukemia in individuals without a predisposing condition. The notion that hGH therapy is linked to development of leukemia should be dispelled and the authors recommend that this issue be discussed with all potential recipients of hGH.

Recurrence of CNS Tumors and Occurrence of Second Malignancies

Because many recipients of hGH have acquired GHD from CNS tumors or their treatment, the possibility of tumor recurrence is of obvious importance. Extensive analysis of the data on 1300 American children treated for a CNS malignancy before receiving hGH has not indicated any increased risk. A similar conclusion has emerged from analysis of a European database. However, one study suggests that GH recipients who had a brain tumor have a slightly higher risk of a second malignancy.[812]

Pseudotumor Cerebri

Pseudotumor cerebri (idiopathic intracranial hypertension) has been reported in at least 26 hGH-treated patients, approximately half of whom had classic GHD.[813] The mechanism of hGH action is unclear, but it may reflect changes in fluid dynamics within the CNS. Pseudotumor cerebri has also been described after thyroid hormone replacement and may represent restoration of a normal physiologic state. In any case, physicians need to be alert to complaints of headache, nausea, dizziness, ataxia, and visual changes; the presence of papilledema warrants temporary discontinuation of GH treatment.

Slipped Capital Femoral Epiphysis

The potential association of slipped capital femoral epiphysis (SCFE) and GHD was first suggested by studies in rats.[814] It is clear that SCFE can be associated with hypothyroidism and GHD.[815,816] The potential role of hGH therapy has been more difficult to determine. This is in part because the incidence of SCFE in the normal population varies by age, sex, race, and geographic locale—being variously reported as between 2 and 142 cases per 100,000. Accordingly, although SCFE cannot at this time be definitively attributed to hGH therapy per se, complaints of hip and knee pain or displaying a limp should receive appropriate evaluation.

Miscellaneous Side Effects

A number of other physical concerns have been raised as possible consequences of hGH treatment, but available data are inadequate to ascribe a causal role to hGH treatment. The potential side effects include prepubertal gynecomastia, increased growth of nevi, behavior changes, scoliosis and kyphosis, worsening of neurofibromatosis, hypertrophy of tonsils and adenoids, and sleep apnea. This list is obviously only partial. It is best for the clinician to remember that GH and the peptide growth factors it stimulates are potent mitogens with diverse metabolic and anabolic actions. All patients receiving hGH treatment, even as replacement therapy, must be carefully monitored for side effects.

For the most part, the side effects of GH are minimal and rare. When they occur, careful history and physical examination are adequate to identify their presence. Management of these side effects may include transient reduction of dosage or temporary discontinuation of GH.[817] The association of GH treatment with insulin resistance is well documented,[818] and one report suggested that there is an increased incidence of development of diabetes in pediatric recipients of GH.[819] Most authorities agree, however, that rather than a side effect of GH this relationship probably represents a common susceptibility of patients to develop growth disorders and diabetes owing to a common genetic trait.[820]

In the absence of other risk factors, there is no evidence that the risk of leukemia, brain tumor recurrence, SCFE, and diabetes is increased in recipients of long-term GH treatment. In any case, any patient receiving GH who has a second major medical condition (such as a tumor survivor receiving GH) should be followed in conjunction with a specialist such as an oncologist or a neurosurgeon when appropriate. Although GH has been shown to increase the mortality of critically ill patients in the intensive care unit,[152] there is no evidence that GH replacement needs to be discontinued during intercurrent illness in children with GHD.

The Question of Long-Term Cancer Risk

Several epidemiologic studies have been published suggesting an association between high serum IGF-1 levels and the incidence of malignancies.[821,822] In addition, the risk of cancer calculated in those studies was increased for patients with low IGFBP-3 levels. Although additional studies are being conducted to verify or disprove the association between serum IGF-1 and cancer risk, the role of GH in this potential phenomenon should be carefully examined.

In a study analyzing the risk of colon cancer, it was shown that IGF-1 was not statistically associated with cancer risk. However, the combination of high IGF-1 and low IGFBP-3 was shown to be related to an increased risk (Table 10-11).[823] Notably, GH positively influences both parameters in parallel. This casts doubt on its role as a driving force in the IGF-cancer equation.

Additional epidemiologic data of note involve the risk of malignancy associated with acromegaly. A number of studies have been published that claimed to identify an association between acromegaly and colon cancer risk,[824-826] whereas others did not find significant associations.[827,828] The interpretation of these studies is hampered by their small size, uncontrolled retrospective nature, and multiple possible sources of bias. The largest study to date, reviewing more than a thousand patients, indicated that overall cancer incidence is not increased in acromegaly.[829] The overall incidence of colon cancer was also not shown to be increased in a study, although mortality from colon cancer was higher in this population—suggesting perhaps an effect of GH or IGF-1 on established tumors.[830]

One prospective analysis of colon cancer and colonic polyps in acromegalics using controlled colonoscopies did not observe an association between these two diseases when using autopsy series or prospective colonoscopy screening series for the control population.[831] It is notable that acromegaly is associated with a dramatic increase in the incidence of benign hyperplasia of several organs, including colonic polyps.[832] These findings raise the possibility that the GH-IGF axis may lead to symptomatic

TABLE 10-11 **Risk of Future Cancer Relative to Serum IGF-I and IGFBP-3 Tertiles** [837]

	IGF-I Lowest Tertile	IGF-I Middle Tertile	IGF-I Upper Tertile
IGFBP-3 upper tertile	—	—	—
IGFBP-3 middle tertile	—	—	—
IGFBP-3 lowest tertile	—	—	Fourfold increased risk

IGF, insulin-like growth factor; IGFBF-3, insulin-like growth factor-binding protein-3.

benign proliferative disease, which could be associated with symptoms (such as rectal bleeding) that would then lead to a potential detection (or ascertainment) bias.

Children receiving GH have not been shown to have an increased risk of de novo tumors. An earlier concern that leukemia risk was increased has been dispelled by the same authors who first published on this topic, showing in a large cohort that the risk for leukemia is the same for GH recipients and controls.[833] Several studies now indicate absolutely no increase in the risk of tumor recurrence in pediatric GH recipients.[834]

In a number of studies, no increased incidence of cancer was found in GH recipients among adults treated for GHD.[835,836] Clearly, these reports represent imperfect uncontrolled studies. However, the experience gained through them demonstrates that even though the IGF-1 levels are normalized, GH therapy is not associated with tumor recurrence or with de novo tumors in the absence of other risk factors. The use of IGF-1 and IGFBP-3 in the monitoring of GH recipients, adult and pediatric, has been recommended and endorsed by international bodies such as the GH Research Society.[817]

Until the issue of cancer risk in GH therapy is fully resolved, the most prudent approach appears to be regular monitoring of IGF-1 and IGFBP-3 and modulation of the GH dose to ensure that the theoretical risk profile induced by GH therapy is favorable. This can be done by avoiding the unlikely situation in which a GH-treated patient will have an IGF-1 level at the upper end and IGFBP-3 levels at the lower end. In the 21st century, many patients with GHD will receive lifetime GH replacement. In that setting, it is especially important that we monitor serum IGF-1 and IGFBP-3 on a regular basis.

Overall, many controversies still surround the issue of the GH-IGF axis and cancer risk, specifically concerning the safety of GH therapy. In general, the currently approved indications for GH therapy in children and adults do not warrant concern regarding future cancer risk. Although additional research coupled with stringent pharmacologic vigilance is clearly warranted, the state of the clinical field mandates that patients' physicians be aware of the vast body of evidence regarding the safety of GH in this regard.[837]

Treatment of Primary Severe IGFD: Use of IGF-I

The production of IGF peptides by recombinant DNA technology has permitted clinical trials of IGF therapy. IGF-I administration to normal adult male volunteers as a single intravenous injection of 100 μg/kg caused hypoglycemia within 15 minutes. On a molar basis, IGF-I has approximately 6% of the hypoglycemic potency of insulin. In contrast, intravenous infusions of IGF-I to normal men at a rate of 20 μg/kg/hr resulted in serum IGF-I levels within the normal range and did not produce hypoglycemia—but did suppress GH levels, increase creatinine clearance, and decrease plasma urea nitrogen.[100,838-846]

The most obvious clinical use of IGF-I therapy is in patients with GHI. A number of short-term growth-related studies with IGF-I treatment at varied doses have been reported since the mid-1990s. Walker and associates[842] reported an increase in growth rate from 6.5 to 11.4 cm/year in a patient with GHRD treated with twice-daily subcutaneous injections of 120 μg/kg. Wilton and coworkers[843] have reported preliminary data in 30 children, aged 3 to 23 years, with GHI (due to GHRD or GHD-IA with anti-GH antibodies). The dosage of IGF-I varied from 40 to 120 μg/kg twice daily. With the exception of the two oldest patients, the growth rates of all subjects increased by at least 2 cm/year. These results have since then been updated and indicate a continued good response by most subjects (n = 32).[844] Observed side effects included hypoglycemia, headache, convulsions, possible urolithiasis, and papilledema—the last indicating the possibility of pseudotumor cerebri, as has been reported with GH therapy. Data from 17 patients in the European collaborative trial, treated for at least 4 years, showed an increase in mean height SD score from –6.5 to –4.9—with two adolescents reaching the third percentile.[846] This emphasizes the importance of early diagnosis and initiation of therapy. Side effects reported were again hypoglycemia, headache, convulsions, and papilledema. The latter, which suggests the possibility of pseudotumor cerebri, resolved spontaneously while the patient was receiving IGF-I. Laron and coworkers[841] reported significant growth acceleration—to rates of 8.8 to 13.6 cm/year in five children treated for 3 to 10 months with a single daily injection of 150 μg/kg. The use of IGF-I in milder forms of primary IGFD has also been the subject of investigation. Vaccarello and coworkers[101] treated six adults with GHRD for 7 days with subcutaneous IGF-I at a dosage of 40 μg/kg every 12 hours. Normal serum IGF-I concentrations were achieved 2 to 6 hours postinjection, followed by a rapid decline—reflecting low serum concentrations of IGFBP-3. Symptomatic hypoglycemia was not observed, but mean 24-hour GH levels were significantly suppressed and urinary calcium level was increased. A randomized double-blind placebo-controlled trial of IGF-I therapy in GHRD was performed in Ecuador, probably the only place where the population is sufficiently large and homogeneous to permit such investigation.[845] Subjects receiving IGF-I showed a significant increase in growth rate (from 2.9 to 8.6 cm/year), which was sustained over the 1-year course of therapy. The placebo group grew 4.4 cm/year during the placebo phase, and their height velocity increased to 8.4 cm/year during the IGF-I phase. Incidents of hypoglycemia were equal in the two experimental groups. One recipient of IGF-I developed papilledema, which resolved spontaneously while the patient was being treated.

In the longest treatment trial from North America, Chernausek and colleagues[840] showed data similar to that found in the European study—with an initial burst of growth followed by slowing to just above baseline by the sixth year of therapy. Height SD score improved from –5.6 to –4.2 by the end of the sixth year (Figure 10-33).

Although these early studies were promising, little was known about the long-term effects of IGF-I or about the optimal dose or frequency of administration. With all clinical studies combined, the total number of children treated is still only several hundred—and relatively few

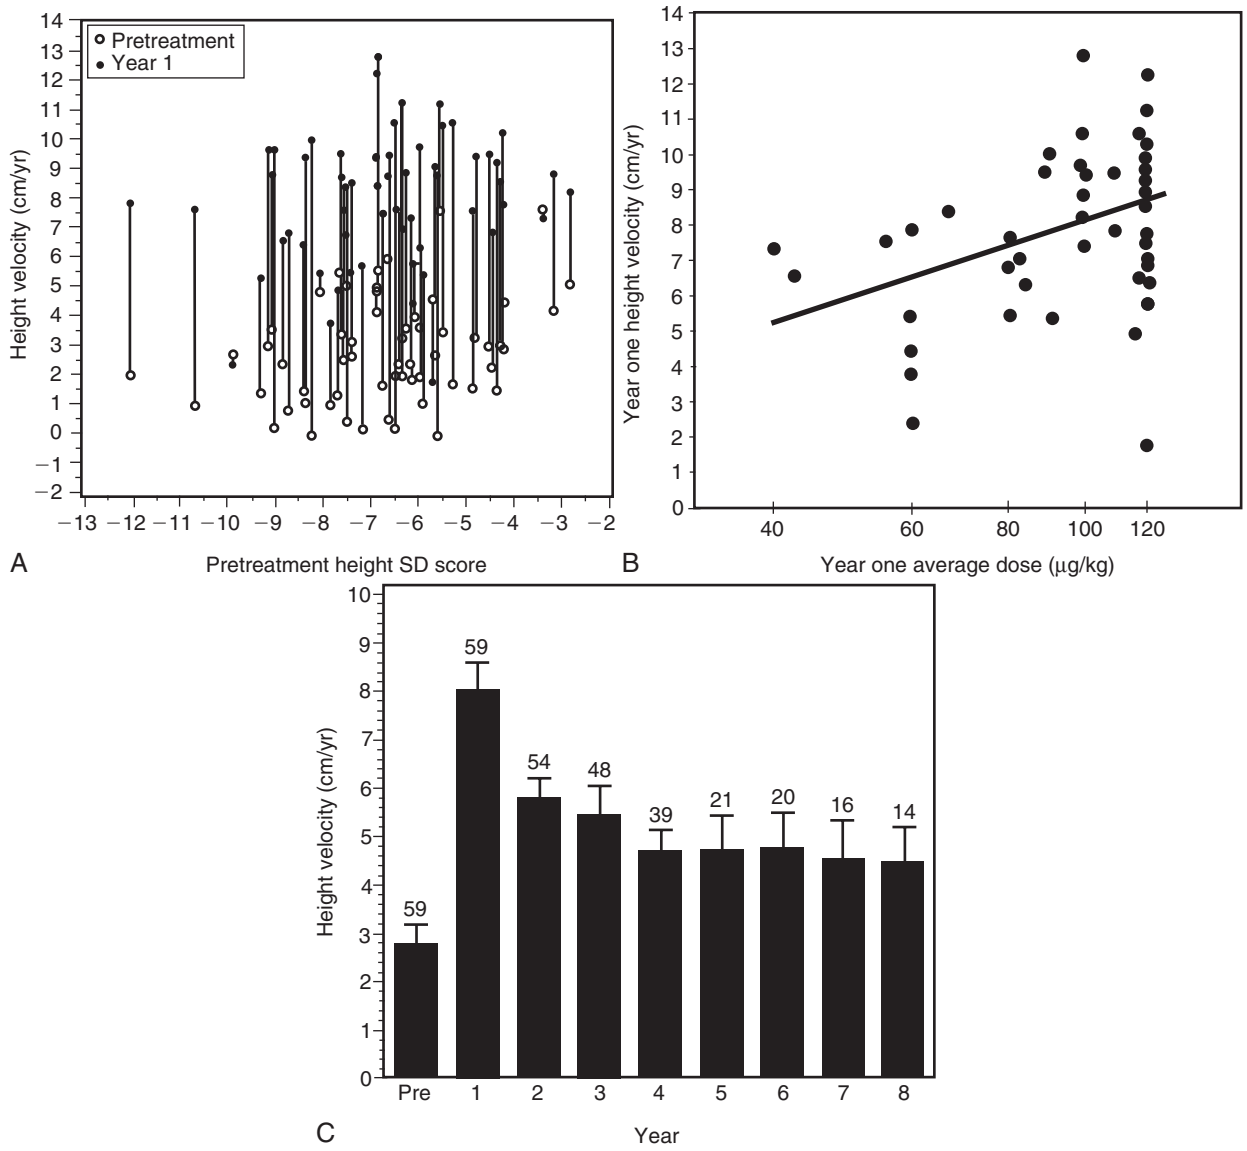

FIGURE 10-33 ■ Linear growth in response to rhIGF-I treatment. **A**, Height velocity (centimeters per year) before (open circle) and during first year of therapy (closed circles) for each child is displayed relative to pretreatment height. **B,** The dose dependency of first-year growth rate is shown. Each point represents a single subject. The equation for the regression line shown is *Height velocity (centimeters per year) = –6.2 + 7.2 log10 rhIGF-I dose (microgram per kilogram, BID)*. **C**, Average growth rates before and during rhIGF-I for first and subsequent years are shown. Error bar shows upper limit of 95% confidence interval. Number of subjects at each year is indicated. (From Chernausek, S. D., Backeljauw, P. F., Frane, J., et al. for the GH Insensitivity Syndrome Collaborative Group (2007). Long-term treatment with recombinant insulin-like growth factor [IGF]-I in children with severe IGF-I deficiency due to growth hormone insensitivity. *J Clin Endocrinol Metab, 92*, 902–910.)

have been treated for more than 5 years. The long-term trial from the United States now has reported on final and near-final adult height from 16 of the patients (9 males, 7 females).[847] Recombinant human IGF-I was administered for a mean of 10 years at a dose of 120 μg/kg subcutaneously twice daily. Mean baseline height SD score improved from −7.1 to −5.2 at last analysis. As a result of IGF-I therapy, the mean estimated gain in height was 13.2 cm (range −0.4 to 23.4 cm). No new safety signals were identified in these patients, which made up a subset of those previously reported.[840] Additional patients from this cohort have completed treatment since then, and data are currently under review for publication. It is likely that this will be the only trial, in the near future, that can provide long-term information on the efficacy and safety of IGF-I therapy in patients who are IGF deficient. Taken together, the IGF-I treatment studies show that, although clinically significant, the growth response is neither as successful nor as long-lived as that of GHD children treated with exogenous GH. The failure of serum levels of IGFBP-3 to increase with IGF-I administration and the suppression of endogenous GH secretion underscores the complexity of the treatment. The possibility that local production of IGF-I at the growth plate may be critical to optimal growth also requires consideration. In addition, suboptimal treatment

adherence with prolonged twice-daily administration may also have contributed to the modest treatment response. Nevertheless, these data indicate that the IGF peptides (long considered to function as autocrine or paracrine growth factors) can act as classic endocrine hormones.

IGF-I has received FDA approval in 2005 for the treatment of severe primary IGF deficiency, defined as serum IGF-I < −3 SD score, height < −3 SD score, and normal GH concentrations. The same indication was also approved in Europe in 2007 (although there the low IGF-I is defined as < 2.5th percentile). The drug shows promise in treatment of severe primary IGFD. However, from analysis of the different cohorts previously treated with IGF-I we learn that the spectrum of GH insensitivity, or IGF deficiency for that matter, is likely much wider that what the small group of patients with GHRD due to homozygous single gene defects would indicate. In the U.S. and European studies, as well as in the Ecuadorian cohort, the height range of the patients was quite variable (from −3 to −4 SD score to −8 to −10 SD score). The best treatment approach to such a broad range of patients still needs to be determined. Additional studies will show which patients will benefit the most from IGF-I therapy. One such trial was a 1-year, randomized, open-label trial of 136 short, prepubertal subjects with low IGF-I (height and IGF-I SD scores < −2, stimulated GH ≥ 7 ng/mL). IGF-I was administered subcutaneously twice daily, using a weight-based approach (80 or 120 μg/kg; n = 111), or subjects were observed without therapy (n = 25). First-year height velocity for subjects completing the trial was increased for both IGF-I treated groups versus the untreated control group (7 ± 1.0, 7.9 ± 1.4, and 5.2 ± 1 cm/year, respectively; all $P < 0.0001$).[848] These results indicate that IGF-I therapy in these short subjects with relatively low IGF-I and normal GH achieved growth responses similar to—but not superior to—those that have been reported in patients with idiopathic short stature on standard GH therapy. Based on this information, a logical management approach for patients with milder forms of IGF deficiency would be to combine GH therapy with IGF-I therapy. The theoretical basis for this combo-treatment approach is the potential enhancement of the direct growth-promoting effects of GH through maintaining normal IGFBPs and ALS concentrations. Preliminary information from such a trial have been presented at endocrinology meetings and seem to indicate a superior growth response with the GH plus IGF-I combination over GH alone in patients with short stature (height < −2 SD score) and low to low-normal IGF-I.[849] As of late 2012, the data from this study have not been subjected to peer review for publication, however. For this reason, it is premature to consider such combination therapy as either efficacious or safe for patients with mild IGF-I deficiency or idiopathic short stature plus low IGF-I.

As promising as all these studies are, IGF-I therapy is still under active investigation and the exact clinical scenarios for which this therapy is most appropriate is still evolving. The failure of serum levels of IGFBP-3 to rise with IGF-I administration underscores the relevance of the IGFBPs to IGF pharmacokinetics.[101,845] Nevertheless, these results also indicate that the IGF peptides (long considered to function primarily as autocrine or paracrine growth factors) are capable of acting as classic endocrine hormones.

EXCESS GROWTH AND TALL STATURE

Tall Stature and Overgrowth Syndromes

On a statistical basis, as many children have heights below −2 SD as have heights above +2 SD, but referral for evaluation of tall stature is much less common than for short stature. This referral pattern speaks eloquently to the psychosocial pressure involved in referral patterns of children with "growth disorders." Nevertheless, it is critical to be able to identify situations in which tall stature or an accelerated growth rate provides a clue to an underlying disorder. Box 10-10 provides a listing of causes of statural overgrowth in infancy and during childhood.

BOX 10-10 Differential Diagnosis of Statural Overgrowth

Fetal Overgrowth

- Maternal diabetes mellitus
- Genetic hyperinsulinism-(KATP channel defects, activating Glud1and GCK, others)
- Cerebral gigantism (Sotos syndrome)
- Weaver syndrome
- Beckwith-Wiedemann syndrome
- Other IGF-2 excess syndromes

Postnatal Overgrowth Leading to Childhood Tall Stature

- Familial (constitutional) tall stature
- Cerebral gigantism
- Beckwith-Wiedemann syndrome
- Exogenous obesity
- Excess GH secretion (pituitary gigantism)
- McCune-Albright syndrome or multiple endocrine neoplasia associated with excess GH secretion
- Precocious puberty
- Marfan syndrome
- Klinefelter syndrome (XXY)
- Weaver syndrome
- Fragile X syndrome
- Homocystinuria
- XYY
- Hyperthyroidism

Postnatal Overgrowth Leading to Adult Tall Stature

- Familial (constitutional) tall stature
- Androgen or estrogen deficiency/estrogen resistance (in males)
- Testicular feminization
- Excess GH secretion
- Marfan syndrome
- Klinefelter syndrome (XXY)
- XYY

GH, growth hormone; IGF, insulin-like growth factor.

Overgrowth in the Fetus

Maternal diabetes constitutes the most common cause of overgrowth in infants who are large for gestational age. Even in the absence of clinical symptoms or a family history, the birth of an excessively large infant should lead to evaluation for maternal (or gestational) diabetes or for a genetic cause of hyperinsulinism most commonly involving inactivating mutations in the KATP genes ABCC8 and KCNJ11 (see Chapter 6). A group of disorders associated with excessive somatic growth and growth of specific organs has been described and collectively referred to as overgrowth syndromes.[850] These overgrowth disorders appear, at least in part, to be caused by excess availability of the IGF-2 encoded by the gene Igf2. The best described of these syndromes is the Beckwith-Wiedemann syndrome, which is an overgrowth malformation syndrome that occurs with an incidence of ~ 1:13,700 births. Children conceived through assisted reproductive techniques (ART) are several-fold more likely to develop Beckwith-Wiedemann syndrome. It is unclear if maternal loss of methylation, seen in children post-ART, is due to the procedure of in vitro fertilization or could be associated to the preexisting decreased fertility or some other genetic/environmental factor inherent to the parents using ART to conceive.

Beckwith-Wiedemann syndrome is manifested as a fetal overgrowth syndrome in which hypertrophy/hemihyperplasia dominates the clinical picture. Typically, macroglossia, omphalocele, hepatosplenomegaly, nephromegaly, and hypoglycemia secondary to pancreatic beta cell hyperplasia in an infant who is large for gestational age constitute the clinical picture at birth. Infants often have the pathognomonic creases and pits of the ear lobes. An additional complication is that these children are predisposed to a specific subset of childhood neoplasms, including Wilms tumor, hepatoblastoma, rhabdomyosarcoma, neuroblastoma, and adrenocortical carcinoma.

Beckwith-Wiedemann syndrome is an imprinting disorder. About 80% to 85% of newly diagnosed cases are sporadic; this means that about 15% 20% of cases are familial. Various lines of investigation have localized several "imprinted" genes involved in Beckwith-Wiedemann syndrome and associated childhood tumors to chromosome 11p15.5.[851] Beckwith-Wiedemann syndrome is due to epigenetic or genomic changes that potentially affect gene clusters in two distinctly imprinted regions on chromosome 11p15.5. The first of these, an area called domain 1, localizes insulin-like growth factor 2 (*IGF2*) and *H19* as two monoallelic expressed genes. In children with Beckwith-Wiedemann syndrome, overexpression of *IGF2* may occur by one of several mechanisms: gene duplication, loss of heterozygosity, and relaxation or loss of maternal imprinting of the Igf2 gene. In each situation, Igf2 gene up-regulation during early embryo and fetal development is thought to play a crucial role in the pathogenesis of Beckwith-Wiedemann syndrome. The *H19* gene, on the other hand, normally encodes a transcript believed to play a role in tumor suppression and has also been implicated in growth restriction. Molecular changes of the domain 1 area are the cause of about 5% of cases of Beckwith-Wiedemann syndrome. The other implicated region, called domain 2, harbors the growth repressor gene *CDKN1C* and the *KCNQ1OT1* gene—also both normally expressed in a monoallelic fashion.[852] Several molecular mechanisms can result in reduced expression of the *CDKN1C* gene. This is a maternally expressed gene that encodes a cyclin-dependent kinase inhibitor that normally negatively regulates cell proliferation. Mutations in *CDKN1C* have been found in about 10% of patients with Beckwith-Wiedemann syndrome. The precise mechanism by which *KCNQ1OT1* leads to Beckwith-Wiedemann syndrome is still not clear yet. Paternal uniparental disomy that incorporates both imprinted gene clusters on chromosome 11p15.5 has now been reported in a total of about 20% of new patients with Beckwith-Wiedemann syndrome.[853] The clinical characteristics of these patients (all with uniparental disomy) include, as noted before, hemihyperplasia of several regions of the body; at the same time, these patients present with varying degrees of somatic mosaicism. For this reason, the molecular defect causing this disorder is most likely due to postzygotic somatic recombination.[854] Finally, other investigations into new cases of Beckwith-Wiedemann syndrome have described mutations outside the chromosome 11p15.5 region.[855] Mutations in GPC3 located at Xq26.2, a glypican gene that codes for an IGF-2 neutralizing membrane receptor, cause the related Simpson-Golabi-Behmel overgrowth syndrome.[856] Key features include large birth weight, tall stature as adults, macrocephaly, coarse facies, vertebral anomalies, polydactyly and syndactyly, and thickened dark skin. There is some evidence for a nonfunctional GPC3 to increase IGF2 signaling. However, certain other defects in cellular signaling, potentially involving Wnt or fibroblast growth factors, also may be responsible for the clinical features of Simpson-Golabi-Behmel syndrome.

Children with cerebral gigantism (also known as Sotos syndrome) are typically above the 90th percentile for both length and weight at birth, and macrocrania may also be noted at that time.[857] Mutations and (micro) deletions of the NSD-1 gene (located at chromosome 5q35.2–35.3) and coding for a histone methyltransferase implicated in transcriptional regulation were first found to be the basis for this disorder. Fluorescence in situ hybridization (FISH) analysis, MLPA, or multiplex quantitative PCR allow the detection of total/partial NSD-1 deletions—and direct sequencing allows detection of NSD-1 mutations. The large majority of NSD-1 abnormalities arise as de novo mutations, and there are few familial cases. The specific cause is haploinsufficiency of the nuclear receptor binding SET domain protein-1, which explains about 60% to 90% of cases. Genome wide SNP array analysis has indicated that other genetic regions (e.g., pathogenic copy number variants on chromosomes 10, 14, 15, and the X chromosome) could also be involved in some of the patients diagnosed with Sotos syndrome.

Although most cases are sporadic, several reports of autosomal-dominant inheritance have been described.[857] Growth is rapid, and by 1 year of age affected infants are over the 97th percentile in length. Accelerated

growth continues for the first 4 to 5 years and then returns to a normal rate. Puberty usually occurs at the normal time but may occur slightly early. Adult height is usually in the upper normal range. The hands and feet are large, with thickened subcutaneous tissue. The head is large and dolichocephalic, the jaw is prominent, there is hypertelorism, and the eyes have an antimongoloid slant. Clumsiness and awkward gait are characteristic, and affected children have great difficulty in sports, in learning to ride a bicycle, and in other tasks requiring coordination.

Some degree of mental retardation affects most patients. In some children, perceptual deficiencies may predominate. Osseous maturation is compatible with the patient's height. Results of tests of GH and IGF-1 levels and of other endocrine studies are usually normal. There are no distinctive chemical or radiologic markers for Sotos syndrome. Abnormal electroencephalograms are common. Imaging studies frequently reveal a dilated ventricular system. Most cases are sporadic. Familial cases are usually consistent with autosomal-dominant inheritance and occasionally with autosomal-recessive inheritance. Affected patients may be at increased risk for neoplasia; particularly hepatic carcinoma and Wilms, ovarian, and parotid tumors have been reported.

Weaver syndrome is a clinical entity of rapid growth and skeletal maturation, combined with craniofacial dysmorphism, a hoarse and low-pitched cry, hypertonia, and camptodactyly. The accelerated growth has a prenatal onset, and weight is more increased that height. Clinical presentation resembles Sotos syndrome in some way, but there are specific differences in facial appearance and the risk of malignancy (elevated risk in Sotos syndrome, not in Weaver syndrome). The genetic basis of Weaver syndrome has not been identified, but mutations in the EZH2 gene or NSD-1 gene have been implicated.[858] Most cases of Weaver syndrome are sporadic, with only a few familial cases reported.

Tall Stature and Postnatal Statural Overgrowth

The normal distribution of height predicts that 2.5% of the population will be taller than 2 SD above the mean. The social acceptability and even desirability of tallness ("heightism") makes tall stature an uncommon complaint, however. In North America, it is extremely unusual for males to seek help regarding excessive height—although in Europe it has been somewhat more common in previous decades. Even in females, tall stature has become more socially acceptable— although an occasional tall girl may still approach the physician with a desire to curb her growth rate.

Differential Diagnosis of Tall Stature

Box 10-10 lists the causes of tall stature in childhood and adolescence. Of these, the normal variant familial or constitutional tall stature is by far the most common cause. Almost invariably, a family history of tallness can be elicited—and no pathologic process is present. The child is often tall throughout childhood and enjoys excellent health. The parent of the constitutionally tall adolescent may reflect unhappily on his or her own adolescence as a tall teenager. There are typically no abnormalities in the physical examination, and the laboratory studies (if obtained) are always negative. Bone maturation tends to be commensurate with chronologic age,

As was described for the child with growth failure, crossing height percentiles between infancy and the onset of puberty always warrants further evaluation. Although such growth patterns frequently are of no concern to parents, an alert pediatrician will recognize that overly rapid statural growth can indicate a serious underlying problem. Furthermore, as with short stature, children with tall stature must be evaluated in the context of their familial growth and pubertal patterns.

Klinefelter syndrome (XXY syndrome) is a relatively common (1:500 to 1:1000 live male births) abnormality associated with tall stature, mild mental retardation, gynecomastia, and decreased upper-to-lower body segment ratio. The testes are invariably small, although androgen production by Leydig cells is often at the low-normal range. Spermatogenesis and Sertoli cell function are defective, resulting in infertility. XYY syndrome is associated with tall stature and possible behavioral and mental problems.

Marfan syndrome is an autosomal-dominant connective tissue disorder consisting of tall stature, increased arm span, and decreased upper-to-lower body segment ratio. The cause of Marfan syndrome is a mutation in the *FBN1* gene located on chromosome 15. FBN1 encodes a glycoprotein called fibrillin-1, which is a crucial in the development of the extracellular matrix and elastin. Additional physical abnormalities include arachnodactyly, ocular abnormalities (including usually an upward/superotemporal lens subluxation), and cardiac anomalies. Homocystinuria is an autosomal-recessive inborn error of amino acid metabolism causing mental retardation when untreated. Homocystinuria is due to a deficiency in cystathionine beta synthase. It has many features resembling Marfan syndrome, particularly ocular manifestations (lens subluxation is usually downward/inferonasal). Hyperthyroidism in adolescence is associated with rapid growth but normal adult height. It is almost always caused by Graves' disease and is much more common in females. Other clinical entities, mostly rare ones, have been associated with increased growth—at least for part of postnatal life.[858] These include a contiguous deletion syndrome known as 22q13 deletion syndrome or Phelan-McDermid syndrome, Bannayan-Riley-Ruvalcaba syndrome (an autosomal dominant disorder caused by haploinsufficiency of the phosphatase and tensin homologue (PTEN) gene at 10q23.31), and Proteus syndrome (asymmetric and disproportionate overgrowth of body parts only now known to be due to an activating mutation in AKT1).[859] In neurofibromatosis type 1, many patients are described to have suboptimal growth in childhood, but some patients have tall stature. Perlman syndrome (macrosomia, nephromegaly, hypotonia, and often death in early infancy), and Nevo syndrome (a subtype of Ehlers-Danlos syndrome with increased length early in life and caused by mutations in the PLOD1 gene on chromosome 1, important for hydroxylation of lysyl residues in collagen proteins) are extremely rare.

Much more common is exogenous obesity, a frequently occurring condition in childhood and adolescence

associated with rapid linear growth and early maturation. This association is so characteristic that the child with a combination of obesity and short stature should always be evaluated for an underlying pathologic process such as hypothyroidism, GHD, Cushing syndrome, and various syndromes (such as Prader-Willi). In exogenous obesity, bone age is usually modestly accelerated—and thus puberty and epiphyseal fusion occur early, resulting in normal adult height. As stated, cerebral gigantism and Beckwith-Wiedemann syndrome are associated with rapid pre- and perinatal growth, but rapid postnatal growth usually ends by early to mid-childhood. Nevertheless, these conditions should be considered when tall stature in childhood is accompanied by the characteristic phenotypic features, a history of unexplained fetal overgrowth, or the presence of the childhood tumors mentioned previously.

Precocious and Delayed Puberty

Precocious puberty, whether mediated centrally (increased gonadotropin secretion) or peripherally (increased secretion of androgens, estrogens, or both), results in accelerated linear growth in childhood—mimicking the pubertal growth spurt. Because skeletal maturation is also accelerated, adult height, when left untreated, can be compromised. The diagnostic evaluation and management of precocious puberty are discussed in Chapters 15 and 17.

Although delayed puberty may be associated with short stature in childhood, as with constitutional delay, failure to eventually enter puberty and complete sexual maturation may result in sustained growth during adult life—with ultimate tall stature. The reports of tall stature in men with open epiphyses, resulting from mutations of the estrogen receptor or of the aromatase gene, underscores the fundamental role of estrogen in promoting epiphyseal fusion and termination of normal skeletal growth.[18,332]

Diagnosing Familial Tall Stature

The purpose of the diagnostic evaluation of tall stature is to distinguish the commonly occurring normal variant constitutional (or familial) variety from the rare pathologic conditions. Often, when the history is suggestive of familial tall stature and the physical examination is entirely normal, laboratory tests are not indicated. It is valuable to obtain a bone age radiograph to be able to predict adult height, which serves as a basis for discussions with the family and for management decisions. If, however, the history is suggestive for any of the previously mentioned disorders or the physical examination reveals abnormalities, additional laboratory tests should be obtained to evaluate for brain disorders, GH excess, chromosomal abnormalities, or other rare causes of tallness. For some of these disorders, genetic screening is available.

IGF-1 and IGFBP-3 are excellent screening tests for GH excess and can be verified with a glucose suppression test. Laboratory evidence of GH excess mandates MRI evaluation of the pituitary and the consideration of the McCune-Albright syndrome with should be made (see below). Thyroid function tests are useful to diagnose or rule out hyperthyroidism when Graves' disease is suspected.

Management of Constitutional and Syndromic Tall Stature

Reassurance of the family and the patients is the key to the management of normal variant tall stature. The use of the bone age evaluation and a careful assessment of pubertal status to predict adult height may provide some comfort for them, as will general supportive discussions on the social acceptability of this condition. Although treatment is available for girls and boys with excessive growth, its use should be restricted to patients with predicted adult height greater than 3 SD above the mean (198 cm in males or 180 cm in females) and evidence of significant psychosocial impairment.

For the child with extreme familial tall stature (or another condition, such as Marfan syndrome) whose parents feel strongly about treatment, a trial of sex steroids is possible. This therapy is designed to accelerate puberty and epiphyseal fusion and is therefore of little benefit when given in late puberty. Therapy is initiated ideally prepubertally or in early puberty. Oral estrogens in various doses have successfully reduced the predicted height of females by 5 to 6 cm on the average (and maximum 10 cm).[860]

This is a direct result of the known effects of sex steroids on promoting epiphyseal fusion, and therapy must therefore begin before the bone age has reached 12 years. Oral ethinyl estradiol at a dose of 0.15 to 0.5 mg/day until cessation of growth occurs has been used successfully in girls. If necessary, a progestational agent can be added after 1 year of unopposed estrogen. In boys, treatment should begin before the bone age reaches 13.5 to 14 years. One trial compared the effect of two treatment approaches using different androgen dosages; testosterone enanthate given at a dose of 250 mg every 2 weeks was as effective in reducing adult height as a dose of 500 mg every 2 weeks[861]; the lower dose is recommended.

Whereas no long-term complications of sex steroid therapy have been clearly documented, short-term side effects are common. These include lipid abnormalities, thromboembolism, cholelithiasis, hypertension, nausea, menstrual irregularities, and acne fulminans. The lack of extensive experience with this form of therapy and the risks involved should be carefully weighed and discussed with the family before embarking on therapy.

The mechanism of estrogen action affects both GH and IGF production. Perhaps more important, however, is the action of estrogen on the epiphyses. Studies have demonstrated that it is estrogen that mediates epiphyseal fusion in both females and males. In prepubertal girls, adult height is reportedly decreased by as much as 5 to 6 cm relative to pretreatment predictions. When therapy is initiated after the onset of puberty, the decrement in adult height is not likely to be as large. Therapy in boys with tall stature is even more problematic. For the reasons discussed, estrogen is likely to be most efficacious in accelerating epiphyseal fusion but is obviously undesirable in males. Androgens will also accelerate skeletal maturation, presumably through aromatization to estrogen, but at the price of rapid virilization.

Although psychoemotional arguments constitute the main reason for treating tall (predominantly) girls, prospective well-structured psychological evaluation of potential treatment candidates is often not pursued. In addition, more than 50 years of experience with growth-attenuating intervention has not yielded objective information indicating that being (too) tall when an adolescent or adult results in unequivocal lifelong psychosocial damage. The practice of treating girls with tall stature has certainly become less prevalent. This may in part be related to data from sociologic studies that confirm a tall woman can experience beneficial effects of her stature. These studies indicate positive influences of height on women's character perception.[862] Taller women are now more often perceived by their peers—and by men as well—as more intelligent, assertive, and ambitious compared to their shorter counterparts.

Excess GH Secretion and Pituitary Gigantism

In young persons with open epiphyses, overproduction of GH results in gigantism. In persons with closed epiphyses, the result is acromegaly. Often, some acromegalic features are seen with gigantism—even in children and adolescents. After closure of the epiphyses, the acromegalic features become more prominent. Famous examples of gigantism include Robert Wadlow (the Alton giant), who stood 271.8 cm at the time of his death in his mid-20s, and the well-known Andre Rousimoff (Andre the Giant), who was 190.5 cm at age 12 and reached a height of 223.5 cm by adulthood.[523] Pituitary gigantism is rare, and its cause is most often a pituitary adenoma—but gigantism has been observed in a 2.5-year-old boy with a hypothalamic tumor that presumably secreted GHRH. Other tumors, particularly in the pancreas, have produced acromegaly by secretion of large amounts of GHRH with resultant hyperplasia of the somatotrophs.[863] Activating mutations of Gsα as seen in the McCune-Albright syndrome can be associated with gigantism-acromegaly as discussed later.

The cardinal clinical feature of gigantism is longitudinal growth acceleration secondary to the GH excess. The usual manifestations consist of coarse facial features and enlarging hands and feet. In young children, rapid growth of the head may precede linear growth. Some patients have behavioral and visual problems. In most of the recorded cases, the abnormal growth became evident at puberty—but the condition has been established as early as the newborn period in one child and at 21 months of age in another. Giants may grow to a height of 243.8 cm or more. Acromegalic features consist chiefly of enlargement of the distal parts of the body, but manifestations of abnormal growth involve all portions.

The circumference of the skull increases, the nose becomes broad, and the tongue is often enlarged—with coarsening of the facial features. The mandible grows excessively, and the teeth become separated. Visual field defects and neurologic abnormalities are common. Signs of increased intracranial pressure appear later. The fingers and toes grow chiefly in thickness. There may be dorsal kyphosis. Fatigue and lassitude are early symptoms. GH levels are elevated and may occasionally exceed 100 ng/mL. There is typically no suppression of GH levels by the hyperglycemia of a glucose tolerance test. IGF-1 and IGFBP-3 levels are consistently elevated in gigantism, whereas other growth factors are not. Gigantism is extremely rare, with only several hundred reported cases. The presentation of gigantism is usually dramatic, unlike the insidious onset of acromegaly in adults.

The tumor mass itself may cause headaches, visual changes from optic nerve compression, and hypopituitarism. About half of the patients also have marked hyperprolactinemia as a result of plurihormonal adenomas that secrete GH and prolactin. This is because mammosomatotrophs are the most common type of GH-secreting cells involved in childhood gigantism. GH-secreting tumors of the pituitary are typically eosinophilic or chromophobe adenomas. Adenomas may compromise other anterior pituitary function through growth or cystic degeneration. Secretion of gonadotropins, thyrotropin, or corticotropin may be impaired. Delayed sexual maturation or hypogonadism may occur. When GH hypersecretion is accompanied by gonadotropin deficiency, accelerated linear growth may persist for decades. In some cases, the tumor spreads outside the sella—invading the sphenoid bone, optic nerves, and brain. GH-secreting tumors in pediatric patients are more likely to be locally invasive or aggressive than are those in adult patients.[522]

The cause of these tumors is uncertain, although studies of acromegalics have suggested that many cases result from mutations that generate constitutively activated G proteins with reduced GTPase activity. The resultant rise in intracellular cyclic AMP in the pituitary leads to increased GH secretion. McCune-Albright syndrome, which can also be caused by mutations resulting in constitutively activated G proteins, may also include the presence of somatotrophic tumors and excess GH secretion. In fact, approximately 20% of patients with gigantism are those with McCune-Albright syndrome (commonly consisting of a triad of precocious puberty, café-au-lait spots, and fibrous dysplasia). GH-secreting tumors have also been reported in multiple endocrine adenomatosis and in association with neurofibromatosis, tuberous sclerosis, and Carney complex.[864,865]

Activating mutations of the stimulatory Gsa protein have been found in the pituitary lesions in patients with McCune-Albright syndrome and are believed to be responsible for the other glandular adenomas observed in this condition as well. Somatic point mutations of the Gsa protein have also been identified in somatotrophs of up to 40% of sporadic GH-secreting pituitary adenomas.

Mutations in several additional genes have been identified. The aryl hydrocarbon receptor interacting protein (AIP) gene is implicated in about 15% of familial isolated pituitary adenomas (FIPA), a small number of cases of sporadic acromegaly, and an unknown number of sporadic prolactinomas. Defects in cyclin-dependent kinase inhibitor (CDKI) genes have also been demonstrated in a few families with features similar to MEN type 1. A report on a large cohort of children and adolescents with pituitary adenomas found that germline AIP and MEN1 gene mutations (found in 5 of 11 [45.5%] cases with GH- or PRL-secreting tumors) are common in pediatric patients with GH-secreting pituitary adenomas.[866] A positive family history is often not present.

Diagnosis of GH Excess

The "gold standard" for making the diagnosis of GH excess is a failure to suppress serum GH levels to less than 5 ng/dL after a 1.75-g/kg oral glucose challenge (maximum, 75 g). This test measures the ability of IGF-1 to suppress GH secretion because the glucose load results in insulin secretion, leading to suppression of IGFBP-1, which results in an acute increase in free IGF-1 levels. The increased free IGF-1 suppresses GH secretion within 30 to 90 minutes.[867] This test can be abnormal in diabetic patients. Note that a single measurement of GH is inadequate because GH is secreted in a pulsatile manner. Therefore, the use of a random GH measurement can lead to both false-positive and false-negative results.

Measurement of serum IGF-1 concentration is a sensitive screening test for GH excess. An excellent linear dose-response correlation between serum IGF-1 levels and 24-hour mean GH secretion has been demonstrated. An elevated IGF-1 level in a patient with appropriate clinical suspicion is almost always indicative of GH excess. Potential confusion may arise when evaluating normal adolescents because significantly higher IGF-1 levels occur during puberty than in adulthood.

For accurate control comparison, the IGF-1 level must be age and gender matched. Serum IGFBP-3 levels may also be useful in the diagnosis of GH excess. In patients with confirmed somatotroph adenomas, increased IGFBP-3 levels have been reported to be a sensitive marker of GH elevations and may be elevated despite normal IGF-1 levels. If laboratory findings suggest GH excess, the presence of a pituitary adenoma should be confirmed using MRI. In rare cases, a pituitary mass may not be identified. This may be an occult pituitary microadenoma or an ectopic tumor. Computed tomography is acceptable when MRI is unavailable.

Treatment of GH Oversecretion

The goals of therapy are to remove or shrink the pituitary mass, to restore GH and secretory patterns to normal, to restore IGF-1 and IGFBP-3 levels to normal, to retain the normal pituitary secretion of other hormones, and to prevent recurrence of disease. For well-circumscribed pituitary adenomas, trans-sphenoidal surgery is the treatment of choice and may be curative.[868] If possible, the tumor should be removed completely. The likelihood of surgical cure depends greatly on the surgeon's expertise as well as on the size and extension of the mass. Intraoperative GH measurements can improve the results of tumor resection. Trans-sphenoidal surgery to resect the tumors has been shown to be as safe in children as in adults. At times, a transcranial approach may be necessary. The primary goal of treatment is to normalize GH levels. GH levels ($<$ 1 ng/mL within 2 hours after a glucose load) and serum IGF-1 levels (age-adjusted normal range) are the best tests to define a biochemical cure.

If GH secretion is not normalized by surgery, the options include pituitary radiation and medical therapy. In general, radiation therapy is recommended if GH hypersecretion is not normalized by surgery. Further growth of the tumor is prevented by radiation in more than 99% of the patients. The main disadvantage is the delayed efficacy in decreasing GH levels. GH is reduced approximately 50% from the initial concentration by 2 years and 75% by 5 years, and approaches 90% by 15 years. Hypopituitarism is a predictable outcome, occurring in 40% to 50% of patients 10 years after irradiation.

It is now clear that surgery fails to cure a significant number of patients, and therefore medical therapy has taken on a more important role in the management of patients with GH excess. Indeed, the greatest progress in recent years in the treatment of GH excess has been within the realm of medical therapy. Treatment has been improved by the availability of effective and well-tolerated long-acting somatostatin analogs and dopamine agonists, as well as by novel GH antagonists.

The somatostatin analogs have been found to be highly effective in the treatment of patients with GH excess. Octreotide suppresses GH to less than 2.5 ng/mL in 65% of patients with acromegaly, and it normalizes IGF-1 levels in 70%. Studies of patients for more than 14 years have shown that the effects of octreotide are well sustained over time. Tumor shrinkage also occurs with octreotide, but it is generally modest. Consistent GH suppression has been obtained with a continuous subcutaneous pump infusion of octreotide in a pubertal boy with pituitary gigantism.[869] New long-acting formulations, including octreotide and lanreotide, have been shown to produce consistent GH and IGF-1 suppression in acromegalic patients with once-monthly intramuscular depot injections. They both appear equivalent for control of these biochemical markers and symptoms. Octreotide as well as lanreotide inhibit GH secretion better than native somatostatin because they possess greater potency and demonstrate a longer plasma half-life. The sustained-release preparations have not been formally tested in children. Octreotide injection in the pediatric population has been used at doses of 1 to 40 mg/kg/day.

Dopamine agonists, such as bromocriptine, bind to pituitary dopamine type 2 (D2) receptors and suppress GH secretion—although the precise mechanism of action remains unclear. Prolactin levels are often adequately suppressed. However, GH levels and IGF-1 levels are rarely normalized with this treatment modality. Less than 20% of patients achieve GH levels less than 5 ng/mL, and less than 10% achieve normalization of IGF-1 levels. Tumor shrinkage occurs in a minority of patients. It is generally used as adjuvant medical treatment for GH excess. Its effectiveness may be additive to that of octreotide.[870] The dose of bromocriptine needed ranges between 10 and 60 mg orally divided four times a day. Only a minority of patients benefit from doses greater than 20 mg/day. It has been found to be safe when used in children for an extended period of time, but side effects may include nausea, vomiting, abdominal pain, arrhythmias, nasal stuffiness, orthostatic hypotension, sleep disturbances, and fatigue. Another dopamine agonist, cabergoline, may inhibit GH secretion more efficiently than bromocriptine and has therefore become the preferred drug in this category. In a meta-analysis of 15 studies of cabergoline

treatment in acromegaly (n = 227), cabergoline achieved normal IGF-1 levels in 34% of patients, whereas when combined with a somatostatin analogue, 52% normalized IGF-1 concentrations.[871]

An addition to the armamentarium for the treatment of GH excess is the novel GHR antagonist, pegvisomant. This is a mutated GH molecule that has a polymer chain attached at several sites to prolong its half-life. Despite its similar binding affinity compared to wild-type GH, pegvisomant blocks endogenous GH from binding to its GHR, and it does not activate the post-GHR intracellular signaling cascade, thereby avoiding the undesirable effect of GH excess—exactly what needs to be blocked. Pegvisomant has now been approved for use in adults with acromegaly. Pegvisomant is administered as a daily subcutaneous injection. The initial daily dose is 10 mg. The serum IGF-1 concentration should be measured every 4 to 6 weeks and the dose can be adjusted, in 5-mg increments, to a maximum of 30 mg/day. The ultimate goal is to keep the serum IGF-1 within the normal range. It has been shown to effectively suppress GH and IGF-1 levels in patients with acromegaly from pituitary tumors as well as ectopic GHRH hypersecretion.[872] Normalization of IGF-1 levels occurs in up to 90% of patients treated daily with this drug for 3 months or longer.[873] More long-term studies need to be performed, as it remains uncertain, based on initial data from postmarketing surveillance studies, if long-term GH suppression continues as was reported in the initial studies. Although experience with this therapy in pediatrics is limited, the well-tolerated long-term efficacy of pegvisomant was reported in an 8-year-old girl who had protracted GH excess after surgical removal of a pituitary macroadenoma and failure to suppress GH with long-acting somatostatin analogs.[874]

CONCLUSIONS

The advancement in our understanding of the molecular mechanisms of growth has resulted in a dramatic enhancement of our ability to diagnose and treat growth disorders. Further rapid changes to the available genetic diagnostic tools are expected. These will continue to alter the manner by which pediatric endocrinologists shall evaluate and manage patients with growth disorders in the near future. Undoubtedly, in the coming years, new and improved methods of identifying specific abnormalities leading to short stature (particularly in the form of genetic tests) will refine even more the diagnostic process. Although hormonal testing is still the mainstay of endocrine assessment in the evaluation of growth disorders, we can now start to envision the age of the "gene-chip" approach. In addition, the therapies available to treat growth disorders will continue to undergo constant improvements and in the future will surely allow more efficacious, safer, and easier-to-tolerate management of growth abnormalities. These changes, both in our diagnostic capabilities and in the area of pharmacogenomics, will allow for a more individualized approach to the patient with a growth disorder.

QUESTIONS

1. You are seeing a 2.8-year-old boy for severe growth failure. His mother reports he has a good appetite, but he often wakes up once at night to take a bottle. His exam reveals frontal bossing, midface hypoplasia, and micrognathia. He also has small hands and feet. His abdomen is slightly protuberant, with a fat distribution that is more pronounced on his trunk than on his extremities. You are very concerned about his growth and obtain laboratory tests that include the following:
   - Random GH = 10 ng/mL
   - IGF-I = 11 ng/mL (normal 31 to 160)
   - IGFBP-3 = 0.7 mg/L (normal 1.4 to 3)
   - ALS, acid-labile subunit = 0.2 mg/L (normal 0.9 to 9.3)
   - GHBP = 59 pmol/L (normal 125 to 762)
   - Prolactin = 13 ng/mL (normal 3 to 18)
   - Free T4 = 2.2 ng/dL (normal 1 to 2.8)
   - TSH = 2.45 μIU/mL (normal 0.5 to 4)

   What is the most likely diagnosis for this patient?
   a. IGF-I gene defect
   b. GH gene defect
   c. STAT5 B defect
   d. ALS defect
   e. GH receptor defect

   Answer: e

2. An 8-year-old boy is referred by his pediatrician because of an advanced skeletal age. The film was obtained because the pediatrician was worried about rapid growth in this patient. The boy's mother states that her son has always been tall compared to his classmates. Midparental height is at the 50th to 75th percentile. The boy has mild developmental delay with some speech impairment. On physical exam, his height and weight are both at +3 SD score. He has a flat nasal bridge with a wide tip, large ears, broad philtrum, and a small chin. His skin is relatively loose. He has deep-set nails. He has clinodactyly and overriding toes. There is limited extension at the elbows and the knees, mild kyphosis, and obvious scoliosis by inspection. He underwent an orchidopexy early in life. Small testes are palpable in the scrotal sac. This boy's constellation of features is most consistent with which of the following diagnoses?
   a. Weaver syndrome
   b. Fragile X syndrome
   c. Beckwith-Wiedemann syndrome
   d. Marfan syndrome
   e. McCune-Albright syndrome

   Answer: a

3. You are preparing a lecture for medical students addressing genetic abnormalities that result in combined pituitary hormone deficiency. Which of the following does *not* lead to this multiple hormone insufficiency?
   a. PROP1 gene mutation
   b. HESX1 gene mutation
   c. STAT5B gene mutation
   d. LHX3 gene mutation
   e. POU1F1 gene mutation

   Answer: c

4. The measurement of serum IGF-I concentrations, as part of the evaluation of short stature, can be affected by all *except* which of the following factors?
   a. Estradiol
   b. Melatonin
   c. Growth hormone
   d. Thyroxine
   e. Testosterone

   Answer: b

5. The parents of a 6-year-old girl want to know how tall their daughter will be as an adult. The mother is 155 cm (5′1″). The father is 178 cm (5′10″). Despite all the nuances involved in the determination of the predicted adult height that you plan to discuss with them, you calculate her midparental height to be closest to which of the following?
   a. 155 cm
   b. 168 cm
   c. 165 cm
   d. 160 cm
   e. 175 cm

   Answer: d

CHAPTER 11

Disorders of the Posterior Pituitary

Joseph A. Majzoub, MD • Louis J. Muglia, MD, PhD • Abhinash Srivatsa, MD

CHAPTER OUTLINE

INTRODUCTION

Maintenance of the tonicity of extracellular fluids within a very narrow range is crucial for proper cell function.[1,2] Extracellular osmolality regulates cell shape as well as intracellular concentrations of ions and other osmolytes. Furthermore, proper extracellular ionic concentrations are necessary for the correct function of ion channels, action potentials, and other modes of intercellular communication. Extracellular fluid tonicity is regulated almost exclusively by the amount of water intake and excretion, whereas extracellular volume is regulated by the level of sodium chloride intake and excretion. In children and adults, normal blood tonicity is maintained over a 10-fold variation in water intake by a coordinated interaction among thirst, vasopressin, and renal systems. Dysfunction in any of these systems can result in abnormal regulation of blood osmolality, which if not properly recognized and treated may cause life-threatening dysfunction in neuronal and other cellular activities.

The posterior pituitary, or the neurohypophysis, secretes the nonapeptide hormones vasopressin and oxytocin. Vasopressin controls water homeostasis, and oxytocin regulates smooth muscle contraction during parturition and lactation. Disorders of vasopressin secretion and action lead to clinically important derangements in water metabolism. This chapter summarizes the physiology of water and volume regulation, presents a symptom-based approach to the differential diagnosis of the diseases of water homeostasis, and provides a review of the pathology and treatment of disorders involving these systems. (See Chapter 13 for a discussion of defects in mineralocorticoid regulation that result in disturbances in volume regulation.)

PHYSIOLOGY OF OSMOTIC AND VOLUME REGULATION

The control of plasma tonicity and intravascular volume involves a complex integration of endocrine, neural, and paracrine pathways. Osmotic sensor and effector pathways control the regulation of vasopressin release and signal transduction, whereas volume homeostasis is determined largely through the action of the renin-angiotensin-aldosterone system, with contributions from both vasopressin and the natriuretic peptide family. An improved understanding of the anatomic structures and molecules involved has developed through detailed molecular biologic and physiologic studies.

Osmotic Sensor and Effector Pathways

Vasopressin and Oxytocin Biochemistry

Vasopressin and oxytocin are evolutionarily related peptides (paralogs), having arisen from gene duplication of a phylogenetically common molecule approximately 450 million years ago.[3,4] Both peptides consist of a 6-amino-acid disulfide ring plus a 3-amino-acid tail, with amidation of the carboxy terminus.[5,6] As early as 1895, a potent biologic principle—consisting of vascular pressor activity, "birth quickening," and milk secretory effects—was recognized in neurohypophyseal extracts.[7] The sequences of the

individual peptides with pressor and antidiuretic capacity (vasopressin) and oxytocic capacity were determined by du Vigneaud and colleagues during the mid-1950s,[6] culminating in the synthesis of each hormone in its biologically active form.[8,9] In most mammals, vasopressin and oxytocin differ in only two amino acids—one substitution within the ring and one within the tail structure (Figure 11-1). Exploration of the structure-function relationship of specific amino acids within both vasopressin and oxytocin has allowed characterization of molecules with substantial clinical use. Most notably, by replacement of l-arginine with d-arginine at position 8 of the vasopressin molecule, and amino-terminal deamidation, an analog with enhanced, prolonged antidiuretic to pressor activity was found (desmopressin [desamino-d-arginine vasopressin; dDAVP], see Figure 11-1).[10] Desmopressin, with an antidiuretic potency more than double that of its parent vasopressin, is now routinely used in clinical practice.

The association of vasopressin and oxytocin with specific proteins, the neurophysins, while stored in the neurohypophysis, was apparent as early as 1900.[11] Subsequent isolation and characterization of the neurophysins revealed two distinct forms, one type exclusively associated with vasopressin and the other exclusively associated with oxytocin.[12,13] Both are single-polypeptide chains of molecular weight 10,000 daltons. Despite extensive biophysical characterization, including crystallography of the oxytocin-neurophysin complex,[14,15] the biologic function of the neurophysins remains unclear. Possible roles for the neurophysins include stabilization against degradation during intracellular storage, more efficient packaging within secretory granules, and enhancement of posttranslation processing by the proenzyme convertases.

The common origin of vasopressin and its neurophysin from a single larger precursor was first proposed by Sachs and colleagues,[16,17] who showed increased incorporation of ^{35}S cysteine, infused into the canine third ventricle, into vasopressin isolated from the hypothalamus compared with vasopressin isolated from the posterior pituitary. Isolation of the larger precursor from the hypothalamus followed by trypsin digestion produced fragments of size similar to that of vasopressin and its neurophysin, with vasopressin immunoreactivity in the 1000-dalton component.[18,19]

Since 1990, molecular genetic analyses have furthered the understanding of the synthesis, the processing, and the evolution of the vasopressin and oxytocin preprohormones. Human, mouse, rat, and bovine vasopressin and oxytocin genes each consist of three exons (Figure 11-2).[20,21] The first exon encodes the 19-amino-acid signal peptide, followed by vasopressin or oxytocin nonapeptides. This is followed by a 3-amino-acid protease cleavage site leading into the first nine amino acids of neurophysin II (for vasopressin) or neurophysin I (for oxytocin). After interruption of the coding region by an intron, exon 2 continues with neurophysin coding sequences. The third exon completes the sequence of the neurophysin and, for vasopressin only, is followed by coding information for an additional 39-amino-acid glycopeptide (copeptin) whose function is unclear. Preprovasopressin contains 16 cysteines, which likely participate in eight disulfide bridges that determine the tertiary structure of the protein (Figure 11-3). One cysteine pair is present in vasopressin peptide, whereas the rest are in neurophysin.

In all mammalian species analyzed thus far, oxytocin and vasopressin genes are adjacent in chromosomal location (chromosome 20 in the human[22]) and linked tail to tail, in opposite transcriptional orientation. In the human, they are separated by 12 kb.[22] This likely explains their origin from the ancient duplication of a common ancestral gene.[23] Whether this adjacent linkage is of regulatory significance is under investigation.

Vasopressin and oxytocin genes are expressed in the hypothalamic paraventricular and supraoptic nuclei.[18,24] The magnocellular components of each of these nuclei are the primary neuronal populations involved in water balance, with vasopressin synthesized in these areas carried by means of axonal transport to the posterior pituitary, its primary site of storage and release into the systemic circulation (Figure 11-4). The bilaterally paired hypothalamic paraventricular and supraoptic nuclei are separated from one another by relatively large distances (approximately 1 cm). Their axons course caudally, converge

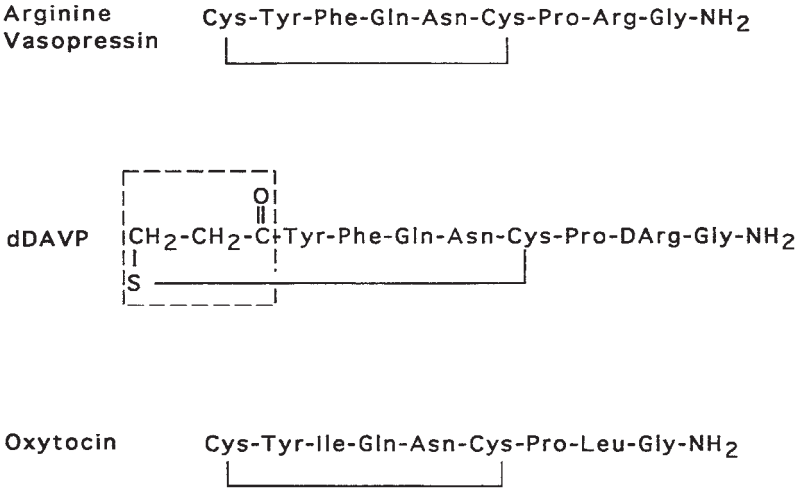

FIGURE 11-1 ■ Structures of vasopressin, dDAVP, and oxytocin. In dDAVP, the de-amidated cysteine is enclosed in the box.

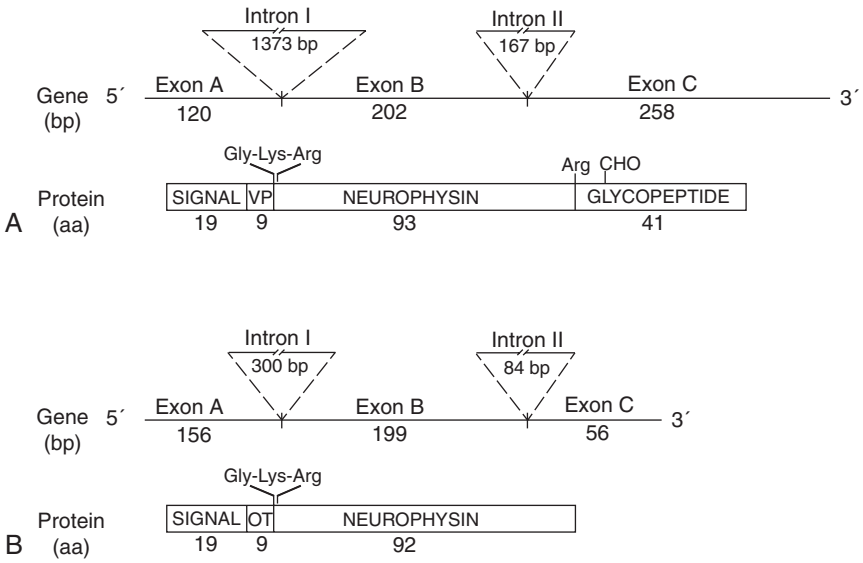

FIGURE 11-2 ■ Structure of the human genes and peptide products of vasopressin (VP) (**A**) and oxytocin (OT) (**B**). Shown are the sizes of exons and intron, in nucleotide base pairs (bp) and peptide products in amino acids (aa). Depicted are the amidation-dibasic cleavage signal (Gly-Lys-Arg) at the carboxy terminus of vasopressin and oxytocin and the monobasic cleavage signal at the end of neurophysin. Signal, signal peptide; VP, vasopressin; OT, oxytocin; CHO, carbohydrate.

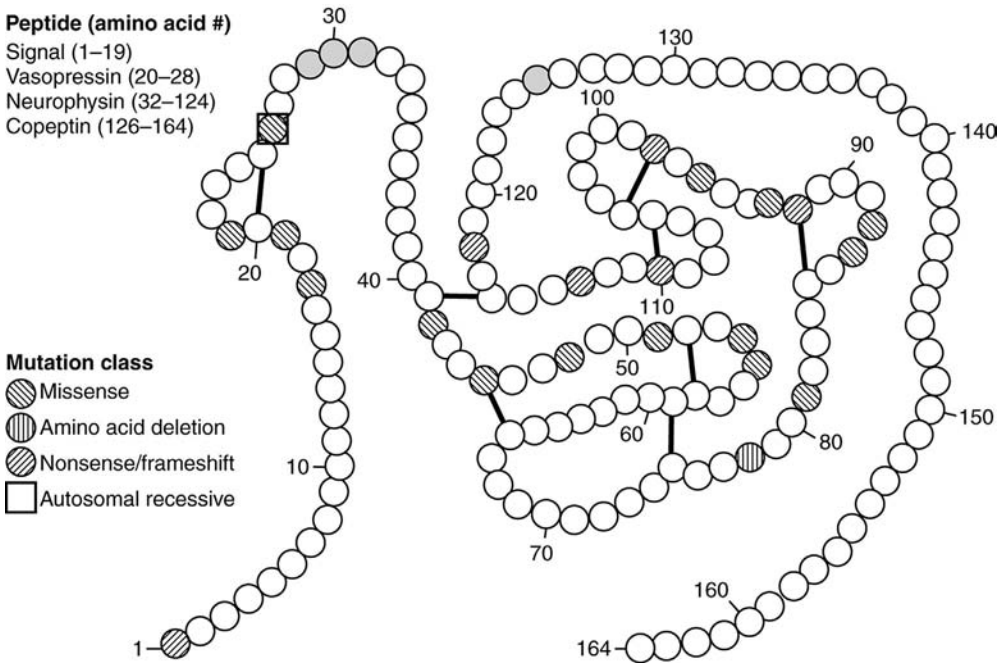

FIGURE 11-3 ■ Structure of preprovasopressin peptide. The 164-amino-qcid preprovasopressin peptide consists of signal peptide, vasopressin, neurophysin, and copeptin. The latter three entities are separated by basic residues (gray), which serve as cleavage sites for proconvertase enzymes. The 16 cysteines are connected by eight putative disulfide bridges. Amino acid mutations are classified as missense, in-frame deletion, or nonsense/frameshift mutations. Most mutations are inherited with an autosomal dominant pattern. The one that has an autosomal recessive pattern is boxed. (Reproduced with permission from *Uyeki TM, Barry FL, Rosenthal SM, et al.* Successful treatment with hydrochlorothiazide and amiloride in an infant with congenital nephrogenic diabetes insipidus. *Pediatr Nephrol 1993;* 7:554-6.)

at the infundibulum, and terminate at different levels within the pituitary stalk and the posterior pituitary gland (see Figure 11-4). Vasopressin is also synthesized in the parvocellular neurons of the paraventricular nucleus, where it has a role in modulating hypothalamic-pituitary-adrenal axis activity. In this site, vasopressin is colocalized in cells that synthesize corticotropin-releasing hormone,[25,26] and both are secreted at the median eminence and carried through the portal-hypophyseal capillary system to the anterior pituitary, where together they act as the major regulators of adrenocorticotropic hormone synthesis and release.[27] Vasopressin is also present in the hypothalamic suprachiasmatic nucleus, the circadian pacemaker of the body, where its function is unknown.

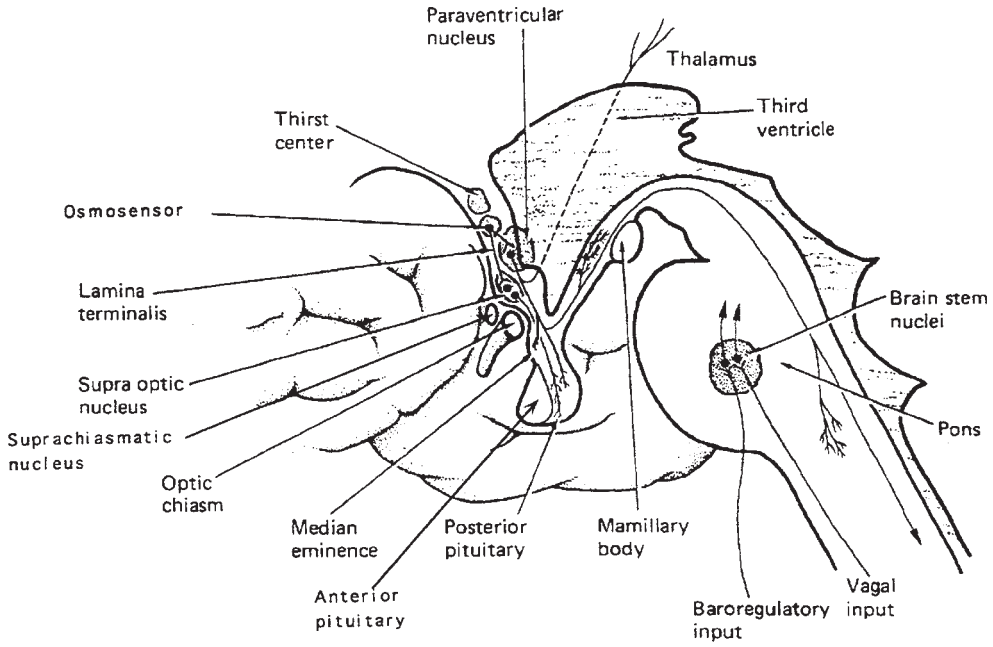

FIGURE 11-4 ■ Vasopressin cells in the hypothalamus. Diagram of vasopressin cell bodies in the supraoptic, paraventricular, and suprachiasmatic hypothalamic nuclei, and axonal termination in the posterior pituitary and median eminence. Because vasopressin axons terminate at different levels in the pituitary stalk and posterior pituitary, the amount of permanent cell loss following neurosurgical insult is determined by the highest level of damage, which will dictate the degree of vasopressin axon transection and retrograde neuronal degeneration. (Modified with permission from reference 507 Baylis, P. H. (1989). Vasopressin and its neurophysin. In L. D. Degroot (Ed.), *Endocrinology*, (2nd ed.) (p. 213). Philadelphia: WB Saunders.)

Regulation of Vasopressin Secretion and Thirst

Osmotic Regulation. The rate of secretion of vasopressin from the paraventricular and supraoptic nuclei is influenced by several physiologic variables, including plasma osmolality and intravascular volume, as well as nausea and a number of pharmacologic agents. The major osmotically active constituents of blood are sodium, chloride, and glucose (with insulin deficiency). Normal blood osmolality ranges between 280 and 290 mOsm/kg H_2O.

The work of Verney[28] first demonstrated the relationship of increased vasopressin release in response to increasing plasma osmolality, as altered by infusion of sodium chloride or sucrose. At that time, it was postulated that there existed intracranial sensors sensitive to changes in plasma osmolality. Multiple researchers have subsequently confirmed that plasma vasopressin concentration increases in response to increasing plasma tonicity, although the exact nature of the osmosensor has not been defined.[29,30] Neurons of the supraoptic nucleus can respond directly to hypertonic stimuli with depolarization and vasopressin secretion,[31] but the majority of evidence indicates that osmosensor- and vasopressin-secreting neurons are anatomically distinct.[32,33] The osmosensor is likely to reside outside the blood-brain barrier, as implicated by differential vasopressin secretory response to similar changes in plasma osmolality depending on whether the change was induced by salt, sucrose, or urea.[28,34] The organ vasculosum of the lamina terminalis (OVLT) and the subfornical organ (SFO), areas of the preoptic hypothalamus outside the blood-brain barrier, are likely sites of osmosensing, because lesions of the OVLT result in impaired vasopressin secretion and hypernatremia.[32,33] Also, the site of action of angiotensin II infused intracerebrally or peripherally to produce vasopressin secretion and antidiuresis resides within the OVLT.[35-37]

The pattern of secretion of vasopressin into blood has been characterized extensively in normal individuals and in those with abnormalities in water homeostasis. Normally, at a serum osmolality of less than 280 mOsm/kg, plasma vasopressin concentration is at or below 1 pg/mL, the lower limit of detection of most radioimmunoassays.[29,30] Above 283 mOsm/kg—the normal threshold for vasopressin release—plasma vasopressin concentration increases in proportion to plasma osmolality, up to a maximum concentration of about 20 pg/mL at a blood osmolality of approximately 320 mOsm/kg (Figure 11-5). The osmosensor can detect as little as a 1% change in blood osmolality. Plasma concentrations in excess of 5 pg/mL are also found with nausea, hypotension, hypovolemia, and insulin-induced hypoglycemia, but further increments in urine concentration do not occur, because the peak antidiuretic effect is achieved at 5 pg/mL. The rate of increase of plasma vasopressin concentration, and thus the sensitivity of the osmosensor, exhibits substantial (as much as 10-fold) interindividual variation as plasma osmolality increases.[38] The set point for vasopressin secretion varies in a single individual in relation to changes in volume status and hormonal environment (e.g., pregnancy[39]) or glucocorticoid status.[40,41] After the seventh week of gestation, osmotic thresholds for both vasopressin release and thirst are reduced by

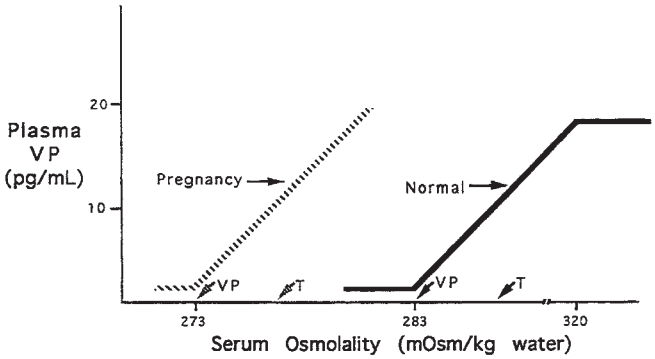

FIGURE 11-5 ■ Osmotic thresholds for vasopressin and thirst. The threshold for vasopressin release is below that for thirst. In nonpregnant persons there is linear increase in vasopressin (VP) release up to a serum osmolality of 320 mOsm/kg, after which no further increase occurs. In pregnancy, there is a decreased threshold for vasopressin release and thirst sensation, with no change in the sensitivity (slope) of the vasopressin-osmolality relationship. Vasopressin secretion in pregnancy presumably also plateaus at some level of hyperosmolality, although this has not been studied. Normal nonpregnant persons indicated by solid line and arrows; pregnant women indicated by dashed line and arrows.

approximately 10 mOsm/kg (see Figure 11-5), such that normal blood osmolality during pregnancy is approximately 273 mOsm/kg (serum sodium 135 mEq/L).[39,42] Similarly, thresholds for vasopressin release and thirst during the luteal phase of the menstrual cycle are approximately 5 mOsm/kg lower than those in the follicular phase.[43,44] Human chorionic gonadotropin during pregnancy[45] and luteinizing hormone during the second half of the menstrual cycle may contribute to these changes in osmotic thresholds.

The sensation of thirst, a more integrated cortical activity, is determined by other anatomically distinct hypothalamic neurons, with afferents involving the ventromedial nucleus.[46] The activation of the thirst mechanism is also probably mediated by angiotensin II.[47] Whether the osmosensor for thirst and vasopressin release are the same is not certain, although this is suggested by lesions in the anteroventral region of the third ventricle that abolish both thirst sensation and vasopressin release.[48] It makes physiologic sense that the threshold for thirst (293 mOsm/kg) is approximately 10 mOsm/kg higher than that for vasopressin release (see Figure 11-5). Otherwise, during the development of hyperosmolality, the initial activation of thirst and water ingestion would result in polyuria without activation of vasopressin release, causing a persistent diuretic state. Immediately after water ingestion, before a change in blood osmolality or volume, vasopressin concentration falls and thirst ceases.[49] The degree of suppression is directly related to the coldness[50] and volume[51] of the ingested fluid. This effect is probably mediated by chemoreceptors present in the oropharynx, which guard against the rapid overdrinking of fluids after intense thirst during the time before the lowering of blood osmolality.

As noted earlier, water balance is regulated in two ways: (1) vasopressin secretion stimulates water reabsorption by the kidney, thereby reducing future water loss, and (2) thirst stimulates water ingestion, thereby restoring previous water loss. Ideally, these two systems work in parallel to efficiently regulate extracellular fluid tonicity (Figure 11-6); however, each system by itself can maintain plasma osmolality in the near-normal range. For example, in the absence of vasopressin secretion but with free access to water, thirst drives water ingestion up to the 5 to 10 L/m^2 of urine output seen with vasopressin deficiency. Conversely, an intact vasopressin secretory system can compensate for some degree of disordered thirst regulation. When both vasopressin secretion and thirst are compromised, however, by either disease or iatrogenic means, there is great risk of the occurrence of life-threatening abnormalities in plasma osmolality.

Nonosmotic Regulation. Separate from osmotic regulation, vasopressin has been shown to be secreted in response to alterations in intravascular volume. Afferent baroreceptor pathways arising from the right and left atria and the aortic arch (carotid sinus) are stimulated by increasing intravascular volume and stretch of vessel walls, and they send signals through the vagus and glossopharyngeal nerves, respectively, to the brainstem nucleus tractus solitarius.[52,53] Noradrenergic fibers from the nucleus tractus solitarius synapse on the hypothalamic paraventricular nucleus and the supraoptic nucleus and, on stimulation, inhibit vasopressin secretion.[54,55] Experimental verification of this pathway has included demonstration of increased vasopressin concentration after interruption of baroreceptor output to the brainstem and decreased plasma vasopressin concentration after mechanical stimulation of baroreceptors, an effect diminished by vagotomy.[56,57]

The pattern of vasopressin secretion in response to volume as opposed to osmotic stimuli is markedly different (Figure 11-7). Although minor changes in plasma

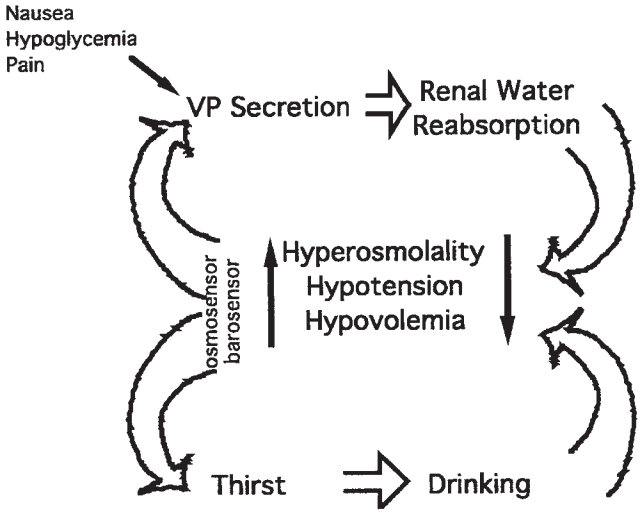

FIGURE 11-6 ■ Regulation of vasopressin secretion and serum osmolality. Hyperosmolality, hypovolemia, or hypotension are sensed by osmosensors, volume sensors, or barosensors, respectively. These stimulate both vasopressin (VP) secretion and thirst. Vasopressin, acting on the kidney, causes increased reabsorption of water (antidiuresis). Thirst causes increased water ingestion. The results of these dual negative feedback loops cause a reduction in hyperosmolality or hypotension/hypovolemia. Additional stimuli for vasopressin secretion include nausea, hypoglycemia, and pain.

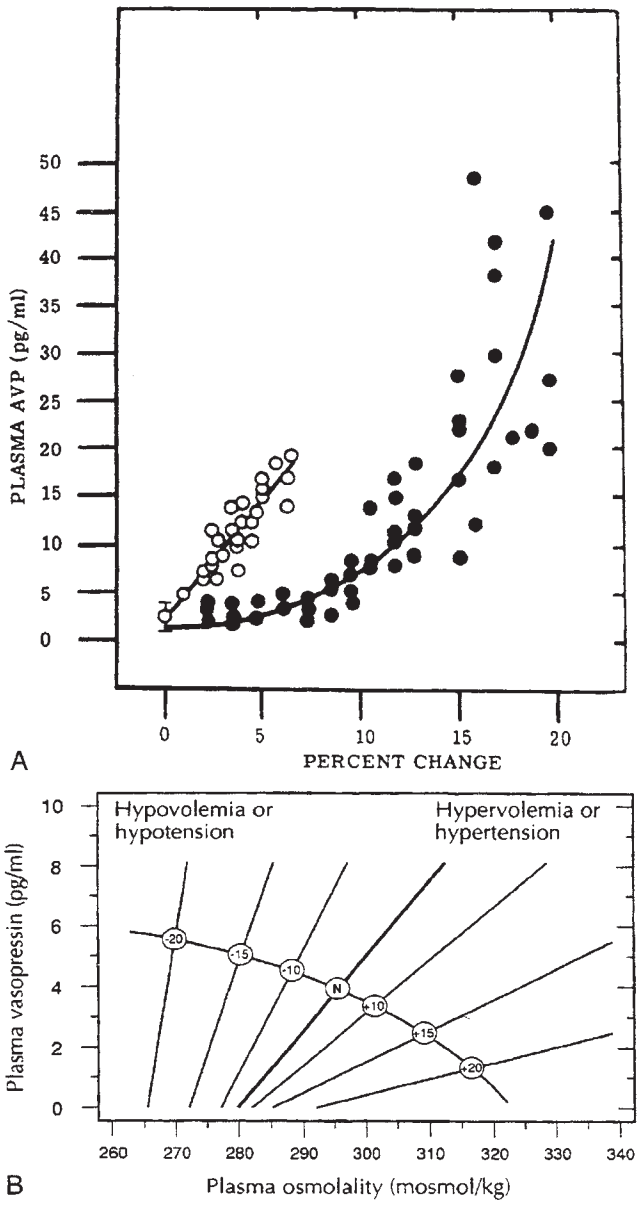

FIGURE 11-7 ■ Relationships between osmotic and nonosmotic stimuli for vasopressin release. **A,** Relationship of plasma vasopressin (AVP) concentration to the percentage increase in blood osmolality (open circles) or decrease in blood volume (closed circles). **B,** Alteration of sensitivity of osmotic stimulation of vasopressin secretion by volume or pressure stimuli. function of several tissue types by binding to members of a family of G protein–coupled cell surface receptors, which subsequently transduce ligand binding into alterations of intracellular second messenger pathways.[79] Biochemical and cell biologic studies have defined at least three receptor types, designated V1, V2, and V3 (or V1b). The major sites of V1 receptor expression are on vascular smooth muscle[80] and hepatocytes,[81-84] where receptor activation results in vasoconstriction[85,86] and osmolality above 280 mOsm/kg evoke linear increases in plasma vasopressin, substantial alteration in intravascular volume is required for alteration in vasopressin output.[58-60] No change in vasopressin secretion is seen until blood volume decreases by approximately 8%. With intravascular volume deficits exceeding 8%, vasopressin concentration increases exponentially. Furthermore, osmotic and hemodynamic stimuli can interact in a mutually synergistic fashion, so that the response to either stimulus may be enhanced by the concomitant presence of the other (see Figure 11-7). When blood volume (or blood pressure[61-63]) decreases by approximately 25%, vasopressin concentrations are evident of 20- to 30-fold above normal and vastly exceeding those required for maximal antidiuresis. Surprisingly, the use of vasopressin antagonists has suggested that the high concentration of vasopressin observed with hypotension does not contribute to the maintenance of blood pressure in humans.[64]

Nausea—as evoked by apomorphine,[65] motion sickness,[66] and vasovagal reactions—is a very potent stimulus for vasopressin secretion. This effect is likely mediated by afferents from the area postrema of the brainstem and may result in vasopressin concentrations two to three orders of magnitude above basal levels. Nicotine is also a strong stimulus for vasopressin release.[67] These pathways probably do not involve osmotic or hemodynamic sensor systems, because blockade of the emetic stimulus with dopamine or opioid antagonists does not alter the vasopressin response to hypernatremia or hypovolemia.

Vasopressin secretion is inhibited by glucocorticoids; for this reason, loss of negative regulation of vasopressin secretion occurs in the setting of primary or secondary glucocorticoid insufficiency.[68,69] The effects of cortisol loss of both enhancing hypothalamic vasopressin production and directly impairing free water excretion[70] are important considerations in the evaluation of the patient with hyponatremia, as is subsequently discussed.

Vasopressin Metabolism

Once in the circulation, vasopressin has a half-life of only 5 to 10 minutes, owing to its rapid degradation by a cysteine amino-terminal peptidase called vasopressinase. A synthetic analog of vasopressin, desmopressin, is insensitive to aminoterminal degradation and thus has a much longer half-life of 8 to 24 hours. During pregnancy, the placenta secretes increased amounts of this vasopressinase,[71] resulting in a fourfold increase in the metabolic clearance rate of vasopressin.[72] Normal women compensate with an increase in vasopressin secretion, but women with preexisting deficits in vasopressin secretion or action,[73] or those with increased concentrations of placental vasopressinase associated with liver dysfunction[74] or multiple gestations,[75] may develop diabetes insipidus in the last trimester, which resolves in the immediate postpartum period.[76] As expected, this form of diabetes insipidus responds to treatment with desmopressin but not with vasopressin.[77,78]

Sites of Vasopressin Action

Vasopressin Receptors. Vasopressin released from the posterior pituitary and the median eminence affects the

glycogenolysis,[87] respectively. The latter activity may be augmented by stimulation of glucagon secretion from the pancreas.[87] The V1 receptor on platelets also stimulates platelet aggregation.[88] V1 receptor activation mobilizes intracellular calcium stores through phosphatidylinositol hydrolysis.[86,89] Despite its initial characterization as a powerful pressor agent, the concentration of vasopressin needed to significantly increase blood pressure is several-fold higher than that required for maximal antidiuresis,[90] although substantial vasoconstriction in renal and splanchnic vasculature can occur at physiologic concentrations.[91] The cloning of the V1 receptor[80,81,83] has greatly elucidated the relationship of the vasopressin (and oxytocin[92,93]) receptors and, through sensitive in situ hybridization analysis, has further localized V1 expression to the liver and the vasculature of the renal medulla, as well as to many sites within the brain, including the hippocampus, the amygdala, the hypothalamus, and the brainstem.[82,84] Compared to their normal counterparts, mice genetically modified to be deficient in the V1 receptor (V1a KO) have been found to manifest insulin resistance, increased hepatic glucose production, decreased hepatic glycogen content, decreased aldosterone secretion despite a lower plasma volume, lower basal blood pressure, a greater degree of lipolysis, and impaired nuclear transport of the renal tubular mineralocorticoid receptor.[94] The V3 (or V1b) receptor is present on corticotrophs in the anterior pituitary[95] and acts through the phosphatidylinositol pathway[96] to increase adrenocorticotropic hormone secretion. Its binding profile for vasopressin analogs resembles more closely that of the V1 than the V2 receptor. The structure of this receptor has been determined in humans by cloning of its complementary DNA.[96,97] Its structure is similar to that of the V1 and oxytocin receptors, and it is expressed in the kidney as well as in the pituitary. Mice with deletion of the V1b (V3) receptor gene (V1bKO) have been created and studied.[97-99] As expected, they have defective activation of the pituitary-adrenal axis following some acute and chronic stressors. Male V1bKO mice were also found to have decreased aggression and social motivation. [100]

Modulation of water balance occurs through the action of vasopressin on V2 receptors located primarily in the renal collecting tubule, along with other sites in the kidney, including the thick ascending limb of the loop of Henle and periglomerular tubules.[82,84,101] It is also present on vascular endothelial cells in some systemic vascular beds, where vasopressin stimulates vasodilation,[102] possibly through the activation of nitric oxide synthase.[103] Vasopressin also stimulates von Willebrand factor, factor VIIIa, and tissue plasminogen activator through V2-mediated actions. For this reason, desmopressin is used to improve the prolonged bleeding times characteristic of uremia, type I von Willebrand disease, and hemophilia.[104] The V2 receptor consists of 370 amino acids encoding seven transmembrane domains characteristic of the G protein–coupled receptors.[101,105] These transmembrane domains share approximately 60% sequence identity with the V1 receptor but substantially less with other members of this family (Figure 11-8). Unlike the V1 and

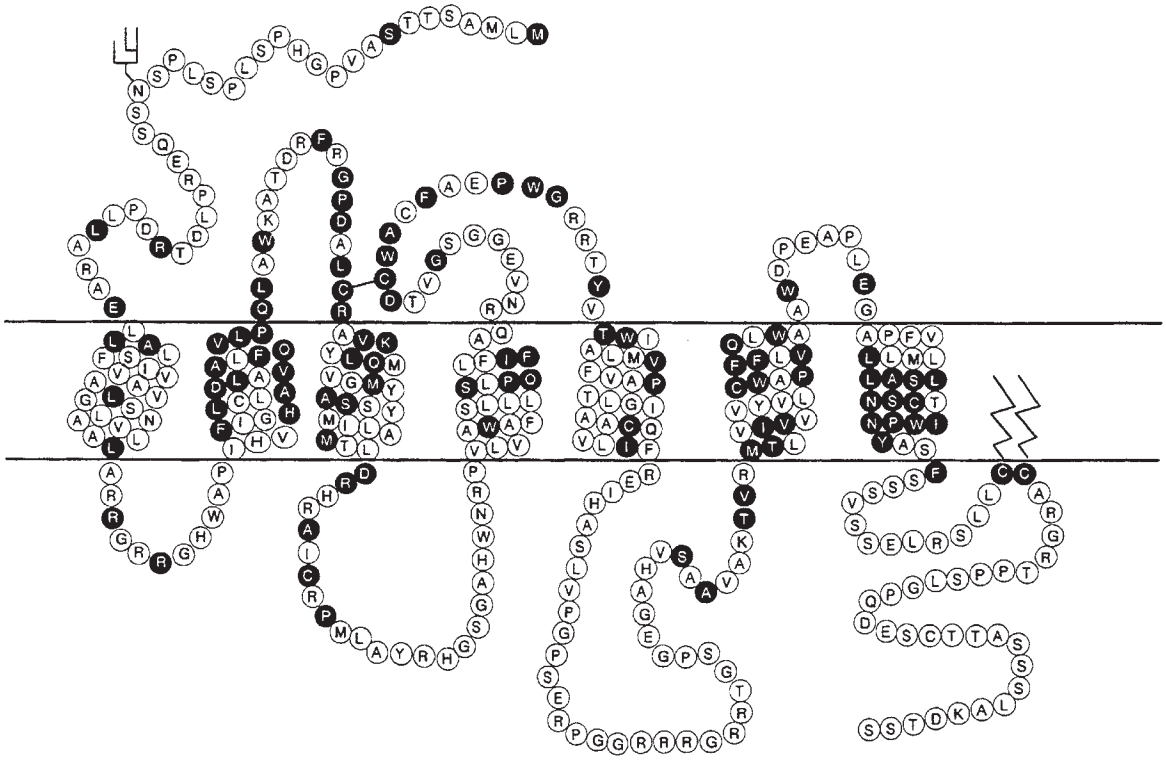

FIGURE 11-8 ■ Structure of the V1 and V2 vasopressin receptors and the oxytocin receptor. Amino acids in open circles encode the V1 receptor, whereas those in black circles are common to all three receptors. (Reproduced with permission from reference (510) Bichet, D. G. (1995). The posterior pituitary. In S. Melmed (Ed.), *The pituitary* (p. 277). Cambridge: Blackwell Science.)

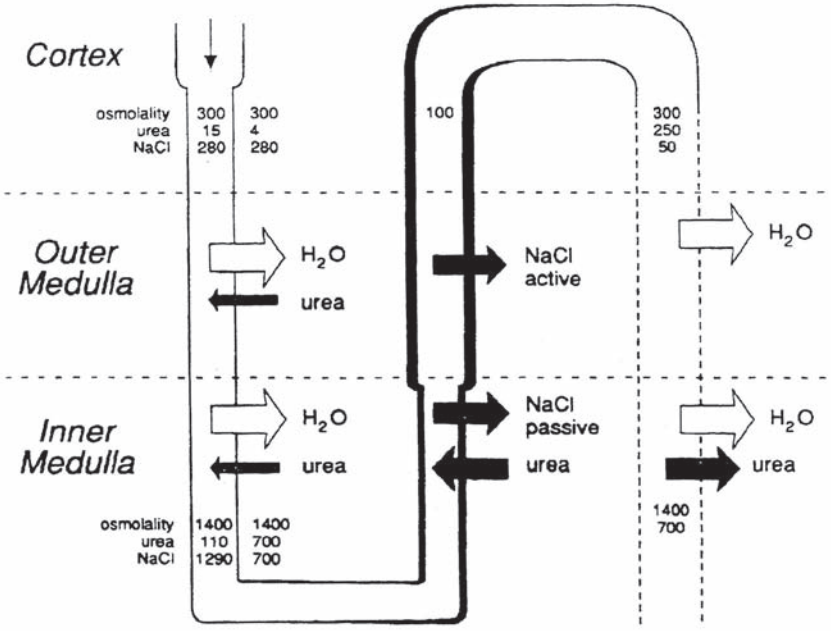
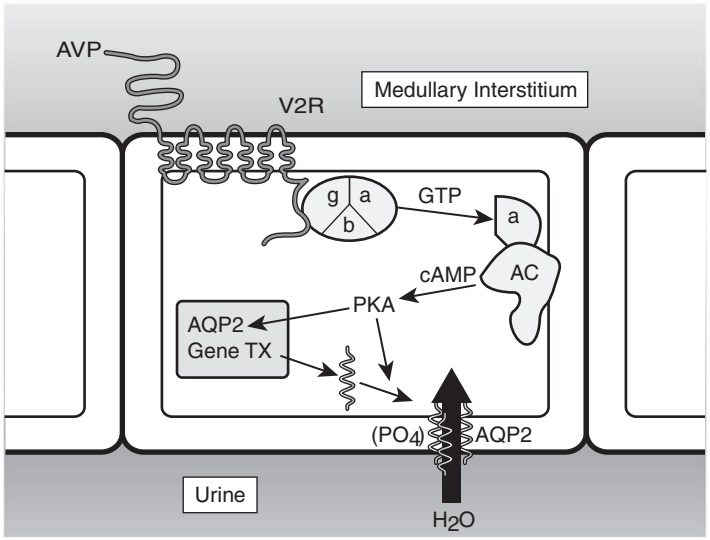
V3 receptors, the V2 receptor acts through adenylate cyclase to increase intracellular cyclic adenosine monophosphate (AMP) concentration. The human V2 receptor gene is located on the long arm of the X chromosome (Xq28),[106,107] at the locus associated with congenital, X-linked vasopressin-resistant diabetes insipidus. Mice in which *V2R* has been deleted have a similar phenotype. [108]

Renal Cascade of Vasopressin Function. Vasopressin-induced increases in intracellular cyclic AMP as mediated by the V2 receptor triggers a complex pathway of events resulting in increased permeability of the collecting duct to water and efficient water transit across an otherwise minimally permeable epithelium (Figure 11-9).[109] Activation of a cyclic AMP-dependent protein kinase imparts



A



B

FIGURE 11-9 ■ Vasopressin action in the kidney. **A,** Solute and water handling in the kidney. **B,** Action of vasopressin in the collecting duct cell. Vasopressin (AVP) binds to the V2 receptor (V2R), causing the binding of GTP to the stimulatory alpha G protein subunit (α). This activates adenylate cyclase (AC), resulting in an increase in cAMP and activation of protein kinase A (PKA). The catalytic subunit of PKA, via phosphorylation of serine 256 of the water channel, aquaporin-2 (AQP2), causes aggregation of AQP2 homotetramers in membrane vesicles and their fusion with the collecting duct luminal membrane, resulting in an increase in water flow from the urine into the renal medullary interstitium. Demeclocycline, lithium, high calcium, and low potassium interfere with these processes, possibly at the level of cAMP generation and AQP2 synthesis or action. (**A** from reference (511) Reeves, W. B., & Andreoli, T. E. (1989). Nephrogenic diabetes insipidus. In C. R. Scriver, A. L. *The metabolic basis of inherited disease* Beaudet, & W. S. Sly (Eds.), (6th ed.) (p. 1985) New York: McGraw-Hill.)

remodeling of cytoskeletal microtubules and microfilaments that culminate in the insertion of aggregates of water channels into the apical membrane.[110] These mechanisms may involve a vesicle-associated membrane protein-2–like protein (VAMP-2), which also regulates synaptic vesicle activity in neuronal terminals[111] and its associated receptor syntaxin-4.[112]

Insertion of the water channels causes an up to 100-fold increase in water permeability of the apical membrane, allowing water movement along its osmotic gradient into the hypertonic inner medullary interstitium from the tubule lumen and excretion of a concentrated urine (see Figure 11-9). The molecular analysis of the water channels has revealed a family of related proteins, designated aquaporins, that differ in their sites of expression and pattern of regulation.[113] Each protein consists of a single polypeptide chain with six membrane-spanning domains (Figure 11-10). Although functional as monomers, they are believed to form homotetramers in the plasma membrane.[109]

Aquaporin-2 is expressed mostly within the kidney,[114] primarily within the collecting duct.[115] It is also expressed in the vas deferens, at least in the rat, although it is not regulated by vasopressin in this location.[116] Studies with immunoelectron microscopy have demonstrated large amounts of aquaporin-2 in the apical plasma membrane and subapical vesicles of the collecting duct, consistent with the "membrane shuttling" model of water channel aggregate insertion into the apical membrane after vasopressin stimulation.[116] Studies analyzing the mechanism by which aquaporin-2 traffics to the apical plasma membrane have demonstrated that vasopressin-induced, protein kinase A–mediated serine phosphorylation at amino acid 256 is required for its exocytosis,[117] a process also requiring a heterotrimeric G protein of the G_i family.[118] In response to water restriction or desmopressin infusion in humans, the content of urinary aquaporin-2 in both soluble and membrane-bound forms has been found to increase.[119] Mice with targeted deletion of the aquaporin-2 gene have been made.[120] As expected, they have nephrogenic diabetes insipidus that is unresponsive to treatment with vasopressin.

In addition to aquaporin-2, different aquaporins appear to be involved in other aspects of renal water handling. In contrast to the apical localization of aquaporin-2, aquaporin-3 and aquaporin-4 are expressed on the basolateral membrane of the collecting duct epithelium. They appear to be involved in the flow of water and urea from the inside of the collecting duct cell into the extracellular renal medullary space. Mice made genetically deficient in aquaporin-4 demonstrate a mild urinary concentrating defect,[121] whereas those with deficiency of aquaporin-3 alone, or together with aquaporin-4, demonstrate more severely impaired urinary concentrating ability.[122] Mice made genetically deficient in aquaporin-1 demonstrate a urinary concentrating defect caused by decreased water permeability in the proximal tubule.[123]

Volume Sensor and Effector Pathways

Renin-Angiotensin-Aldosterone System

In contrast to the vasopressin system, the classic, or peripheral, renin-angiotensin system primarily affects

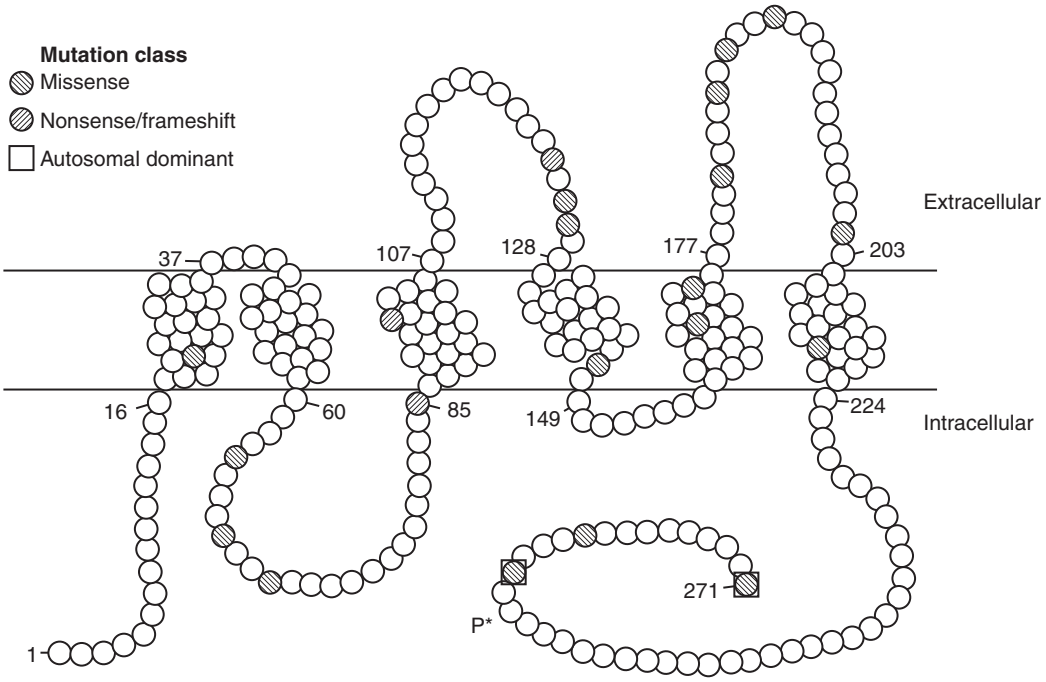


FIGURE 11-10 ■ Structure of the aquaporin-2 protein inserted into the luminal membrane of the distal tubule. The 271-amino-acid protein consists of five transmembrane domains, four intracellular domains, and three extracellular domains. Amino acid mutations are denoted by filled circles. Most mutations are transmitted with an autosomal recessive pattern; the two dominant mutations are bounded by squares. Vasopressin-dependent, protein kinase A–mediated phosphorylation of serine at amino acid 256 (P*) is noted. (Reproduced with permission from *Uyeki TM, Barry FL, Rosenthal SM, et al.* Successful treatment with hydrochlorothiazide and amiloride in an infant with congenital nephrogenic diabetes insipidus. *Pediatr Nephrol 1993;* 7:554-6.)

maintenance of intravascular volume as opposed to plasma tonicity. In addition to the well-established endocrine regulatory system, several local renin-angiotensin systems have emerged, with both autocrine and paracrine effects in their tissue of synthesis, whose regulation is independent of the classic system. Finally, brain and pituitary angiotensin systems involved in blood pressure, autonomic function, and fluid balance have been characterized with extensive interaction with the vasopressin system, and vasopressin has been found to play a role in the normal action of aldosterone on the renal tubular epithelium.[124]

Endocrine Renin-Angiotensin-Aldosterone System

Anatomy and Biochemistry. Renin, which is synthesized by the renal juxtaglomerular apparatus, is a proteolytic enzyme that catalyzes the cleavage of angiotensinogen, synthesized by hepatocytes, into the decapeptide angiotensin I.[125,126] Angiotensin I possesses no intrinsic vasoreactive or mineralocorticoid secretagogue activity but is efficiently cleaved by angiotensin-converting enzyme in the lungs, as well as other peripheral sites, to generate the octapeptide angiotensin II. Angiotensin II is further metabolized to the heptapeptide angiotensin III by removal of one aminoterminal amino acid. Angiotensin II possesses greater vasopressor activity and is present in approximately a fourfold greater amount than angiotensin III. Angiotensins II and III possess equivalent mineralocorticoid secretory activity on the adrenal glomerulosa cells.

Angiotensin II and III act through cell surface receptors (AT_1) on the adrenal glomerulosa cells to activate the phospholipase C/protein kinase C pathway.[127-131] This activation results in increased production of pregnenolone from cholesterol by side-chain cleavage enzyme (20,22-desmolase) and of aldosterone from corticosterone by the glomerulosa-specific corticosterone methyloxidase I and II activities (18-hydroxylation and dehydrogenation, respectively).[132-135] A distinct receptor subtype for angiotensin II, the AT_2 receptor, is not G protein coupled and is of unclear physiologic significance in the periphery.[136-138] Aldosterone, the primary and most potent endogenous mineralocorticoid released by the zona glomerulosa, acts on target tissues expressing the nuclear mineralocorticoid (or type I glucocorticoid) receptor to promote sodium absorption and potassium excretion. For control of intravascular volume, the primary target of action of aldosterone is the distal nephron. Here, aldosterone increases synthesis of apical membrane sodium channels, mitochondrial enzymes involved in adenosine triphosphate production, and components of Na^+,K^+ adenosine triphosphatase to increase sodium reabsorption and potassium excretion.[139]

Regulation of Secretion. Decreased intravascular volume as sensed by the renal juxtaglomerular apparatus results in release of renin.[125,140] Increased plasma renin activity then allows increased conversion of angiotensinogen to angiotensin I, which in turn is converted peripherally to angiotensins II and III. Increased angiotensin II activity causes vasoconstriction and blood pressure elevation, whereas both angiotensins II and III stimulate aldosterone release from the zona glomerulosa and subsequent salt and water retention and potassium excretion by the distal tubule of the kidney. Conversely, expanded intravascular volume causes decreased renin output and less sodium and water resorption in the kidney, serving to decrease intravascular volume and restore homeostasis.

Changes in vascular volume are not the only regulators of the renin-angiotensin-aldosterone system. Serum potassium concentration directly modulates aldosterone release by the adrenal glomerulosa by its effects on plasma membrane potential and activation of voltage-gated calcium channels.[126,141] By membrane depolarization, increased serum potassium leads to increased aldosterone synthesis, which promotes renal potassium excretion, whereas low serum potassium reduces aldosterone synthesis and decreases urinary potassium losses. Pituitary adrenocorticotropin hormone and vasopressin act through their respective receptors on the glomerulosa cells to increase acute aldosterone secretion. These effects are of short duration because long-term chronic infusions do not chronically elevate aldosterone concentrations. Direct inhibitors of aldosterone secretion, and thus promoters of natriuresis, include atrial natriuretic peptide (ANP),[142,143] somatostatin,[144-146] and dopamine.[147,148]

Local Renin-Angiotensin Systems

Anatomy and Biochemistry. In addition to the well-defined endocrine circuit, the components of the renin-angiotensin system have been found in a wide variety of tissues, including brain, pituitary, arterial wall, heart, ovary, kidney, and adrenal where paracrine and autocrine regulatory functions[149-153] have been postulated, undergoing regulation independent of the systemic counterpart. From the standpoint of regulation of water and volume homeostasis, the brain renin-angiotensin system merits further description.[154] It has long been known that peripherally synthesized angiotensin II could increase blood pressure by effects on the brain outside the blood-brain barrier, at sites such as the OVLT, SFO, area postrema, and median eminence as revealed by ligand-binding studies.[35,154-156] Since the early 2000s, it has become clear that the complete system for generation of angiotensin II is present within the brain. Angiotensinogen has been localized to astrocytes by both immunohistochemical peptide localization and in situ hybridization analysis of messenger RNA.[157] In contrast, renin has been found in high concentration in nerve terminals, with enhanced release on nerve depolarization.[158] Angiotensin-converting enzyme has been found within vascular, choroid plexus, and neuronal components of the central nervous system,[159-161] most notably the SFO and many hypothalamic nuclei, sites of endogenous angiotensin II receptor expression, primarily of the AT_1 subtype, as well as sites not expressing the angiotensin II receptor such as the basal ganglia. The primary effector molecule, angiotensin II, has been localized specifically to neurons and subcellularly to synaptic vesicles.[162] Two of the most significant sites include the circumventricular organs and the paraventricular nucleus of the hypothalamus. Within the paraventricular nucleus, angiotensin II immunoreactivity colocalizes with magnocellular vasopressin, whereas its receptors are within the parvocellular region of the paraventricular nucleus.[163]

Regulation of Secretion. The forebrain angiotensin II pathway, of which the paraventricular nucleus is one component, and circumventricular organ angiotensin II pathway are important control centers for maintenance of osmotic and volume homeostasis.[164] Increased concentration of peripheral angiotensin II, as would be expected in intravascular volume depletion, stimulates drinking behavior.[35] This action of peripheral angiotensin II can be abolished by destruction of the OVLT or SFO, regions whose destruction has long been recognized as causing adipsia.[36] Further effects of central angiotensin II action include augmentation of sodium appetite and stimulation of vasopressin release, all serving, as with peripheral angiotensin II, to restore intravascular volume and maintain blood pressure.[35] The signal of hypovolemia is transduced through the vagal nerve from volume sensors to the brainstem and the region of the nucleus tractus solitarius. Efferents from these brainstem centers project to the median preoptic nucleus and paraventricular nucleus, as does the forebrain angiotensin II pathway, where drinking and pressor effects as well as vasopressin release are elicited.[165-170]

Separate pathways for vasopressin release mediate the response to either peripheral angiotensin II or purely osmotic stimulation of the osmosensors.[171] The release of vasopressin in response to osmotic stimulation is not increased by peripheral angiotensin II, and pure osmotic stimulation does not increase salt appetite. Central angiotensin II, in contrast, may function as a transmitter in the osmosensing circuit, leading to vasopressin release.[172]

The Natriuretic Peptide System

In addition to the classic vasopressin and renin-angiotensin-aldosterone systems, the natriuretic peptide families of ligands and their receptors add further potential for the modulation of salt and water balance. The interaction of the natriuretic peptide system occurs both in the central nervous system, through effects on vasopressin secretion, and peripherally, through its ability to both directly promote natriuresis in the kidney and indirectly inhibit adrenal aldosterone production.

Anatomy and Biochemistry. Atrial natriuretic peptide was initially discovered as a component of cardiac atrial muscle that was able to induce natriuresis, a decrease in blood pressure, and an increase in hematocrit when injected into rats.[173,174]

The biologically active form of ANP consists of a 28-amino-acid peptide that includes a 17-amino-acid ring structure[175] (Figure 11-11). The primary sequence of the peptide has been conserved among mammalian species and, in addition to synthesis in cardiac atrial tissue,[176] has been detected in brain, spinal cord, pituitary, and adrenal gland.[177-180] Within the brain, ANP synthesis occurs at several critical neuroendocrine regulatory sites, including the periventricular, arcuate, anteroventral preoptic, and lateral hypothalamic nuclei.[181,182] ANP is synthesized as a 151-amino-acid preprohormone and is stored as a 126-amino-acid prohormone after removal of the signal peptide sequence.[175,183] Coupled with secretion of pro-ANP is its cleavage between amino acids 98 and 99 to yield the mature 28-amino-acid 99–126 fragment.

Subsequent investigation defined a second peptide from porcine brain with structural homology to ANP.[184] This peptide, designated brain natriuretic peptide (BNP), was later found to be secreted by the heart as well, in this case from both ventricular and atrial tissue.[185-187] Human BNP consists of a 32-amino-acid processed from a larger preprohormone[188] sharing a central ring structure with

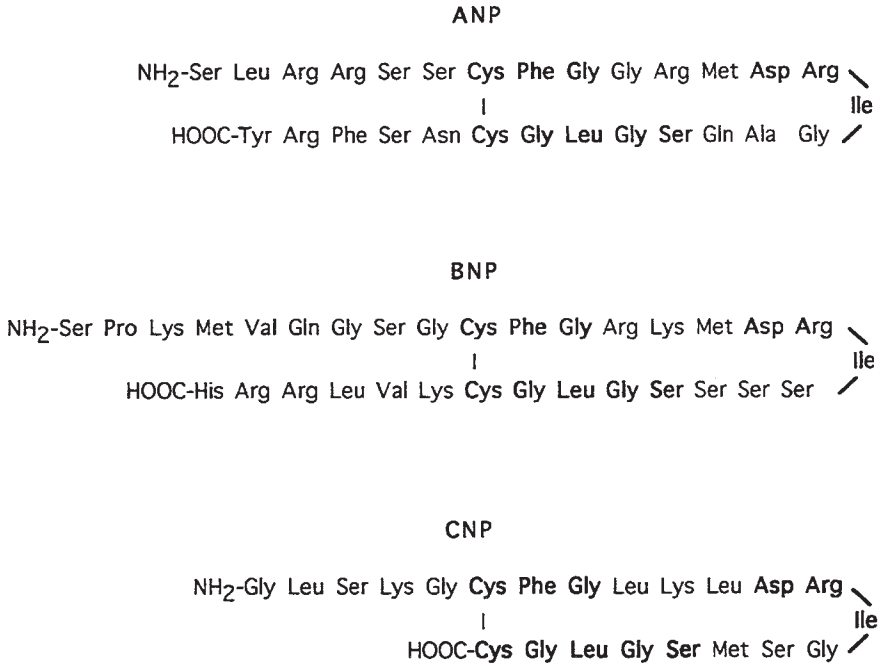

FIGURE 11-11 ■ Amino acid composition of the human natriuretic peptides. Amino acids identical between the three peptides are indicated by bold letters, and the disulfide bond between Cys residues is shown.

ANP (see Figure 11-11), although it is less conserved between species than ANP.

A third member of this family, C-type natriuretic peptide (CNP), was also isolated from porcine brain.[189] In brain, CNP is the most abundant member of the natriuretic peptide family. Within the hypothalamus, specific sites of synthesis largely overlap sites of ANP expression.[182] Little CNP can be detected in plasma, and in marked contrast to ANP and BNP, CNP does not increase in plasma in the setting of cardiac failure.[190,191] Outside the brain, CNP is synthesized in endothelial and vascular smooth muscle. In tissues capable of CNP gene expression, two forms of the peptide are produced, a 53-amino-acid peptide and a less abundant 22-amino-acid molecule[192] (see Figure 11-11).

Three distinct endogenous receptors exist for the natriuretic peptides. The first of these receptors, isolated NPR-A or GC-A, was cloned by virtue of its homology to sea urchin sperm guanylyl cyclase and was later found to have ANP and BNP as its normal ligands.[193-195] A second guanylyl cyclase type receptor (NPR-B) has substantial homology to NPR-A; however, it binds CNP with substantially greater affinity than ANP or BNP.[196] A third receptor, NPR-C,[197] does not possess guanylyl cyclase activity and probably functions to clear all three natriuretic peptides from the circulation.[198] In situ hybridization studies using probes capable of distinguishing the different receptor types have revealed some interspecies discrepancy in distribution. The NPR-A receptor has been localized to kidney, adrenal, pituitary, brain, and heart in the monkey, with NPR-B limited to adrenal, pituitary, and brain.[199] In the rat, broad tissue distribution of both NPR-A and NPR-B has been described.[200] The NPR-C receptor has similarly been found in adrenal, heart, brain, and pituitary.[199]

Regulation of Secretion and Action. Secretion of ANP by cardiac tissue occurs in response to increasing atrial transmural pressure, from both left and right atria.[191,201] Studies employing intravascular volume expansion, exercise, and hypoxia demonstrate increased plasma concentration of ANP after these stimuli in both animal and human paradigms.[190,201-203] Also, increased heart rate, especially increased atrial contractile frequency, results in increased ANP secretion. In the setting of supraventricular tachycardia, high plasma concentration of ANP as well as suppressed concentration of vasopressin (both probably caused by an increase in atrial volume and pressure) contribute to the polyuria associated with this syndrome.[204-206] Ventricular production of ANP has also been demonstrated; it is increased in states of left-sided overload associated with ventricular hypertrophy.[186] ANP synthesized within the central nervous system varies in a volume-dependent fashion in a manner similar to peripheral ANP, suggesting similar function.[177]

The physiologic ramifications of increased ANP production are several. Infusion of ANP in the setting of normovolemia causes natriuresis, diuresis, and a small increase in divalent cation excretion.[190,191,207] ANP, through the NPR-A receptor, primarily inhibits sodium reabsorption within the renal inner medullary collecting duct but also opposes the salt-retaining effects of angiotensin II at the level of the proximal tubule.[207] ANP similarly inhibits the actions of vasopressin and aldosterone in the renal tubules.[208-210] Direct cardiovascular effects of ANP include arterial smooth muscle relaxation, both acutely and with chronic administration. In part, this effect may be mediated through opposition of angiotensin II action.[211]

ANP modulates mineralocorticoid production in a manner that results in the reduction of intravascular volume or pressure. Although direct reduction in plasma renin activity has been described with ANP infusion,[212,213] the most dramatic response to ANP occurs at the level of the adrenal glomerulosa cell. ANP inhibits aldosterone production by inhibiting action of most aldosterone secretagogues, with the most pronounced reduction being angiotensin II activity.[190,201,207] The serum concentration of ANP at which the effects on PRA and aldosterone production occur is within the physiologic range, although the importance of this pathway in normal human physiology remains incompletely defined.

Direct injection of ANP into the central nervous system of animals has suggested an important role for ANP (or CNP) in cardiovascular and salt homeostasis. Vasodepression and bradycardia have both been observed,[214] as has inhibition of vasopressin, adrenocorticotropic hormone, and gonadotropin-releasing hormone secretion.[177,215] Thus, the antagonistic actions of ANP and angiotensin II on intravascular volume and blood pressure remain congruent between central and peripheral systems.

BNP synthesis and secretion from cardiac ventricular tissue are augmented in congestive heart failure and, as for ANP, with hypertension, chronic renal, and chronic liver failure.[187,191] BNP binds the NPR-A receptor, where it is capable of stimulating cyclic guanosine monophosphate production.[193] Infusion of BNP inhibits aldosterone production and results in natriuresis similar to that reported for ANP. With infusion rates generating BNP concentrations 10-fold greater than baseline, reduction in blood pressure has also been found. In addition to modulating sodium homeostasis, ANP and BNP, via NPR-A receptors, stimulate the transition of white to beige fat, and therefore may be involved in thermoregulation and energy balance.[216]

In contrast to ANP and BNP, CNP expression primarily causes activation of the NPR-B receptor.[196] Plasma concentration of CNP does not change significantly with volume overload, and it is believed most CNP action occurs in a paracrine fashion both within the brain and vasculature.[191] CNP synthesized within vascular endothelium acts on receptors in vascular smooth muscle to cause relaxation.[217] CNP infusions in dogs acutely reduce blood pressure and right atrial pressure but do not result in natriuresis, whereas, in humans, moderately supraphysiologic doses cause neither hypotension nor natriuresis.[218] In contrast to ANP, intracerebroventricular infusion of CNP leads to a reduction in blood pressure, suggesting a role for CNP in central control of arterial pressure.[219] CNP inhibits angiotensin II–stimulated vasopressin secretion but stimulates thirst.[220] The overall importance of the CNP central pathways in the modulation of water balance in humans remains to be defined.

APPROACH TO THE PATIENT: DIFFERENTIAL DIAGNOSIS OF DISORDERS OF WATER METABOLISM

Hyponatremia

Hyponatremia (serum sodium, 130 mEq/L) in children is usually associated with severe systemic disorders. It is most often caused by intravascular volume depletion or excessive salt loss and is also encountered with hypotonic fluid overload, especially in infants. Inappropriate vasopressin excess is one of the least common causes of hyponatremia in children, except after vasopressin administration for treatment of diabetes insipidus.

In evaluating the cause of hyponatremia, one should first determine whether the patient is dehydrated and hypovolemic. This is usually evident from the physical examination (decreased weight, skin turgor, central venous pressure) and laboratory data (high blood urea nitrogen, renin, aldosterone, uric acid). With a decrease in the glomerular filtration rate, proximal tubular reabsorption of sodium and water will be high, leading to a urinary sodium value less than 10 mEq/L. Patients with decreased "effective" intravascular volume from congestive heart failure, cirrhosis, nephrotic syndrome, or lung disease will present with similar laboratory data but will also have obvious signs of their underlying disease, which often includes peripheral edema. Patients with primary salt loss will also appear volume depleted. If the salt loss is from the kidney (e.g., diuretic therapy or polycystic kidney disease), the urine sodium level will be elevated, as may urine volume. Salt loss from other regions (e.g., the gut in gastroenteritis or the skin in cystic fibrosis) will cause urine sodium to be low, as in other forms of systemic dehydration. Cerebral salt wasting is encountered with central nervous system insults and results in high serum ANP concentrations, leading to high urine sodium and urine excretion.

The syndrome of inappropriate antidiuresis (SIAD) exists when a primary elevation in vasopressin secretion or inappropriate activation of the vasopressin V2 receptor is the cause of hyponatremia. It is characterized by hyponatremia, an inappropriately concentrated urine (>100 mOsm/kg), normal or slightly elevated plasma volume, and a normal-to-high urine sodium (because of volume-induced suppression of aldosterone and elevation of ANP). Serum uric acid is low in patients with SIAD, whereas it is high in those with hyponatremia caused by systemic dehydration or other causes of decreased intravascular volume.[221] Measurement of plasma vasopressin is often not very useful because it is elevated in nearly all causes of hyponatremia except for primary hypersecretion of ANP[222] or mutations in the vasopressin receptor that lead to inappropriate regulation of its activity. Because cortisol and thyroid deficiency cause hyponatremia by several mechanisms, discussed subsequently, they should be considered in all hyponatremic patients. Drug-induced hyponatremia should be considered in patients on potentially offending medications, as discussed later. In children with SIAD who do not have an obvious cause, a careful search for a tumor (thymoma, glioma, bronchial carcinoid) should be considered.

Polyuria, Polydipsia, and Hypernatremia

In children, it must first be determined whether pathologic polyuria or polydipsia (exceeding 2 L/m2/day) is present. The following questions are asked: Is there a psychosocial reason for either polyuria or polydipsia? Can either be quantitated? Has either polyuria or polydipsia interfered with normal activities? Is nocturia or enuresis present? If so, does the patient also drink after nocturnal awakening? Does the history (including longitudinal growth data) or physical examination suggest other deficient or excessive endocrine secretion or an intracranial neoplasm?

If pathologic polyuria or polydipsia is present, the following should be obtained. In the outpatient setting: serum osmolality; serum concentrations of sodium, potassium, glucose, calcium, and blood urea nitrogen; and urinalysis, including measurement of urine osmolality, specific gravity, and glucose concentration. A serum osmolality greater than 300 mOsm/kg, with urine osmolality less than 300 mOsm/kg, establishes the diagnosis of diabetes insipidus. If serum osmolality is less than 270 mOsm/kg or urine osmolality is greater than 600 mOsm/kg, the diagnosis of diabetes insipidus is unlikely. If, on initial screening, the patient has a serum osmolality less than 300 mOsm/kg but the intake/output record at home suggests significant polyuria and polydipsia that cannot be attributed to primary polydipsia (i.e., the serum osmolality is greater than 270 mOsm/kg), the patient should undergo a water deprivation test to establish a diagnosis of diabetes insipidus and to differentiate central from nephrogenic causes.

After a maximally tolerated overnight fast (based on the outpatient history), the child is admitted to the outpatient testing center in the early morning of a day when an 8- to 10-hour test can be carried out, and the child is deprived of water.[223,224] The physical signs and biochemical parameters shown in the accompanying protocol are measured (Figure 11-12). If at any time during the test, the urine osmolality exceeds 1000 mOsm/kg, or 600 mOsm/kg and is stable over 1 hour, the patient does not have diabetes insipidus. If at any time the serum osmolality exceeds 300 mOsm/kg and the urine osmolality is less than 600 mOsm/kg, the patient has diabetes insipidus. If the serum osmolality is less than 300 mOsm/kg and the urine osmolality is less than 600 mOsm/kg, the test should be continued unless vital signs disclose hypovolemia.

A common error is to stop a test too soon, based on the amount of body weight lost, before either urine osmolality has plateaued above 600 mOsm/kg or a serum osmolality above 300 mOsm/kg has been achieved. Unless the serum osmolality increases above the threshold for vasopressin release, a lack of vasopressin action (as inferred by a nonconcentrated urine) cannot be deemed pathologic. If the diagnosis of diabetes insipidus is made, aqueous vasopressin (Pitressin, 1 U/m2) should be given subcutaneously. If the patient has central diabetes insipidus, urine volume should fall and osmolality should at least double during the next hour, compared with the value before vasopressin therapy. If there is less than a twofold increase in urine osmolality after vasopressin

Water Deprivation Test

ENDOCRINE FUNCTION TEST | Patient Name

DIAGNOSIS: Suspected Diabetes Insipidus

TEST: Water Deprivation

COMMENTS:

FIGURE 11-12 ■ Protocol for evaluation of diabetes insipidus using water deprivation. IV, intravenous; OSM, osmolality; S.G., urinary specific gravity; SQ, subcutaneous.

administration, the patient probably has nephrogenic diabetes insipidus. Desmopressin should not be used for this test, because it has been associated with water intoxication in small children in this setting.[225] Patients with long-standing primary polydipsia may have mild nephrogenic diabetes insipidus because of dilution of their renal medullary interstitium. This should not be confused with primary nephrogenic diabetes insipidus, because patients with primary polydipsia should have a tendency toward hyponatremia, rather than hypernatremia, in the basal state. Patients with a family history of X-linked nephrogenic diabetes insipidus can be evaluated

for the disorder in the prenatal or perinatal period by DNA sequence analysis, thus allowing therapy to be initiated without delay.[226]

The water deprivation test should be sufficient in most patients to establish the diagnosis of diabetes insipidus and to differentiate central from nephrogenic causes. Plasma vasopressin concentrations may be obtained during the procedure (see Figure 11-12), although they are rarely needed for diagnostic purposes in children.[227] They are particularly helpful in differentiating between partial central diabetes insipidus and nephrogenic diabetes insipidus, in that they are low in the former and high in the latter situation.[228] If urine osmolality concentrates normally, but only after serum osmolality is well above 300 mOsm/kg, the patient may have an altered threshold for vasopressin release, also termed a reset osmostat. This may occur after head trauma, neurosurgery, or brain tumors.[229] More recently, an immunoassay for copeptin, the carboxy-terminus of the vasopressin precursor, has been developed, which may replace the measurement of vasopressin in the evaluation of diabetes insipidus.[230] Copeptin is more stable than vasopressin, and blood concentrations of the two peptides are highly correlated.[230]

Magnetic resonance imaging (MRI) is not very helpful in distinguishing central diabetes insipidus from nephrogenic diabetes insipidus.[231] Normally, the posterior pituitary is seen as an area of enhanced brightness in T1-weighted images after administration of gadolinium.[232] The posterior pituitary "bright spot" is diminished or absent in both forms of diabetes insipidus, presumably because of decreased vasopressin synthesis in central, and increased vasopressin release in nephrogenic, disease.[232-234] In primary polydipsia, the bright spot is normal, probably because vasopressin accumulates in the posterior pituitary during chronic water ingestion,[232] whereas it is decreased in SIADH, presumably because of increased vasopressin secretion.[231] Dynamic, fast-frame, MRI analysis has allowed the estimation of blood flow to the posterior pituitary.[235] With this technique, both central and nephrogenic diabetes insipidus are associated with delayed enhancement in the area of the neurohypophysis.[236]

In the inpatient, post-neurosurgical setting, central diabetes insipidus is likely if hyperosmolality (serum osmolality $>$ 300 mOsm/kg) is associated with urine osmolality less than serum osmolality. One must beware of intraoperative fluid expansion with subsequent hypo-osmolar polyuria masquerading as diabetes insipidus.

SPECIFIC DISORDERS OF WATER METABOLISM

Hyponatremia with Normal Regulation of Vasopressin

Hyponatremia with Appropriate Decreased Secretion of Vasopressin

Increased Water Ingestion (Primary Polydipsia). In a hypo-osmolar state with vasopressin secretion normally suppressed, the kidney can excrete urine with an osmolality as low as 50 mOsm/kg. Under these conditions, a daily solute load of 500 mOsm/m^2 could be excreted in 10 L/m^2 of urine per day. Neonates cannot dilute their urine to this degree and are prone to develop water intoxication at levels of water ingestion above 4 L/m^2/day (approximately 60 mL/hr in a newborn). This may happen when concentrated infant formula is diluted with excess water, either by accident or in a misguided attempt to make it last longer.[237] A primary increase in thirst, without apparent cause, leading to hyponatremia has been reported in infants as young 5 weeks of age.[238] In older children, with a normal kidney and the ability to suppress vasopressin secretion, hyponatremia does not occur unless water intake exceeds 10 L/m^2/day, a feat that is almost impossible to accomplish. Long-standing ingestion of large volumes of water will decrease the hypertonicity within the renal medullary interstitium, which will impair water reabsorption and guard against water intoxication.[239] Hyponatremia will occur at lower rates of water ingestion when renal water clearance is impaired, either because of inappropriately elevated vasopressin secretion or for other reasons.

The rare patient in whom the osmotic thresholds for thirst and vasopressin release are reversed illustrates the importance of the normal relationship between these two responses to osmotic stimulation.[240] If thirst is activated below the threshold for vasopressin release, water intake and hypo-osmolality will occur and suppress vasopressin secretion, leading to persistent polydipsia and polyuria. As long as daily fluid intake is less than 10 L/m^2, hyponatremia will not occur. Despite the presence of polyuria and polydipsia, this entity should not be confused with diabetes insipidus because of the absence of hypernatremia. Desmopressin treatment of such a patient may lower serum osmolality below the threshold for thirst, suppressing water ingestion and the consequent polyuria.

Decreased Renal Free Water Clearance. Adrenal insufficiency, either primary or secondary, has long been known to result in compromised free water excretion.[40,70] The mechanisms by which glucocorticoids and mineralocorticoids modulate water diuresis have been the subject of substantial investigation. Some studies have demonstrated increased plasma vasopressin activity in the context of glucocorticoid insufficiency,[241,242] consistent with more recent molecular biologic evidence that glucocorticoids inhibit transcription of the vasopressin gene.[243] Other investigators, however, have failed to detect vasopressin in plasma of patients with adrenal insufficiency and abnormal water clearance.[244] Consistent with vasopressin-independent actions of adrenal steroids on water metabolism, Brattleboro rats with hypothalamic diabetes insipidus manifest impaired excretion of a water load after adrenalectomy.[70] In adrenalectomized Brattleboro rats, glucocorticoid administration restored urine flow rate but did not restore maximal urinary diluting capacity. Conversely, mineralocorticoid administration restored maximal urinary diluting capacity but not flow rate. Thus, both mineralocorticoids and glucocorticoids are required for normal free water clearance. In part, these vasopressin-independent actions of mineralocorticoids and glucocorticoids have been attributed to the increased glomerular filtration rate arising

from reexpansion of extracellular fluid volume (reduced owing to salt wasting) and improved cardiovascular tone, respectively.[41,245,246] By restoring the glomerular filtration rate, more free water is delivered to the distal tubule for excretion. Additionally, volume repletion reduces the nonosmotic stimuli for vasopressin release of volume depletion and hypotension. Nitric oxide has been found to stimulate cyclic guanosine monophosphate–dependent membrane insertion of aquaporin-2 into renal epithelial cells.[247] Because glucocorticoid has been shown to inhibit endothelial nitric oxide synthase,[248] it is possible that under conditions of glucocorticoid deficiency high levels of nitric oxide synthase result in elevated levels of endothelial nitric oxide in the renal vasculature, which in the distal renal tubule stimulate increased, vasopressin-independent, aquaporin-2 activity and decreased free water clearance.

Direct effects of glucocorticoid or mineralocorticoid insufficiency on aquaporin expression and function have not been reported. In addition to impairing maximal renal diluting capacity, adrenal insufficiency compromises maximal urine-concentrating capacity.[249] This effect has been shown to result from reduced tubular response to vasopressin.

Thyroid hormone is also required for normal free water clearance, and its deficiency likewise results in decreased renal water clearance and hyponatremia. Although some studies suggest that vasopressin mediates the hyponatremia of hypothyroidism because ethanol increases free water excretion in hypothyroid patients, this effect has not been found in other reports.[250] Additionally, in severe hypothyroidism, hypovolemia is not present and hyponatremia is accompanied by appropriate suppression of vasopressin.[251] Similar to the consequences of isolated glucocorticoid deficiency described earlier, hypothyroidism impairs free water clearance more than maximal urine diluting capacity.[252] This decrease in free water clearance may result from a diminished glomerular filtration rate and delivery of free water to the diluting segment of distal nephron, as suggested by both animal[253] and human studies.[254]

Given the often subtle clinical findings associated with adrenal and thyroid deficiency, all patients with hyponatremia should be suspected of having these disease states and have appropriate diagnostic tests performed if indicated. Moreover, patients with coexisting adrenal failure and diabetes insipidus may have no symptoms of the latter until glucocorticoid therapy unmasks the need for vasopressin replacement.[255,256] Similarly, resolution of diabetes insipidus in chronically polyuric and polydipsic patients may suggest inadequate glucocorticoid supplementation or noncompliance with glucocorticoid replacement.

Some drugs may cause hyponatremia by inhibiting renal water excretion without stimulating secretion of vasopressin (Table 11-1), an action that could be called nephrogenic SIAD. In addition to augmenting vasopressin release, both

carbamazepine[257,258] and chlorpropamide[259,260] increase the cellular response to vasopressin. Acetaminophen also increases the response of the kidney to vasopressin[259]; however, this has not been found to cause hyponatremia. High-dose cyclophosphamide treatment (15 to 20 mg/kg intravenous bolus) is often associated with hyponatremia, particularly when it is followed by a forced water diuresis to prevent hemorrhagic cystitis.[261-263] Plasma vasopressin concentrations are normal, suggesting a direct effect of the drug to increase water resorption.[264] Similarly, vinblastine, independent of augmentation of plasma vasopressin concentration or vasopressin action,[265] and cisplatin[266,267] cause hyponatremia. These drugs may damage the collecting duct tubular cells, which are normally highly impermeable to water, or they may enhance aquaporin-2 water channel activity and thereby increase water reabsorption down its osmotic gradient into the hypertonic renal interstitium.

Treatment. Hyponatremia due to cortisol or thyroid hormone deficiency reverses promptly after the institution of hormone replacement. Because the hyponatremia is often chronic, too rapid an increase in the serum sodium concentration should be avoided if possible to reduce the risk of developing central pontine myelinolysis. When drugs that impair free water excretion must be used, water intake should be limited, as if the patient has SIADH, to 1 $L/m^2/24$ hr, using the regimen discussed.

Hyponatremia with Appropriate Increased Secretion of Vasopressin

Increased vasopressin secretion causing hyponatremia may be either an appropriate response or an inappropriate response to a pathologic state. Inappropriate secretion of vasopressin or V2 receptor activity (SIAD) is the much less common of the two entities.[268,269] Whatever the cause, hyponatremia is a worrisome sign often associated with increased morbidity and mortality.[270]

Causes

Systemic Dehydration. Systemic dehydration (water in excess of salt depletion) initially results in hypernatremia, hyperosmolality, and activation of vasopressin secretion, as discussed earlier. In addition, the associated fall in the renal glomerular filtration rate results in an increase in proximal tubular sodium and water reabsorption, with a concomitant decrease in distal tubular water excretion. This limits the ability to form a dilute urine and, along with the associated stimulation of the renin-angiotensin-aldosterone system and suppression of ANP secretion, results in the excretion of urine that is very low in sodium. As dehydration progresses, hypovolemia and hypotension become major stimuli for vasopressin release, much more potent than hyperosmolality. This effect, by attempting to preserve volume, decreases free water clearance further and may lead to water retention and hyponatremia, especially if water replacement in excess of salt is given. In many cases, hyponatremia caused by intravascular volume depletion is evident from physical and laboratory signs such as decreased skin turgor, low central venous pressure, hemoconcentration, and elevated blood urea nitrogen levels. The diagnosis may be subtle, however. For example, patients with meningitis may present with hyponatremia, for which water restriction has been advocated in the belief that it is due to central SIAD. Several studies have found that volume depletion, rather than SIAD, is often the cause of the hyponatremia[271,272] and that it resolves more readily when supplemental, rather than restricted, fluid and solute are administered.[273] In patients with hyponatremia after head trauma, volume depletion rather than central SIAD is the cause in approximately half of cases.[274] Similarly, many patients with gastroenteritis who present with mild hyponatremia and elevated plasma vasopressin levels[275] have these on the basis of systemic dehydration rather than SIAD, and they benefit from volume expansion rather than fluid restriction.[276] More generally, most hospitalized pediatric patients with hyponatremia benefit from isotonic rather than hypotonic fluid replacement, suggesting that the underlying cause of the electrolyte disturbance is dehydration.[277]

Primary Loss of Sodium Chloride. The kidney can lose salt, as it does in patients with congenital polycystic kidney disease, acute interstitial nephritis, and chronic renal failure. Mineralocorticoid deficiency, pseudohypoaldosteronism (sometimes seen in children with urinary tract obstruction or infection), diuretic use, and gastrointestinal disease (usually gastroenteritis with diarrhea or vomiting) can also result in an excess loss of sodium chloride. Hyponatremia can also result from salt loss in sweat in cystic fibrosis, although obstructive lung disease with an elevation of plasma vasopressin probably plays a more prominent role, as has been discussed. With the onset of salt loss, any tendency toward hyponatremia will initially be countered by suppression of vasopressin and increased water excretion. With continuing salt loss, hypovolemia or hypotension ensues, causing nonosmotic stimulation of vasopressin. This, plus increased thirst, which leads to ingestion of hypotonic fluids with low solute content, results in hyponatremia. Weight loss is usually evident, as is the source of sodium wasting. If it is the kidney, it is accompanied by a rate of urine output and a urine sodium content greater than those associated with most other causes of hyponatremia except a primary increase in ANP secretion.

Decreased Effective Plasma Volume. Congestive heart failure, cirrhosis, nephrotic syndrome, positive-pressure mechanical ventilation,[278] severe burns,[279] lung disease (bronchopulmonary dysplasia[280-282] [in neonates]), cystic fibrosis with obstruction,[283,284] and severe asthma[285,286] are all characterized by a decrease in "effective" intravascular volume.[250,287] This occurs because of impaired cardiac output, an inability to keep fluid within the vascular space, or impaired blood flow into the heart, respectively. As with systemic dehydration, in an attempt to preserve intravascular volume, water and salt excretions by the kidney are reduced; and decreased barosensor stimulation results in a compensatory, appropriate increase in vasopressin secretion, leading to an antidiuretic state and hyponatremia.[288] Because of the associated stimulation of the renin-angiotensin-aldosterone system, these patients also have an increase in the total-body content of sodium chloride and may have peripheral edema, which distinguishes them from those with systemic dehydration.

In patients with impaired cardiac output and elevated atrial volume (e.g., congestive heart failure or lung disease), ANP concentrations are elevated, which contributes to hyponatremia by promoting natriuresis.

Treatment. Patients with systemic dehydration and hypovolemia should be rehydrated with salt-containing fluids such as normal saline or lactated Ringer solution. Because of activation of the renin-angiotensin-aldosterone system, the administered sodium will be avidly conserved and a water diuresis will quickly ensue as volume is restored and vasopressin concentrations fall.[289] Under these conditions, caution must be taken to prevent too rapid a correction of hyponatremia, which may itself result in brain damage.

Hyponatremia caused by a decrease in effective plasma volume from cardiac, hepatic, renal, or pulmonary dysfunction is more difficult to reverse. The most effective therapy is the least easily achieved: treatment of the underlying systemic disorder. Patients weaned from positive-pressure ventilation undergo a prompt water diuresis and resolution of hyponatremia as cardiac output is restored and vasopressin concentrations fall. The only other effective route is to limit water intake to that required for the renal excretion of the obligate daily solute load of approximately 500 mOsm/m^2 and to replenish insensible losses. In a partial antidiuretic state with a urine osmolality of 750 mOsm/kg H_2O and insensible losses of 500 mL/m^2, oral intake would have to be limited to approximately 1200 mL/m^2/day. Because of concomitant hyperaldosteronism, the dietary restriction of sodium chloride needed to control peripheral edema in patients with heart failure may reduce the daily solute load and further limit the amount of water that can be ingested without exacerbating hyponatremia. Hyponatremia in these settings is often slow to develop, rarely causes symptoms, and usually does not need treatment. If the serum sodium falls below 125 mEq/L, water restriction to 1 L/m^2/day is usually effective in preventing a further decline. Because water retention in these disorders is a compensatory response to decreased intravascular volume, an attempt to reverse it with drugs such as demeclocycline or specific V2 receptor antagonists (which induce nephrogenic diabetes insipidus as discussed subsequently) could worsen hypovolemia, with potentially dire consequences.[290]

In general, patients with hyponatremia caused by salt loss require ongoing supplementation with sodium chloride and fluids. Initially, intravenous replacement of urine volume with fluid containing sodium chloride (150 to 450 mEq/L depending on the degree of salt loss) may be necessary; oral salt supplementation may be required subsequently.[222] This treatment contrasts to that of SIAD, in which water restriction without sodium supplementation is the mainstay.

Precautions in the Emergency Treatment of Hyponatremia. Most children with hyponatremia develop the disorder gradually, are asymptomatic, and should be treated with water restriction alone. The development of acute hyponatremia, or a serum sodium concentration below 120 mEq/L, may be associated with lethargy, psychosis, coma, or generalized seizures, especially in younger children. Acute hyponatremia causes cell swelling owing to the entry of water into cells (Figure 11-13), which can lead to neuronal dysfunction from alterations in the ionic environment or to cerebral herniation because of the

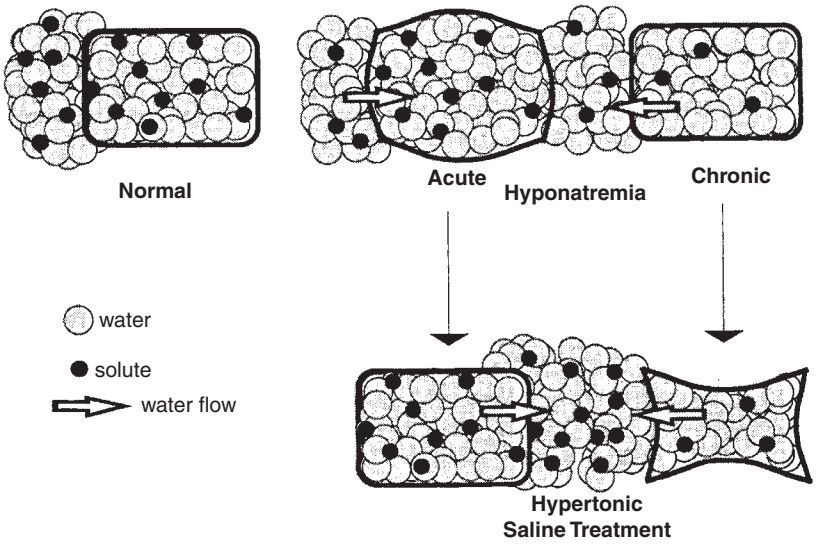

FIGURE 11-13 ■ Changes in organic osmolytes with hyponatremia and after its correction. Under normal conditions, osmotic balance exists between extracellular and intracellular compartments. With acute hyponatremia, water enters cells, causing cell swelling. After approximately 24 hours of continued hyponatremia, intracellular organic osmolytes decrease, restoring cell volume toward normal. Hypertonic saline treatment of acute hyponatremia results in restoration of normal cell volume, whereas the same treatment of chronic hyponatremia results in cell shrinkage. Large circle, water; closed smaller circle, solute; arrow, direction of water flow.

encasement of the brain in the cranium. If present for more than 24 hours, cell swelling triggers a compensatory decrease in intracellular organic osmolytes, resulting in the partial restoration of normal cell volume in chronic hyponatremia.[291]

The proper emergency treatment of cerebral dysfunction depends on whether the hyponatremia is acute or chronic.[1,292] In all cases, water restriction should be instituted. If hyponatremia is acute, and therefore probably not associated with a decrease in intracellular organic osmolyte concentration, rapid correction with hypertonic 3% sodium chloride administered intravenously may be indicated. As a general guide, this solution, given in the amount of 12 mL/kg, will result in an increase in serum sodium concentration of approximately 10 mEq/L. If hyponatremia is chronic, hypertonic saline treatment must be undertaken with caution, because it may result in both cell shrinkage (see Figure 11-13) and the associated syndrome of central pontine myelinolysis.[293] This syndrome, affecting the central portion of the basal pons as well as other brain regions, is characterized by axonal demyelination, with sparing of neurons. It becomes evident within 24 to 48 hours after too rapid correction of hyponatremia, has a characteristic appearance by computed tomography and MRI, and often causes irreversible brain damage.[293-295] If hypertonic saline treatment is undertaken, the serum sodium concentration should be raised only high enough to cause an improvement in mental status, and in no case faster than 0.5 mEq/L/hr or 12 mEq/L/day.[292-295] In the case of systemic dehydration, the increase in serum sodium level may occur rapidly using this regimen. The associated hyperaldosteronism will cause avid retention of the administered sodium, leading to rapid restoration of volume and suppression of vasopressin secretion and resulting in a brisk water diuresis and an increase in the serum sodium concentration.[289]

Acute treatment of hyponatremia is more difficult in patients with decreased effective plasma volume. This is both because the underlying disorder makes it difficult to maintain the administered fluid within the intravascular space and because an associated increase in ANP promotes natriuresis and loss of the administered salt. Furthermore, patients with cardiac disease who are administered hypertonic saline may require concomitant treatment with a diuretic such as furosemide to prevent worsening of heart failure, which will also increase natriuresis.

Hyponatremia with Abnormal Regulation of Vasopressin

Hyponatremia with Inappropriate Increased Secretion of Vasopressin or Increased Vasopressin V2 Receptor Activity (Syndrome of Inappropriate Antidiuresis [SIAD])

Causes of SIAD. SIAD is uncommon in children.[268,269,296] It can occur with encephalitis, brain tumor,[297] head trauma,[274,298] or psychiatric disease[299]; in the postictal period after generalized seizures[300]; and after prolonged nausea,[301,302] pneumonia,[303,304] or AIDS.[305] Many drugs have been associated with impaired free water clearance as indicated in Table 11-1. Impaired free water clearance can result from alteration in vasopressin release, increased vasopressin effect at the same plasma vasopressin concentration, or vasopressin-independent changes in distal collecting tubule water permeability. Common drugs that have been shown to increase antidiuretic hormone (ADH) secretion and result in hyponatremia include carbamazepine,[258] chlorpropamide,[306] vinblastine,[265] vincristine,[307] and tricyclic antidepressants.[308,309] Newer sulfonylurea agents, including glyburide, are not associated with SIAD.[310] Other rarer causes of SIAD in children are listed in Table 11-2. Although it has been believed to be the cause of hyponatremia associated with viral meningitis, volume depletion is more commonly the etiology.[271,273] In contrast, the majority of children with tuberculous meningitis have hyponatremia and SIADH, which predict more severe disease and poor outcome.[311-313] SIAD is the cause of the hyponatremic second phase of the triple-phase response seen after hypothalamic-pituitary surgery. Hyponatremia with elevated vasopressin secretion is found in up to 35% of patients 1 week after transsphenoidal pituitary surgery.[314,315] The mechanism is most likely retrograde neuronal degeneration with cell death and vasopressin release. Secondary adrenal insufficiency causing stimulation of vasopressin release[69] may also play a role, because hyponatremia most commonly follows the removal of adrenocorticotropin hormone-secreting corticotroph adenomas.[315] In the majority of children with SIAD, the cause is the excessive administration of vasopressin to treat either central diabetes insipidus,[225,316] or, less commonly, bleeding disorders[317] (as has been discussed previously), or, most uncommonly, following dDAVP therapy for enuresis.

Two unrelated infants with mutations in the vasopressin V2 receptor that presented with severe hyponatremia in the first months of life heralded a new genetic cause of hyponatremia.[318] These two infants had missense mutations at codon 137 that converted arginine to cysteine or leucine and lead to constitutive activation of the V2 receptor with appropriately suppressed arginine vasopressin plasma concentration. This genetic disorder has been termed "nephrogenic syndrome of inappropriate antidiuresis (NSIAD)." It remains unclear what portion of isolated early onset chronic SIAD results from activating mutations of the V2 receptor, though the incidence is likely to be very low. Interestingly, this same codon is also the site of a loss-of-function mutation (R137H) that leads to X-linked nephrogenic diabetes insipidus.[319] A total of 16 patients with NSIAD have been reported.[320]

Treatment of SIAD. Chronic SIAD is best treated by chronic oral fluid restriction. Under full vasopressin antidiuretic effect (urine osmolality of 1,000 mOsm/L), a normal daily obligate renal solute load of 500 mOsm/m^2 would be excreted in 500 mL/m^2 H_2O. This, plus a daily nonrenal water loss of 500 mL/m^2, would require that oral fluid intake be limited to 1000 mL/m^2/day to avoid hyponatremia, as has been discussed more fully. In young children, this degree of fluid restriction may not provide adequate calories for growth. In this situation, the creation of nephrogenic diabetes insipidus using demeclocycline therapy may be indicated to allow sufficient fluid intake for normal growth.[315]

Demeclocycline is superior to lithium for this purpose.[316] Lithium and demeclocycline, however, are associated with significant toxicities—which may limit their use in pediatric patients. Oral urea has been effectively used to treat adult patients with chronic SIAD by virtue of its ability to induce an effective osmotic diuresis. This therapy was also demonstrated to be safe and effective in four children with chronic SIAD, including two with mutations in the vasopressin V2 receptor.[317] Specific nonpeptide V2 receptor antagonists (vaptans) have also been developed for use in subacute or chronic SIAD due to inappropriate increased vasopressin secretion.[318-320] The aquaretic effects of the vaptans, after either parental or oral administration, have a rapid onset of action, exert peak effects within a few hours, and subside within 24 hours.[321,322] In a large series of adult patients with euvolemic or hypervolemic hyponatremia resulting from cirrhosis, heart failure, or SIAD, these vasopressin receptor antagonists were effective in sustained elevation of serum sodium concentration.[320] Another study in adults, limited to subjects with SIAD arising from inappropriate vasopressin secretion, demonstrated the efficacy of long-term treatment with an orally active vaptan in conjunction with fluid restriction to 1.5 L per day.[323] Substantial variability in the degree of serum sodium elevation was observed, however. This variability resulted from both interindividual differences in drug efficacy/disposition and the failure to adequately restrict water consumption. The primary adverse effect from these agents is inflammation at infusion sites, though rises in serum sodium above rates recommended to prevent myelinolysis have also been found.[321] Limited experience with vaptans has been reported in children, though they have been used to promote hydration during chemotherapy with malignancy-associated SIAD.[324] These agents have not been effective in treating activating mutations of the V2 receptor,[325] although low-dose urea has been useful.[320] Because the predictability of hypertonic saline administration for acute, severe forms of SIAD is greater than that of vaptans, hypertonic saline infusion for symptomatic hyponatremia due to inappropriate vasopressin secretion remains the recommended intervention.[321] Of note, some of these V2 receptor antagonists facilitate the proper transport of loss-of-function V2 receptor mutants to the cell surface.[321]

Acute treatment of hyponatremia due to SIAD is only indicated if cerebral dysfunction is present. In that case, treatment is dictated by the duration of hyponatremia and the extent of cerebral dysfunction. Because patients with SIAD have volume expansion, salt administration is not very effective in raising the serum sodium concentration because it is rapidly excreted in the urine due to suppressed aldosterone and elevated atrial natriuretic peptide concentrations.

Hyponatremia with Inappropriate Decreased Secretion of Vasopressin, Due to Increased Secretion of Atrial Natriuretic Peptide

Although atrial natriuretic peptide does not usually play a primary role in the pathogenesis of disorders of water metabolism, it may have an important secondary role.[280,326-328] Patients with SIAD have elevated atrial natriuretic peptide concentrations, probably due to hypervolemia, which may contribute to the elevated natriuresis of SIAD and which decrease as water intake is restricted.[326] Likewise, the suppressed atrial natriuretic peptide concentrations found in central diabetes insipidus, probably due to the associated hypovolemia, rise after dDAVP therapy.[326] However, hyponatremia in some patients, primarily those with central nervous system disorders including brain tumor, head trauma, hydrocephalus, neurosurgery, cerebral vascular accidents, and brain death, may be due to the primary hypersecretion of atrial natriuretic peptide.[222,329-331] This syndrome, called cerebral salt wasting, is defined by hyponatremia accompanied by elevated urinary sodium excretion (often more than 150 mEq/L), excessive urine output, hypovolemia, suppressed vasopressin, and elevated atrial natriuretic peptide concentrations (> 20 pmol/L). Thus, it is distinguished from SIAD, in which normal or decreased urine output, euvolemia, only modestly elevated urine sodium concentration, and elevated vasopressin concentration occur. Direct measurement of intravascular volume status with a central venous line is often helpful. The distinction is important because the therapies of the two disorders are markedly different. There is controversy regarding the prevalence of cerebral salt wasting.[332] In patients in an intensive care setting with the initial diagnosis of cerebral salt wasting, none of them upon further investigation were hypovolemic, one of the cardinal criteria of the syndrome.[333]

Treatment of Cerebral Salt Wasting

Treatment of patients with cerebral salt wasting consists of restoring intravascular volume with sodium chloride and water, as with the treatment of other causes of systemic dehydration. The underlying cause of the disorder, which is usually acute brain injury, should also be treated if possible.

Other Causes of True and Factitious Hyponatremia

True hyponatremia occurs with hyperglycemia, which causes the influx of water into the intravascular space. Serum sodium will decrease by 1.6 mEq/L for every 100-mg/dL increment in blood glucose above 100 mg/dL. Glucose is not ordinarily an osmotically active agent and does not stimulate vasopressin release, probably because it is able to equilibrate freely across plasma membranes. However, in the presence of insulin deficiency and hyperglycemia, glucose acts as an osmotic agent, presumably because its normal intracellular access to osmosensor sites is prevented.[334] Under these circumstances, an osmotic gradient exists, and this stimulates vasopressin release. In diabetic ketoacidosis, this, together with the hypovolemia caused by the osmotic diuresis secondary to glycosuria, results in marked stimulation of vasopressin secretion.[335-338] Rapid correction of hyponatremia may follow soon after the institution of fluid and insulin therapy. Whether this contributes to the pathogenesis of cerebral edema occasionally seen following treatment of diabetic ketoacidosis is not known. Elevated concentrations of triglycerides may cause factitious hyponatremia, as can obtaining a blood sample downstream from an intravenous infusion of hypotonic fluid.

Hypernatremia with Inappropriate Decreased Vasopressin Secretion or Action

Central Diabetes Insipidus

Causes of Central Diabetes Insipidus. Central (hypothalamic, neurogenic, or vasopressin-sensitive) diabetes insipidus can be caused by disorders of vasopressin gene structure; accidental or surgical trauma to vasopressin neurons; congenital anatomic hypothalamic or pituitary defects; neoplasms; infiltrative, autoimmune, and infectious diseases affecting vasopressin neurons or fiber tracts; and increased metabolism of vasopressin. The etiology of central diabetes insipidus is not apparent in anywhere between 9% and 55% of children and young adults in different series published in the literature.[339,340] *Long-term surveillance can identify an underlying cause that is not apparent at the time of initial diagnosis sometimes after as long as 21 years.*[341]

Genetic Causes. Familial, autosomal dominant central diabetes insipidus is manifest within the first half of the first decade of life.[342] Vasopressin secretion, initially normal, gradually declines until diabetes insipidus of variable severity ensues. Patients respond well to vasopressin replacement therapy. The disease has a high degree of penetrance, but it may be of variable severity within a family[343] and may spontaneously improve in middle age.[343,344] Vasopressin-containing neurons are absent from the magnocellular paraventricular neurons[345] but present in parvocellular regions.[346] Several different oligonucleotide mutations in the vasopressin structural gene have been found to cause the disease (www.medcon.mcgill.ca/nephros/avp_npii.html). To date, more than 25 mutations have been detected in the coding region of the vasopressin gene (see Figure 11-3). Most mutations are in the neurophysin portion of the vasopressin precursor, except for five in either the signal peptide or vasopressin peptide regions of the gene. This suggests that neurophysin has a valuable function, possibly in the proper intracellular sorting or packaging of vasopressin into secretory granules. There are no disease-causing mutations in the copeptin region of the vasopressin precursor. This suggests either that this region has a low mutation rate or more likely that it does not serve a critical function in vasopressin biology.

A family with a missense mutation within the vasopressin peptide region (Proline→Leucine at amino acid 7) of the gene, causing markedly reduced biologic activity, was reported.[347] The disease in this family is transmitted with an autosomal recessive pattern. This indicates that haploinsufficiency is not the basis for the autosomal dominant nature of the disease in families with the more common mutations in the neurophysin region of the gene. Rather, the abnormal gene product may interfere with the processing and secretion of the product of the normal allele,[348] or it may cause neuronal degeneration and cell death.[349] In support of this theory, mutant vasopressin precursors impair the secretion of the normal protein in cell models,[348] and in a transgenic mouse model of the disease, a progressive loss of hypothalamic vasopressin-containing neurons occurs as the mice develop diabetes insipidus.[350] Heterozygous mice with a mutation (C67X) in the vasopressin gene, known to cause autosomal dominant familial neurohypophyseal diabetes insipidus in humans, developed diabetes insipidus by 2 months of age. They were found to have retention of the precursor of vasopressin within the neurons and the induction of an endoplasmic reticulum chaperone protein (BiP).[351]

Vasopressin deficiency is also found in the DIDMOAD syndrome, consisting of diabetes insipidus, diabetes mellitus, optic atrophy, and deafness.[352,353] The gene for this syndrome complex, also known as Wolfram syndrome, was localized to human chromosome 4p16 by polymorphic linkage analysis[348] and isolated.[349] The Wolfram syndrome gene, *WFS1*, encodes an 890-amino-acid tetrameric transmembrane protein that primarily localizes to the endoplasmic reticulum. It is thought to function as a calcium channel or regulator of a calcium channel.[354,355]

Trauma. The axons of vasopressin-containing magnocellular neurons extend uninterrupted to the posterior pituitary over a distance of approximately 10 mm. Trauma to the base of the brain can cause swelling around or severance of these axons, resulting in either transient or permanent diabetes insipidus.[356] Permanent diabetes

insipidus can occur after seemingly minor trauma. Approximately half of patients with fractures of the sella turcica will develop permanent diabetes insipidus,[357] which may be delayed as long as a month following the trauma, during which time neurons of severed axons may undergo retrograde degeneration.[358] Septic shock[359] and postpartum hemorrhage associated with pituitary infarction (Sheehan syndrome)[360,361] may involve the posterior pituitary with varying degrees of diabetes insipidus. Diabetes insipidus is never associated with cranial irradiation of the hypothalamic-pituitary region, although this treatment can cause deficits in all of the hypothalamic releasing hormones carried by the portal-hypophyseal system to the anterior pituitary (see the discussion of growth hormone in Chapter 10). This occurs because vasopressin is carried directly to the posterior pituitary via magnocellular axonal transport, whereas radiation affects hypothalamic releasing hormone function by interrupting the portal-hypophyseal circulation, which is absent from the vasopressin circuitry.

Neurosurgical Intervention. One of the most common causes of central diabetes insipidus is the neurosurgical destruction of vasopressin neurons following pituitary-hypothalamic surgery. It is important to distinguish polyuria associated with the onset of acute postsurgical central diabetes insipidus from polyuria due to the normal diuresis of fluids given during surgery. In both cases, the urine may be very dilute and of high volume, exceeding 200 mL/m^2/hr. However, in the former case, serum osmolality will be high, whereas in the latter case it will be normal. A careful examination of the intraoperative record should also help distinguish between these two possibilities. Vasopressin axons traveling from the hypothalamus to the posterior pituitary terminate at various levels within the stalk and gland (see Figure 11-4). Because surgical interruption of these axons can result in retrograde degeneration of hypothalamic neurons, lesions closer to the hypothalamus will affect more neurons and cause greater permanent loss of hormone secretion. Not infrequently, a "triple phase" response is seen.[362] Although the exact incidence of this phenomenon remains unknown, in a small study nearly one in three children who underwent surgery for a craniopharyngioma developed it.[363] Following surgery, an initial phase of transient diabetes insipidus is observed, lasting a half-day to 2 days, and possibly due to edema in the area interfering with normal vasopressin secretion. If significant vasopressin cell destruction has occurred, this is often followed by a second phase of SIAD, which may last up to 10 days, and is due to the unregulated release of vasopressin by dying neurons. A third phase of permanent diabetes insipidus may follow if more than 90% of vasopressin cells are destroyed. Usually, a marked degree of SIAD in the second phase portends significant permanent diabetes insipidus in the final phase of this response. In patients with coexisting vasopressin and cortisol deficits (e.g., in combined anterior and posterior hypopituitarism following neurosurgical treatment of craniopharyngioma), symptoms of diabetes insipidus may be masked because cortisol deficiency impairs renal free water clearance, as discussed subsequently. In such cases, the institution of glucocorticoid therapy alone may precipitate polyuria, leading to the diagnosis of diabetes insipidus.

Congenital Anatomic Defects. Midline brain anatomic abnormalities such as septo-optic dysplasia with agenesis of the corpus callosum,[364] the Kabuki syndrome,[365] holoprosencephaly,[366] and familial pituitary hypoplasia with absent stalk[367] may be associated with central diabetes insipidus. These patients need not have external evidence of craniofacial abnormalities.[366] Central diabetes insipidus due to midline brain abnormalities is often accompanied by defects in thirst perception,[364] suggesting that a common osmosensor may control both vasopressin release and thirst perception. Some patients with suspected defects in osmosensor function but with intact vasopressin neurons may have recumbent diabetes insipidus, with a baroreceptor-mediated release of vasopressin while upright and vasopressin-deficient polyuria while supine.[368]

Neoplasms. Several important clinical implications follow from knowledge of the anatomy of the vasopressin system. Because hypothalamic vasopressin neurons are distributed over a large area within the hypothalamus, tumors that cause diabetes insipidus must either be very large or infiltrative or be strategically located at the point of convergence of the hypothalamoneurohypophyseal axonal tract in the infundibulum. Germinomas and pinealomas typically arise near the base of the hypothalamus where vasopressin axons converge before they enter the posterior pituitary and for this reason are among the most common primary brain tumors associated with diabetes insipidus. Germinomas causing the disease can be very small[369,370] and undetectable by magnetic resonance imaging (MRI) for several years following the onset of polyuria.[371] For this reason, quantitative measurement of the β-subunit of human chorionic gonadotropin, often secreted by germinomas and pinealomas, and regularly repeated MRI scans should be performed in children with idiopathic or unexplained diabetes insipidus. Empty sella syndrome, possibly due to unrecognized pituitary infarction, can be associated with diabetes insipidus in children.[372] Craniopharyngiomas and optic gliomas can also cause central diabetes insipidus when very large, although this is more often a postoperative complication of the treatment for these tumors. Hematologic malignancies can cause diabetes insipidus. In some cases, such as with acute myelocytic leukemia, the cause is infiltration of the pituitary stalk and sella.[373-375] However, more than 30 patients with monosomy or deletion of chromosome 7 associated with acute blast transformation of myelodysplastic syndrome presented with central diabetes insipidus[376-379] without evidence of infiltration of the posterior pituitary by neoplastic cells, leaving the cause of the diabetes insipidus unresolved.

Infiltrative, Autoimmune, and Infectious Diseases. Langerhans cell histiocytosis and lymphocytic hypophysitis are the most common types of infiltrative disorders causing central diabetes insipidus. Approximately 10% of patients with histiocytosis will have diabetes insipidus. These patients tend to have more serious, multisystem disease for longer periods of time than those without diabetes insipidus,[380,381] and anterior pituitary deficits often accompany posterior pituitary deficiency.[382] MRI characteristically

shows thickening of the pituitary stalk.[383] One report suggests that in patients with Langerhans cell histiocytosis, radiation treatment to the pituitary region within 14 days of the onset of symptoms of diabetes insipidus may result in return of vasopressin function in more than one third of affected patients.[384]

Lymphocytic infundibuloneurohypophysitis may account for more than a third of patients with "idiopathic" central diabetes insipidus.[385] This entity may be associated with other autoimmune diseases.[386] Image analysis discloses an enlarged pituitary and thickened stalk,[385,387] and biopsy of the posterior pituitary reveals lymphocytic infiltration of the gland, stalk, and magnocellular hypothalamic nuclei.[388] A necrotizing form of this entity has been described, which also causes anterior pituitary failure and responds to steroid treatment.[389] Diabetes insipidus can also be associated with pulmonary granulomatous diseases[390] including sarcoidosis.[391]

Whether antibody-mediated destruction of vasopressin cells occurs is controversial. More than half of patients with central diabetes insipidus of a nontraumatic cause have antibodies directed against vasopressin-containing cells,[392] and patients with other autoimmune diseases have such antibodies without evidence of diabetes insipidus.[393] Many patients with central diabetes insipidus also have antivasopressin peptide antibodies, although their appearance usually follows the institution of vasopressin treatment.[394] It is possible that antibodies directed against vasopressin-containing cells or vasopressin are not pathogenetic but instead are markers of prior neuronal cell destruction.

Infections involving the base of the brain, such as meningococcal,[395] cryptococcal, listeria,[396] and toxoplasmosis[397] meningitis, congenital cytomegalovirus infection,[398] and nonspecific inflammatory disease of the brain,[399] can cause central diabetes insipidus. The disease is often transient, suggesting that it is due to inflammation rather than destruction of vasopressin-containing neurons.

Brain Death. Central diabetes insipidus can appear in the setting of hypoxic brain death.[400] Although its presence has been suggested as a marker for brain death in children,[401] in some studies only a minority of patients with brain death manifest the disorder,[402] and up to 15% of patients with cerebral insults and diabetes insipidus ultimately recover brain function.[403] Polyuria in the setting of brain death can be accompanied by high concentrations of plasma vasopressin,[404] suggesting that some cases mistaken for diabetes insipidus are actually due to other causes, such as cerebral salt wasting with polyuria, as discussed subsequently.

Increased Metabolism of Vasopressin. The metabolic clearance rate of vasopressin increases fourfold during pregnancy due to the elaboration of a vasopressinase by the placenta.[72] If the mother cannot respond with a concomitant increase in vasopressin action because of preexisting subclinical central or nephrogenic diabetes insipidus,[73] overt, transient disease will appear, usually early in the third trimester and resolve within a week of delivery.[76,405] Even without prior defects, vasopressin function—an extreme elevation in vasopressinase concentrations in primigravidas with either preeclampsia, liver dysfunction, or multiple gestation[74,75,78,406-408]—may result in the development of the syndrome.

Drugs. The most common agent associated with the inhibition of vasopressin release and impaired urine concentrating ability is ethanol.[409] Because the inhibition of vasopressin release by ethanol can be overcome in the setting of concurrent hypovolemia, clinically important diabetes insipidus due to ethanol ingestion is uncommon.[410] Phenytoin, opiate antagonists, halothane, and β-adrenergic agents have also been associated with impaired vasopressin release.[411,412]

Children with Primary Enuresis. Although normal children have a nocturnal rise in plasma vasopressin associated with an increase in urine osmolality and a decrease in urine volume, those with primary enuresis have a blunted or absent rise in vasopressin and excrete a higher urine volume of lower tonicity.[413,414] This has suggested that enuretic children have a primary deficiency in vasopressin secretion, although the same outcome could be caused solely by excessive water intake in these children. The use of the V2 agonist dDAVP is highly effective in abolishing bed-wetting episodes, although relapse is high once therapy ends.[415-417] Fluid intake must be limited while a child is exposed to the antidiuretic action of dDAVP to guard against water intoxication.

Treatment of Central Diabetes Insipidus

Fluid Therapy. Patients with otherwise untreated diabetes insipidus crave cold fluids, especially water. With complete central diabetes insipidus, maximum urine concentrating ability is approximately 100 mOsm/kg. Because 5 L of urine would be required to excrete an average daily solute load of 500 mOsm/m^2, fluid intake must match this to maintain normal plasma tonicity. With an intact thirst mechanism and free access to oral fluids, a person with complete diabetes insipidus can maintain plasma osmolality and sodium in the high normal range, although at great inconvenience. Furthermore, long-standing intake of these volumes of fluid in children can lead to hydroureter,[418] and even hyperfluorosis in communities that provide fluoridated water.[419] With fluid management alone or with the use of medications other than vasopressin or its analogs, these children can develop nonobstructive hydroureteronephrosis, bladder wall thickening and trabeculation, overflow incontinence, and impaired renal function requiring a drainage procedure.[420] These complications are more likely to occur in children with nephrogenic as opposed to central diabetes insipidus because treatment with vasopressin analogs is used most of the time in children with central diabetes mellitus.

There are two situations in which central diabetes insipidus may be treated solely with high levels of fluid intake, without vasopressin. Vasopressin therapy coupled with excessive fluid intake (usually greater than 1 L/m^2/day, as discussed subsequently) can result in unwanted hyponatremia. Because neonates and young infants receive all of their nutrition in liquid form, the obligatory high oral fluid requirements for this age (3 L/m^2/day) combined with vasopressin treatment are likely to lead to this dangerous complication.[316] In infants, oral tablet and intranasal liquid desmopressin are not only difficult to administer accurately, but also their use is associated with significant fluctuations in the serum sodium levels.

Such neonates may be better managed with fluid therapy alone. A reduced solute load diet will aid in this regard. Human milk is best for this purpose (75 mOsm/kg H_2O), whereas cow's milk is the worst option (230 mOsm/kg H_2O). For example, in an infant with diabetes insipidus with a fixed urine osmolality of 100 mOsm/kg H_2O, 300 mL of urine per day is required to excrete the amount of solute consumed in human milk, whereas 900 mL of urine per day is required to excrete the higher amount of solute consumed in cow's milk. The Similac PM 60/40 formula has a renal solute load of 92 mOsm/kg H_2O. Additionally, supplementation free water may be needed depending on the severity of the diabetes insipidus. Options such as 20 to 30 mL of supplemental free water for every 120 to 160 mL of formula or dilution of the formula with free water have been used. Although children managed with such a regimen may be chronically thirsty, parents may have difficulty keeping up with the voluminous fluid intake and urine output, and poor growth may occur if adequate calories are not provided along with water,[238] these problems are more easily addressed than is life-threatening hyponatremia. Alternatively, thiazide (chlorothiazide, 5 to 10 mg/kg/dose, twice or thrice daily [421]) or amiloride diuretics may be added to facilitate renal proximal tubular sodium and water reabsorption[422] and thereby decrease oral fluid requirements. This therapy may be accompanied by a mild degree of dehydration. More recently, parenteral desmopressin (0.02 to 0.08 μg/dose given once or twice daily) has been administered subcutaneously in infants with good results, although this method has not been approved by the Food and Drug Administration (FDA).[423] Parenteral desmopressin was originally formulated at a concentration of 4 μg/mL, to be used at a 0.3-μg/kg/dose to treat bleeding diatheses such as hemophilia A and von Willebrand disease type 1. Thus, care must be taken if it is used at one fortieth to one fourth of this dose to treat infants with diabetes insipidus. In older children on more calorie-dense solid diets, the use of short-acting agents such as arginine vasopressin (Pitressin) or lysine vasopressin (Diapid; lypressin), or longer-acting desmopressin will decrease fluid needs while minimizing the possible occurrence of hyponatremia (see "Vasopressin and Vasopressin Analogs," presented later in the chapter).

In the acute postoperative management of central diabetes insipidus occurring after neurosurgery in children, vasopressin therapy may be successfully employed,[424,425] [426] but extreme caution must be exerted with its use. While under the full antidiuretic effect of vasopressin, a patient will have a urine osmolality of approximately 1000 mOsm/kg and become hyponatremic if she or he receives an excessive amount of fluids, depending on the solute load and nonrenal water losses. With a solute excretion of 500 mOsm/m^2/day, normal renal function, and nonrenal fluid losses of 500 mL/m^2/day, fluid intake of greater than 1 L/m^2/day (two thirds of the normal maintenance fluid requirement) will result in hyponatremia. In addition, vasopressin therapy will mask the emergence of the SIAD phase of the triple phase neurohypophyseal response to neurosurgical injury (as has been discussed).

Because of the concerns associated with perioperative vasopressin administration, two different approaches to managing central diabetes insipidus in the surgical patient have been employed. The first approach may be particularly useful for managing acute postoperative diabetes insipidus in young children. It employs fluids alone and avoids the use of vasopressin.[427] This method consists of matching input and output hourly using between 1 to 3 L/m^2/day (40 to 120 mL/m^2/hr). If intravenous therapy is used, a basal 40 mL/m^2/hr should be given as 5% dextrose (D5) in one-fourth normal saline (normal saline = 0.9% sodium chloride) and the remainder, depending on the urine output, as 5% dextrose in water. Potassium chloride (40 mEq/L) may be added if oral intake is to be delayed for several days. No additional fluid should be administered for hourly urine volumes less than 40 mL/m^2/hr. For hourly urine volumes above 40 mL/m^2/hr, the additional volume should be replaced with 5% dextrose up to a total maximum of 120 mL/m^2/hr. For example, in a child with a surface area of 1 m^2 (approximately 30 kg), the basal infusion rate would be 40 mL/hr of 5% dextrose in one-fourth normal saline. For an hourly urine output of 60 mL, an additional 20 mL/hr 5% dextrose would be given, for a total infusion rate of 60 mL/hr. For urine outputs above 120 mL/hr, the total infusion rate would be 120 mL/hr. In the presence of diabetes insipidus, this will result in a serum sodium concentration in the 150 mEq/L range and a mildly volume contracted state, which will allow one to assess both thirst sensation as well as the return of normal vasopressin function or the emergence of SIAD. Patients may become mildly hyperglycemic with this regimen, particularly if they are also receiving postoperative glucocorticoids. However, because it does not use vasopressin, this fluid management protocol prevents any chance of hyponatremia.

Vasopressin and Vasopressin Analogs. Evidence suggests that perioperative use of intravenous vasopressin in children with central diabetes insipidus may be the treatment modality of choice in most situations, resulting in excursions of serum sodium of smaller magnitude and few adverse sequelae.[426] Although intravenous therapy with synthetic aqueous vasopressin (Pitressin) had been shown to be useful in the management central diabetes insipidus of acute onset,[424,425] concern existed as to the safety of its administration in the complex, rapidly changing course of the child recovering from hypothalamic/pituitary surgery. If continuous vasopressin is administered, fluid intake must be limited to 1 L/m^2/day or two-thirds maintenance fluid administration (assuming normal solute intake and nonrenal water losses as described). The potency of synthetic vasopressin is still measured using a bioassay and is expressed in bioactive units, with 1 milliunit (mU) equivalent to approximately 2.5 ng of vasopressin. For intravenous vasopressin therapy, 1.5 mU/kg/hr results in a blood vasopressin concentration of approximately 10 pg/mL,[428] twice that needed for full antidiuretic activity.[429] Vasopressin's effect is maximal within 2 hours of the start of infusion,[429] and one must beware of it sticking to intravenous bottles and tubing. Occasionally following hypothalamic (but not trans-sphenoidal) surgery, higher initial concentrations of vasopressin are required to treat acute diabetes insipidus, which may be attributable to the release of a

substance related to vasopressin from the damaged hypothalamoneurohypophyseal system, which acts as an antagonist to normal vasopressin activity.[430] Much higher rates of vasopressin infusion, resulting in plasma concentrations above 1000 pg/mL, should be avoided, as they may cause cutaneous necrosis,[431] rhabdomyolysis,[431,432] and cardiac rhythm disturbances.[433]

In light of the considerations described in the previous paragraph, an effective and safe algorithm for the management of perioperative central diabetes insipidus with central diabetes insipidus has been utilized with encouraging results.[426] This algorithm starts with the child receiving an intravenous infusion of normal saline at two-thirds maintenance or 1 L/m^2/day. A tentative diagnosis of intraoperative or postoperative central diabetes insipidus is made by documenting a serum sodium concentration of greater than 145 mEq/L along with urine output of greater than 4 mL/kg/hr. Additional confirmatory evidence includes plasma osmolarity above 300 mOsm/kg H_2O and a relatively hypotonic urine. When documentation of parameters consistent with central diabetes insipidus is obtained, an intravenous infusion of aqueous vasopressin begins at 0.5 mU/kg/hr with no change in intravenous fluid administration. The dose of vasopressin is titrated upward in 0.5-mU/kg/hr increments to establish a urine output rate of less than 2 mL/kg/hr at approximately 10-minute intervals. The vasopressin and intravenous fluid administration then remain stable at these rates, with additional normal saline, or equivalent volume expanding solutions, given only to replace ongoing blood loss or to maintain hemodynamic stability. Postoperatively this management paradigm requires intensive care unit monitoring, with frequent assessment of electrolytes (hourly initially), urine output and osmolarity/specific gravity, and vital signs. This management scheme can also be followed for patients with established central diabetes insipidus requiring general surgery and prolonged restriction of oral intake. In this situation, the usual dose of chronic, long-acting vasopressin is withheld or reduced immediately prior to surgery depending on the timing of surgery in relation to the usual administration times. In preparation for surgery, normal saline is infused at two-thirds maintenance (1 L/m^2/day). When measures consistent with emergence of central diabetes insipidus due to termination of efficacy of the presurgical dose are obtained, the intravenous vasopressin is initiated and titrated as described previously.

Patients treated with vasopressin for post-neurosurgical diabetes insipidus should be switched from intravenous to oral fluid intake at the earliest opportunity, because thirst sensation, if intact, will help regulate blood osmolality, as discussed. Intravenous dDAVP (desmopressin) should not be used in the acute management of postoperative central diabetes insipidus, for it offers no advantage over vasopressin, and its long half-life (8 to 12 hours) compared with that of vasopressin (5 to 10 minutes) is a distinct disadvantage, as it may increase the chance of water intoxication.[225] In fact, the use of intravenous dDAVP, 0.3 μg/kg, to shorten the bleeding time in a variety of bleeding disorders (as has been discussed) has been associated with water intoxication,[317] particularly in young children who have high obligate oral fluid needs.

A special problem arises when a patient with established central diabetes insipidus must receive a high volume of fluid for therapeutic reasons (e.g., accompanying cancer chemotherapy). Such patients can be managed by discontinuing antidiuretic therapy and increasing fluid intake to 3 to 5 L/m^2/day (rendering the patient moderately hypernatremic). Although 5 L/m^2/day is typically adequate to maintain serum sodium concentration in the range of 150 mEq/L in children with central diabetes insipidus, this rate may not be adequate in the setting of chemotherapy administration when solute excretion increases due to cell death and the release of cellular contents. By using a low dose of intravenous vasopressin (0.08 to 0.1 mU/kg/hr, approximately one eighth of the full antidiuretic dose, titrated upward as needed), a partial antidiuretic effect allows the administration of higher amounts of fluid without causing hyponatremia.[434] Data suggest that excretion of a hypotonic urine, as would occur in patients with diabetes insipidus management with fluids alone, increases the risk of developing nephrotoxicity during therapy with platinum-based antineoplastic agents.[435] By allowing the administration of 0.45 normal saline at rates of approximately 3 L/m^2/day, the low-dose vasopressin infusion yields a urine osmolarity higher than that achievable with fluids alone[434] and may have the additional benefit of conferring renal protection.

In the outpatient setting, treatment of central diabetes insipidus in older children should begin with oral (discussed later) or intranasal dDAVP (10 μg/0.1 mL), 0.025 mL (2.5 μg) given by rhinal tube at bedtime and the dose increased to the lowest amount that gives an antidiuretic effect. If the dose is effective but has too short a duration, it should be increased further or a second, morning dose should be added. Patients should escape from the antidiuretic effect for at least an hour before the next dose to ensure that any excessive water will be excreted. Otherwise, water intoxication may occur. dDAVP is also available as a nasal spray in the same concentration, with each spray delivering 10 μg (0.1 mL). This is the standard preparation used to treat primary enuresis. Oral dDAVP tablets have come into widespread use and have largely replaced intranasal therapy. Although when given orally dDAVP is at least 20-fold less potent than when given via the intranasal route, oral dDAVP in doses of 25 to 300 μg every 8 to 12 hours is reported to be highly effective and safe in children.[436-438] Lysine vasopressin (Diapid) nasal spray (50 U/mL) may be used if a duration less than that of dDAVP is desired. One spray delivers 2 U (0.04 mL), with a duration of action between 2 and 8 hours.

As noted previously, cortisol deficiency may cause decreased free water clearance by stimulating a nitric oxide–mediated pathway, which results in the insertion of aquaporin-2 channels into the apical membranes of collecting duct cells, in a vasopressin-independent fashion.[247,248] Conversely, it is possible that excessive amounts of cortisol, due to endogenous release during stress or to treatment with exogenous drug, may inhibit the insertion of water channels. This may explain why patients with central diabetes insipidus treated with desmopressin

become "resistant," and require an increased dosage, during times of stress or treatment with glucocorticoids.

In addition to polyuria and polydipsia, decreased bone mineral density has been reported in patients with central diabetes insipidus.[439] The decreased bone density was not corrected by vasopressin analog treatment alone, suggesting that the institution of bisphosphonate or other therapies designed to prevent bone loss may be of long-term benefit in the treatment of diabetes insipidus.

Nephrogenic Diabetes Insipidus

Causes of Nephrogenic Diabetes Insipidus. Nephrogenic (vasopressin-resistant) diabetes insipidus can be the result of genetic or acquired causes. Genetic causes are less common but more severe than acquired forms of the disease, although genetic etiologies are more common in children than in adults.

Genetic Causes.

Congenital, X-Linked Diabetes Insipidus: V2 Receptor Mutations. Congenital, X-linked nephrogenic diabetes insipidus is caused by inactivating mutations of the vasopressin V2 receptor. Due to its mode of transmission, it is a disease of males, although rarely females may be affected, presumably due to extreme lyonization during X chromosome inactivation.[440] In keeping with a germline, as opposed to somatic, mutation in the V2 receptor, these patients are deficient in all systemic V2 receptor-mediated actions[441,442] and have intact V1-receptor-mediated responses.[443,444] As expected, the V2 receptor defect is proximal to the activation of renal adenylate cyclase.[445,446] Unlike the function of other G protein-coupled seven transmembrane receptors such as the parathyroid hormone (PTH) and thyroid-stimulating hormone (TSH) receptors, that of the V2 receptor is unaffected in patients with pseudohypoparathyroidism, who have inactivating mutations in the alpha subunit of G_s.[447]

Because of vasopressin resistance in congenital nephrogenic diabetes insipidus, the kidney elaborates large volumes of hypotonic urine with osmolality ranging between 50 and 100 mOsm/kg. Manifestations of the disease are usually present within the first several weeks of life,[448] but they may only become apparent after weaning from the breast. The predominant symptoms are polyuria and polydipsia. Thirst may be more difficult to satisfy than in central diabetes insipidus. Many infants initially present with fever, vomiting, and dehydration, often leading to an evaluation for infection. Growth failure in the untreated child may be secondary to the ingestion of large amounts of water, which the child may prefer over milk and other higher-caloric substances.[449] Mental retardation of variable severity may result from repeated episodes of dehydration.[450] Intracerebral calcification of the frontal lobes and basal ganglia is not uncommon in children with X-linked nephrogenic diabetes insipidus.[451-454] Because this appears early and is not seen in children with central diabetes insipidus of equivalent severity, cerebral calcification is probably unrelated to the level of dehydration or therapeutic intervention. It is possible that elevated vasopressin concentrations, acting via intact V1 or V3 receptors, contribute to some of the unique manifestations of X-linked nephrogenic diabetes insipidus, such as cerebral calcification, intense thirst, vomiting, and growth failure. Older children may present with enuresis or nocturia. They may learn to reduce food intake (and therefore solute load) to decrease polyuria, which may contribute to growth failure. After long-standing ingestion and excretion of large volumes of water, patients may develop nonobstructive hydronephrosis, hydroureter, and megabladder.[418]

Although one founder (arriving in North America from Scotland in 1761 on the ship *Hopewell*) was initially postulated to be the ancestor of most North American subjects with congenital, X-linked nephrogenic diabetes insipidus,[455] more than 209 mutations in the V2 receptor have been found, with some appearing to have arisen independently more than once[456-469] (Figure 11-14). These are mostly single base mutations that result in either amino acid substitutions, translational frame shifts, or termination of peptide synthesis, and are distributed fairly evenly throughout the receptor protein (www.hgmd.cf.ac.uk/ac/gene.php?gene5AVPR2). Mutations may affect vasopressin binding, cyclic AMP generation, or possibly transcriptional regulation.[470-474] Patients with different mutations will likely be found to exhibit phenotypic heterogeneity, including in severity of disease and response to treatment. Genetic heterogeneity may underlie the variable response of patients with X-linked diabetes insipidus to dDAVP treatment. In a family with a known mutation, prenatal or early postnatal DNA screening can unambiguously identify affected males, allowing the institution of appropriate therapy.[226]

Congenital, Autosomal Nephrogenic Diabetes Insipidus: Aquaporin-2 Mutations. After the initial description of X-linked nephrogenic diabetes insipidus,[475] several patients were reported with similar clinical findings except for autosomal recessive transmission of the disease[476] or normal V2 receptor function outside of the kidney.[477] With the cloning of the complementary DNA for the renal water channel, aquaporin-2, many patients with autosomal recessive nephrogenic diabetes insipidus have been reported who have a total of 51 mutations different in this gene (www.hgmd.cf.ac.uk/ac/gene.php?gene5AQP2).[471] Most are missense mutations, although four are nonsense or frameshift mutations. They are scattered throughout the molecule, including within four of the five transmembrane domains, two of three extracellular domains, and two of four intracellular domains (see Figure 11-10). An autosomal dominant mode of inheritance for nephrogenic diabetes insipidus has been described, associated with mutations in aquaporin-2. One of these dominant mutations results in mixed tetramers of the wild-type and mutant alleles being retained in the Golgi apparatus.[478] Aquaporin-2 mutations impair the ability of the luminal membrane to undergo an increase in water permeability following signaling through the V2 receptor. They could include patients previously described who had a normal rise in urinary cyclic AMP in response to vasopressin, without a concomitant increase in urine osmolality.[445] Aquaporin-2 protein has been shown to be excreted in the urine in both soluble and membrane-bound forms. Aquaporin-2 excretion is low in untreated central and nephrogenic diabetes insipidus, but following dDAVP

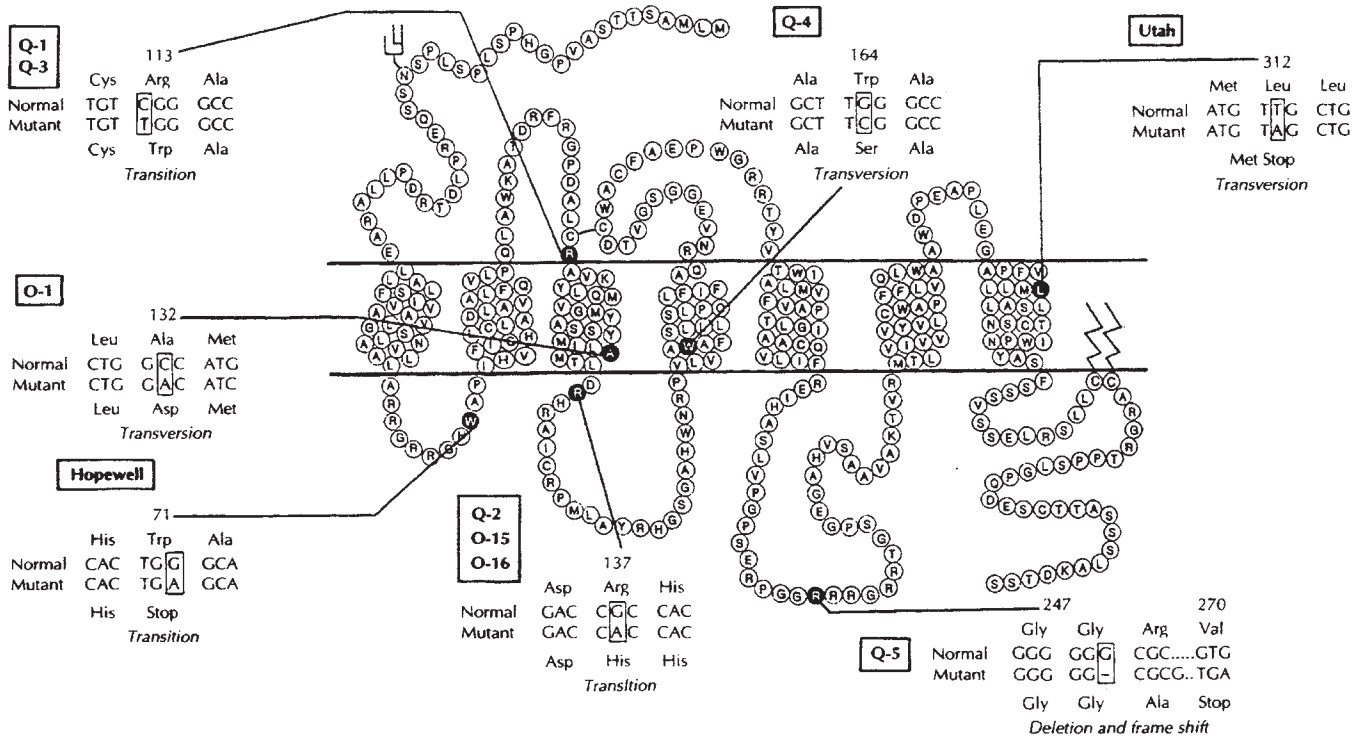

FIGURE 11-14 ■ Schematic representation of seven of the more than 180 V2 receptor mutations in families with X-linked nephrogenic diabetes insipidus. Q, families from Quebec; F, families from France; O, other families. (Reproduced with permission from Bichet, D. G. (1995). The posterior pituitary. In S. Melmed (Ed.), *The pituitary* (p. 277). Cambridge: Blackwell Science.)

administration it increases markedly in the former, but not latter, disease.[119] For this reason, its measurement in urine has been suggested as an aid in the differential diagnosis of diabetes insipidus.[119]

Acquired Cause. Acquired causes of nephrogenic diabetes insipidus are more common and less severe than genetic causes. Nephrogenic diabetes insipidus may be caused by drugs such as lithium and demeclocycline, both of which are thought to interfere with vasopressin-stimulated cyclic AMP generation or action. Approximately 50% of patients receiving lithium have impaired urinary concentrating ability, although only 10% to 20% of them develop symptomatic nephrogenic diabetes insipidus, which is almost always accompanied by a reduction in the glomerular filtration rate.[479,480] The risk increases with the duration of therapy. Lithium impairs the ability of vasopressin to stimulate adenylate cyclase,[481] resulting in a 90% fall in aquaporin-2 messenger RNA expression in the renal collecting duct[482] and which may be the basis for its causing nephrogenic diabetes insipidus.

Demeclocycline treatment causes nephrogenic diabetes insipidus by inhibiting transepithelial water transport.[483] For this reason, it is useful in the treatment of dilutional hyponatremia associated with the inappropriate secretion of vasopressin as discussed previously. Other agents that cause nephrogenic diabetes insipidus include hypercalcemia, hyperkalemia, and therapy with foscarnet (used in the treatment of cytomegalovirus infection in immunosuppressed patients),[484,485] clozapine,[485] amphotericin,[486] methicillin,[487] or rifampin.[488] Whether any of these agents cause nephrogenic diabetes insipidus by interfering with the expression or insertion into apical collecting duct membranes of aquaporin-2 water channels is not yet known. Ureteral obstruction,[489] chronic renal failure, polycystic kidney disease, medullary cystic disease, Sjögren syndrome[490] and sickle cell disease can also impair renal concentrating ability. Osmotic diuresis due to glycosuria in diabetes mellitus, or to sodium excretion with diuretic therapy, will interfere with renal water conservation. Primary polydipsia can result in secondary nephrogenic diabetes insipidus because the chronic excretion of a dilute urine lowers the osmolality of the hypertonic renal interstitium, thus decreasing renal concentrating ability. Finally, decreased protein or sodium intake also can lead to diminished tonicity of the renal medullary interstitium and nephrogenic diabetes insipidus.

Treatment of Nephrogenic Diabetes Insipidus. The treatment of acquired nephrogenic diabetes insipidus focuses on elimination, if possible, of the underlying disorder, such as offending drugs, hypercalcemia, hypokalemia, or ureteral obstruction. Congenital nephrogenic diabetes insipidus is often difficult to treat. The main goals should be to ensure the intake of adequate calories for growth and to avoid severe dehydration. Foods with the highest ratio of caloric content to osmotic load should be ingested to maximize growth and minimize the urine volume required to excrete urine solute. However, even with the early institution of therapy, growth and mental retardation are not uncommon.[491]

Thiazide diuretics in combination with amiloride or indomethacin are the most useful pharmacologic agents in the treatment of nephrogenic diabetes insipidus. Thiazides work both by enhancing sodium excretion at the expense of water, as well as by causing a fall in glomerular filtration rate, which results in proximal tubular sodium and water reabsorption.[422,492] Indomethacin, 2 mg/kg/day, further enhances proximal tubular sodium and water reabsorption,[422,493,494] although this effect is not mediated by inhibition of cyclo-oxygenase.[495] The combination of thiazide and amiloride diuretics is the most commonly used regimen for the treatment of congenital, X-linked nephrogenic diabetes insipidus, because amiloride counteracts thiazide-induced hypokalemia,[448] avoids the nephrotoxicity associated with indomethacin therapy, and is well tolerated, even in infants.[496] In addition, amiloride decreases the uptake of lithium by renal epithelial cells, and for this additional reason it has been proposed in combination with thiazide as treatment for lithium-induced nephrogenic diabetes insipidus.[497] High-dose dDAVP therapy, in combination with indomethacin, has been reported to be helpful in treating some subjects with nephrogenic diabetes insipidus.[498] This treatment may prove to be useful in patients with genetic defects in the V2 receptor, which reduce the binding affinity for vasopressin.

A therapy that has thus far only been employed in mice and not yet available for humans, in which abnormal stop codons are bypassed,[499] may prove useful to treat patients with nonsense mutations in AVPR2 and AQP2.

CONCLUDING REMARKS

Precise regulation of water balance is necessary for the proper function of multiple cellular pathways. Vasopressin released from the posterior pituitary, stimulated by both hyperosmolar and nonosmotic factors, acts via the kidney V2 vasopressin receptor to stimulate both an increase in aquaporin-2 expression and its insertion into collecting duct luminal membrane, thereby enhancing renal water reabsorption to minimize subsequent water loss. Thirst controls the second major physiologic response to hyperosmolality and results in increased water intake to make up for past water loss. The renin-angiotensin-aldosterone and atrial natriuretic peptide systems also make important contributions to water and volume regulation by modulating sodium intake and output.

The proper diagnosis of disorders caused by deficient and excessive action of vasopressin requires a thorough understanding of the physiologic regulation of this hormone. Advances in molecular medicine have revealed mutations in the vasopressin gene and the V2 receptor or aquaporin-2 genes, responsible for familial central and nephrogenic diabetes insipidus, respectively. Molecular methods allow the diagnosis of these disorders in the prenatal or early postnatal periods. Nevertheless, the most frequent cause of central diabetes insipidus remains a destructive lesion of the central nervous system caused by tumor or neurosurgical insult, and pharmacologic toxicity remains the most common cause of nephrogenic diabetes insipidus.

Hyponatremia is a common occurrence in childhood but is rarely due to a primary increase in vasopressin secretion or an increase in intrinsic activity of the V2 receptor (SIAD). It is more commonly caused by hypovolemia (either primary or secondary to decreased effective vascular volume), salt loss, excessive ingestion of hypotonic fluids, or cortisol deficiency. Hyponatremia due to increased vasopressin action is most commonly caused by excessive vasopressin administration during the treatment of central diabetes insipidus or coagulopathies.

Central diabetes insipidus is best treated in infants with fluid therapy, which avoids the administration of vasopressin or its V2 receptor analog, dDAVP, whereas in older children, dDAVP is the drug of choice. Nephrogenic diabetes insipidus remains a therapeutic challenge. Hyponatremia due to SIAD is best managed by restricting water intake, whereas salt and water replacement is indicated when hyponatremia is due to hypovolemia or excessive secretion of atrial natriuretic peptide, as occurs in cerebral salt wasting. Hyponatremia causing central nervous system dysfunction is a medical emergency. Blood sodium must be raised promptly, but at a rate not greater than 0.5 mEq/L/hr to avoid the occurrence of central pontine myelinolysis.

QUESTIONS

1. What is the relationship between vasopressin and neurophysin?
   a. They are produced by different genes and bind together in the bloodstream.
   b. They are produced by the same gene and bind together in the vasopressin neuron.
   c. They are made from a common precursor protein, separated by copeptin.

Answer: b

2. Mutations in the vasopressin (AVP) gene
   a. Cause autosomal dominant disease
   b. Cause central diabetes insipidus that has its onset in the neonatal period
   c. Cause nephrogenic diabetes insipidus

Answer: a

3. A child develops central diabetes insipidus and is otherwise well. A brain MRI is normal. You should be concerned that she may have which of the following conditions? (Choose one best answer.)
   a. A small germinoma
   b. An elevated beta hCG level in the CNS
   c. A prolactinoma
   d. An elevated prolactin level in the blood
   e. a and b
   f. c and d

Answer: e

4. A patient with polydipsia and polyuria is given a water deprivation test. After several hours the urine osmolality plateaus at 400 mOsm/kg H_2O and rises no further with vasopressin administration. This is compatible with
   a. Partial central DI
   b. Primary polydipsia
   c. Partial nephrogenic DI
   d. a or b
   e. b or c
   f. a or c

Answer: e

5. Rapid correction of severe hyponatremia (Na $<$ 120 mEq/L) is warranted if
   a. The hyponatremia has been present for several days
   b. The patient is having an acute generalized seizure
   c. The patient has congestive heart failure
   d. The patient is hyperglycemic

Answer: b

6. A neonate with central DI should not be treated with
   a. A low-salt diet
   b. Oral desamino-D arginine vasopressin (dDAVP)
   c. A thiazide diuretic

Answer: b

CHAPTER 12

Thyroid Disorders in Children and Adolescents

Scott A. Rivkees, MD

CHAPTER OUTLINE

INTRODUCTION

Thyroid disease can present with overt symptoms, insidiously, or with isolated thyromegaly. Thyroid disease in children can encompass isolated biochemical abnormalities that have little or no physiologic consequence or with overt clinical symptoms. Clinically, hypothyroidism occurs more commonly than hyperthyroidism. Thyroid nodules and masses occur much less commonly than functional disorders, but they can portend the presence of thyroid cancer. This chapter focuses on the most common conditions that affect the thyroid gland of children and adolescents.

Box 12-1 provides a classification of thyroid disorders in children. Thyroid system development, fetal thyroid physiology, thyroid dysfunction in premature infants, and congenital thyroid disorders (including inborn defects in thyroid hormone synthesis, metabolism, and action and thyroid binding protein abnormalities) are discussed in Chapter 6.

Thyroid Hormones and Their Action

Few hormones exert as profound and essential role in human physiology as thyroid hormones.[1,2] The major hormones released by the thyroid gland include tetraiodothyronine, or thyroxine (T4), and triiodothyroine (T3).[1] The production of these hormones involves several discrete biochemical steps that are depicted in Figure 12-1. Of these hormones, T3 plays the pivotal role in affecting physiology, being the molecule that principally binds to the thyroid hormone receptor (TRs). The thyroid hormone nuclear receptor belongs to the steroid hormone–retinoic acid receptor superfamily and is a regulator of DNA transcription.[1,3,4] Two genes encode the TR; one on chromosome 17 designated alpha (TRa) and one on chromosome 3 designated beta (TRb).[3,4] The TRs can exist as monomers or homodimers, and they can dimerize with other members of the family of nuclear receptors.[3,4] After T3 binding to the TR, gene transcription is regulated in many tissues.[4]

BOX 12-1 Thyroid Disorders in Childhood and Adolescence

Autoimmune Thyroid Disease
- Hashimoto thyroiditis, juvenile acquired hypothyroidism
- Stimulating antibody, Graves disease
- Blocking antibody, hypothyroidism

Infectious Thyroiditis
- Suppurative thyroiditis
- Subacute thyroiditis

Binding Protein Abnormalities
- Complete TBG deficiency
- Partial TBG deficiency
- TBG excess
- Transthyretin variants

TSH Receptor Mutations
- Loss-of-function hypothyroidism
- Gain-of-function hyperthyroidism

Thyroid Hormone Resistance Syndromes
- Thyroid hormone beta receptor (TRβj) mutations
- Peripheral tissue resistance syndrome
- Pituitary resistance syndrome
- Thyroid hormone membrane transport defects

Iodine Deficiency Syndromes
- Goiter
- Mental impairment
- Cretinism

Diffuse Nontoxic Goiter
- Nonthyroidal illness
- Thyroid neoplasia
  - Adenoma
  - Nonfunctional
  - Functional
  - Papillary-follicular carcinoma
  - Medullary carcinoma
  - MEN 2A, 2B, Ret mutations
  - Sporadic
  - Undifferentiated
  - Metastatic

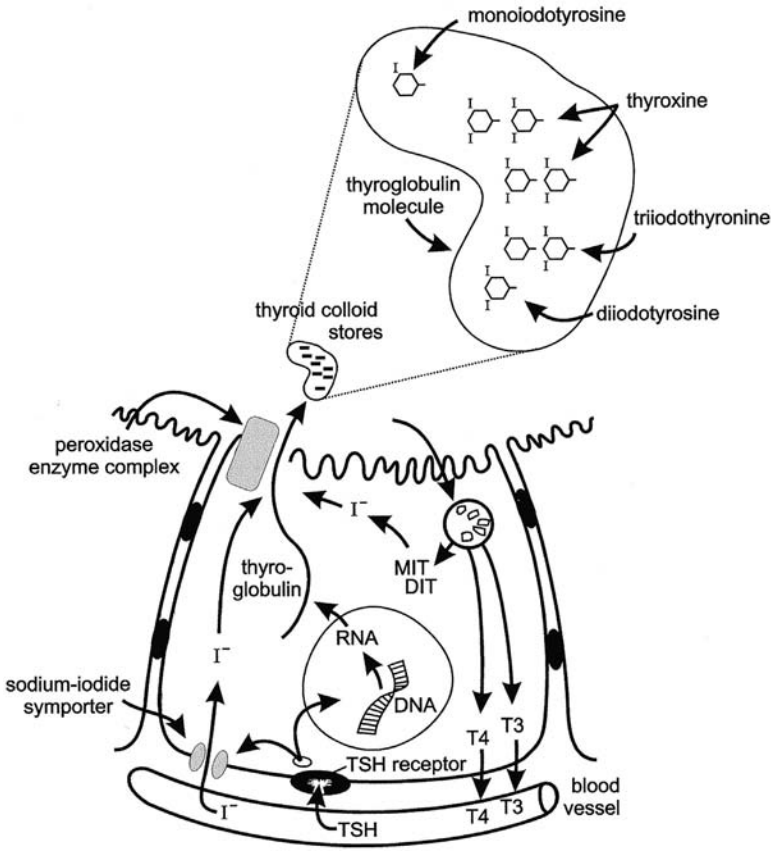

FIGURE 12-1 ■ Illustration of thyroid hormone synthesis and secretion. TSH regulates the process via the G–protein-linked plasma membrane TSH receptor. TSH binding stimulates thyroglobulin synthesis and sodium-iodide symporter (iodide transporter) uptake of circulating iodide. Iodide diffuses in the cytosol to the apical membrane and is transported to the apical lumen by Pendrin, an anion-bicarbonate family exchanger, making iodide available to the enzyme organification complex (Pendrin; thyroid peroxidase, TPO, THOX). The tyrosine residues of thyroglobulin are iodinated at the apical cell membrane and are catalyzed by thyroid peroxidase, the organification enzyme. The resulting monoiodotyrosine (MIT) and diiodotyrosine (DIT) residues couple to form the iodothyronines thyroxine (T4) and triiodothyronine (T3) within the stored thyroglobulin molecule. TSH stimulates micropinocytosis of colloid droplets and progressive thyroglobulin proteolysis within the resulting phagolysosomes. T4 and T3 are secreted into the circulation. The uncoupled MIT and DIT are deiodinated by iodotyrosine deiodinase (DEHAL) to release iodide, which is largely recycled within the follicular cell. (From Fisher and Greuters [2008] Thyroid disorders in childhood and adolescence. In *Pediatric Endocrinology*, (3rd ed.) (pp 227-253). Philadelphia: Saunders.)

T4 is the predominant hormone released from thyroid follicular cells. After release it circulates in protein-bound and free states at a ratio of about 1000 to 1. Thyroid hormone-binding proteins in the blood include thyroxine-binding globulin (TBG), prealbumin or transthyretin, and albumin.[5-7] TBG is the predominant carrier protein for T4; TBG and albumin also carry T3.[5-7] In the euthyroid steady, the circulating concentration of free T4 (FT4) and free T3 are about 0.03% and 0.30%, respectively, of total hormone concentrations.

It is important to recognize that circulating levels of thyroid hormones and carrier proteins change with age (Tables 12-1 and 12-2). Absolute mean free T4 and free T3 concentrations are about 10 and 4 pg/mL, respectively, and differ according to age. In adolescents and adults, the plasma concentrations of the several binding proteins are 1 to 3 mg/dL for TBG, 20 to 30 mg/dL for TBPA, and 2 to 5 g/dL for albumin.[2,5-7] TBG concentrations are greater in children than in adults, and they decline to adult levels during adolescence.[2] Because the thyroid-hormone binding proteins are produced in the liver, they are acute phase reactants, with concentrations increasing during acute illness[2,5-7]; they also increase in response to estrogen exposure.

Conversion of T4 to T3 involves the deiodination of T4 (Figure 12-2). Monodeiodination of the beta or outer ring by monodeiodinase (MD) type II produces T3.[8,9] Monodeiodination of the alpha or inner-ring produces reverseT3 (rT3), which is inactive metabolically. Under normal circumstances, T3 and rT3 are produced at similar rates. About 70% to 90% of circulating T3 is derived from peripheral conversion of T4, and 10% to 30% of circulating T3 is from the thyroid gland.[2] Reflecting the age-related changes in the hormones that regulate T4 stability, the clearance of T4 generally decreases from infancy to adulthood (Table 12-3).

Regulation of Thyroid Function

The production of T4 and T3 within the thyroid gland is regulated by the thyroid stimulating hormone (TSH; also called thyrotropin), which is released from the anterior pituitary gland (Figure 12-3).[10,11] TSH receptors are present on thyroid follicular cells and are G protein–coupled receptors with a large extracellular amino terminus.[12] Mutations of the TSH receptor can result in constitutive activation of the receptor with severe hyperthyroidism, whereas inactivating mutations result in TSH unresponsiveness and hence hypothyroidism.[12]

TSH receptor activation stimulates adenylate cyclase accumulation within follicular cells, which in turn causes accumulation of cyclic adenosine monophosphate (cAMP). Increased cellular concentrations of cAMP promote iodide trapping, iodotyrosine synthesis, thyroglobulin (Tg) synthesis, and hormone release.

TSH release is regulated by the hypothalamic hormone *thyrotropin releasing hormone* (TRH) (see Figure 12-3).[13,14] This peptide hormone is produced in medial neurons of the paraventricular nucleus of the hypothalamus and is released into the portal circulation of the pituitary gland.[13,14] Several different neurotransmitters have been observed to influence THRH release.[15,16]

In addition to normal regulation of TSH receptor activity by TSH, thyroid function can be adversely affected by antibodies that can either stimulate or block

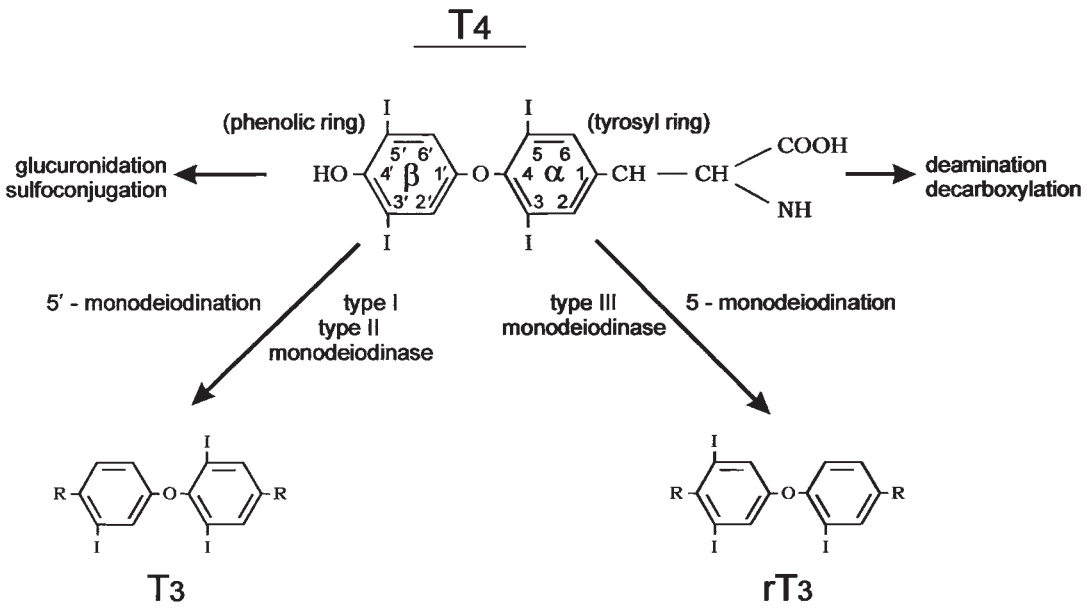

FIGURE 12-2 ■ The metabolism of thyroxine (tetraiodothyronine). The major metabolic pathway is progressive monodeiodination mediated by the three iodothyronine monodeiodinase enzymes type I, type II, and type III. Outer (phenolic) ring 5′monodeiodination produces active 3,5,3′ triiodothyronine. Inner (tyrosyl) ring 5′monodeiodination produces inactive reverse 3,3,5′ triiodothyronine. Type I deiodinase is also capable of inner-ring monodeiodination. The alanine side chain of the tyrosyl ring is also subject to degradative reactions, including deamination and decarboxylation. Sulfoconjugation and glucuronide conjugation reactions at the 4′ phenolic ring site occur largely in liver tissue. (From Fisher and Greuters [2008] Thyroid disorders in childhood and adolescence. TSH action. TSH receptor–stimulating immunoglobulin antibodies (TSI), or thyroid receptor antibodies (TRAb), are present in the circulation of individuals with Graves disease and activate TSH receptors.[17-19] Conversely, TSH receptor–blocking immunoglobulins (TBI) antagonize TSH action and can lead to hypothyroidism.[17-19]

CLINICAL AND BIOCHEMICAL ASSESSMENT OF THYROID STATUS

Clinical Evaluation of Thyroid Function

Thyroid disease can present with overt symptoms, insidiously, or with isolated thyromegaly. Thus, evaluation of the thyroid gland should be included in the routine examination of children. The thyroid gland can be visualized by having the patient look to the ceiling and swallow. As the thyroid moves, the margins of the gland are viewed to estimate size and symmetry. The thyroid should be palpated to assess size, consistency, and symmetry. This is best performed with the clinician standing behind the patient and palpating the neck with the fingertips. The texture of the thyroid can be assessed to determine if it is smooth or irregular, and the texture may feel firm or soft if nodules are present. If any asymmetry or abnormal thyroid fullness is noted, ultrasonographic evaluation is recommended, as pathologic thyroid nodules may feel like normal tissue.

To assess gland size, one may estimate the size of each thyroid lobe relative to that of a teaspoon (5 g) or a

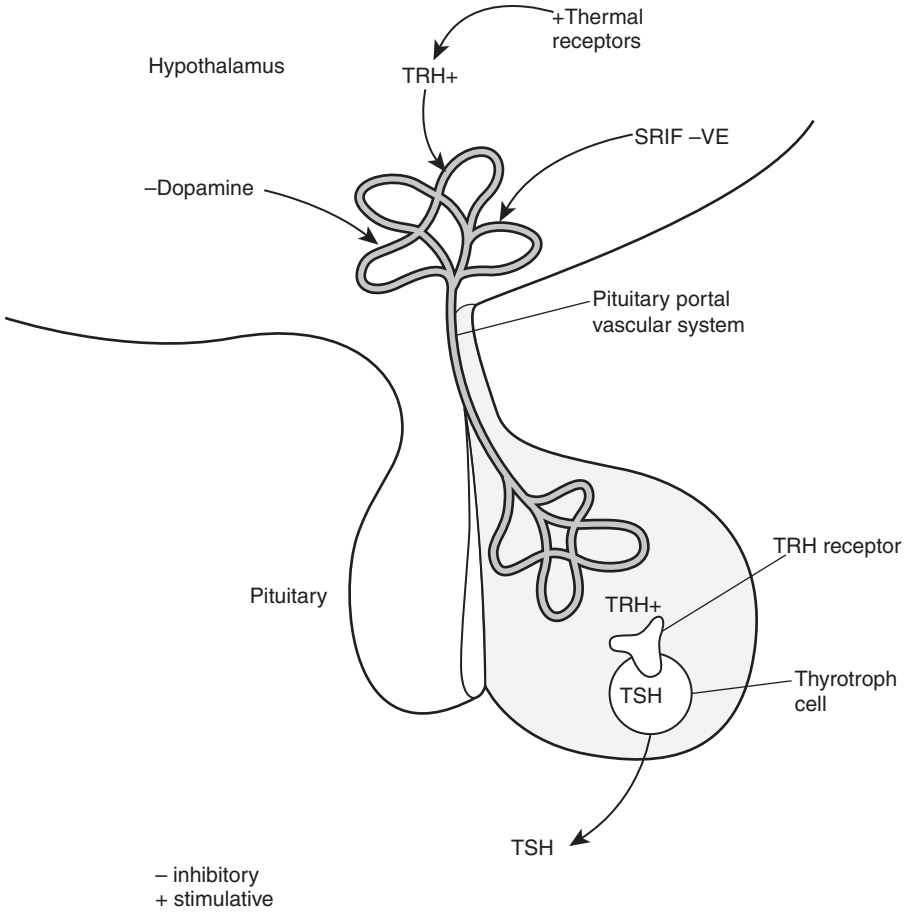

FIGURE 12-3 ■ The hypothalamic-pituitary TSH axis. Thyrotropin-releasing hormone (TRH) secreted into the pituitary portal vascular system stimulates TSH synthesis and secretion from the pituitary thyrotroph cell. TRH secretion is modulated by central and peripheral thermal sensors. Dopamine or somatostatin (SRIF) can inhibit TSH release. (From Fisher and Greuters [2008] Thyroid disorders in childhood and adolescence. In *Pediatric Endocrinology*, (3rd ed.) (pp 227-253). Philadelphia: Saunders.)

tablespoon (15 g). Generally, until the end of puberty, gland size (in grams) approximates the patient's age in years times 0.5 to 0.7.[20] Thus, each thyroid lobe of a 10-year-old is approximately one half of a teaspoon for a total gland size of 5 to 7 g.[20] For teens and adults, each lobe of the thyroid may reach one teaspoon in size for an approximate total gland size of about 10 g.[20]

In newborns and young infants, the thyroid can be examined by placing the infant supine on the parent's lap, with the head toward the parent's knees. The head can then be gently lowered backward to expose the neck, which facilitates thyroid palpation. If the examiner can palpate each ring of the trachea from the sternal notch to above the larynx, then the absence of pretracheal thyroid tissue is suggested with a lingual thyroid gland or complete absence (athyreosis). Failure to detect pretracheal thyroid tissue in older children warrants visual examination of the base of the tongue for ectopic thyroid tissue.

When a sublingual thyroid gland is discovered late in childhood or in adolescence, the tissue should be palpated with a gloved finger during regular office visits, because nodules and malignancies may develop in ectopic thyroid glands.[21] In contrast, when an ectopic thyroid is detected in infancy and replacement therapy is initiated, the residual thyroid tissue becomes atrophic and does not present long-term problems.

Biochemical Evaluation of Thyroid Function

Thyroid function can be assessed by measurement of total T4 and T3 levels, along with indices that reflect thyroid hormone-binding proteins (T3 or T4 resin uptake).[22] The levels of estimated free (unbound) T4 (FT4) are measured to assess thyroid hormone status without the confounding influences of carrier proteins.

Several conditions occur in which thyroid hormone levels are abnormal, yet the individual is euthyroid. Because of their confusing nature, these conditions may result in the patient being erroneously diagnosed or treated for hypothyroidism or hyperthyroidism. When FT4 values are normal yet total T4 values are high, familial dysalbuminemic hyperthyroxinemia needs to be considered as the cause.[23,24] In the United States, this autosomal dominant disorder is most commonly seen in Hispanic individuals and can be diagnosed by thyroid hormone–binding protein electrophoresis. If FT4 values are normal but total T4 values are low, the possibility of TBG deficiency must be entertained. TBG deficiency is an X-linked disorder that may be associated with color blindness.[25] In these and other conditions affecting thyroid hormone binding, treatment is not needed and the patient should be educated

about the condition to avoid unnecessary treatment by unsuspecting practitioners.

As indicated previously, T4 is much more abundant in the circulation, but T3 is the more metabolically active thyroid hormone. The majority of T3 is produced peripherally from T4, but some (10% to 30%) is also secreted by the thyroid gland. A metabolically inactive form of T3, reverse T3, also is produced, and its concentration is elevated in conditions such as euthyroid sick syndrome[26] (see Figure 12-2). Ultrasensitive thyrotropin or thyroid stimulating (TSH) assays have been developed, and assessment of TSH has greatly improved the evaluation of thyroid status.[27] TSH concentrations help to distinguish many thyroid disorders that present with either low or high T4 concentration. TSH values within the normal range for the assay are indicative of a euthyroid state if the hypothalamic pituitary axis is intact. Elevations of TSH above the normal levels for age generally indicate primary thyroid hypofunction; suppressed or undetectable TSH values generally indicate hyperthyroidism, providing that there are no substances in the circulation such as drugs or endogenous antibodies that interfere with the assay. When both FT4 and TSH levels are elevated, TSH-producing pituitary adenomas or thyroid hormone resistance needs to be considered.

Critical in the interpretation of thyroid hormone concentration is the recognition that concentrations of T4, T3, and TSH vary with age (see Box 12-1). TSH values in children differ from those in adults, defined by an upper limit value of about 4 μU/mL or less.[28-31] In comprehensive studies of this issue, the upper limit of TSH values in healthy children and adolescents without thyroid disease is about 7 μU/mL.[32-34] The application of an adult reference range to children results in the erroneous diagnosis of subclinical hypothyroidism and the unnecessary referral of children for subspecialty care by primary care providers.

HYPOTHYROIDISM

Disorders of the thyroid lead to hypothyroidism much more commonly than to hyperthyroidism. Hypothyroidism may be present at birth, acquired during childhood or adolescence, present with or without symptoms, or be present after long-standing onset or acutely.

The public and many practitioners commonly believe that hypothyroidism is associated with and is a cause of obesity, yet there is little support for the notion that the hypothyroid state contributes to obesity.[35,36] It is also important to note that TSH levels are slightly higher in obese individuals than nonobese individuals.[37-40] With weight loss, TSH levels normalize in these children.[37-39,41] Thus, slight elevations in TSH in obese individuals are physiologic, reflecting an attempt by the body to increase metabolism and limit adipose tissue deposition and, hence, do not warrant therapy.

Hypothyroidism signs may be elusive, with symptoms elicited only in retrospect. In the extreme, hypothyroidism can be associated with cold intolerance, bradycardia, carotenemia, coarse and brittle hair, dry skin, pallor, and myxedema. These symptoms may not be distressing, which allows prolonged hypothyroidism to escape detection.

The most common causes of hypothyroidism in children are autoimmune processes resulting in Hashimoto thyroiditis.[42,43] Autoimmune thyroiditis also leads to juvenile acquired hypothyroidism that can present with growth failure when chronically present.[44] Hypothyroidism in children can be caused by iodine exposure or hypothalamic-pituitary dysfunction. Other causes of hypothyroidism include exogenous goitrogens,[45,46] cystinosis,[47,48] acute and subacute thyroiditis,[49] and thyroid irradiation during cancer treatment.[50] Hypothyroidism in the newborn is a serious health concern and is detected by newborn screening programs as detailed in Chapter 7

Hashimoto or Autoimmune Thyroiditis

Autoimmune thyroiditis with thyroid enlargement is one of the most common presentations of childhood thyroid disease.[43,51] It is associated with antibodies against thyroglobulin and thyroperoxidase and is characterized by lymphocytic infiltration of the thyroid gland, which results in thyromegaly.[43,51] Depending on the nature of the antithyroid antibodies, Hashimoto disease may be associated with a euthyroid state, hypothyroidism, or transient hyperthyroidism.[43,51] Damage to the thyroid gland reflects both antibody-mediated and cell-mediated injury.

Hashimoto thyroiditis may rarely occur in very young infants[52] but typically presents in adolescents, affecting females three to five times more commonly than males.[43] The thyroid gland is usually diffusely enlarged and may seem to have an irregular, cobblestone texture on palpation. Asymmetric thyroid enlargement, mimicking a thyroid nodule, may be noted. The presence of antithyroid antibodies and the absence of nodules on ultrasonography can distinguish inflammation from other pathologic processes.

Importantly, the presence of antithyroid antibodies does not portend the development of complete or partial thyroid failure that will warrant therapy. In the healthy adult population, up to 5% of individuals had circulating antithyroid antibodies present.[53] Less than 10% of these individuals (i.e., only 0.5% of those with antibodies) will develop hypothyroidism, and those who have elevated antithyroperoxidase (TOP) antibodies are much more at risk than those who have antithyroglobulin (TG) antibodies.[53]

In children, the incidence of antithyroid antibodies in the population is not defined. Of those children with antithyroid antibodies, about 20% are reported to develop hypothyroidism that requires treatment with exogenous thyroid hormone,[54,55] and these children often have very high antithyroid antibody titers. If a child is found to have low concentrations of antithyroid antibodies, it is reasonable to assess thyroid indices every 6 to 12 months and initiate therapy when the TSH rises above the upper limit of normal for children. If high titers are present at presentation, it is reasonable to initiate therapy at that time.

In some children, untreated Hashimoto thyroiditis can result in progressive thyromegaly and hypothyroidism.[43] Treatment with levothyroxine prevents hypothyroidism

and the TSH elevations that stimulate gland enlargement. When T4 levels are modestly depressed (< 5 µg/dL) or normal, treatment can be initiated with 1 to 2 µg/kg/day of levothyroxine. If profound hypothyroidism is present, pseudotumor cerebri may develop when children are treated with conventional doses.[56] Thus, treatment is initiated with one third to one half of the usual dose of levothyroxine. After 2 to 4 weeks, the patient can be advanced to conventional doses. However, children with profound hypothyroidism can develop pseudotumor cerebri even if treatment is initiated with low doses of levothyroxine.[57-59]

It has been reported that some children with profound TSH elevations (> 250 mIU/mL) and those with severe hypothyroidism may experience complete spontaneous resolution of the hypothyroid state without treatment and restoration of a euthyroid state occurs.[60] Based on the experience of others, this is very uncommon.

Although it has been reported that there are some differences in the oral bioavailability of different levothyroxine preparations,[61-63] from a practical vantage these differences are minor.[62-64] Thus, the routine use of less expensive generic compounds versus more expensive brand-name products is justified.

The timing of levothyroxine ingestion has been the subject of study. In contrast to the standard recommendation that thyroid replacement be taken on an "empty stomach," taking the medication at bedtime is associated with higher T4 levels and lower TSH levels over the course of the day.[65,66] This is believed to be related to better gastrointestinal absorption in the evening than during the day.[65,66]

The suggestion has also been made that hypothyroidism in adolescents can be treated with a single dose given weekly.[67] This approach is not recommended, because thyroid hormone levels are high shortly after the dose is administered and are low by the week's end.[67] Treatment of congenital hypothyroidism with weekly doses of levothyroxine can result in mental retardation.[68] It is also recognized that excessive soy intake, iron tablets, and excessive fiber can interfere with the absorption of levothyroxine.[69-71]

Other potential therapies that may theoretically alter the autoimmune process have been tested. Among the proposed remedies, no benefit has been observed in patients who have taken selenium.[72]

Hashitoxicosis

Uncommonly, patients may present with hashitoxicosis, in which the immunologic destruction of thyroid tissue results in the release of preformed thyroid hormone, leading to elevated T4 levels in the circulation with symptoms and signs of hyperthyroidism.[73] In contrast to Graves disease, hyperthyroidism is transient, eye findings are absent, radionuclide uptake is low, and levels of thyroid-stimulating immunoglobulins are not elevated.[73]

Hashimoto thyroiditis may be associated with other autoimmune diseases, including diabetes mellitus, adrenal insufficiency, vitiligo, and hypoparathyroidism.[74] Autoimmune thyroiditis is also seen in patients with inflammatory bowel disease and juvenile arthritis.[75,76] Annual surveillance of thyroid gland size and TSH levels should thus be considered for children with other autoimmune problems, and clinicians should be vigilant for signs of hyperthyroidism or hypothyroidism. Conversely, children with autoimmune thyroiditis should be observed for signs of diabetes mellitus and Addison disease (see Chapter 20 for a discussion of autoimmune polyglandular syndromes).

The incidence of coexisting celiac disease in the setting of Hashimoto thyroiditis is about 1%.[77] If patients manifest abdominal discomfort, weight loss, or gastrointestinal symptoms, celiac disease screening should be performed, but does not need to be done routinely in children with thyroid disease. We have found a 1% incidence of autoimmune liver disease in children with autoimmune thyroid disease. Because such liver disease can be occult, we annually assess circulating transaminase values (alanine amino transferase [ALT] and aspartate amino transferase [AST]). If values are elevated, evaluation of possible autoimmune liver disease is initiated and level of antineutrophil antibodies (ANA) as well as smooth muscle and liver-kidney microsomal antibodies obtained.[78]

Several groups of children are at risk for autoimmune thyroiditis. Because girls with Turner syndrome are predisposed to autoimmune thyroiditis,[79] TSH levels should be assessed annually. Turner syndrome should be considered in girls with hypothyroidism, especially if the child is prepubertal at presentation.[80,81] Children with Down syndrome warrant annual screening for hypothyroidism because they are more prone to develop autoimmune disorders.[82,83]

Subclinical Hypothyroidism

Subclinical hypothyroidism refers to a situation where circulating T4 and T3 concentrations are normal but TSH values are elevated.[36,84] As noted previously, many children are erroneously diagnosed with this condition when TSH concentrations are found to be elevated relative to adult reference range values.[33] However, if appropriate pediatric-based TSH values are applied, the majority of children so diagnosed will not have hypothyroidism. Thus, some experts have questioned if subclinical hypothyroidism is a real entity in children.[36,84]

Studies of children with mild TSH elevations (5 to 10 µU/mL) reveal that only a small fraction will progress to TSH elevations > 10 µU/mL.[36,84] Data also show that treatment of children with TSH values of 5 to 10 µU/mL do not exhibit somatic or other benefits when treated with levothyroxine.[36,84] Thus, treatment of children with TSH levels < 10 µU/mL is not needed. For children with TSH levels > 10 µU/mL, treatment with low doses of levothyroxine is indicated.

Juvenile Acquired Hypothyroidism

When autoimmune thyroiditis occurs during childhood, it is referred to as juvenile acquired hypothyroidism. In children, severe hypothyroidism can be well tolerated. Thus, prolonged hypothyroidism may not be detected until growth failure occurs.[44,85]

Because untreated infantile hypothyroidism is associated with mental retardation, the assumption is often

made that juvenile hypothyroidism is associated with learning problems and poor academic performance. This notion is not correct, as children with juvenile hypothyroidism can be successful academically and do not manifest overt learning problems or cognitive impairment related to the hypothyroid state,

Children with severe hypothyroidism may manifest cold intolerance, decreased frequency of bowel movements, and decreased physical activity.[44,85] Bradycardia, facial puffiness, delayed reflexes, and carotenemia may be present. In comparison with Hashimoto thyroiditis, the thyroid gland is either small or only modestly enlarged. [44,85] Antithyroid antibodies usually are present.[44,85] These patients are generally not obese, and body mass index values are similar before and after treatment.[35,86] The development of slipped capital femoral epiphyses may antedate the detection of hypothyroidism.[87]

Some children with juvenile hypothyroidism may present with signs of puberty but without pubic hair.[88-90] Boys may present with testicular enlargement and girls may present with menarche, with or without breast development.[91] With treatment of the hypothyroid state, these characteristics may regress.[88-90] Available evidence suggests that the hypothyroid state leads to increased gonadotropin secretion, which triggers gonadal activity.[88,91] Alternatively, it has been suggested that extreme high levels of TSH cross-react with the follicle-stimulating hormone (FSH) receptor in the gonads. This entity is referred to as the "overlap" or Van Wyk–Grumbach syndrome.[92,93] The very high TSH values reflect pituitary hyperplasia of thyrotrophs and may be associated with an appearance of an enlarged pituitary on imaging studies that might be mistaken for a pituitary TSH secreting adenoma.[94] However, these findings resolve with treatment of the hypothyroid state. In some children, true puberty may develop within a year or two of treatment onset, which may limit catch-up growth due to earlier closure of epiphyses induced by sex steroids.[44]

Juvenile hypothyroidism may not be recognized until a sizable statural deficit is present, and the lost height is usually not recovered.[44] Children with juvenile hypothyroidism who present with growth failure manifest very low T4 values that are often less than 2 μg/dL and profoundly elevated TSH levels that are higher than 250 μU/mL.[44] Hypercholesterolemia and anemia may be present.[44]

The magnitude of the height deficit is proportional to the duration of hypothyroidism, which can be estimated as the difference between the chronologic and bone age.[44] When the individual is treated with conventional doses of levothyroxine, accelerated skeletal maturation is observed, with the skeletal age advancing disproportionately faster than gains in height.[44] Thus, predicted heights fall, and genetic growth potential is not achieved.

Because of the potential poor growth outcomes of patients with hypothyroidism, we have treated these patients with low doses of levothyroxine (0.25 to 0.5 μg/kg/day; e.g., 50 μg for a 10-year-old). With this regimen we find that, with low-dose levothyroxine therapy, T4 values normalize (6 to 7 μg/dL) within 2 months, and TSH levels normalize or remain only modestly elevated. Moreover, serial bone age determinations do not show the disproportionate advancement of skeletal age seen with conventional therapy. However, we do not know if this approach leads to more favorable height outcomes.[95] Some physicians have also suggested that treating these children with gonadotropin-releasing hormone analogs to delay puberty will lead to improved long-term growth.[96-100] However, we have found that catch-up growth slows markedly in some hypothyroid children receiving gonadotropin-releasing hormone analog therapy so that predicted adult heights is less and others have not observed added benefit.[101] Because the loss in adult height is proportional to the duration of hypothyroidism,[44] early detection of this disorder is the best intervention for preventing statural deficits.

Iodine-Induced Hypothyroidism

Sixty percent of the weight of T4 is iodine, and iodine is the rate-limiting substrate for synthesis of thyroid hormones[2] (see Figure 12-1). Iodine is present in small amounts (15 to 20 mg) in humans. The recommended dietary allowance of iodine is 100 μg/day for adolescents and adults, and 150 μg/day for pregnant and lactating women. It is 60 to 100 μg/day for children aged 1 to 10 years, 40 μg/day for infants aged 6 to 12 months, and 30 μg/day for infants 6 months of age or younger. In areas of low iodine intake, the recommended dietary intake should be 90 μg for infants aged less than 1 year.[2]

Although modest iodine intake is essential for thyroid function, high-level iodine exposure results in an acute block in the release of preformed thyroid hormone and impaired thyroid hormone synthesis, a phenomenon referred to as the Wolff-Chaikoff effect.[102] When iodine-induced hypothyroidism is suspected, it can be diagnosed by the detection of high iodine levels in urine samples.[103]

In children, iodine can be absorbed through the skin, and iodine-induced hypothyroidism has been observed after cutaneous iodine or Betadine use.[103-105] Iodine-induced suppression of thyroid hormone production has also been observed in children with central intravenous lines when regular cleansing of the insertion site with iodine was included in central line care. Neonatal hypothyroidism has also been associated with maternal povidone (iodine) exposure at the time of delivery.[104]

In preterm infants, iodine-induced hypothyroidism warrants special attention, because the suggestion has been made that cutaneous iodine exposure is a major cause of hypothyroidism in premature infants.[106] Studies show that iodine-induced hypothyroidism is infrequent in the United States.[107]

Significant iodine exposure also occurs from amiodarone, an antiarrhythmic drug that contains 37% iodine.[108] Hypothyroidism occurs in 10% of individuals treated with this compound.[109] Amiodarone can also reach the fetus by transplacental passage and induce fetal hypothyroidism.[108]

In addition to iodine excess, iodine deficiency also leads to hypothyroidism. Estimates indicate that more than 1 billion people worldwide are at risk for iodine deficiency.[110] Clinically, iodine deficiency is associated with goiter, hypothyroidism,[110] and endemic cretinism.[111] Endemic cretinism is classified into neurologic or

myxedematous type,[112] with severe mental retardation, mutism, and cerebral diplegia found in neurologic type. Children with the myxedematous type, have less severe mental retardation and have severe growth retardation and myxedema.[112]

Geographic areas of iodine deficiency exist, even in the United States.[113,114] With the prevalent use of iodized salt, however, the incidence of iodine deficiency has been markedly reduced, and hypothyroidism and goiter due to iodine deficiency are rare in the developed world.[113,114] Iodine intake in the United States has declined, an issue that may have future clinical implications.[113,114] In Australia, a reduction in iodine intake has been reported, with potential implications for pregnant and lactating women,[115] as reduced iodine intake may predispose to maternal and child hypothyroidism predisposing to hypothyroidism or developmental delay.[112] The exclusive use of deiodized salt, which includes sea salt, is thus not recommended.

Hypothalamic-Pituitary Dysfunction

Central hypothyroidism should be considered in children with a history of head trauma, brain tumors, meningitis, central nervous system irradiation, or congenital nervous system malformations. Central hypothyroidism has also been associated with the use of retinoid X receptor-selective ligands in the treatment of lymphomas.[116]

In contrast to primary hypothyroidism, the diagnosis of hypothyroidism secondary to hypothalamic-pituitary dysfunction may be difficult to establish. Often, circulating concentrations of T4 are in the low-normal range, and TSH may be low, normal, or elevated.[117,118] FT4 values, however, are usually low.

Whereas congenital central hypothyroidism will be diagnosed in states that perform T4 screening of newborns, neonatal screening programs that rely on TSH determinations will not detect this condition. Central hypothyroidism should therefore be suspected in infants with cholestasis, poor growth, hypoglycemia, structural nervous system problems, or pituitary insufficiency.[119] When neonatal T4 values are interpreted, care should also be taken to use infant thyroid hormone values for comparison, because infantile T4 levels are higher than those seen in adults[120] (see Tables 12-1 and 12-2; also see Chapter 7).

Importantly, up to 30% of children who will develop central hypothyroidism may have normal T4 and TSH levels at birth.[121] Thus, all children with evidence of hypopituitarism should be regularly monitored for central hypothyroidism onset.

When central hypothyroidism is suspected, the thyrotropin releasing hormone (TRH) test helps distinguish pituitary (secondary) and hypothalamic (tertiary) hypothyroidism.[118,120,122] Typically, there is a minimal rise in serum TSH levels in response to TRH in patients with pituitary disease, whereas there is a delayed response (> 60 minutes) in patients with hypothalamic disease. However, responses to this test are variable, making it difficult to distinguish between pituitary and hypothalamic hypothyroidism.[118,120,122] Central nervous system imaging should be performed to look for congenital malformations or hypothalamic-pituitary lesions. Care should be taken to search for other pituitary hormone deficiencies, especially abnormalities of the hypothalamic-pituitary adrenal and growth hormone axes, as gene defects that adversely affect hypothalamic pituitary dysfunction, include mutations in the LIM/homeobox protein 3 (LHX3) and 4, prophet of pit-1 (PROP1), and pituitary transcription factor (PIT).[123-125]

Treatment consists of replacement therapy with levothyroxine. Some children with central hypothyroidism require doses lower than those used to treat primary hypothyroidism.[126] Because TSH values are not helpful in guiding treatment, measurement of FT4 levels is recommended.[126] Furthermore, a dose of 1.6 µg/kg of levothyroxine is recommended to maintain the FT4 levels in the upper half of the reference range.[127]

Giant Hemangiomas

Hypothyroidism has been associated with giant hemangiomas.[128] In some infantile hemangiomas, the endothelium of these vascular structures produces type 3 iodothyronine deiodinase, which degrades circulating T4 (see Figure 12-2). Treatment of hypothyroidism in this setting requires high doses of levothyroxine.[128]

Hypothyroidism in Cancer Survivors

It is well recognized that children who are cancer survivors and who have had head and neck irradiation are at increased risk for differentiated thyroid cancer.[129,130] More common, though, is the development of mild hypothyroidism.[131-133] Up to 30% of children who have had head and neck irradiation will develop primary hypothyroidism.[133] Thus, annual TSH screening is suggested. In addition, ultrasound studies are recommended beginning 5 years after radiation exposure.

Practitioners who argue that palpation alone is sufficient for the follow-up of individuals who have had head and neck irradiation need to recognize that ultrasonography will detect thyroid nodules well before palpation.[130,134] It must also be recognized that earlier rather than later recognition of thyroid cancer can lead to less extensive surgery, lower administered activities of ^{131}I, and a better chance of cure.[135]

THYROID HORMONE RESISTANCE

Thyroid hormones exert their effects by binding to a specific nuclear receptors to regulate cellular gene expression.[136] When the thyroid hormone receptor is mutated, impaired tissue responsiveness results, leading to thyroid enlargement, elevated levels of T4 and T3, tachycardia, and behavioral problems.[137-140] Unlike Graves disease, TSH values are normal or slightly elevated.

The most common forms of thyroid hormone resistance are caused by mutations of the thyroid hormone receptor beta gene.[138-140] More than 100 mutations have been identified that result in impaired affinity for T3.[138] Mutant thyroid hormone receptors also block the function of normal thyroid hormone receptors.[138] Thus,

thyroid hormone resistance is a dominant-negative mutation, and inheritance is autosomal dominant.[138] Detection of thyroid hormone resistance in the index case may therefore lead to diagnosis of the condition in other family members. In up to 50% of children with thyroid hormone resistance, the mutations are spontaneous.

Most individuals with resistance to thyroid hormone have generalized thyroid hormone resistance.[138] These individuals are eumetabolic and asymptomatic, with TSH levels in the normal range.

In contrast, some individuals have isolated pituitary thyroid hormone resistance. These individuals have symptoms of hyperthyroidism, because they are sensitive to the effects of increased circulating thyroid hormone in the periphery, where the thyroid receptors are functionally intact.[141] Resistance to thyroid hormone can be associated with central nervous system problems. Approximately 50% of individuals with resistance to thyroid hormone have attention deficit hyperactivity disorder and a minority have mental retardation.[142]

Because individuals compensate for thyroid hormone resistance by secreting more thyroid hormone, treatment is generally not necessary.[138,143] However, some patients with thyroid hormone resistance may be improperly diagnosed as having Graves disease and undergo ablation of the thyroid. In this situation, replacement therapy with appropriate doses of exogenous thyroid hormone is needed. With the earlier recognition of resistance to thyroid hormone due to newborn screening, the issue of whether children with resistance to thyroid hormone should be treated prenatally or during infancy has been raised.[138,143] Treatment is generally reserved for infants who show elevated TSH levels, growth failure, seizures, and developmental delay.[138,143]

In some cases, TSH secretion may be profound, leading to massive thyromegaly, which may adversely impact upper airway function.[144,145] These cases are associated with severe loss of function mutations. Treatment with high doses of triiodiothyroine every other day has been shown to be somewhat effective in this setting.[144,145] In other cases, thyroidectomy is needed to prevent airway compromise.[144,145]

HYPERTHYROIDISM

Hyperthyroidism occurs less commonly in children than hypothyroidism, yet is far more symptomatic.[146-150] Graves disease is the most common cause of childhood thyrotoxicosis and is characterized by diffuse goiter, hyperthyroidism, and occasionally ophthalmopathy. Other causes of hyperthyroidism in children include autonomously functioning thyroid nodules, neonatal thyrotoxicosis, and infections of the thyroid. Hyperthyroidism also results from thyroid hormone ingestion, McCune-Albright syndrome, struma ovarii, and TSH-producing pituitary adenomas. Epidemic hyperthyroidism has also been seen when thyroid tissue has been inadvertently included in meat products.[151] In contrast to these disorders, thyroid hormone resistance may appear similar to hyperthyroidism yet is best left untreated.

Graves Disease

Graves disease is the most common cause of hyperthyroidism in children and adults and occurs when the thyroid gland is stimulated by immunoglobulins.[51,148,152] In children, the incidence of Graves disease is about 1:10,000.[153] Current treatment approaches for Graves disease include the antithyroid drugs (ATDs) propylthiouracil (PTU) or methimazole (MMI), surgery, and radioactive iodine (RAI; ^{131}I), therapies that have been used since the 1960s.[148,154-157]

Medical Therapy

PTU and MMI reduce thyroid hormone synthesis by inhibiting the oxidation and organic binding of thyroid iodide.[158] Importantly, these medications are not curative. Rather, they palliate the hyperthyroid state until it spontaneously resolves or definitive treatment is rendered. In 2008, serious complications related to the use of PTU in children were noted and a review of adverse events related to ATD use in the pediatric population was reported.[153] The risk of PTU-induced liver failure leading to transplantation was estimated to be 1 in 2000 children. The number of children developing PTU-induced liver injury that was reversible was estimated to be at least 10-fold greater than the number of children who develop liver failure requiring transplantation. Because PTU-induced liver injury is of rapid onset and can be rapidly progressive, biochemical monitoring of liver function tests and transaminase levels is not useful in managing the hepatotoxicity risk in a PTU-treated patient.[153] Considering the risk of PTU-related hepatotoxicity in children, it is now recommended that the use of PTU be stopped, and children taking the medication should be considered for alternative treatments.[159]

Although PTU use should be avoided in favor of MMI, there is a role for the limited use of PTU. PTU use should be considered in circumstances when neither prompt surgery nor ^{131}I treatments are readily available options, or when a toxic reaction to MMI has occurred but therapy for Graves disease is necessary. In this situation, PTU use should be used for the short term only. Because of potential teratogenic effects of MMI,[160] PTU also is the drug of choice over the first trimester of pregnancy.[161] In the United States and many other countries, MMI (or carbimazole) is available and is the drug of choice for Graves disease. The typical MMI dose is 0.2 to 0.5 mg/kg/day, with a range from 0.1 to 1 mg/kg/day.[152] Although many practitioners give MMI in divided administered doses, data do not support a need for such titration.[162]

Overall MMI has a better safety profile than PTU, but MMI can be associated with minor adverse events;[163] major adverse events include agranulocytosis and allergic reactions. Agranulocytosis has been reported in about 0.3% of adult patients taking MMI or PTU.[156,164,165] Agranulocytosis is dose dependent with MMI and rarely occurs at low doses.[156,164,165] When it develops, agranulocytosis occurs over the first 100 days of therapy in 95% of individuals.[156,164,165] If patients taking MMI develop fever, pharyngitis, or feel ill, the medication should be

immediately discontinued by the patient, a physician contacted, and a white blood cell count obtained.

The issue of how long anti-thyroid drugs (ATDs) should be used in children before considering radioactive iodine or surgery is a topic of controversy and warrants further study. Prospective studies in adults show that if remission does not occur within 18 months, there is little chance of remission with prolonged therapy.[166] In children, when ATDs are used for 1 to 2 years, remission rates are generally 20% to 30%.[167-169] The chance of remission after 2 years of ATD use will be low if the thyroid gland is large (> 2.5 normal size for age),[170] the child is young (< 12 years)[168,169,171] not Caucasian, initial serum TRAb levels are high, or FT4 levels are high at diagnosis (> 4 ng/dL; 50 pmol/l). [169]

Studies of large cohorts of pediatric patients with Graves disease treated with ATDs for extended periods[170,172] have revealed low remission rates that are comparable to those seen with 2 years of therapy. In view of these data, many practitioners will consider a trial of MMI for 1 or 2 years and proceed to surgery or ^{131}I therapy if remission does not occur. Practitioners may also elect to continue ATDs for many years, as long as toxic reactions and progressive thyromegaly do not occur. Most recently, higher remission rates for children treat with antithyroid medications have been reported.[173] Yet, these studies are at variance with most other studies[148] and warrant additional follow-up.

Radioactive Iodine Therapy

The use of RAI has been reported in more than 1200 children.[157] Patients as young as 1 year of age have been treated with ^{131}I with excellent outcomes.[157] Overall studies of ^{131}I use in children report remission rates that exceed 95%.[157,174,175] The goal of ^{131}I therapy for Graves disease is to induce hypothyroidism. ^{131}I doses are typically calculated to deliver the desired amount of radiation based on gland size and 24-hour ^{123}I uptake. Some centers administer all patients the same fixed dose of ^{131}I with excellent outcome.[176] To achieve thyroid ablation or hypothyroidism, more than 150 uCi of ^{131}I per gram of thyroid tissue should be administered.[177,178] With larger glands (30 to 80 g), higher administered doses of ^{131}I (200 to 300 uCi of ^{131}I per g) may be needed.[177] To assess gland size when the thyroid is large, ultrasonography is recommended with gland size determined by the formula, lobe size = [length × width × depth × 0.6] and the volumes of each lobe summed. Radioactive iodine is often not effective with large glands (> 80 g).[179] Thus, surgery may be preferable to ^{131}I in these patients, although patients can be given a repeat RAI treatment.

Some centers administer a fixed dose of about 15 mCi ^{131}I to all children[176] rather than providing individually calculated doses. One potential advantage of calculated versus fixed dosing, though, is that it may be possible to administer lower doses of ^{131}I when the administered dose is calculated, especially when uptake is high. Less than 10% of children complain of mild tenderness over the thyroid in the first week after therapy, which can be treated effectively with acetaminophen or nonsteroidal anti-inflammatory agents for 24 to 48 hours[175,177] There are rare reports of pediatric patients with severe hyperthyroidism who have developed thyroid storm after receiving ^{131}I.[180] Thyroid storm in this setting is believed to reflect progression of the uncontrolled hyperthyroid state. Thus, if T4 values are > 20 μg/dL or freeT4 values are > 5 ng/dL (60 pmol/l), children should be treated with MMI until T4 or free T4 levels normalize before proceeding with ^{131}I therapy.[177]

Hypothyroidism typically develops by 2 to 3 months posttreatment.[176,177] When administered doses > 150 uCi of ^{131}I per gram of thyroid tissue are administered, hypothyroidism rates are about 95%.[152,157,181] If hyperthyroidism persists 4 to 6 months after therapy, retreatment with ^{131}I is indicated.

The thyroid gland is unique in its developmental sensitivity to malignancy following low-level radiation exposure.[182,183] When individuals are younger than 20 years at the time of exposure to low-level thyroid irradiation, thyroid cancer risks increase the younger the patient is at the time of exposure.[182,183]

Detractors of ^{131}I therapy point to the increased rates of thyroid cancer and thyroid nodules observed in young children exposed to radiation from nuclear fallout at Hiroshima or after the explosion at the Chernobyl nuclear reactor.[183,184] The risk of thyroid neoplasms, however, is greatest with exposure to low level external radiation (0.1 to 25 Gy; ~0.09 to 30 uCi/g),[182-185] not with the higher doses used to treat Graves disease. We are not aware of cases of thyroid cancer developing in patients treated with > 150 uCi of ^{131}I per gram of thyroid tissue for childhood Graves disease attributable to RAI therapy.

Although RAI is being used in progressively younger ages, we do not know if there is an age below which high-dose ^{131}I therapy should be avoided. Risks of thyroid cancer after external irradiation are highest in children less than 5 years of age and progressively decline with advancing age.[174,182,183,186] If there is residual thyroid tissue in young children after RAI treatment, there is a theoretic risk of thyroid cancer.

In addition to thyroid cancer risks, potential influences of ^{131}I therapy on other cancers need to be considered. This issue has been examined in several large cohorts of adults in the United States and other countries. These studies have not revealed increased cancer incidence or mortality in adults treated with ^{131}I for Graves disease.[187-193]

In comparison with the studies in adults, few studies have focused on populations exposed to ^{131}I in childhood for the treatment of Graves disease. The longest follow-up study of pediatric patients involved 36-year outcomes of 116 patients who were less than 20 years of age when treated with ^{131}I between 1953 and 1973.[174] This group did not have an increased cancer rate.

The total-body radiation dose after ^{131}I varies with age, and the same absolute dose of ^{131}I will result in more radiation exposure to a young child than to an adolescent or adult.[194,195] At present, we do not have dosimetry information regarding ^{131}I use in children with Graves disease to assess total body exposure in children. But, based on theoretic calculations, we feel it is prudent to avoid radioactive iodine therapy in very young children (< 5 years) and to avoid > 10 mCi in patients younger

than 10 years of age. It is important to recognize that there may be circumstances in which ^{131}I therapy is required in young children. This situation may occur when a child has developed a reaction to antithyroid medications, proper surgical expertise is not available, or the patient is not a suitable surgical candidate. In this situation, ^{131}I therapy is needed.

Surgery

Surgery is an acceptable form of therapy for Graves disease in children.[196] When performed, near total or total thyroidectomy is recommended, as subtotal thyroidectomy is associated with a higher relapse rate.[197] Surgery is preferred in young children (< 5 years) when definitive therapy is required and can be performed by an experienced thyroid surgeon. In individuals with large thyroid glands (> 80 g), the response to ^{131}I may be poor,[179,198] and surgery is recommended for these patients.

Data in adults show that acute complications following thyroidectomy include hypocalcemia (40%), hematoma (2%), and recurrent laryngeal nerve paresis (2%).[199,200] Children aged 0 to 6 years had complication rates of 22%, whereas those aged 7 to 12 years had complication rates of 11%, and those aged 13 to 17 years had complication rates of 11%. These rates are higher than those seen in adults. Thus, surgery may not be an optimal option for some pediatric patients with Graves disease, especially in young children. In circumstances where local pediatric thyroid surgery expertise is not available, referral of a child with Graves disease to a high-volume thyroid surgery center of excellence that also has pediatric experience should be considered.

Stratification of Treatment

Based on what is known about the risks of different treatments and the pathogenesis of Graves disease, we can be more selective in our approach to therapy.[148] To reduce treatment risks and expedite cure, the treatment options can be guided by the patient's age and the nature of the intrinsic autoimmune disease (Figure 12-4).

In determining if drug therapy is likely to be successful, TRAb levels and thyroid size may be predictive of remission rates. The presence of low TRAb levels and a small thyroid suggests the possibility of remission on medical therapy. Yet if TRAb levels are high and the thyroid is large, the odds of spontaneous remission are low.[201,202] However, TRAb levels and thyroid size may not always be indicative of the likelihood for remission.

For children younger than 5 years of age, we consider MMI as a first-line therapy. Because young children are less likely to have remission than older children on drug treatment,[168,171] prolonged drug therapy may be needed. If there are no toxic effects, continuing MMI is reasonable until the child is considered old enough for radioactive iodine therapy. Alternatively, thyroidectomy or ablative radioactive iodine therapy can be considered if reactions to medications develop or there is the desire to avoid prolonged drug use.

Fifteen percent of children with Graves disease will present between 6 and 10 years of age.[147] MMI therapy as a first-line measure for this age group is reasonable. Yet as the child approaches 10 years of age, either radioactive iodine or drug therapy can be considered as initial therapy.

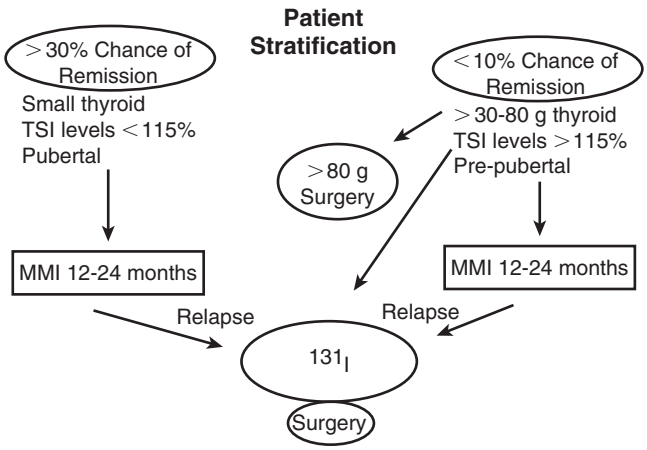

FIGURE 12-4 ■ Graves disease therapy in children: Stratification by clinical characteristics. Patients can be grouped into those with a better or worse chance of remission based on age, TSI levels, and thyroid size. For very large glands (> 80 g), surgery is the treatment of choice. Patients can be treated with antithyroid drugs for 12 to 24 months and the drug withdrawn to see if remission is achieved. If there is no remission, either surgery of radioactive iodine can be administered. Alternatively, the patient can be restarted on antithyroid medication. Only methimazole or carbimazole should be used.

Children 10 years of age and older account for 80% of the pediatric cases of Graves disease. For this age group, radioactive iodine or MMI can be considered as first-line treatment options.

Finally, irrespective of the treatment option selected, careful follow-up is needed for all patients treated for Graves disease. Long-term follow-up should include regular examination of the thyroid gland and measurement of circulating levels of thyroid hormones once or twice a year. All newly appearing thyroid nodules should be biopsied or excised.

In addition to assessing thyroid function in children with Graves disease, attention also needs to focus on body composition and weight change in children after treatment onset. Data now show that Graves disease therapy can be associated with a significant increase in body weight.[86,203]

OTHER CAUSES OF HYPERTHYROIDISM

Neonatal Thyrotoxicosis

Thyrotoxicosis in the neonate is a severe and life-threatening condition that call be associated with lasting neurologic problems.[204,205] If a mother has Graves disease, the chance is 1 in 80 that TSI (or TRAbs) will be transferred to the fetus, which will result in intrauterine or neonatal hyperthyroidism.[206] Rarely, neonatal thyrotoxicosis will persist, like the Graves disease seen in older children.[205] In other rare cases, persistent neonatal thyrotoxicosis is caused by the activation of the TSH receptor.[207,208]

The fetal thyroid gland is responsive to maternal TSI, which, if present at elevated levels, may result in

hyperthyroidism.[209-212] Fetal hyperthyroidism manifests during the second half of gestation, as transfer of TSI from the mother to the fetus increases with the progression of pregnancy.[209-211]

The risk of fetal hyperthyroidism and neonatal Graves disease is proportional to the magnitude of elevation of TSI levels.[209-211] Fetal hyperthyroidism is generally associated with levels of TSI more than two- to fourfold greater than the upper limit of normal for assay.[209-211] Because the fetus is at risk for hyperthyroidism when there is active or past maternal Graves disease, fetal growth and heart rate should be regularly assessed from midpregnancy onward.[209-211] Excessive fetal heart rate (> 160 beats per minute after 20 weeks) and the presence of a fetal goiter suggest hyperthyroidism in the fetus. In addition, accelerated maturation of the femoral ossification center is seen with fetal hyperthyroidism.[210]

If a mother with Graves disease is taking antithyroid medications during pregnancy, fetal thyroid hormone synthesis will be inhibited, which will prevent the development of intrauterine hyperthyroidism.[213] However, the infant may be born with a goiter and hypothyroidism.[165] At birth, circulating levels of T4 may be low and TSH levels elevated. In most cases, the effects of antithyroid drugs wane, and thyroid function normalizes within a week.[206] If significant transplacental passage of TSI has occurred, however, thyrotoxicosis will develop.[206,214]

If a mother with a history of Graves disease is not taking antithyroid drugs during pregnancy, the fetus may develop intrauterine hyperthyroidism.[205] If the condition is not recognized, it may result in profound intrauterine thyrotoxicosis and growth retardation.[205] Such infants have prematurely fused cranial sutures, advanced skeletal age, long-term learning problems, and mental retardation.[205,215] If hyperthyroidism is recognized prenatally because of fetal tachycardia (heart rate higher than 160 beats per minute after 22 weeks), treatment of the mother with antithyroid drugs will reduce the severity of intrauterine thyrotoxicosis.[213,216,217]

Treatment of thyrotoxic infants consists of administration of antithyroid medications (PTU 5 to 10 mg/kg/day or MMI 0.5 to 1 mg/kg/day) and beta-blockers (propranolol 1 mg/kg/day). Lugol solution or saturated potassium iodide may be given (one to two drops every 8 hours) for 7 to 10 days to more rapidly control biochemical hyperthyroidism. After approximately 2 weeks of antithyroid drug therapy, thyroid hormone levels will decline. When thyroid hormone levels fall below normal (8 μg/dL), supplementary levothyroxine (37.5 μg/day for full-term infants) is added to prevent hypothyroidism. As TRAbs are cleared from the infant's circulation, the half-life of IgG being approximately 3 weeks, spontaneous recovery usually begins within 3 months and is usually complete by 6 months.[205,214] Thus, the infant can be weaned from treatment after 3 months. Monitoring of the infant's TSI levels is also a useful predictor of when antithyroid medication can be tapered.[218,219]

Infectious Thyroiditis

Occasionally a child presents with hyperthyroidism, tenderness over the thyroid gland, and fever due to bacterial infection of the thyroid, a condition called acute thyroiditis.[220] Acute thyroiditis can be associated with the presence of a fistula connecting the piriform sinus on the left side of the pharynx to the thyroid.[220] Fevers can be high and erythrocyte sedimentation rates and white counts elevated. Ultrasonography may reveal a local abscess. In contrast to Graves disease, uptake of technetium 99-pertechnetate or radioiodine is reduced when thyroid scanning is performed.

The offending bacteria include *Haemophilus influenza* and *group A streptococci.*[220] Thus, treatment with an antibiotic resistant to disruption by beta-lactamase is recommended. In severe cases, hospitalization and intravenous antibiotic administration is indicated, because lymphatic drainage into the mediastinal region may occur. Surgical drainage is needed if a localized abscess develops and the response to antibiotics is poor.[220]

Because the infectious process results in destruction of thyroid tissue, release of preformed thyroid hormone and clinical hyperthyroidism may occur during infection. The hyperthyroid state is usually transient, and treatment with antithyroid drugs is not indicated.[220] If the patient becomes symptomatic, beta-blockers may be used.

After the child has recovered, pharyngography is indicated to test for a patent piriform sinus tract. Occasionally, the tract may close as the result of the infection. If the tract persists, however, and acute thyroiditis recurs, resection is needed.

Subacute Thyroiditis

Viral infections of the thyroid may occur and result in subacute thyroiditis.[221] In comparison with acute thyroiditis, subacute thyroiditis may be less severe.[221,222] Fever, thyroid tenderness, and hyperthyroidism may be present and may last for several weeks.[223] Because clinically distinguishing between bacterial and viral thyroid infections is difficult, antibiotic treatment is indicated when infectious thyroiditis is suspected.

Hyperfunctioning Nodules

Warm or hot nodules lead to excessive production of thyroid hormone and can be associated with clinical and biochemical hyperthyroidism.[224] Activating mutations of the TSH receptor and Gs have been discovered in hyperfunctioning nodules.[225,226] Although hyperfunctioning nodules may be ablated with radioiodine, surgical excision of hyperfunctioning nodules is recommended in children and adolescents, because radiation-exposed normal thyroid tissue will remain after the hyperfunctioning nodule is ablated. Although the risk of malignancy in hyperfunctioning nodules is low, thyroid cancers have been described in warm nodules.[227,228]

Toxic Multinodular Goiters

Multinodular goiters are uncommon in children, but patients with this condition can develop thyrotoxicosis, which is usually related to the time the goiter has been present and goiter size. In this setting, hyperthyroidism

develops as a single nodule in the thyroid, becomes overly active, and functions autonomously.[229,230] Forty-six percent of patients may have T3 thyrotoxicosis, and nodules are 3 cm or more in diameter.[229,230]

In adults, ^{131}I is routinely used in the treatment of isolated toxic adenomas and toxic multinodular goiters.[229,230] The use of radioiodine to treat these conditions in children is uncommon, however, and few follow-up data are available. Although strong justification exists for the use of radioiodine in the treatment of childhood Graves disease, especially when appropriate doses are used, we recommend that radioiodine be avoided in children with toxic adenomas or multinodular goiters.

When a toxic nodule is present, either as an isolated nodule or in the setting of a multinodular goiter, thyroid function is suppressed in the nontoxic regions. When radioiodine is given, uptake will be limited to the autonomously functioning tissue, and if large doses are administered, the remaining thyroid tissue will receive external irradiation. Because the risk of thyroid cancer following external radiation is very low after 20 years of age,[231,232] the use of radioiodine for toxic nodule ablation in adults is not associated with increased thyroid cancer risks. In the child or adolescent treated with ^{131}I for toxic nodules, however, low-level irradiation to the remaining thyroid tissue may be associated with an increased thyroid cancer risk.

THYROID NODULES AND THYROID CANCER

Nodule Evaluation

Thyroid nodules in children are uncommon and encompass nonfunctional and functional lesions and benign and malignant tumors.[135,233,234] Thyroid cancer needs to be suspected when thyroid nodules are detected in children and adolescents. In a compilation of 16 studies that examined the malignancy rate of thyroid nodules in children, 299 of 1134 nodules were malignant for an overall rate of 26%.[235]

When thyroid nodules are detected, serum TSH, estimated FT4 or T4, and a neck ultrasound should be obtained. Calcitonin levels should be assessed to screen for medullary thyroid cancer, which accounts for 3% to 5% of pediatric thyroid cancers.[236,237] If the TSH is suppressed, a radionuclide scan may identify a hyperfunctioning nodule.

Ultrasound characteristics suggestive of malignancy include microcalcifications, indistinct margins, and a variable echotexture.[130,234,238] Ultrasound can determine the intrathyroidal location of nodules, identify additional nodules, and assess if there is lymph node involvement.[130,234,238] After the Chernobyl disaster, the most reliable ultrasound diagnostic criteria for malignancy in children were an irregular, subcapsular location and an increased intranodular vascularization by Doppler technique.[239] Ultrasonographic appearance alone, though, cannot reliably distinguish between benign and malignant lesions. Thus, fine-needle aspiration (FNA) is indicated for children with thyroid nodules.[234]

FNA is the most accurate means to evaluate if a thyroid nodule is malignant.[234] Reports of FNAs performed in children describe similar specificity and sensitivity as adults.[240-242] Difficulty arises when the FNA is nondiagnostic or the cytology is "indeterminate," as malignancy can be present up to 50% of the time with such cytologic features.[243] If this occurs, the clinician may repeat the ultrasound study and FNA within 3 to 6 months. The nodule size at which point FNA should be performed in children is a matter for discussion.[244] In adults, recommendations suggest that FNA be performed when nodule diameter is or exceeds 1 cm.[234] However, as about 30% of pediatric thyroid nodules are malignant, and FNA can be performed in nodules smaller than 1 cm, it is reasonable to biopsy smaller lesions in children if such capabilities are available, especially for nodules 0.5 to 1 cm. Ultrasound-guided FNA is recommended especially in children because of the difficulty to biopsy small nodules, which rarely can be palpated.[245] When FNA is performed in children, because this is an uncommon procedure, special expertise outside of pediatric departments may be needed.

Thyroid Cancer

Pediatric thyroid cancer is a rare and treatable disease with an excellent prognosis.[135,236] Compared with adults, epithelial-derived differentiated thyroid cancer (DTC), which includes papillary thyroid cancer (PTC) and follicular thyroid cancer (FTC), presents at more advanced stages of disease in children and is associated with higher rates of recurrence. Thyroid cancer in the pediatric population is rare, as a total of 1753 patients with malignant thyroid neoplasms were identified with an age-adjusted annual incidence of 0.54 cases per 100,000 persons. The thyroid cancer types in children in the United States are PTC in 60%, follicular variant of papillary in 23%, FTC in 10% (FTC), and medullary in 5% (MTC)[236] (Box 12-2). Algorithm for the evaluation and follow-up of DTC are presented in Figures 12-5 and 12-6.

Compared with adults, children with DTC present with more extensive disease.[246-255] Lymph node involvement at diagnosis is seen in 40% to 90% of children[246-256] compared with 20% to 50% of adults.[257] The prevalence

of distant metastases, most commonly lung, is 20% to 30% in children versus 2% in adults.[246-255,258] Multifocal disease is more common in children than adults and is seen in about 40% of childhood PTC cases.

In general, DTC that first presents when a person is younger than 10 years of age appears to have higher recurrence and mortality rates than when presentation occurs at older ages.[258,259] DTC that first presents when a person is older than 10 years of age behaves similar to that in young adults.[258] DTC is generally more widespread at presentation and more likely to recur in younger than older children.[260] Other investigators, though, have found that DTC has similar biologic properties in younger children and adolescents.[261]

Even in the presence of metastatic disease, long-term follow-up data show 30-year survival rates of 90% to 99% for children with DTC (see Figure 12-2).[251,252,262] Even with distant metastases, mortality rates are more favorable in children than adults,[263] and pulmonary metastases can remain stable for extended periods.[264] The favorable prognosis reflects the fact that most young patients have well-differentiated tumor types, few have bone metastasis, and most tumors respond well to RAI therapy.

In most cases, specific risk factors for DTC cannot be identified in children; however, risk factors are found in a subset of patients. Exposure to low-level head and neck irradiation has been recognized for more than six decades as predisposing to DTC.[265,266] Low-level radiation doses to the thyroid of less than 30 Gy (3000 cGy or Rad) increase the risk for cancer, with the risk being higher at progressively younger ages.[183-185] Above 20 years of age, the risk of thyroid cancer following low-level irradiation is either very low or undetectable.[183,185] The latency period between the time of radiation exposure and cancer onset in children is typically 10 to 20 years.[183,185,266]

Thyroid cancer in children can also be observed in families. Familial nonmedullary differentiated thyroid cancer (FNMTC) is diagnosed when three or more individuals in the family have DTC.[267-270] Although studies are under way to identify specific genes leading to cancer risk in FNMTC, specific common molecular signatures have yet to be identified.[271-273] When FNMTC is present, it is recommended that thyroid ultrasonography be performed every year or 2 beginning at 8 years as part of tumor surveillance. DTC in children with FNMTC has been identified in children as young as 8 years of age, and the age of cancer occurrence is generally younger in the second than in the first generation.[274]

Other rare genetic syndromes are associated with thyroid cancer. Cowden syndrome is caused by mutation in the PTEN gene and is a rare autosomal dominant disorder associated with hamartomas of mucosal surfaces and DTC.[275-277] Cancer in Cowden syndrome has been identified in children as young as 8 years.[278] Gardner syndrome (familial colorectal polyposis) is a genetically transmitted, autosomal dominant condition associated with multiple polyps in the colon and other tumors including DTC.[279-281] Gardner syndrome is caused by mutation in the APC gene located on chromosome 5q21.[279,280] Werner syndrome, caused by a mutation in the WRN gene, a DNA helicase, is a very rare autosomal recessive disorder characterized by premature aging.[277] The syndrome is associated with DTC, melanomas, and sarcomas.[277] Certain forms of congenital hypothyroidism, caused by mutations in the TPO gene, can lead to thyroid nodules goiter[282] and rarely DTC.[283] Mutations in the RET protooncogene typically lead to medullary

carcinoma of the thyroid in MEN2a, MEN2b, and isolated familial medullary carcinoma of the thyroid, which are not forms of DTC.[284] (See Chapter 14 for a discussion of MEN syndromes.)

Recognizing that thyroid cancer is rare in children, studies reporting outcomes of more than 100 children are few,[246,285-287] and there are a small number of reports with sample sizes between 25 and 100 patients.[251,253,260,288,289] Outcomes of some of these studies* were recently independently tabulated by Thompson and Luster.[250,253] In general, the following observations about pediatric DTC can be made: (1) about 70% of children present with disease that is metastatic to lymph nodes. (2) About 15% of children present with distant metastatic disease, most commonly to the lungs. In more than 50% of these cases, lung tumors are micrometastases that are not apparent with chest radiographs or computerized tomography (CT) scanning but are apparent with RAI scans.[258] (3) Recurrence rates over 5 to 20 years are as high as 30%. (4) About 10% to 20% of children will have complications related to surgery. (5) A standardized approach to the care of children with DTC is lacking. Some children are routinely treated with RAI, whereas others are not. Some children are treated by lobectomy, and others are treated by total thyroidectomy and central compartment lymph node dissection. Collectively, these studies show that DTC recurrence risk can be reduced by performing total thyroidectomy versus lobectomy, performing compartment lymph node dissection versus selective or no lymph node dissection, and administering RAI.

Surgical Options

The preoperative evaluation of pediatric patients with thyroid disease involves both a general examination to rule out comorbid conditions and a thyroid focused evaluation.[233,234,304] A neck ultrasound using a high-resolution probe (7.5 MHz or higher) should be performed to examine the contralateral thyroid lobe and the central and lateral neck compartments.[305-308] Most children with PTC will have metastatic cervical lymph node disease.[246,256,285,301,309-313] FNA prior to surgery of suspicious lymph nodes should be performed prior to surgery. Ultrasonography may not detect the full of lymph node involvement.[314,315] When further delineation of potential neck disease is needed, imaging using contrast-enhanced CT or magnetic resonance imaging (MRI) may be considered.

The extent of lymph node surgery has been the subject of attention.[316,317] Cancer recurrence most commonly takes place in lymph nodes in the laryngotracheal region.[318] In children and adults, the greater the lymph node involvement in recurrent disease, the greater is the risk of distant metastasis and mortality.[236,250,253-255] Lymph node metastasis is a pervasive component of DTC in children, as up to 90% of children with DTC will have nodal disease. Importantly, in up to 50% of cases, DTC involvement of lymph nodes is not detectable by preoperative ultrasonography.[319,320]

Pediatric data summarized by Thompson and Luster revealed complication rates ranging from 0 to 40% for recurrent laryngeal nerve injury and 0 to 32% for permanent hypoparathyroidism.[250,253] A database analysis of thyroidectomy complications in the United States showed that children aged 0 to 6 years have higher complication rates (22%) than older children (15% for those aged 7 to 12 years and 11% for those aged 13 to17 years).[199] Children had higher endocrine-specific complication rates than adults after thyroidectomy (9.1% versus 6.3%).[199] Importantly, surgical outcome was significantly optimized when surgeries were performed by high-volume surgeons, defined as those performing 30 or more thyroid operations per year.[199] Yet, even when surgery is performed by high-volume thyroid surgeons, complication rates reach 6%.[199]

Recognizing data from children and adults, as such, for children with DTC, we recommend total or near-total thyroidectomy along with central compartment lymph node dissection as part of the initial operation. In addition, lateral compartment dissection with lymph node removal is indicated when lymph node involvement is localized preoperatively by imaging studies or FNA. To minimize the risk of complications, high-volume thyroid surgeons should perform the surgery.

Radioactive Iodine Therapy

Radioactive iodine (RAI, ^{131}I, also referred to as radioiodine) was observed to kill thyroid tumor cells more than 60 years ago.[321,322] Based on available evidence from studies of adults,[233,234,323-335] the following conclusions can be tendered: (1) RAI treatment leads to a reduced risk of recurrence and mortality in patients with DTC with postsurgical residual disease. (2) RAI benefit is clearly demonstrated in adult patients with stage 2 and 3 disease, but not in stage 1. (3) RAI treatment of remnant tissue results in lower rates of DTC recurrence and metastasis. (4) Relatively high cumulative activities of RAI (> 300 mCi; 11 GBq) may be associated with an increased risk of second primary malignancies (SPM). (5) Different approaches have been used to determine activities including empiric dosaging, blood-based upper-limit dosimetry, and tumor dosimetry. (6) RAI efficacy is dependent on factors that include tumor biology and the radiation dose to the tumor. (7) Six decades after the introduction of DTC therapy, RAI use is still under refinement and viewed with controversy.

The overwhelming majority of pediatric patients will have nodal involvement.[246-250,336] In this setting, based on studies showing the potential extent of lymph node spread,[337-339] it must be assumed that there will be residual lymph tissue containing micrometastases following compartment dissection. Lymph node spread is associated with increased mortality and distant metastatic spread,[334,336,340,341] and adjunctive RAI will reduce recurrence risk.[285,286] Thus, RAI is favored in children with DTC.

Administered ^{131}I activities to be applied should range from 100 to 200 mCi (3.7 to 7.4 GBq) in physically mature

*See references 246, 256, 259, 263, 264, 285, and 290-303.

children and may be corrected for body weight 1.35 to 2.7 mCi/kg (50 to 100 MBq/kg) in younger children. New analyses show that treatment with at least 200 MBq/kg (5.4 mCi/kg), and in most patients even much higher activities, is possible without a risk of exceeding bone marrow tolerance limits.[342]

For the uncommon low-risk pediatric patient with microcarcinoma (tumor < 1 cm) and no lymph node involvement, treatment with 30 mCi (1.2 GBq) for the purposes of remnant ablation may be administered and additional courses given if there is Tg persistence. Based on studies in adults,[343-345] about 10% of patients administered ^{131}I for remnant ablation will have biochemical evidence of remaining thyroid tissue and will require retreatment. Alternatively, as suggested,[233] RAI may be withheld for the child with microcarcinoma, and the patient monitored for disease persistence and recurrence via concentrations of Tg and ultrasonography. If Tg levels rise in the absence of gross disease, RAI can be later administered.

Levothyroxine Therapy

It is standard practice to treat thyroid cancer patients with levothyroxine postoperatively, as it is well recognized that TSH suppression can reduce rates of recurrence.[346,347] The optimal degree of TSH suppression is debated in low-risk patients, as it is not clear if complete suppression of TSH secretion confers benefit.

In adults, the long-term impact of supraphysiologic doses of thyroid hormone on bone mineral density and cardiovascular risks is well recognized.[348,349] In children, high levels of thyroid hormones can have effects on growth and profoundly impact on behavior and learning ability.[350] On the other hand, children generally need considerably higher doses of levothyroxine to completely suppress TSH as compared to adults. To date, studies of the effects of treatment resulting in subclinical hyperthyroidism in children treated for DTC have yet to be performed to assess impact.

In adults with low-risk disease, it is recommended to maintain TSH levels in the low normal range (0.5 to 2.5 μU/mL).[351,352] The American Thyroid Association Taskforce recommends more aggressive suppression (TSH 0.1 to 0.5 μU/mL).[234] For high-risk adult patients, TSH values should be suppressed to < 0.1 μU/mL.[234]

One scheme proposed for children is to initially suppress TSH levels to < 0.1 μU/mL and then allow the TSH to rise to 0.5 μU/mL once the patient enters remission.[353] These recommendations seem appropriate for children when one considers that most recurrent DTC develops 5 years after initial treatment.[354]

In pediatrics it is well recognized that medical compliance can be a major problem, especially for teens and young adults, including those with serious medical conditions.[355-358] Although TSH suppression is desirable, clinicians must recognize that TSH-suppression may be difficult to enforce in the pediatric population. As such, TSH-suppressive therapy cannot be practically considered to be a mainstay of therapy, supporting surgical and RAI approaches that minimize recurrence risk in children.

Follow-up

Follow-up care of the child with DTC involves the regular assessment of circulating thyroid hormone levels, ultrasonography of the neck, measurement of Tg, and whole-body radioiodine scans[135,258] (see Figure 12-6).

A very pertinent issue is the criteria used to assess if a patient is disease free. With more sensitive Tg assays, one can aim for an undetectable Tg level as indicative of a disease-free state, rather than a Tg of < 2 μg/L, which had been standard practice. Although an ^{131}I uptake of < 0.1% is considered an indication of being disease free, small metastases or thyroid remnants may be present even with such low uptake values; modern gamma cameras can reliably detect thyroid remnants with an uptake as low as 0.01%.

In general, a follow-up ultrasound and a TSH-suppressed Tg level assessment are performed 6 months after initial therapy, and at least annually thereafter, although following patients every 6 months for at least 5 years after diagnosis may be preferred for patients with more advanced initial or metastatic DTC. TSH-stimulated Tg levels are assessed 6 months after initial therapy, and 6 to 12 months thereafter, based on the suspicion of residual disease. Assessment of T4, T3, and TSH levels is indicated every 6 months and 1 to 2 months after dose changes.[234,359]

Overall, ample evidence suggests that more extensive surgery is associated with lower rates of recurrence.[135] Surgery is associated with clear and definable rates of complications that can be minimized when surgery is performed by high-volume thyroid surgeons. Evidence shows that, properly administered, RAI is associated with lower recurrence rates. Evidence also shows that DTC is associated with an increase secondary primary malignancy (SPM) risk, which reflects intrinsic factors related to having DTC itself. Evidence also suggests that relatively high doses of ^{131}I may contribute to an increased risk of SPM. Thus, the proven benefit of ^{131}I in preventing cancer recurrence and cancer-related deaths needs to be weighed against potential long-term risks. Long-term follow-up for the child with DTC is essential, as disease can recur decades after initial diagnosis and therapy.

MEDULLARY THYROID CARCINOMA

Medullary thyroid carcinoma (MTC) accounts for about 5% of thyroid cancer in children.[360] In comparison with differentiated thyroid cancer, MTC arises from the parafollicular or C cells of the thyroid gland that produce calcitonin.[360] Hereditary forms of MTC account for about 30% of cases and include multiple endocrine neoplasia type 2A (MEN2A), MEN2B, and familial MTC (FMTC).[361] However, most patients with MTC have sporadic disease. MEN 2A includes MTC, pheochromocytomas, and hyperparathyroidism.[362] MEN 2B includes MTC, pheochromocytomas, and multiple mucosal neuromas[362] (Table 12-4). Mucosal neuromas usually have a distinctive appearance, and children with MEN2B may have thick and bumpy lips, a prominent jaw and a marfanoid habitus.[362] FMTC is said to be present when four

TABLE 12-4 **Classification of Hereditary Medullary Thyroid Cancer**

Phenotype	MTC	MN	PCT	HPT
MEN2A	100%	100%	50%	20%
MEN2B	100%	N	50%	N
FMTC	100%	N	N	N

MTC, medullary thyroid carcinoma; MN, mucosal neuromata; PCT, pheochromocytoma; HPT, hyperparathyroidism; N = not present.

or more family members have MTC. In comparison with MEN 2A and 2B, FMTC occurs at later ages, between 20 to 40 years of age.[360]

MTC is caused by autosomal-dominant gain-of-function mutations in the RET protooncogene on chromosome 10.[362] The RET gene includes 21 exons and encodes a plasma membrane–bound tyrosine kinase enzyme.[362] RET is expressed in neuroendocrine and neural cells, including thyroid C cells, adrenal medullary cells, parathyroid cells, and colonic ganglion cells.[362] There are three RET isoforms with 9,43 or 51 distinct amino acids in the intracellular C-terminal tail. These isoforms have different roles in kidney differentiation, in sympathetic neuronal growth and function, and in neuronal signaling.[362] Activating RET mutations may also be associated with short segment Hirschsprung disease, and inactivating RET mutations are associated with congenital megacolon. Activating gain-of-function germline mutations are responsible for FMTC and its variants (see Chapter 14 for a discussion of pheochromocytoma and multiple endocrine neoplasia syndromes).

Numerous mutations of the RET protooncogene have been identified and found to correlate with disease type and tumor aggressiveness.[363,364] Mutation at codon 634 is present in 85% of MEN2A patients, and mutations in codons 609, 611, 618, and 620 in 10% to 15%. A single point mutation at codon 918 of the intracellular tyrosine kinase domain of the RET oncogene is present in 95% of patients with MEN2B. In cases of sporadic MEN2A, MEN2B, and FMTC, new mutations in the RET gene are found in most cases in the paternal allele, and somatic RET mutations are also found in sporadic MTC. These most frequently occur in codon 918, but a variety of mutations, including multiple mutations, have been characterized.[363,364]

Serum calcitonin is the most reliable marker of MTC. In children, calcitonin levels usually do not exceed 20 pg/mL.[365,366] When the compound pentagastrin was available, the pentagastrin test was used to distinguish C-cell hyperplasia from MTC, with stimulated calcitonin concentrations between 30 and 100 pg/mL associated with C-cell hyperplasia and levels in the 100- to 1000-pg/mL associated with microscopic MTC localized to the thyroid gland.[367-369] In contrast, stimulated calcitonin levels greater than 10,000 pg/mL are associated with macroscopic MTC, and 20% of these patients have distant metastases.[367-369] Because pentagastrin is not available, basal levels of calcitonin are used to assess disease.[370,371] The doubling rate of circulating calcitonin levels is also of prognostic significance.[372,373]

Genetic testing of the RET protooncogene is commercially available, and the treatment is based on the mutation present. The goal of mutation analysis is to optimize the timing of surgery so that surgery can be performed before the onset of malignancy. MTC risk based on mutation analysis is divided into three categories called levels 1 through 3, with 3 being highest risk.[362,374-376] For individuals in the highest-risk group (mutated exons 883 or 918 in MEN2B patients), thyroidectomy is recommended before age 6 months (or preferably within the first month of life).[362,374-376] In the case of risk level 2, thyroidectomy before age 5 is indicated. With level 1 mutations, it is recommended that thyroidectomy be performed between 5 and 10 years of age[362,374-376] (Table 12-5). When surgery is performed, it is important that it be performed by a "high-volume" thyroid surgeon.[200,377]

TABLE 12-5 **Laboratory Tests for the Management of MEN2 and FMTC**

Test Name	Patient Preparation	Specimen Requirements
Calcitonin (ICMA), post calcium-pentagastrin stimulation	NPO after midnight; with the patient supine, give 20 mg/kg calcium gluconate (2 mg elemental calcium) intravenously over 1 minute, followed by pentagastrin 0.5 μg/kg as a bolus over 5 seconds; draw blood at 0, 1, 2, 5, and 10 minutes	3 mL frozen serum (red top tube)
Catecholamines	Avoid alcohol, coffee, tea, tobacco, and strenuous exercise prior to specimen collection	—
Plasma		4 mL frozen plasma (green top tube)
Random urine		10 mL refrigerated aliquot of 24-hour urine preserved in 25 mL of 6N HCl; record 24-hour urine volume
Random urine		10 mL refrigerated aliquot of random urine specimen
Calcium, total, serum	Overnight fasting preferred	1 mL refrigerated serum (red top tube)
PTH, intact (ICMA)	None	2 mL refrigerated serum (red top tube) Centrifuge and separate immediately

Before surgery, patients should be screened for pheochromocytomas. Pheochromocytomas in MEN patients are diagnosed after MTC in 90% of patients. Pheochromocytomas in MEN2 patients are typically intra-adrenal and are rare in the first decade of life.[378,379] Screening can be performed by assessment of circulating catecholamine levels or via timed urinary collections.[378,379] Direct visualization of the adrenal gland is also indicated when a tumor is suspected by either CT or MRI methods.[378,379]

Patients should also be screened for hypercalcemia. Parathyroid hyperplasia is associated most commonly with codon 634 mutations and less frequently with codon 609, 611, 618, 620, 790, and 791 mutations. Assessment of circulating PTH concentrations relative to calcium concentration is needed when the diagnosis is considered.

SYNOPSIS

Whereas many thyroid disorders are common in children and adults, the diagnosis and treatment of pediatric thyroid disease require a specialized approach. Clinicians need to recognize that normative thyroid hormone values for adults may not apply to children, especially for TSH values that trend higher for children than adults. Children with autoimmune thyroid disease need individualized treatment to help maximize their growth when they present with growth delay due to hypothyroidism, and they need individually tailored regimens to minimize the risks of therapy when they present with Graves disease. Because of the rarity of thyroid cancer, children need to be cared for in centers with proven expertise in the care of patients with thyroid cancer. We are now in an era where the benefits of personalized medicine are recognized. The opportunity before us is to recognize the nature of the thyroid disorder affecting the child and to best optimize that child's treatment.

QUESTIONS

1. A 12-year-old Hispanic girl presents with a thyroxine level of 19.8 μg/dL, a free T4 level of 2.2 ng/dL, a total T3 level of 125 ng/dL, and a TSH of 1.1 uU/mL. Her mother has been treated for Graves disease. What condition does the patient have?
   a. Graves disease
   b. Thyroid hormone resistance
   c. Subclinical hyperthyroidism
   d. Familial dysalbuminemic hyperthyroxinemia
   e. Thyroid hormone ingestion

Answer: d

2. A 4-year-old girl presents with tachycardia and thyromegaly. The T4 is 12.9 μ/dL, total T3 is 587 ng/dL, and the TSH is 4.7 uU/ml. There is no history of thyroid disease in any family members. What condition does the patient have?
   a. Graves disease
   b. Thyroid hormone resistance
   c. Subclinical hyperthyroidism
   d. Familial dysalbuminemic hyperthyroxinemia
   e. Thyroid hormone ingestion

Answer: b

3. A 16-year-old girl presents with mild thyromegaly, a T4 level of 14 μ/dL, a free T4 level of 3.7 ng/Dl, and a TSH of 0.01 uU/mL What is the likelihood this individual will undergo spontaneous remission of Graves disease after 2 years of antithyroid medication therapy?
   a. 50%
   b. 40%
   c. 30%
   d. 20%
   e. 10%

Answer: d

4. An 8-year-old boy presents with left-sided thyromegaly. A fine-needle aspiration indicates the presence of papillary thyroid carcinoma. A neck ultrasound does not reveal enlarged lymph nodes. What is the most appropriate operation?
   a. Left-hemithyroidectomy
   b. Total thyroidectomy
   c. Total thyroidectomy with central compartment lymph node dissection
   d. Continued observation with serial ultrasound studies

Answer: c

5. A 12-year-old boy presents with hyperthyroidism Graves disease. The child is treated with methimazole for 2 years. What condition is most likely to be associated with this patient?
   a. Excessive weight gain
   b. A 10% risk of celiac disease
   c. A 5% risk of autoimmune hepatitis
   d. Development of antineutrophil cytoplasmic antibodies (ANCA)

Answer: a

6. A 10-year-old girl presents with a total T4 of 10.1 μ/dL, total T3 of 85 ng/dL, a TSH of 6.2 uU/mL, and no antithyroid antibodies are present. What is the most appropriate treatment option?
   a. Treat with low-dose levothyroxine.
   b. Do not treat, but reassess thyroid hormone levels every 6 to 12 months.
   c. Obtain a nuclear medicine scan assess uptake.
   d. Treat with triiodothyronine for thyroid hormone resistance.

Answer: b

CHAPTER 13

Adrenal Cortex and its Disorders

Walter L. Miller, MD • Christa E. Flück, MD

CHAPTER OUTLINE

HISTORY, EMBRYOLOGY, AND ANATOMY

The adrenal cortex produces three principal categories of steroid hormones that regulate a wide variety of physiologic processes from fetal to adult life. *Mineralocorticoids*, principally aldosterone, regulate renal retention of sodium and thus profoundly influence electrolyte balance, intravascular volume, and blood pressure. *Glucocorticoids*, principally cortisol, are named for their carbohydrate-mobilizing activity, but they are ubiquitous physiologic regulators that influence a wide variety of bodily functions. *Adrenal androgens* serve no known physiologic role but do mediate some secondary sexual characteristics in women (e.g., pubic and axillary hair), and their overproduction may result in virilism. Thus, the adrenal cortex is of considerable interest because of the widespread effects of its secretions and because derivatives of these secreted steroids are widely used as pharmacologic agents. Disorders of the adrenal cortex, once thought to be rare, are being recognized with increasing frequency. The severe congenital adrenal hyperplasias affect nearly 1 in 10,000 persons, and the very mild forms may affect as many as 1 in 100 in some

populations. Cushing disease, once regarded as a true rarity in pediatrics, may affect as many children as adults.

History

The history of adrenal research has been reviewed.[1] The adrenal glands apparently were first described in 1563 by the Italian anatomist Bartolomeo Eustaccio, better known for his description of the eustachian tube of the ear. Medical interest in the adrenals as something other than an anatomic curiosity began in the mid-19th century with Addison's classic description of adrenal insufficiency and Brown-Sequard's experimental creation of similar disorders in animals subjected to adrenalectomy. The signs and symptoms of glucocorticoid excess due to adrenal tumors were well known by 1932, when Cushing described the pituitary tumors that cause what is now known as Cushing disease. Effects of adrenalectomy on salt and water metabolism were reported in 1927, and by the late 1930s, Selye had proposed the terms *glucocorticoid* and *mineralocorticoid* to distinguish the two broad categories of actions of adrenal extracts.

Numerous adrenal steroids were painstakingly isolated and their structures determined during the 1930s in the laboratories of Reichstein and Kendall, leading to their sharing the 1950 Nobel Prize in medicine. Many of these steroids were synthesized chemically, providing pure material for experimental purposes. The observation in 1949 that glucocorticoids ameliorated the symptoms of rheumatoid arthritis greatly stimulated interest in synthesizing new pharmacologically active analogs of naturally occurring steroids. The structures of the various adrenal steroids suggested precursor/product relationships, leading in 1950 to the first treatment of congenital adrenal hyperplasia with cortisone by both Wilkins and Bartter. This opened a vigorous era of clinical investigation of the pathways of steroidogenesis in a variety of inherited adrenal and gonadal disorders. The association of cytochrome P450 with 21-hydroxylation was made in 1965, and some of the steroidogenic enzymes were then isolated in the 1970s, but it was not until the genes for most of these enzymes were cloned in the 1980s that it became clear which proteins participated in which steroidal transformations.[2] The identification of these genes (Table 13-1) then led to an understanding of the genetic lesions causing heritable disorders of steroidogenesis. At the same time, studies of steroid hormone action led to the discovery of steroid hormone receptors in the 1960s, but it was not until they were cloned in the 1980s that their biology has begun to be understood.[3]

Embryology

The cells of the adrenal cortex are of mesodermal origin, in contrast to cells of the adrenal medulla, which are derived from the neuroectoderm. In human embryos,

TABLE 13-1 **Physical Characteristics of Human Genes Encoding Steroidogenic Enzymes**

Enzyme	Gene	Gene Size (kb)	Chromosomal Location	Exons (n)	mRNA Size (kb)

adrenogonadal progenitor cells first appear at around the fourth week of gestation as a thickening of the coelomic epithelium (or intermediate mesoderm) between the urogenital ridge and dorsal mesentery[4] (Figure 13-1). These progenitor cells give rise to the steroidogenic cells of the gonads and to the adrenal cortex. The adrenal and gonadal cells then separate, with the adrenal cells migrating retroperitoneally to the cranial pole of the mesonephros and the gonadal cells migrating caudally. Between the seventh and eighth week of development, the adrenal primordium is invaded by sympathetic cells derived from the neural crest that give rise to the adrenal medulla. By the end of the eighth week, the rudimentary adrenal has become encapsulated and is clearly associated with the upper pole of the kidney, which at this time is much smaller than the adrenal.[5]

The fetal adrenal cortex consists of an outer "definitive" zone, the principal site of glucocorticoid and mineralocorticoid synthesis, and a much larger "fetal" zone that makes androgenic precursors (DHEA, DHEAS), which the placenta converts to estriol. A putative "transitional" zone exists between these regions toward the end of fetal development, but its role is unclear. The fetal adrenal glands are huge in proportion to other structures, and continue to grow well into the third trimester (Figure 13-2). At birth, the adrenals weigh 8 to 9 g, about the same size of adult adrenals, and represent approximately 0.4% of total body weight. However, the fetal adrenal zone rapidly involutes following birth and has virtually disappeared by 6 to 12 months of postnatal life. Thereafter, adrenal growth is comparatively slow so that the adrenal glands represent only 0.01% of body weight in the adult.

The complex mechanisms regulating adrenal development are still relatively poorly understood. However, important insight into key factors has been obtained

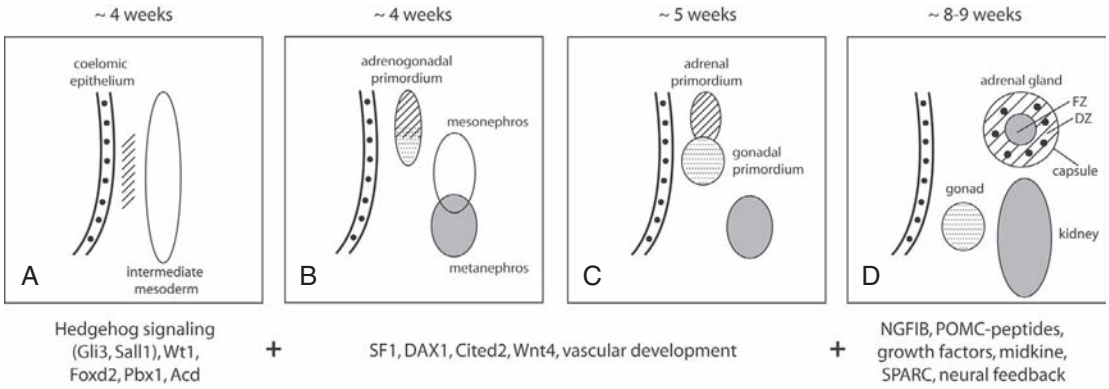

FIGURE 13-1 ■ Overview of human adrenal development. **A-C,** The adrenogonadal primordium develops at around 4 weeks' gestation, after which the adrenal primordium becomes a distinct structure that then migrates retroperitoneally to the cranial pole of the mesonephros. **D,** By 8 to 9 weeks' gestation, the adrenal gland is encapsulated, contains chromaffin cells (black), and has distinct fetal (FZ) and definitive zones (DZ). Some of the signaling molecules, transcription factors and growth factors implicated in adrenal development are shown here, although the exact timing and interaction of many of these factors remains poorly understood at present. from studies of transgenic mice and from patients with disorders of adrenal development.[6] For example, the early stages of adrenal differentiation and development involve a number of signaling pathways (hedgehog/GLI3, WNT3/WNT4/WNT11, midkine), transcription factors (SALL1, FOXD2, PBX1, WT1, SF1 [NR5A1], DAX1 [NR0B1]), co-regulators (CITED2), matrix proteins (SPARC), and regulators of telomerase activity (ACD).[7] Subsequent fetal adrenal growth is highly dependent on the tropic effects of adrenocorticotropin (ACTH), its receptor (MC2R), and its downstream signaling pathways, as well as growth factor signaling pathways such as insulin-like growth factor II (IGFII), basic fibroblast growth factor (bFGF), and epidermal growth factor (EGF).

Anatomy

The adrenals, once termed *suprarenal glands*, derive their name from their anatomic location, sitting on top of the upper pole of each kidney. Unlike most other organs, the arteries and veins serving the adrenal do not run in parallel. Arterial blood is provided by several small arteries arising from the renal and phrenic arteries, the aorta, and sometimes the ovarian and left spermatic arteries. The veins are more conventional, with the left adrenal vein draining into the left renal vein and the right adrenal vein draining directly into the vena cava. Arterial blood enters the sinusoidal circulation of the cortex and drains toward the medulla, so that medullary chromaffin cells are bathed in very high concentrations of steroid hormones. High concentrations of cortisol are required for the expression of medullary phenylethanolamine-N-methyltransferase, which converts norepinephrine to epinephrine, linking the adrenal cortical and medullary responses to stress.[8]

The adrenal cortex consists of three histologically recognizable zones: the *glomerulosa* is immediately below the capsule, the *fasciculata* is in the middle, and the *reticularis* lies next to the medulla. The glomerulosa, fasciculata, and reticularis, respectively, constitute about 15%, 75%, and 10% of the adrenal cortex of the older child and adult. These zones appear to be distinct functionally as well as histologically, but considerable overlap exists, and immunocytochemical data show that the zones physically interdigitate. After birth, the large fetal zone begins to involute and disappears by about 3 to 6 months of age. The definitive zone simultaneously enlarges, but two of the adult zones—glomerulosa and fasciculata—are not fully differentiated until about 3 years of age, and the reticularis may not be fully differentiated until about 15 years of age. The origin of the distinct adrenocortical zones and the mechanisms that regulate their proliferation are still poorly understood. One model suggests that a population of undifferentiated stem cells exists between the zona glomerulosa and zona fasciculata, which represents a pool of common precursor cells that can contribute to either the inner or outer zones. In contrast, the "cell-migration" theory proposes that a subcapsular population of stem cells exists. In this model, precursor cells first differentiate within the zona glomerulosa but change their characteristics as they migrate centripetally into the zona fasciculata then zona reticularis.

STEROID HORMONE SYNTHESIS

Early Steps: Cholesterol Uptake, Storage, and Transport

Much is now known about steroid biosynthesis,[9] and the early steps in the intracellular trafficking of cholesterol have been reviewed.[10] The human adrenal can synthesize cholesterol de novo from acetate, but most of its supply of cholesterol comes from plasma low-density lipoproteins (LDL) derived from dietary cholesterol. Rodent adrenals derive most of their cholesterol from high-density lipoproteins via a receptor termed SR-B1, but this pathway appears to play a minor role in human steroidogenesis. Adequate concentrations of LDL will suppress 3-hydroxy-3-methylglutaryl co-enzyme A (HMG CoA) reductase, the rate-limiting enzyme in cholesterol synthesis. ACTH, which stimulates adrenal steroidogenesis, also stimulates the activity of HMG CoA reductase, LDL receptors, and uptake of LDL cholesterol. LDL cholesterol esters are taken up by receptor-mediated endocytosis, then they are stored directly or converted to free cholesterol and used for steroid hormone synthesis. Cholesterol can be esterified by acyl-CoA:cholesterol transferase (ACAT), stored in lipid droplets, and accessed by activation of hormone-sensitive lipase (HSL) and by the so-called NPC proteins, which derive their name from their causative role in Niemann-Pick type C disease. ACTH stimulates HSL and inhibits ACAT, thus increasing the availability of free cholesterol for steroid hormone synthesis.

Steroidogenic Enzymes

Cytochrome P450

Most steroidogenic enzymes are members of the cytochrome P450 group of oxidases.[9] *Cytochrome P450* is a generic term for a group of oxidative enzymes, all of which have about 500 amino acids and contain a single heme group. They are termed P450 (pigment 450) because all absorb light at 450 nm in their reduced states. It is sometimes stated that certain steroidogenic enzymes are "P450-dependent" enzymes. This is a misnomer, as it implies a generic P450 cofactor to a substrate-specific enzyme; however, the P450 binds the steroidal substrate and achieves its catalysis on an active site associated with the heme group. Human beings have genes for 57 cytochrome P450 enzymes, of which 7 are targeted to mitochondria and 50 are targeted to the endoplasmic reticulum, especially in the liver, where they metabolize countless endogenous and exogenous toxins, drugs, xenobiotics, and environmental pollutants. Each P450 enzyme can metabolize multiple substrates, catalyzing a broad array of oxidations. This theme recurs with each adrenal P450 enzyme.

Five distinct P450 enzymes are involved in adrenal steroidogenesis (Figure 13-3). Mitochondrial P450scc (CYP11A1) is the cholesterol side-chain cleavage enzyme catalyzing the series of reactions formerly termed 20,22 desmolase. Two distinct isozymes of P450c11, P450c11β (CYP11B1) and P450c11AS (CYP11B2), also found in mitochondria, catalyze 11β-hydroxylase, 18-hydroxylase,

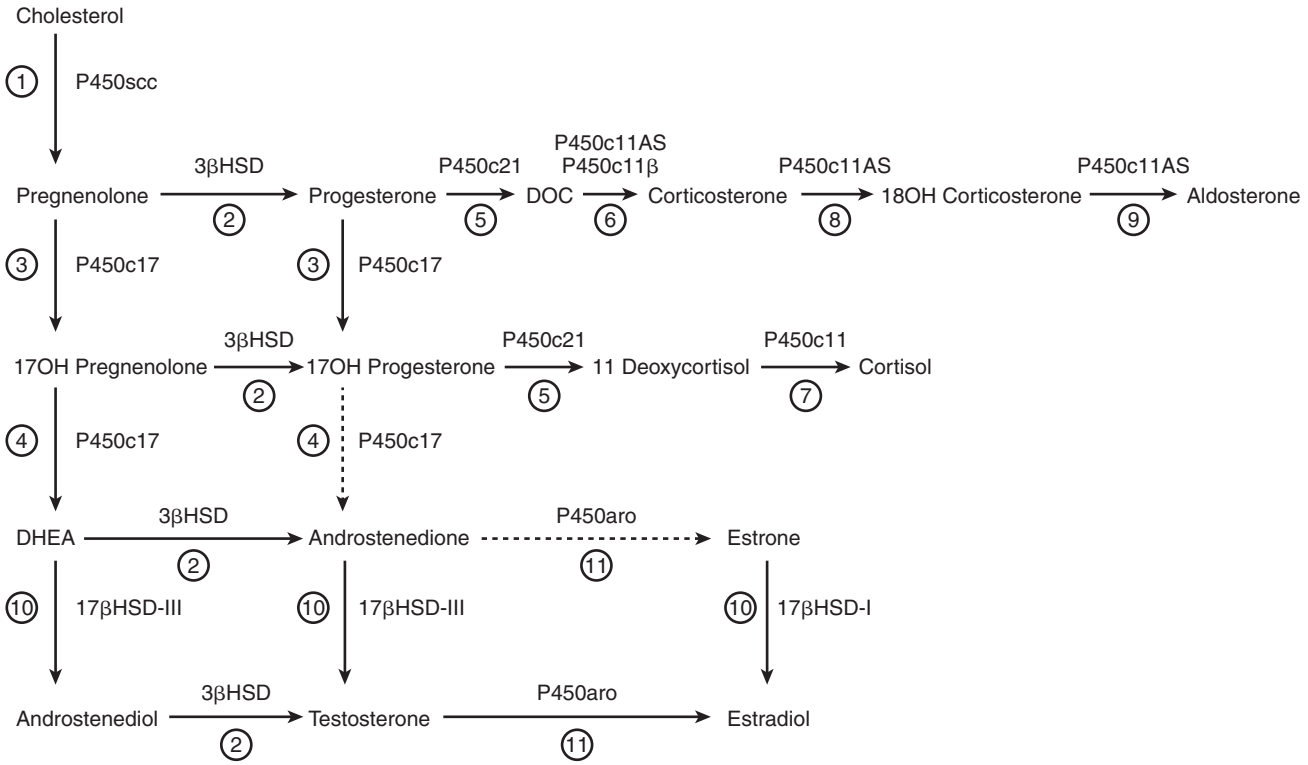

FIGURE 13-3 ■ Principal pathways of human adrenal steroid hormone synthesis. Other quantitatively and physiologically minor steroids are also produced. The names of the enzymes are shown by each reaction, and the traditional names of the enzymatic activities correspond to the *circled numbers.* Reaction 1: Mitochondrial cytochrome P450scc mediates 20α-hydroxylation, 22-hydroxylation, and scission of the C20-22 carbon bond. Reaction 2: 3βHSD mediates 3β-hydroxysteroid dehydrogenase and isomerase activities, converting Δ^5 steroids to Δ^4 steroids. Reaction 3: P450c17 catalyzes the 17α-hydroxylation of pregnenolone to 17OH-pregnenolone and of progesterone to 17OH-progesterone. Reaction 4: The 17,20 lyase activity of P450c17 converts 17OH-pregnenolone to DHEA; only insignificant amounts of 17OH-progesterone are converted to Δ^4 androstenedione by human P450c17, although this reaction occurs in other species. Reaction 5: P450c21 catalyzes the 21-hydroxylation of progesterone to DOC and of 17OH-progesterone to 11-deoxycortisol. Reaction 6: DOC is converted to corticosterone by the 11-hydroxylase activity of P450c11AS in the zona glomerulosa and by P450c11β in the zona fasciculata. Reaction 7: 11-deoxycortisol undergoes 11β-hydroxylation by P450c11β to produce cortisol in the zona fasciculata. Reactions 8 and 9: The 18-hydroxylase and 18-methyl oxidase activities of P450c11AS convert corticosterone to 18OH-corticosterone and aldosterone, respectively, in the zona glomerulosa. Reactions 10 and 11 are found principally in the testes and ovaries. Reaction 10: 17βHSD-III converts DHEA to androstenediol and androstenedione to testosterone, whereas 17βHSD-I converts estrone to estradiol. Reaction 11: Testosterone may be converted to estradiol and androstenedione may be converted to estrone by P450aro.

and 18-methyl oxidase activities. P450c17 (CYP17A1), found in the endoplasmic reticulum, catalyzes both 17α-hydroxylase and 17,20 lyase activities, and P450c21 (CYP21A2) catalyzes the 21-hydroxylation of both glucocorticoids and mineralocorticoids. In the gonads and elsewhere, P450aro (CYP19A1) in the endoplasmic reticulum catalyzes aromatization of androgens to estrogens.

Hydroxysteroid Dehydrogenases

The hydroxysteroid dehydrogenases have molecular masses of about 35 to 45 kilodaltons, do not have heme groups, and require NAD+ or NADP+ as cofactors. Whereas most steroidogenic reactions catalyzed by P450 enzymes are due to the action of a single form of P450, each of the reactions catalyzed by hydroxysteroid dehydrogenases can be catalyzed by at least two, often very different, isozymes. Members of this family include the 3α- and 3β-hydroxysteroid dehydrogenases, the two 11β-hydroxysteroid dehydrogenases, and a series of 17β-hydroxysteroid dehydrogenases; the 5α-reductases are unrelated to this family. Based on their structures, these enzymes fall into two groups: the short-chain dehydrogenase-reductase (SDR) family, characterized by a "Rossman fold," and the aldo-keto reductase (AKR) family, characterized by a triosephosphate isomerase (TIM) barrel motif.[11] The SDR enzymes include 11β-HSDs 1 and 2, and 17β-HSDs 1, 2, 3, and 4; the AKR enzymes include 17β-HSD5, which is important in extraglandular activation of androgenic precursors, and the 3α-hydroxysteroid dehydrogenases that participate in the so-called backdoor pathway of fetal androgen synthesis (discussed later). Based on their activities, it is physiologically more useful to classify them as dehydrogenases or reductases. The dehydrogenases use NAD+ as their cofactor to oxidize hydroxysteroids to ketosteroids, and the reductases mainly use NADPH to reduce ketosteroids to hydroxysteroids. Although these enzymes are typically bidirectional in vitro, they tend to function in only one direction in intact cells, with the direction determined by the cofactor(s) available.[11]

P450scc

Conversion of cholesterol to pregnenolone in mitochondria is the first, rate-limiting, and hormonally regulated step in the synthesis of all steroid hormones.[9,10] This involves three distinct chemical reactions, 20α-hydroxylation, 22-hydroxylation, and scission of the cholesterol side-chain to yield pregnenolone and isocaproic acid. Because 20-hydroxycholesterol, 22-hydroxycholesterol, and 20, 22-hydroxycholesterol could all be isolated from bovine adrenals in significant quantities, it was previously thought that three separate enzymes were involved. However, a single protein, termed P450scc (where SCC refers to the *s*ide *c*hain *c*leavage of cholesterol), encoded by a single gene (*CYP11A1*), on chromosome 15 catalyzes all the steps between cholesterol and pregnenolone. These three reactions occur on a single active site that is in contact with the hydrophobic bilayer membrane. Deletion of the gene for P450scc in the rabbit or mouse eliminates all steroidogenesis, indicating that all steroidogenesis is initiated by this one enzyme.

Transport of Electrons to P450scc: Adrenodoxin Reductase and Adrenodoxin

P450scc functions as the terminal oxidase in a mitochondrial electron transport system.[12] Electrons from NADPH are accepted by a flavoprotein, termed adrenodoxin reductase, that is loosely associated with the inner mitochondrial membrane. Adrenodoxin reductase transfers the electrons to an iron/sulfur protein termed adrenodoxin, which is found in the mitochondrial matrix or loosely adherent to the inner mitochondrial membrane. Adrenodoxin then transfers the electrons to P450scc (Figure 13-4). Adrenodoxin reductase and adrenodoxin serve as generic electron transfer proteins for all mitochondrial P450s, and not just for those involved in steroidogenesis; hence, these proteins are also termed *ferredoxin reductase* and *ferredoxin*. Adrenodoxin forms a 1:1 complex with adrenodoxin reductase, then dissociates, then subsequently reforms an analogous 1:1 complex with a mitochondrial P450 such as P450scc or P450c11, thus functioning as an indiscriminate diffusible electron shuttle mechanism. Adrenodoxin reductase is a membrane-bound mitochondrial flavoprotein that receives electrons from NADPH. The human genes for adrenodoxin reductase and adrenodoxin are expressed in all tissues, indicating they may have other roles. Human mutations in these genes have not been described.

Mitochondrial Cholesterol Uptake: The Steroidogenic Acute Regulatory Protein, StAR

ACTH regulates steroidogenic capacity (chronic regulation) by inducing the transcription of genes for steroidogenic enzymes, but acute regulation, where steroids are released within minutes of a stimulus, is at the level of cholesterol access to P450scc.[13,14] When either steroidogenic cells or intact rats are treated with inhibitors of protein synthesis such as cycloheximide, the acute steroidogenic response is eliminated, suggesting that a short-lived, cycloheximide-sensitive protein acts at the level of the mitochondrion as the specific trigger to the acute steroidogenic response. This factor was first identified as short-lived 30- and 37-kilodalton phosphoproteins that were rapidly synthesized when steroidogenic cells were stimulated with tropic hormones, then cloned from mouse Leydig MA-10 cells and named the steroidogenic acute regulatory protein, StAR.[13,14] The central role of StAR in steroidogenesis was proven by finding that mutations of StAR caused congenital lipoid adrenal hyperplasia.[15,16] Thus, StAR is the acute trigger that is required for the rapid flux of cholesterol from the outer to the inner mitochondrial membrane that is needed for the acute response of aldosterone to angiotensin II, of cortisol to ACTH, and of sex steroids to an LH pulse.

Some adrenal steroidogenesis is independent of StAR; when nonsteroidogenic cells are transfected with StAR

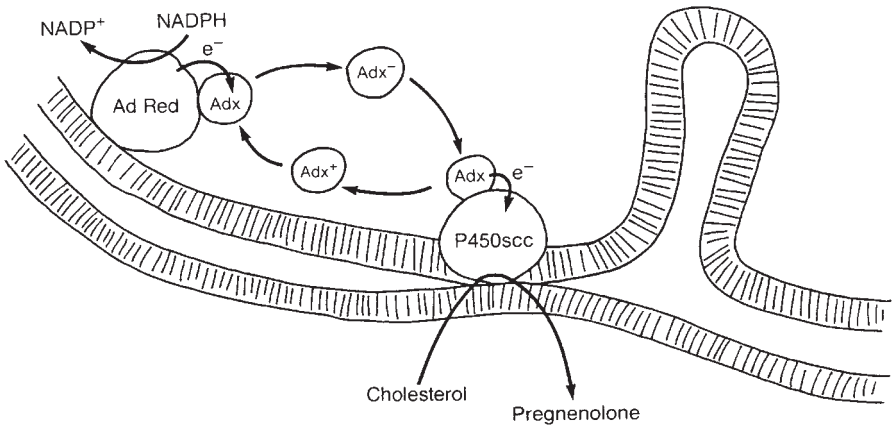

FIGURE 13-4 ■ Electron transport to mitochondrial forms of cytochrome P450. Adrenodoxin reductase (AdRed), a flavoprotein loosely bound to the inner mitochondrial membrane, accepts electrons (e−) from NADPH, converting it to NADP+. These electrons are passed to adrenodoxin (Adx), an iron-sulfur protein in solution in the mitochondrial matrix that functions as a freely diffusible electron shuttle mechanism. Electrons from charged adrenodoxin (Adx−) are accepted by any available cytochrome P450, such as P450c11 or P450scc shown here. The uncharged adrenodoxin (Adx+) may then be again bound to adrenodoxin reductase to receive another pair of electrons. For P450scc, three pairs of electrons must be transported to the P450 to convert cholesterol to pregnenolone. The flow of cholesterol into the mitochondria is facilitated by StAR, which is not shown in this diagram.

and the P450scc system, they convert cholesterol to pregnenolone at about 14% of the StAR-induced rate.[15,16] Furthermore, the placenta utilizes mitochondrial P450scc to initiate steroidogenesis but does not express StAR. The mechanism of StAR-independent steroidogenesis is unclear; it may occur without a triggering protein, or some other protein may exert StAR-like activity to promote cholesterol flux, but without StAR's rapid kinetics. The exact mechanism of StAR's action is unclear, but it is established that StAR acts on the outer mitochondrial membrane, does not need to enter the mitochondria to be active, and undergoes conformational changes on the outer mitochondrial membrane that are required for StAR's activity.[14,17] StAR functions as a component of a molecular machine termed a *transduceosome* on the outer mitochondrial membrane that consists of StAR, TSPO (the translocator protein formerly known as the peripheral benzodiazepine receptor), TSPO-associated protein 7 (PAP7, ACBD3 for acyl-CoA-binding-domain 3), the voltage-dependent anion channel (VDAC-1), and protein kinase A regulatory subunit 1α (PKAR1A).[18] The precise fashion in which these proteins interact and move cholesterol from the OMM to P450scc and the means by which cholesterol is loaded into the OMM remain unclear. It is possible that new disorders of steroidogenesis will be described involving these proteins, but their mutation would be expected to affect many other systems as well.

3β-Hydroxysteroid Dehydrogenase/$\Delta^5 \rightarrow \Delta^4$ Isomerase

Once pregnenolone is produced from cholesterol, it may undergo 17α-hydroxylation by P450c17 to yield 17-hydroxypregnenolone, or it may be converted to progesterone, the first biologically important steroid in the pathway. A single 42-kilodalton microsomal enzyme, 3β-hydroxysteroid dehydrogenase (3βHSD), catalyzes both conversion of the hydroxyl group to a keto group on carbon 3 and the isomerization of the double bond from the B ring (Δ^5 steroids) to the A ring (Δ^4 steroids). [9] Thus, a single enzyme, 3βHSD, converts pregnenolone to progesterone, 17α-hydroxypregnenolone to 17α-hydroxyprogesterone, dehydroepiandrosterone (DHEA) to androstenedione, and androstenediol to testosterone, all with the same enzymologic efficiency (Km and Vmax). As is typical of hydroxysteroid dehydrogenases, there are two isozymes of 3βHSD, encoded by separate genes (*HSD3B1* and *HSD3B2*).[19] These isozymes share 93.5% amino acid sequence identity and are enzymatically very similar. The enzyme catalyzing 3βHSD activity in the adrenals and gonads is the type 2 enzyme, whereas the type 1 enzyme, encoded by a closely linked gene with identical intron/exon organization, catalyzes 3βHSD activity in placenta, breast, and "extraglandular" tissues. Ultrastructural data surprisingly shows that bovine 3βHSD can be found in both the endoplasmic reticulum and in mitochondria. It is not clear if this is also true for human 3βHSD or if this subcellular distribution differs in various types of steroidogenic cells, but this could be a novel point regulating the direction of steroidogenesis.[9]

P450c17

Pregnenolone and progesterone may undergo 17α-hydroxylation to 17α-hydroxypregnenolone and 17α-hydroxyprogesterone (17OHP), respectively. 17OHP may also undergo scission of the C17,20 carbon bond to yield dehydroepiandrosterone (DHEA), but very little 17OHP is converted to androstenedione because the human P450c17 enzyme catalyzes this reaction at only 3% of the rate for conversion of 17α-hydroxypregnenolone to DHEA.[20] These reactions are all mediated by a single enzyme, P450c17 (CYP17A1). This P450 is bound to smooth endoplasmic reticulum, where it accepts electrons from P450 oxidoreductase. As P450c17 has both 17α-hydroxylase activity and 17,20 lyase activity, it is the key branch point in steroid hormone synthesis. Neither activity of P450c17 is present in the adrenal zona glomerulosa, hence pregnenolone is converted to mineralocorticoids; in the zona fasciculata, the 17α-hydroxylase activity is present but 17,20 lyase activity is not, hence pregnenolone is converted to the glucocorticoid cortisol; in the zona reticularis, both activities are present, so that pregnenolone is converted to sex steroids (see Figure 13-3).[9]

17α-Hydroxylase and 17,20 lyase were once thought to be separate enzymes. The adrenals of prepubertal children synthesize ample cortisol but virtually no sex steroids (i.e., have 17α-hydroxylase activity but not 17,20 lyase activity), until adrenarche initiates the production of adrenal androgens (i.e., turns on 17,20 lyase activity). Furthermore, patients had been described lacking 17,20 lyase activity but retaining normal 17α-hydroxylase activity.[21] However, studies of pig P450c17 showed that both 17α-hydroxylase and 17,20 lyase activities reside in a single protein, and cells transfected with a vector expressing P450c17 cDNA acquire both 17α-hydroxylase and 17,20 lyase activities. P450c17 is encoded by a single gene (*CYP17A1*) on chromosome 10q24.3 that is structurally related to the genes for P450c21 (21-hydroxylase).

Thus, the distinction between 17α-hydroxylase and 17,20 lyase is functional and not genetic or structural. Human P450c17 catalyzes 17α-hydroxylation of pregnenolone and progesterone equally well, but the 17,20 lyase activity of human P450c17 strongly prefers 17OH pregnenolone and not 17OH progesterone, consistent with the large amounts of dehydroepiandrosterone (DHEA) secreted by both the fetal and adult adrenal. Furthermore, the 17α-hydroxylase reaction occurs more readily than the 17,20 lyase reaction. The principal factor regulating the 17,20 lyase reaction is electron transport from NADPH.[21]

Electron Transport to P450c17: P450 Oxidoreductase and Cytochrome b_5

P450c17 (and P450c21) receive electrons from a membrane-bound flavoprotein, termed P450 oxidoreductase, which is a different protein from the mitochondrial flavoprotein, adrenodoxin reductase.[12] P450 oxidoreductase receives two electrons from NADPH and transfers them one at a time to the P450. Electron transfer for the lyase reaction is promoted by the action of cytochrome b_5 as an

allosteric factor rather than as an alternate electron donor.[20] 17,20 Lyase activity also requires the phosphorylation of serine residues on P450c17 by a cAMP-dependent protein kinase[21] (Figure 13-5). The availability of electrons determines whether P450c17 performs only 17α-hydroxylation or also performs 17,20 bond scission: increasing the ratio of P450 oxidoreductase or cytochrome b_5 to P450c17 in vitro or in vivo increases the ratio of 17,20 lyase activity to 17α-hydroxylase activity. Competition between P450c17 and P450c21 for available 17-hydroxyprogesterone (17OHP) does not appear to be important in determining whether 17OHP undergoes 21-hydroxylation or 17,20 bond scission. Thus, the regulation of 17,20 lyase activity, and consequently of DHEA production, depends on factors that facilitate the flow of electrons to P450c17: high concentrations of P450 oxidoreductase, the presence of cytochrome b_5, and serine phosphorylation of P450c17.[21]

P450c21

After the synthesis of progesterone and 17-hydroxyprogesterone (17OHP), these steroids are hydroxylated at the 21 position to yield deoxycorticosterone (DOC) and 11-deoxycortisol, respectively[9] (see Figure 13-3). The nature of the 21 hydroxylating step has been of great clinical interest because disordered 21-hydroxylation causes more than 90% of all cases of congenital adrenal hyperplasia. The clinical symptoms associated with this common genetic disease are complex and devastating.[22] Decreased cortisol and aldosterone synthesis often lead to sodium loss, potassium retention, and hypotension, which will lead to cardiovascular collapse and death, usually within a month after birth if not treated appropriately. Decreased synthesis of cortisol in utero leads to overproduction of ACTH and consequent overstimulation of adrenal steroid synthesis; as the 21-hydroxylase step is impaired, 17OHP accumulates because P450c17 converts only miniscule amounts of 17OHP to androstenedione. However, 17-hydroxypregnenolone also accumulates and is converted to DHEA and subsequently to androstenedione and testosterone, resulting in severe prenatal virilization of female fetuses.[22] Congenital adrenal hyperplasia (CAH) has been extensively studied clinically. Variations in the manifestations of the disease, especially the identification of patients without apparent defects in mineralocorticoid activity, suggested that there were two separate 21 hydroxylating enzymes that were differentially expressed in the zones of the adrenal specifically synthesizing aldosterone or cortisol. However, characterization of the P450c21 protein and gene cloning show there is only one 21-hydroxylase encoded by a single functional gene (*CYP21A2*) on chromosome 6p21.[9,23,24] As this gene lies in the middle of the major histocompatibility locus, disorders of adrenal 21-hydroxylation are closely linked to specific HLA types.

Adrenal 21-hydroxylation is mediated by P450c21 found in smooth endoplasmic reticulum. P450c21 employs the same P450 oxidoreductase used by P450c17 to transport electrons from NADPH. 21-hydroxylase activity has also been described in a broad range of adult and fetal extra-adrenal tissues,[25,26] especially in the liver, but is not catalyzed by P450c21.[25] Hepatic 21-hydroxylation is mediated by several enzymes, notably CYP2C19 and CYP3A4, which are principally involved in drug metabolism; these enzymes can 21-hydroxylate progesterone, but not 17OHP, and hence may contribute to the synthesis of mineralocorticoids but not glucocorticoids.[26,27]

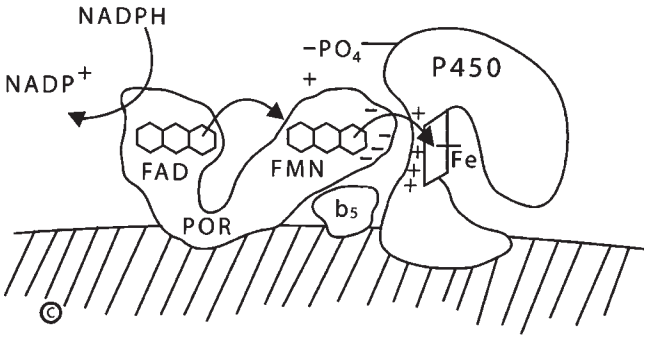

FIGURE 13-5 ■ Electron transport to microsomal forms of cytochrome P450. NADPH interacts with P450 oxidoreductase (POR), bound to the endoplasmic reticulum, and gives up a pair of electrons (e−), which are received by the FAD moiety. Electron receipt elicits a conformational change, permitting the isoalloxazine rings of the FAD and FMN moieties to come close together, so that the electrons pass from the FAD to the FMN. Following another conformational change that returns the protein to its original orientation, the FMN domain of POR interacts with the redox-partner binding site of the P450. Electrons from the FMN domain of POR reach the heme group to mediate catalysis. The interaction of POR and the P450 is coordinated by negatively charged acidic residues on the surface of the FMN domain of POR and positively charged basic residues in the concave redox-partner binding site of the P450. The active site containing the steroid lies on the side of heme ring (Fe) opposite from the redox-partner binding site. In the case of human P450c17, this interaction is facilitated by the allosteric action of cytochrome b_5 and by the serine phosphorylation of P450c17. (Copyright W.L. Miller.)

P450c11β and P450c11AS

Two closely related enzymes, P450c11β and P450c11AS, catalyze the final steps in the synthesis of both glucocorticoids and mineralocorticoids.[9,28,29] These two isozymes have 93% amino acid sequence identity and are encoded by tandemly duplicated genes (*CYP11B1* and *CYP11B2*) on chromosome 8q21-22. Like P450scc, the two forms of P450c11 are found on the inner mitochondrial membrane and use adrenodoxin and adrenodoxin reductase to receive electrons from NADPH. By far the more abundant of the two isozymes is P450c11β, which is the classic 11β-hydroxylase that converts 11-deoxycortisol to cortisol and 11-deoxycorticosterone to corticosterone. The less abundant isozyme, P450c11AS, is found only in the zona glomerulosa, where it has 11β-hydroxylase, 18-hydroxylase, and 18-methyl oxidase (aldosterone synthase) activities; thus, P450c11AS is able to catalyze all the reactions needed to convert DOC to aldosterone.

P450c11β, which is principally involved in the synthesis of cortisol, is encoded by a gene (*CYP11B1*) that is primarily induced by ACTH via cAMP and is suppressed by glucocorticoids. The existence of two distinct functional genes is confirmed by the identification of mutations in each that cause distinct genetic disorders of steroidogenesis. Thus, patients with disorders in P450c11β have classic 11β-hydroxylase deficiency but can still produce

aldosterone, whereas patients with disorders in P450c11AS have rare forms of aldosterone deficiency (so-called corticosterone methyl oxidase deficiency) while retaining the ability to produce cortisol.[9,28,29]

17β-Hydroxysteroid Dehydrogenase

Androstenedione is converted to testosterone, DHEA is converted to androstenediol, and estrone is converted to estradiol by the 17β-hydroxysteroid dehydrogenases (17βHSD; HSD17B), sometimes also termed 17-oxidoreductase or 17-ketosteroid reductase. The terminologies for these enzymes vary, depending on the direction of the reaction being considered.[9,30-32] There is confusion in the literature about the 17βHSDs because (1) there are several different 17βHSDs; (2) some are preferential oxidases whereas others are preferential reductases; (3) they differ in their substrate preference and sites of expression; (4) there is inconsistent nomenclature, especially with the rodent enzymes; and (5) some proteins termed 17βHSD actually have very little 17βHSD activity and are principally involved in other reactions.

Type 1 17βHSD (17βHSD1), also known as estrogenic 17βHSD, is a 34-kilodalton cytosolic reductive SDR enzyme first isolated and cloned from the placenta, where it produces estriol, and is expressed in ovarian granulosa cells, where it produces estradiol.[9,30-32] 17βHSD1 uses NADPH as its cofactor to catalyze reductase activity. It acts as a dimer and only accepts steroid substrates with an aromatic A ring, so that its activity is confined to activating estrogens. The three-dimensional structure of human 17βHSD1 has been determined by x-ray crystallography. No genetic deficiency syndrome for 17βHSD1 has been described.

17βHSD2 is a microsomal oxidase that uses NAD+ to inactivate both estradiol to estrone and testosterone to Δ^4 androstenedione. 17βHSD2 is found in the placenta, liver, small intestine, prostate, secretory endometrium, and ovary. In contrast to 17βHSD1, which is found in placental syncytiotrophoblast cells, 17βHSD2 is expressed in endothelial cells of placental intravillous vessels, consistent with its apparent role in defending the fetal circulation from transplacental passage of maternal estradiol or testosterone.[9,30-32] No deficiency state for 17βHSD2 has been reported.

17βHSD3, the androgenic form of 17βHSD, is a microsomal enzyme that is apparently expressed only in the testis. This is the enzyme that is disordered in the classic syndrome of male pseudohermaphroditism that is often termed 17-ketosteroid reductase deficiency.[9,30-32]

An enzyme termed 17βHSD4 was initially identified as an NAD+-dependent oxidase with activities similar to 17βHSD2, but this peroxisomal protein is primarily an enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase.[9] Deficiency of 17βHSD4 causes a form of Zellweger syndrome, in which bile acid biosynthesis is disturbed but steroidogenesis is not.

17βHSD5, originally cloned as a 3α-hydroxysteroid dehydrogenase, is an AKR enzyme (in contrast to 17βHSD types 1-4, which are SDR enzymes) termed AKR1C3 that catalyzes the reduction of Δ^4 androstenedione to testosterone.[9,33] The 17βHSD activity of 17βHSD5 is quite labile in vitro, and this enzyme catalyzes different activities under different conditions, which has led to confusion in its role in steroidogenesis.[33] The adrenal zona reticularis expresses this enzyme at low levels, accounting for the small amount of testosterone produced by the adrenal.[34]

Steroid Sulfotransferase and Sulfatase

Steroid sulfates may be synthesized directly from cholesterol sulfate or may be formed by sulfation of steroids by cytosolic sulfotransferase (SULT) enzymes.[35,36] At least 44 distinct isoforms of these enzymes have been identified, belonging to five families of SULT genes; many of these genes yield alternately spliced products accounting for the large number of enzymes. The SULT enzymes that sulfonate steroids include SULT1E (estrogens), SULT2A1 (nonaromatic steroids), and SULT2B1 (sterols). SULT2A1 is the principal sulfotransferase expressed in the adrenal, where it sulfates the 3β hydroxyl group of Δ^5 steroids (pregnenolone, 17OH-pregnenolone, DHEA, androsterone) but not of cholesterol. SULT2B1a will also sulfonate pregnenolone but not cholesterol, whereas cholesterol is the principal substrate for SULT2B1b in the skin, liver, and elsewhere. It is not clear whether most steroid sulfates are simply inactivated forms of steroid or if they serve specific hormonal roles. Knockout of the mouse SULT1E1 gene is associated with elevated estrogen levels, increased expression of tissue factor in the placenta, and increased platelet activation, leading to placental thrombi and fetal loss that could be ameliorated by anticoagulant therapy. Mutations ablating the function of human SULT enzymes have not been described, but single nucleotide polymorphisms that alter the amino acid sequences and catalytic activity affecting drug activity are well described. African Americans have a high rate of polymorphisms in SULT2A1 apparently influencing plasma ratios of DHEA:DHEAS, which may correlate with risk of prostatic and other cancers.

To catalyze sulfation, SULT enzymes must receive sulfate in the form of 3'-phosphoadenosine-5'-phosphosulfate (PAPS). The production of PAPS requires PAPS synthase (PAPSS), which first converts ATP and sulfate (SO_4) to adenosine phosphosulfate (APS), and then uses phosphate from another ATP molecule to convert APS to PAPS[36]. There are two human PAPSS genes: *PAPSS1* is expressed ubiquitously, and *PAPSS2* is abundantly expressed in adrenal and liver, where DHEA is sulfated[36]. PAPSS2 deficiency prevents DHEA sulfation so that the adrenal produces more non-sulfated DHEA than normal; this DHEA is converted to excess androgens. Compound heterozygous PAPSS2 deficiency was reported in a 6-year-old girl with premature pubarche and advanced bone age; by age 13 she had acne, hirsutism, and secondary amenorrhea[37]. Her serum concentrations of DHEA were high, DHEAS was very low, and androstendione, testosterone, and DHT were increased. She also had short stature and abnormal bone development, consistent with a role for PAPSS2 in cartilage and bone formation; complete PAPSS2 deficiency causes spondyloepimetaphyseal dysplasia.

Steroid sulfates may also be hydrolyzed to the native steroid-by-steroid sulfatase. Deletions in the steroid sulfatase gene on chromosome Xp22.3 cause X-linked ichthyosis. The fact that males have a single copy of this gene probably accounts for males having higher DHEAS levels than females of the same age. In the fetal adrenal

and placenta, diminished or absent sulfatase deficiency reduces the pool of free DHEA available for placental conversion to estrogen, resulting in low concentrations of estriol in the maternal blood and urine. The accumulation of steroid sulfates in the stratum corneum of the skin causes the ichthyosis.

Aromatase: P450aro

Estrogens are produced by the aromatization of androgens, including adrenal androgens, by a complex series of reactions catalyzed by a single microsomal aromatase, P450aro.[38,39] This typical cytochrome P450 is encoded by a single gene (*CYP19A1*) on chromosome 15q21.1. This gene uses several different promoter sequences, transcriptional start sites, and alternatively chosen first exons to encode aromatase mRNA in different tissues under different hormonal regulation. Aromatase expression in extraglandular tissues, especially adipose tissue, can convert adrenal androgens to estrogens. Aromatase in the epiphyses of growing bone converts testosterone to estradiol. The tall stature, delayed epiphyseal maturation, and osteopenia of males with aromatase deficiency, and their rapid reversal with estrogen replacement indicate that estrogen, not androgen, is responsible for epiphyseal maturation in males. Although it has traditionally been thought that aromatase activity is needed for embryonic and fetal development, infants and adults with genetic disorders in this enzyme have been described, showing that fetoplacental estrogen is not needed for normal fetal development.[39]

5α-Reductase

Testosterone is converted to the more potent androgen, dihydrotestosterone, by 5α-reductase, an enzyme found in testosterone's target tissues. There are two distinct forms of 5α-reductase. The type 1 enzyme, found in the scalp and other peripheral tissues, is encoded by a gene (*SRD5A1*) on chromosome 5; the type 2 enzyme, the predominant form found in male reproductive tissues, is encoded by a structurally related gene (*SRD5A2*) on chromosome 2p23.[40] The syndrome of 5α-reductase deficiency, a disorder of male sexual differentiation, is due to a wide variety of mutations in the gene encoding the type 2 enzyme.[41] The type 1 and 2 genes show an unusual pattern of developmental regulation of expression. The type 1 gene is not expressed in the fetus, then is expressed briefly in the skin of the newborn, and then remains unexpressed until its activity and protein are again found after puberty. The type 2 gene is expressed in fetal genital skin, in the normal prostate, and in prostatic hyperplasia and adenocarcinoma. Thus, the type 1 enzyme may be responsible for the pubertal virilization seen in patients with classic 5α-reductase deficiency, and the type 2 enzyme may be involved in male pattern baldness.[40,41]

11β-Hydroxysteroid Dehydrogenase

Although certain steroids are typically categorized as glucocorticoids or mineralocorticoids, the "mineralocorticoid" (glucocorticoid type 2) receptor has equal affinity for both aldosterone and cortisol. Nevertheless, cortisol does not act as a mineralocorticoid in vivo, even though cortisol concentrations can exceed aldosterone concentrations by 100- to 1000-fold, because mineralocorticoid responsive tissues (such as the kidney) convert cortisol to cortisone, a metabolically inactive steroid. The interconversion of cortisol and cortisone is mediated by two isozymes of 11β-hydroxysteroid dehydrogenase (11βHSD, HSD11B), each of which can catalyze both oxidase and reductase activity, depending on the cofactor available (NADP+ or NADPH).[42-45] The ratio of NADP+ to NADPH is regulated by hexose-6-phosphate dehydrogenase (H6PDH).[46] The type 1 enzyme (11βHSD1; HSD11B1) is expressed mainly in glucocorticoid-responsive tissues such as the liver, testis, lung, and proximal convoluted tubule. 11βHSD1 can catalyze both the oxidation of cortisol to cortisone using NADP+ as its cofactor (K_m 1.6 μM), or the reduction of cortisone to cortisol using NADPH as its cofactor (K_m 0.14 μM); the reaction catalyzed depends on which cofactor is available, but the enzyme can only function with high (micromolar) concentrations of steroid. 11βHSD2 (HSD11B2) catalyzes only the oxidation of cortisol to cortisone using NADH and can function with low (nanomolar) concentrations of steroid (K_m 10 to 100 nM). 11βHSD2 is expressed in mineralocorticoid-responsive tissues and thus serves to "defend" the mineralocorticoid receptor by inactivating cortisol to cortisone, so that only "true" mineralocorticoids, such as aldosterone or deoxycorticosterone, can exert a mineralocorticoid effect. Thus, 11βHSD2 prevents cortisol from overwhelming renal mineralocorticoid receptors, and in the placenta and other fetal tissues 11βHSD2 also inactivates cortisol. The placenta also has abundant NADP+ favoring the oxidative action of 11βHSD1, so that in placenta both enzymes protect the fetus from high maternal concentrations of cortisol, but not from maternally administered betamethasone or dexamethasone. 11βHSD1 is located on the luminal side of the endoplasmic reticulum, and hence is not in contact with the cytoplasm. In this unusual cellular location, 11βHSD1 receives NADPH provided by H6PDH.[44] This links 11βHSD1 to the pentose monophosphate shunt, providing a direct paracrine link between local glucocorticoid production and energy storage as fat.[43-45]

3α-Hydroxysteroid Dehydrogenases

The 3α-hydroxysteroid dehydrogenases (3αHSDs) are not familiar to most endocrinologists, but they are clinically important because of the discovery of the so-called backdoor pathway of steroidogenesis.[47] This remarkable pathway (Figure 13-6), first discovered as the mechanism by which the male marsupial fetal testis makes androgens,[47,48] plays a central role in human male sexual differentiation.[49] In this pathway 17OHP is converted to dihydrotestosterone without going through DHEA, androstenedione, or testosterone, and hence it provides a mechanism for 17OHP to contribute to the virilization of female fetuses with 21-hydroxylase deficiency.[22,50] There are four 3αHSD enzymes, sometimes termed types 1 through 4 but more properly termed AKR1C4-1[31]; the numbering of the 3αHSD nomenclature is reversed in the AKR1C nomenclature, which is confusing and most unfortunate. These enzymes are structurally very similar, are

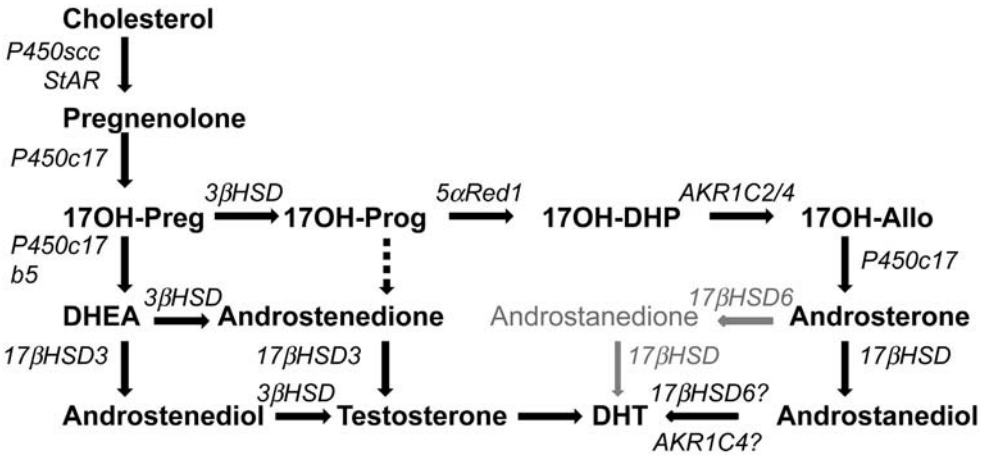

FIGURE 13-6 ■ Pathways to androgens in CAH. In the absence of P450c21 activity, the adrenal can produce androgens by three pathways. First, the pathway from cholesterol to DHEA remains intact in 21-hydroxylase deficiency, and increased production of DHEA will lead to some DHEA being converted to androstenedione and thence to testosterone. Second, although minimal amounts of 17OHP are converted to androstenedione in the normal adrenal, the huge amounts of 17OHP produced in CAH permit some 17OHP to be converted to androstenedione and then to testosterone. Third, the so-called backdoor pathway depends on the 5α and 3α reduction of 17OHP to 17OH-allopregnenolone. This steroid is readily converted to androstanediol, which can then be oxidized to DHT by a 3αHSD enzyme, AKR1C2. Mass spectrometric examinations of human urinary steroids indicate this pathway is a major contributor in CAH.

encoded by a gene cluster on chromosome 10p14-15, and catalyze a wide array of steroidal conversions and other reactions.[9] The backdoor pathway is characterized by both reductive and oxidative 3αHSD activities; the reductive activity can apparently be catalyzed by either AKR1C2 or AKR1C4.[49] The nature of the oxidative activity remains uncertain, but may be catalyzed by retinol dehydrogenase (RoDH).[9] AKR1C3, which converts androstenedione to testosterone in the adrenal, is also known as 17βHSD5. Further studies of the role of the backdoor pathway will be central to pediatric endocrinology.

Fetal Adrenal Steroidogenesis

Adrenocortical steroidogenesis begins early in embryonic life, around 7 weeks after fertilization. Steroidogenic enzymes are immunocytochemically detected principally in the fetal zone at 50 to 52 days postconception, and by 8 weeks postconception the adrenal contains cortisol and responds to ACTH in primary culture systems.[51] This cortisol synthesis is under the regulation of pituitary ACTH and involves transient expression of adrenal 3βHSD2; following the 9th week postconception, expression of 3βHSD2 and synthesis of cortisol wane; 3βHSD2 is barely detectable at 10 to 11 weeks and is absent at 14 weeks. At the same time, the fetal adrenal also produces 17βHSD5,[51] which can convert androstenedione to testosterone. Thus, the fetal adrenal makes cortisol at the same time during gestation that fetal testicular testosterone is virilizing the genitalia of the normal male fetus. This fetal adrenal cortisol apparently suppresses ACTH, which otherwise would drive adrenal testosterone synthesis via 17βHSD5.

Fetuses affected with genetic lesions in adrenal steroidogenesis can produce sufficient adrenal androgen to virilize a female fetus to a nearly male appearance, and this masculinization of the genitalia is complete by the 12th week of gestation. The definitive zone of the fetal adrenal produces steroid hormones according to the pathways in Figure 13-3. By contrast, the large fetal zone of the adrenal is relatively deficient in 3βHSD2 activity after 12 weeks. The fetal adrenal has relatively abundant 17,20 lyase activity of P450c17; low 3βHSD and high 17,20 lyase activity account for the abundant production of dehydroepiandrosterone (DHEA) and its sulfate (DHEAS) by the fetal adrenal, which are converted to estrogens by the placenta (Figure 13-7). The fetal adrenal also has considerable sulfotransferase activity but little steroid sulfatase activity, also favoring conversion of DHEA to DHEAS. The resulting DHEAS cannot be a substrate for adrenal 3βHSD2; instead, it is secreted, 16α-hydroxylated in the fetal liver, and then acted on by placental 3βHSD1, 17βHSD1, and P450aro to produce estriol, or the substrates can bypass the liver to yield estrone and estradiol. Placental estrogens inhibit adrenal 3βHSD activity, providing a feedback system to promote production of DHEAS. Fetal adrenal steroids account for 50% of the estrone and estradiol and 90% of the estriol in the maternal circulation.

Although the fetoplacental unit produces huge amounts of DHEA, DHEAS, and estriol, as well as other steroids, they do not appear to serve an essential role.[52] Successful pregnancy is wholly dependent on placental synthesis of progesterone, which suppresses uterine contractility and prevents spontaneous abortion; however, fetuses with genetic disorders of adrenal and gonadal steroidogenesis develop normally, reach term gestation, and undergo normal parturition and delivery. Mineralocorticoid production is only required postnatally, estrogens are not required, and androgens are only needed for male sexual differentiation. It appears that human fetal glucocorticoids are needed at about 8 to 12 weeks,[51] but it is not clear that they are needed thereafter; if they are, the small amount of maternal cortisol that escapes placental inactivation suffices. A single newborn has been described with profound glucocorticoid resistance who was homozygous for a frameshift mutation at codon

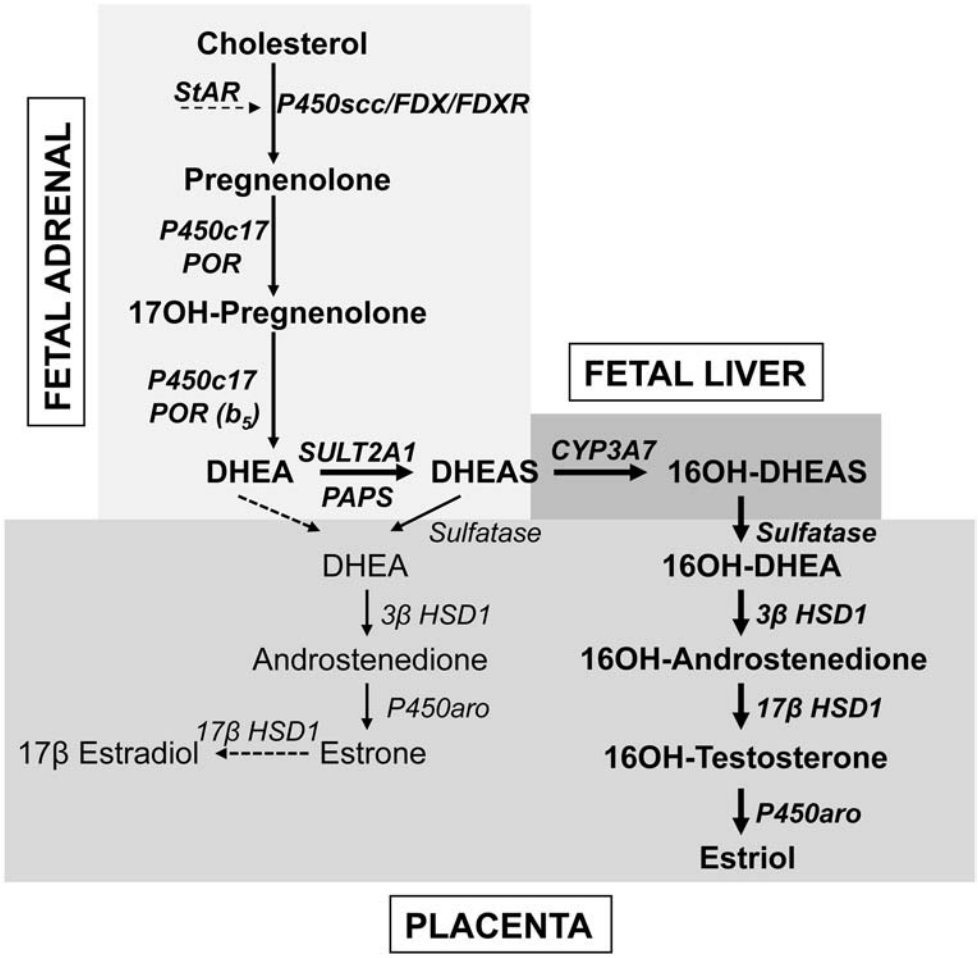

FIGURE 13-7 ■ Steroid synthesis by the fetoplacental system. The fetal adrenal has minimal 3βHSD activity, hence the pathway from cholesterol to DHEA predominates. Most DHEA is converted to DHEAS by the sulfotransferase SULT2A1 and is then 16α-hydroxylated by CYP3A7 in the fetal liver. The 16α-hydroxy DHEAS reaches the placenta, where the sequential action of steroid sulfatase, 3βHSD1, 17βHSD1, and aromatase (P450aro) yield estriol, the principal steroidal product of the placenta. Small amounts of DHEA reach the placenta without being 16α-hydroxylated, where 3βHSD1 and P450aro can convert it to estrone; small amounts of estrone may also be converted to estradiol. About 80% of placental estrogen is estriol, 15% is estrone, and only 5% is estradiol.

772 in the glucocorticoid-binding domain of the glucocorticoid receptor.[53] Although the infant had severe hypoglycemia and hypertension postnatally, pulmonary and other aspects of fetal development were normal, suggesting that glucocorticoid action is not required for normal human fetal development.

The regulation of steroidogenesis and growth of the fetal adrenal are not fully understood, but both are related to ACTH. ACTH effectively stimulates steroidogenesis by fetal adrenal cells in vitro, and excess ACTH is clearly involved in the adrenal growth and overproduction of androgens in fetuses affected with congenital adrenal hyperplasia. Experimental prenatal treatment of such fetuses by administering pharmacologic doses of dexamethasone to the mother at 6 to 10 weeks' gestation can significantly reduce fetal adrenal androgen production and thus reduce the virilization of female fetuses, indicating that the hypothalamic-pituitary-adrenal (HPA) axis functions very early in fetal life.[22] By contrast, anencephalic fetuses lacking pituitary ACTH have adrenals that contain a fairly normal complement of steroidogenic enzymes and retain their capacity for steroidogenesis. Thus, fetal adrenal steroidogenesis may be regulated by both ACTH-dependent and ACTH-independent mechanisms.

REGULATION OF STEROIDOGENESIS

The Hypothalamic-Pituitary-Adrenal Axis

Hypothalamus: CRF and AVP

The principal steroidal product of the human adrenal is cortisol, which is mainly secreted in response to adrenocorticotropic hormone (ACTH, corticotropin) produced in the pituitary; secretion of ACTH is stimulated primarily by corticotropin-releasing factor (CRF) from the hypothalamus. Hypothalamic CRF is a 41-amino-acid peptide synthesized mainly by neurons in the paraventricular nucleus. These same hypothalamic neurons also produce the decapeptide arginine vasopressin (AVP, also known as antidiuretic hormone or ADH).[54] Both CRF and AVP are proteolytically derived from larger precursors with the AVP precursor containing the sequence for neurophysin, which is the AVP-binding protein. CRF

and AVP travel through axons to the median eminence, which releases them into the pituitary portal circulation, although most AVP axons terminate in the posterior pituitary. AVP is co-secreted with CRF in response to stress, and both CRF and AVP stimulate the synthesis and release of ACTH, but they appear to do so by different mechanisms. CRF binds to a G-protein–coupled receptor on the membranes of pituitary corticotropes and activates adenylyl cyclase, increasing cAMP, which activates the protein kinase A (PKA) signaling pathway. PKA triggers ACTH secretion by concerted regulation of cellular potassium and calcium fluxes and enhances POMC gene transcription. AVP binds to its G-protein-coupled receptor and activates phospholipase C, which leads to the release of intracellular Ca++ and to the activation of protein kinase C (PKC). AVP seems to amplify the effects of CRF on ACTH secretion without affecting synthesis. However, CRF is the more important physiologic stimulator of ACTH release, although maximal doses of AVP can elicit a maximal ACTH response. When given together, CRF and AVP act synergistically, as would be expected from their independent mechanisms of action.

Pituitary: ACTH and POMC

Pituitary ACTH is a 39-amino-acid peptide derived from proopiomelanocortin (POMC), a 241-amino-acid protein.[55] POMC undergoes a series of proteolytic cleavages, yielding several biologically active peptides (Figure 13-8). The N-terminal glycopeptide (POMC 1-75) can stimulate steroidogenesis and may function as an adrenal mitogen. POMC 112-150 is ACTH 1-39, POMC 112-126 and POMC 191-207 constitute α- and β-MSH (melanocyte stimulating hormone), respectively, and POMC 210-241 is β-endorphin. POMC is also produced in small amounts by the brain, testis, liver, kidney, and placenta, but this extrapituitary POMC does not contribute significantly to circulating ACTH. Malignant tumors will commonly produce "ectopic ACTH" in adults and rarely in children; this ACTH derives from ectopic biosynthesis of the same POMC precursor. Only the first 20 to 24 amino acids of ACTH are needed for its full biologic activity, and synthetic ACTH 1-24 is widely used in diagnostic tests of adrenal function. However, these shorter forms of ACTH have a shorter half-life than does native ACTH 1-39. POMC gene transcription is stimulated by CRF and inhibited by glucocorticoids.[55]

Actions of ACTH

ACTH stimulates the G-protein–coupled melanocortin 2 receptor (MC2R), which is located almost exclusively in the adrenal cortex. Activation of MC2R triggers the production of cAMP, activating PKA that catalyzes the phosphorylation of many proteins involved in steroidogenesis, thereby modifying their activity. ACTH elicits both acute and long-term effects. ACTH stimulates the biosynthesis of LDL receptors and the uptake of LDL, which provides most of the cholesterol used for steroidogenesis, and stimulates transcription of the gene for HMG-CoA reductase, the rate-limiting step in cholesterol biosynthesis, but adrenal biosynthesis of cholesterol is quantitatively much less important than the uptake of LDL cholesterol.[10] Cholesterol is stored in steroidogenic tissues as cholesterol esters in lipid droplets. ACTH stimulates the activity of cholesterol esterase while inhibiting cholesterol ester synthetase, thus increasing the intracellular pool of free cholesterol, the substrate for P450scc. Finally, ACTH facilitates transport of cholesterol into mitochondria by stimulating the synthesis and phosphorylation of StAR, thus increasing the flow of free cholesterol into the mitochondria.[10] All of these actions are mediated by cAMP and occur within minutes, constituting the "acute" effect of ACTH on steroidogenesis.[14] The adrenal contains relatively modest amounts of steroid hormones; thus, release of preformed cortisol does not contribute significantly to the acute response to ACTH; acute responses occur by the rapid provision of large supplies of cholesterol to mitochondrial P450scc.[10,14]

The long-term "chronic" effects of ACTH are mediated directly at the level of the steroidogenic enzymes. ACTH via cAMP stimulates the accumulation of the

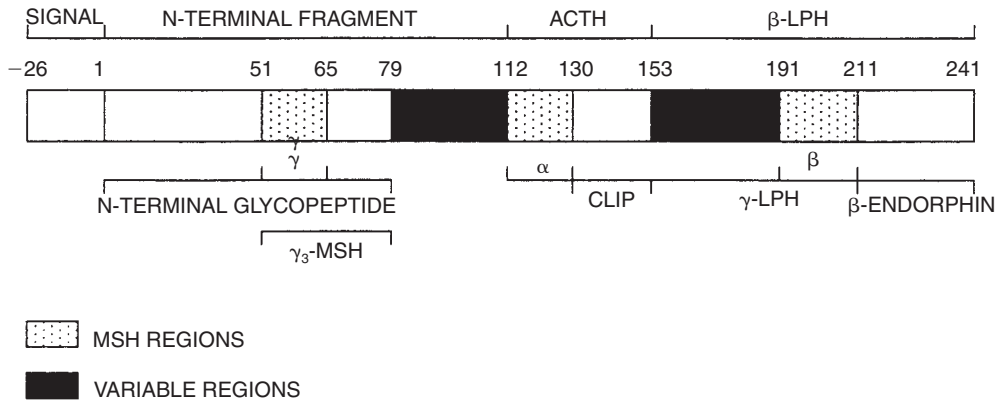

FIGURE 13-8 ■ Structure of human prepro-opiomelanocortin. The numbers refer to amino acid positions, with No. 1 assigned to the first amino acid of POMC after the 26-amino-acid signal peptide. The α-, β-, and γ-MSH regions, which characterize the three "constant" regions, are indicated by stippling; the "variable" regions are *solid.* The amino acid numbers shown refer to the N terminal amino acid of each cleavage site; because these amino acids are removed, the numbers do not correspond exactly with the amino acid numbers of the peptides as used in the text. ACTH, adrenocorticotropic hormone; CLIP, corticotropin-like intermediate lobe peptide; LPH, lipotropic hormone; MSH, melanocyte-stimulating hormone.

steroidogenic enzymes and their mRNAs by stimulating the transcription of their genes.[2,9] ACTH also increases adrenal blood flow, increasing the influx of oxygen and metabolic fuel and the delivery of newly secreted hormones to the circulation.[56] Thus, ACTH increases both the uptake of the cholesterol substrate and its conversion to steroidal products. The stimulation of this steroidogenesis occurs at each step in the pathway, not only at the rate-limiting step, P450scc.

The roles of ACTH and other peptides derived from POMC in stimulating growth of the adult adrenal remain uncertain. However, lack of pituitary POMC causes severe adrenal hypoplasia, and chronic ACTH excess causes adrenal hyperplasia. In the fetal adrenal ACTH stimulates the local production of insulin-like growth factor 2, basic fibroblast growth factor, and epidermal growth factor. These, and possibly other factors work together to mediate ACTH-induced growth of the fetal adrenal.[57]

Diurnal Rhythms of ACTH and Cortisol

Plasma concentrations of ACTH and cortisol tend to be high in the morning and low in the evening. Peak ACTH levels are usually seen at 4 to 6 a.m., and peak cortisol levels follow at about 8 a.m. Both ACTH and cortisol are released episodically in pulses every 30 to 120 minutes throughout the day, but the frequency and amplitude of these pulses are much greater in the morning. The basis of this diurnal rhythm is complex and incompletely understood. The hypothalamic content of CRF itself shows a diurnal rhythm with peak content at about 4 a.m. At least four factors appear to play a role in the rhythm of ACTH and cortisol: intrinsic rhythmicity of synthesis and secretion of CRF by the hypothalamus; light/dark cycles; feeding cycles; and inherent rhythmicity in the adrenal, possibly mediated by adrenal innervation. These factors are clearly interdependent and related. Dietary rhythms may play as large a role as light/dark cycles. Animal experiments show that altering the time of feeding can overcome the ACTH/cortisol periodicity established by a light/dark cycle. In normal human subjects, cortisol is released before lunch and supper, but not at these times in persons eating continuously during the day. Thus, glucocorticoids, which increase blood sugar, appear to be released at times of fasting and are inhibited by feeding.

As all parents know, infants do not have a diurnal rhythm of sleep or feeding. Infants acquire such behavioral rhythms in response to their environment long before they acquire a rhythm of ACTH and cortisol. The diurnal rhythms of ACTH and cortisol begin to be established at 6 to 12 months and often are not well established until after 3 years of age. Once the rhythm is well established in the older child or adult, it is changed only with difficulty. When people move to different parts of the world, their ACTH/cortisol rhythms generally take 15 to 20 days to adjust appropriately.

Physical stress (such as major surgery, severe trauma, blood loss, high fever, or serious illness) can increase the secretion of both ACTH and cortisol, but minor surgery and minor illnesses (such as upper respiratory infections) have little effect on ACTH and cortisol secretion.[58,59] Infection, fever, and pyrogens can stimulate the release of cytokines, such as IL-1 and IL-6, which stimulate secretion of CRH, and also stimulate IL-2 and TNF, which stimulate release of ACTH, providing further stimulus to cortisol secretion during inflammation.[60] Conversely, glucocorticoids inhibit cytokine production in the immune system, providing a negative feedback loop. Most psychoactive drugs, such as anticonvulsants, neurotransmitters, and antidepressants, do not affect the diurnal rhythm of ACTH and cortisol, although cyproheptadine (a serotonin antagonist) effectively suppresses ACTH release.

Adrenal: Glucocorticoid Feedback

The hypothalamic-pituitary-adrenal axis is a classic example of an endocrine feedback system. ACTH increases production of cortisol, and cortisol decreases production of ACTH. Cortisol and other glucocorticoids exert feedback inhibition of both CRF and ACTH (and AVP) principally through the glucocorticoid receptor. Like the acute and chronic phases of the action of ACTH on the adrenal, there are acute and chronic phases of the feedback inhibition of ACTH (and presumably CRF). The acute phase, which occurs within minutes, inhibits release of ACTH (and CRF) from secretory granules. With prolonged exposure, glucocorticoids inhibit ACTH synthesis by directly inhibiting the transcription of the gene for POMC (and AVP). Some evidence also suggests that glucocorticoids can directly inhibit steroidogenesis at the level of the adrenal fasciculata cell itself, but this appears to be a physiologically minor component of the regulation of cortisol secretion.

Mineralocorticoid Secretion: The Renin-Angiotensin System

Renin is a serine protease enzyme synthesized primarily by the juxtaglomerular cells of the kidney, but it is also produced in a variety of other tissues, including the glomerulosa cells of the adrenal cortex. The role of adrenally produced renin is not well established; it appears to maintain basal levels of P450c11AS, but it is not known if angiotensin II is involved in this action. Renin is synthesized as a precursor of 406 amino acids that is cleaved to prorenin (386 amino acids) and finally to the 340-amino acid protein found in plasma.[61] Decreased blood pressure, upright posture, sodium depletion, vasodilatory drugs, kallikrein, opiates, and β-adrenergic stimulation all promote release of renin. Renin enzymatically attacks angiotensinogen, the renin substrate, in the circulation. Angiotensinogen is a highly glycosylated protein and, therefore, has a highly variable molecular weight from 50,000 to 100,000 daltons. Renin proteolytically releases the aminoterminal 10 amino acids of angiotensinogen, referred to as angiotensin I. This decapeptide is biologically inactive until converting enzyme, an enzyme found primarily in the lungs and blood vessels, cleaves off its two carboxyterminal amino acids, to produce an octapeptide, termed angiotensin II. Angiotensin II binds to specific membrane receptors located in the zona glomerulosa of the adrenal cortex to stimulate aldosterone production. Angiotensin converting enzyme can be

inhibited by captopril and related agents; alternatively angiotensin II receptors may be blocked by pharmacologic agents such as irbesartan for the diagnosis and treatment of hyperreninemic hypertension.

Angiotensin II has two principal actions, both of which increase blood pressure. It directly stimulates arteriolar vasoconstriction within a few seconds and it stimulates synthesis and secretion of aldosterone within minutes. Increased plasma potassium is also a powerful and direct stimulator of aldosterone synthesis and release. Aldosterone, secreted by the glomerulosa cells of the adrenal cortex, has the greatest mineralocorticoid activity of all naturally occurring steroids. Aldosterone causes renal sodium retention and potassium loss, with a consequent increase in intravascular volume and blood pressure. Expansion of the blood volume provides the negative feedback signal for regulation of renin and aldosterone secretion. Angiotensin II functions through receptors that stimulate production of phosphatidylinositol, mobilize intracellular and extracellular Ca++, and activate PKC.[62] These intracellular second messengers then stimulate transcription of the P450scc gene by means independent of those employed by ACTH and cAMP. Potassium ion increases uptake of Ca++ with consequent hydrolysis of phosphoinositides to increase phosphatidylinositol. Thus, angiotensin II and potassium work at different levels of the same intracellular second messenger pathway, but these differ fundamentally from the action of ACTH.

Although the renin-angiotensin system is clearly the major regulator of mineralocorticoid secretion, ACTH and possibly other POMC-derived peptides such as γ_3-MSH can also promote secretion of aldosterone when used in high concentrations in animal systems, but the relevance of physiologic concentrations in human beings has not been established. Ammonium ion, hyponatremia, dopamine antagonists, and some other agents can also stimulate secretion of aldosterone, and atrial natriuretic factor is a potent physiologic inhibitor of aldosterone secretion.

Adrenal Androgen Secretion and the Regulation of Adrenarche

DHEA, DHEAS, and androstenedione, which are almost exclusively secreted by the adrenal zona reticularis, are generally referred to as adrenal androgens because they can be peripherally converted to testosterone. However, these steroids have little if any capacity to bind to and activate androgen receptors, hence they are only androgen precursors and not true androgens. The fetal adrenal secretes large amounts of DHEA and DHEAS, and these steroids are abundant in the newborn, but their concentrations fall rapidly as the fetal zone of the adrenal involutes following birth. After the first year of life, the adrenals of young children secrete very small amounts of DHEA, DHEAS, and androstenedione until the onset of adrenarche, usually around age 7 to 8 years, preceding the onset of puberty by about 2 years. Adrenarche is independent of puberty, the gonads, or gonadotropins, and the mechanism by which the onset of adrenarche is triggered remains unknown. The secretion of DHEA and DHEAS continues to increase during and after puberty and reaches maximal values in young adulthood, following which there is a slow, gradual decrease in the secretion of these steroids in the elderly ("adrenopause") (Figure 13-9).[63] Men have higher serum concentrations of DHEAS than women,[63] probably because men have a single copy of the X-linked steroid sulfatase gene.[64] Throughout much of adult life, adrenal secretion of DHEAS exceeds that of cortisol; in adult women, adrenal secretion of androgen precursors and androgens is equal to their secretion from the ovary. Despite the huge increases in the adrenal secretion of DHEA and DHEAS during adrenarche, circulating concentrations of ACTH and cortisol do not change with age. Thus, ACTH plays a permissive role in adrenarche but does not trigger it. Searches for hypothetical polypeptide hormones that might specifically stimulate the zona reticularis have been unsuccessful. Adrenarche is a unique phenomenon confined to few higher primates such as chimpanzees or orangutans, but the significance of adrenarche remains unknown.

Studies of adrenarche have focused on the roles of 3βHSD and P450c17. The abundance of 3βHSD in the zona reticularis appears to decrease with the onset of adrenarche, and the adrenal expression of cytochrome b_5, which fosters the 17,20 lyase activity of P450c17,[20,21] is almost exclusively confined to the zona reticularis; these factors strongly favor the production of DHEA.[65]

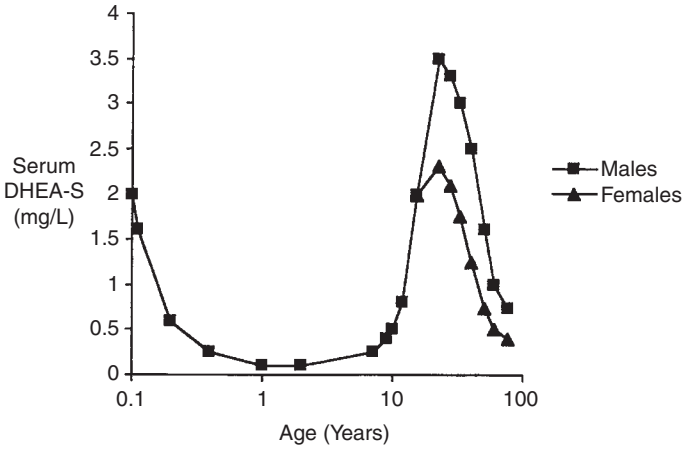

FIGURE 13-9 ■ Concentrations of DHEAS as a function of age. Note that the x-axis is on a log scale.

The phosphorylation of P450c17 also increases 17,20 lyase activity; the responsible kinase has recently been identified as p38α, but its role in adrenarche remains uncertain.[66] Premature and exaggerated adrenarche may be associated with insulin resistance, and girls with premature exaggerated adrenarche appear to be at much higher risk of developing the polycystic ovary syndrome as adults (characterized by hyperandrogenism, fewer ovulatory cycles, insulin resistance, and hypertriglyceridemia). Evidence suggests that infants born small for gestational age may be at increased risk for this syndrome. The suggestion that replacing the DHEA may improve memory and a sense of well-being in the elderly and in adrenal insufficiency remains controversial.[67] Thus, studies of physiology, biochemistry, and clinical correlates of adrenarche are pointing to premature adrenarche as an early sign of a metabolic disorder.

PLASMA STEROIDS AND THEIR DISPOSAL

Structure and Nomenclature

All steroid hormones are derivatives of pregnenolone (Figure 13-10). Pregnenolone and its derivatives that contain 21 carbon atoms are often termed C21 steroids. Each carbon atom is numbered, indicating the location at which the various steroidogenic reactions occur (e.g., 21-hydroxylation, 11-hydroxylation). The 17,20 lyase activity of P450c17 cleaves the bond between carbon atoms 17 and 20, yielding C19 steroids, which include all the androgens; P450aro converts C19 androgens to C18 estrogens. With the exception of estrogens, all steroid hormones have a single unsaturated carbon-carbon double bond. Steroids having this double bond between carbon atoms 4 and 5, including all the principal biologically active steroids, are termed Δ^4 steroids; their precursors having a double bond between carbon atoms 5 and 6 are termed Δ^5 steroids. The two isozymes of 3βHSD convert Δ^5 to Δ^4 steroids.

A rigorous, logically systematic, and unambiguous chemical terminology has been formulated to describe accurately the structure of all the steroid hormones and all their conceivable derivatives. However, this terminology is quite cumbersome (e.g., cortisol is 11β,17α, 21-trihydroxy-pregn-4-ene-3,20-dione, and dexamethasone is 9α-fluoro-11β,17α,21-trihydroxyprena-1,4-diene-3,20-dione). Therefore, we use only the standard "trivial names." Before the structures of the steroid hormones were determined in the 1930s, Reichstein, Kendall, and others identified them as spots on paper chromatograms and designated them A, B, C, and so forth. Unfortunately, some persist in using this outmoded terminology, so that corticosterone is sometimes termed *compound B*, cortisol *compound F*, and 11-deoxycortisol *compound S*. This archaic terminology obfuscates the precursor-product relationships of the steroids, confuses students, and should not be used.

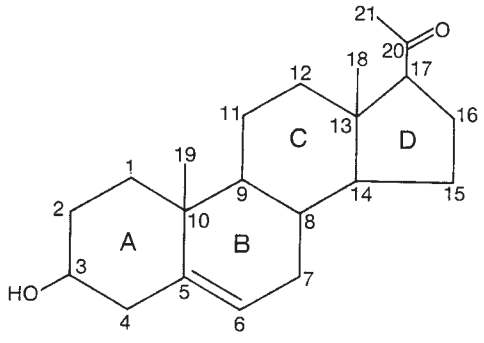

FIGURE 13-10 ■ Structure of pregnenolone. The carbon atoms are indicated by numbers and the rings are designated by letters according to standard convention. Pregnenolone is derived from cholesterol, which has a 6-carbon side chain attached to carbon #21. Pregnenolone is a Δ^5 compound, having a double bond between carbons #5 and 6; the action of 3β-hydroxysteroid dehydrogenase/isomerase moves this double bond from the B ring to carbons #4 and 5 in the A ring, forming Δ^4 compounds. All of the major biologically active steroid hormones are Δ^4 compounds.

Circulating Steroids

Although more than 50 different steroids have been isolated from adrenocortical tissue, the main pathways of adrenal steroidogenesis include only a dozen or so steroids, of which only a few are secreted in sizable quantities. The adult secretions of DHEAS and cortisol are each about 20 mg/24 hours, and the secretion of corticosterone, a weak glucocorticoid, is about 2 mg/24 hours. Although glucocorticoids, such as cortisol, and mineralocorticoids, such as aldosterone, are both needed for life and hence are of "equivalent" physiologic importance, diagrams such as Figure 13-3 fail to indicate that these steroids are not secreted in molar equivalents. The adult secretion rate of aldosterone is only about 0.1 mg/24 hour. This 100- to 1000-fold molar difference in the secretory rates of cortisol and aldosterone must be borne in mind when considering the effects of steroid-binding proteins in plasma and when conceptualizing the physiologic manifestations of incomplete defects in steroidogenesis due to single amino acid changes causing the partial loss of activity of a steroidogenic enzyme.

Most circulating steroids are bound to plasma proteins, including corticosteroid-binding globulin (CBG, also termed transcortin), albumin, and α_1 acid glycoprotein.[68,69] CBG has a very high affinity for cortisol but a relatively low binding capacity, albumin has a low affinity and high capacity, and α_1 acid glycoprotein is intermediate for both variables. The result is that about 90% of circulating cortisol is bound to CBG and a little more is bound to other proteins. These steroid-binding proteins are not transport proteins, as the biologically important steroids are water soluble in physiologically effective concentrations, and absence of CBG does not cause a detectable physiologic disorder. Instead, these plasma proteins act as a reservoir for steroids. This ensures that all peripheral tissues will be bathed in approximately equal concentrations of cortisol, and this greatly diminishes the physiologic effect of the great diurnal variation in cortisol secretion. Most synthetic glucocorticoids used in therapy do not bind significantly to CBG and bind poorly to albumin, partially accounting for their increased potencies, which are also associated with increased receptor-binding affinities. Aldosterone is not bound well by any plasma protein; hence, changes in plasma protein concentration do not affect plasma aldosterone concentrations but greatly influence plasma cortisol

concentrations. Estradiol and testosterone bind strongly to a different plasma protein termed sex steroid-binding globulin and also bind weakly to albumin.

Because steroids are hormones it is often thought that the concentration of "free" (i.e., unbound) circulating steroids determines biologic activity. However, the target tissues for many steroid hormones contain enzymes that modify those steroids. Thus, many actions of testosterone are actually due to dihydrotestosterone produced by local 5α-reductase; cortisol will have differential actions on various tissues due to the presence or absence of the two isozymes of 11βHSD, which can inactivate cortisol to cortisone or reactivate cortisone back to cortisol. Similar peripheral metabolism occurs via "extraglandular" 21-hydroxylase, P450aro, 3βHSD, and 17βHSD. Thus, circulating steroids are both classic hormones and precursors to locally acting autocrine or paracrine factors.

Steroid Catabolism

Only about 1% of circulating plasma cortisol and aldosterone are excreted unchanged in the urine; the liver metabolizes the remainder. A large number of hepatic metabolites of each steroid is produced; most contain additional hydroxyl groups and are linked to a sulfate or glucuronide moiety, rendering them more soluble and readily excretable by the kidney. A great deal is known about the various urinary metabolites of the circulating steroids because their measurement in pooled 24-hour urine samples has been an important means of studying adrenal steroids. The measurement of urinary steroid metabolites by modern mass spectrometric techniques has been a research tool but is beginning to be used by clinical reference laboratories, which will permit increased diagnostic capacities.

CLINICAL AND LABORATORY EVALUATION OF ADRENAL FUNCTION

Clinical Evaluation

Astute clinical evaluation can generally reveal the presence of primary adrenal deficiency or hypersecretion before performing laboratory tests. Thomas Addison described adrenal insufficiency in 1849, long before immunoassays became available. Virtually all patients with chronic adrenal insufficiency will have weakness, fatigue, anorexia, weight loss, hypotension, and hyperpigmentation. Patients with acute adrenal insufficiency may have hypotension, shock, weakness, apathy, confusion, anorexia, nausea, vomiting, dehydration, abdominal or flank pain, hyperthermia, or hypoglycemia. Deficient adrenal androgen secretion will compromise the acquisition of virilizing secondary sexual characteristics (pubic and axillary hair, acne, axillary odor) in female adolescents. Early signs of glucocorticoid excess include increased appetite, weight gain, and growth arrest without a concomitant delay in bone age. Chronic glucocorticoid excess in children results in typical cushingoid facies, but the "buffalo hump" and centripetal distribution of body fat that are characteristic of adult Cushing disease are seen only in long-standing undiagnosed disease. Mineralocorticoid excess is mainly characterized by hypertension, but patients receiving very low sodium diets (e.g., the newborn) will not be hypertensive, as mineralocorticoids increase blood pressure primarily by retaining sodium and thus increasing intravascular volume. Moderate hypersecretion of adrenal androgens is characterized by mild signs of virilization, whereas substantial hypersecretion of adrenal androgens is characterized by accelerated growth with a disproportionate increase in bone age, increased muscle mass, acne, hirsutism, deepening of the voice, and more profound degrees of virilism. A key feature of any physical examination of a virilized male is careful examination and measurement of the testes. Bilaterally enlarged testes suggest true (central) precocious puberty; unilateral testicular enlargement suggests testicular tumor; prepubertal testes in a virilized male indicate an extratesticular source of androgen, such as the adrenal.

Imaging studies are of limited utility in adrenal cortical disease. Computed tomography (CT) will only rarely detect pituitary tumors hypersecreting ACTH, and magnetic resonance imaging (MRI) will detect fewer than half of these, even with gadolinium enhancement. The small size, odd shape, and location near other structures also compromise the use of imaging techniques for the adrenals. Patients with Cushing disease or congenital adrenal hyperplasia will have modestly enlarged adrenals, but such enlargement is not detectable by imaging techniques with any useful degree of certainty. The gross enlargement of the adrenals in congenital lipoid adrenal hyperplasia, their hypoplasia in adrenal hypoplasia congenita or in the hereditary ACTH unresponsiveness syndrome, and many malignant tumors can be usefully diagnosed by imaging studies; however, many adrenal adenomas are too small to be detected. Thus, imaging studies may establish the presence of pituitary or adrenal tumors, but they can never establish their absence.

Laboratory Evaluation

The diagnostic evaluation of adrenal function is essentially chemical. The nonspecificity of many of the clinical signs described previously and the disappointing results with imaging studies remind us that any proper evaluation of hypothalamic-pituitary-adrenal function must rely on a series of carefully performed physiologic maneuvers associated with hormonal assays. The development of highly specific, exquisitely sensitive assays that can be done on small volumes of plasma now permit the direct examination of virtually every hormone involved in adrenal metabolism.

Plasma Concentrations of Cortisol and Other Steroids

Plasma cortisol is measured routinely by a variety of techniques including radioimmunoassay, immunoradiometric assay, and high-pressure liquid chromatography (HPLC). Other procedures, such as fluorimetric assays and competitive protein binding assays, are useful research tools but are not in general clinical use. It is of considerable importance to know what procedure one's laboratory is employing and

precisely what it is measuring. All immunoassays have some degree of cross-reactivity with other steroids. Most cortisol immunoassays will detect both cortisol and cortisone; by contrast, these are readily distinguished by HPLC. As the newborn's plasma contains mainly cortisone rather than cortisol during the first few days of life, a comparison of newborn data obtained by HPLC to published standards obtained by immunoassays may incorrectly suggests adrenal insufficiency. Tables 13-2 and 13-3 summarize the normal plasma concentrations for a variety of steroids. With the notable exception of dehydroepiandrosterone sulfate, most adrenal steroids exhibit a diurnal variation based on the diurnal rhythm of ACTH. Because the stress of illness or hospitalization can increase adrenal steroid secretion and because diurnal rhythms may not be well established in children younger than 3 years of age, it is best

TABLE 13-2 Mean Sex Steroid Concentration in Infants and Children

								T		DHT

2-10 years	As adults	0.3		1.2	0.3→0.8*	8.3
10-15 years	As adults			0.7	0.1→0.6*	3.3
Adults (8 a.m.)	280-550	0.2	12	0.6	0.2→0.4*	2.8→4*
(4 p.m.)	140-280		3.8			

*Two values separated by an arrow indicate those in supine and upright posture.
All values in nmol/L except plasma renin activity (μg/L/s). To convert cortisol to μg/dL, multiply by 0.0363; to convert other values to ng/dL, multiply nmol/L by the following values: corticosterone, 34.7; 18OH corticosterone, 36.2; aldosterone, 36; DOC, 33.1.
DOC, deoxycorticosterone.

to obtain two or more samples for the measurement of any steroid.

As shown in Tables 13-2 and 13-3, data exist for the concentrations of a large number of steroid hormones throughout normal infancy, childhood, and adolescence. Not all endocrine laboratories perform all of these assays, and, depending on the assay procedures employed, various laboratories may have different "normal" values. Most central hospital and commercial laboratories are designed primarily to serve adult, rather than pediatric, patients. Thus, it is important to know whether the available assays will be sufficiently sensitive with small volumes of blood to be useful in measuring pediatric values. This is especially true for the measurement of sex steroids (and gonadotropins), which can exhibit pathologic elevations in children and still remain below the limit of detection of most "adult" assays.

Plasma Renin

Renin (which must not be confused with the digestive enzyme, rennin) is usually assayed by its enzymatic activity, although direct measurements of its concentration are becoming available. Plasma renin activity (PRA) is simply an immunoassay of the amount of angiotensin I generated per milliliter of serum per hour at 37° C. In normal serum, the concentration of both renin and angiotensinogen (the renin substrate) are limiting. Therefore, another test, plasma renin content (PRC), measures the amount of angiotensin I generated in 1 hour at 37° C in the presence of excess concentrations of angiotensinogen.

Plasma renin activity is sensitive to dietary sodium intake, posture, diuretic therapy, activity, and sex steroids. Because PRA values can vary widely with these variables, it is best to measure PRA twice, once in the morning after overnight supine posture and then again after maintenance of upright posture for 4 hours. A simultaneous 24-hour urine for total sodium excretion is generally needed to interpret PRA results. Decreased dietary and urinary sodium, decreased intravascular volume, diuretics, and estrogens will increase PRA. Sodium loading, hyperaldosteronemia, and increased intravascular volume decrease PRA.

The greatest use of renin measurements is in the evaluation of hypertension and in the management of CAH. However, several additional situations require assessment of the renin-angiotensin system. Children with simple virilizing adrenal hyperplasia who do not have clinical evidence of urinary salt wasting (hyponatremia, hyperkalemia, acidosis, hypotension, shock) may nevertheless have increased PRA, especially when dietary sodium is restricted. This was an early clinical sign that this form of 21-hydroxylase deficiency was simply a milder form of the more common, severe, salt-wasting form. Treatment of simple virilizing 21-hydroxylase deficiency with sufficient mineralocorticoid to suppress PRA into the normal range will reduce the child's requirement for glucocorticoids, thus maximizing final adult height. Children with CAH need to have their mineralocorticoid replacement therapy monitored routinely by measuring PRA.[22] Measurement of angiotensin II is also possible in some research laboratories, but most antibodies to angiotensin II strongly cross-react with angiotensin I. Thus, PRA remains the usual way of evaluating the renin-angiotensin-aldosterone system.

Urinary Steroid Excretion

The measurement of 24-hour urinary excretion of steroid metabolites is one of the oldest procedures for assessing adrenal function and still useful. Examination of the total 24-hour excretion of steroids eliminates the fluctuations seen in serum samples as a function of time of day, episodic bursts of ACTH and steroid secretion, and transient stress (such as a visit to the clinic or difficult venipuncture). Collection of a complete 24-hour urinary sample can be quite difficult in the infant or small child. Two consecutive 24-hour collections should be obtained, and each should be assayed for creatinine to monitor the completeness of the collection. Because of the diurnal and episodic nature of steroid secretion, one should never obtain 8- or 12-hour collections and attempt to infer the 24-hour excretory rate from such partial collections.

The analytic procedures for urinary steroid analysis typically rely on a chromatographic procedure for separating steroids followed by a colorimetric, immunologic, or other assay. Failure to employ a chromatographic separation step is the most common source of error. Such classic analyses of urinary steroids are now being replaced by gas chromatography followed by mass spectrometry (GC/MS). Advances in these techniques permit sensitive and specific assays of urinary steroids. However, each secreted steroid is metabolized to multiple forms before being excreted in urine, and this metabolism can vary with age and sex in pediatric populations, so that the analyses are complex and require specialized expertise that is not yet widely available.

Urinary 17-hydroxycorticosteroids (17OHCS), assayed by the colorimetric Porter-Silber reaction, measure 17,21-dihydroxy-20-ketosteroids by the generation of a colored compound after treatment with phenylhydrazine. The reaction is highly specific for the major urinary metabolites of cortisol and cortisone. It will also measure metabolites of 11-deoxycortisol, which will be increased in 11-hydroxylase deficiency or after treatment with metyrapone, a commonly used diagnostic agent (discussed later). Urinary 17OHCS secretion is increased in obesity, hyperthyroidism, and anorexia nervosa; it is decreased in starvation, hypothyroidism, renal failure, liver disease, and pregnancy. Drugs that induce hepatic enzymes, such as phenobarbital, can give low urinary 17OHCS values by stimulating hepatic metabolism of circulating steroids to excreted compounds not detected by the Porter-Silber reaction. Other drugs, including phenothiazines, spironolactone, hydroxyzine, and some antibiotics, can interfere with the colorimetric assay directly, giving falsely elevated values.

Measurement of 17OHCS should be replaced by measurement of urinary free cortisol, thus avoiding the nonspecificity and drug interference problems inherent in 17OHCS. In adults, this test is highly reliable in the diagnosis of Cushing syndrome. Free cortisol is extracted from the urine and measured by immunoassay or HPLC, providing the advantage of specificity. Excretion of urinary free cortisol and of total cortisol metabolites is

closely correlated with age, body surface area, and adiposity, but it is typically 11 ± 5 μg/m²/day.[70,71] Values vary substantially among different reference laboratories, reflecting variations in assay technologies, thus it is essential to utilize a laboratory with good data for normal children. It remains important to measure urinary creatinine to monitor the completeness of the collection.

Urinary 17-ketosteroids (17KS), assayed by the Zimmerman reaction, measure 17-ketosteroids by the generation of a colored compound after treatment with *meta*-dinitrobenzene and acid. The reaction principally measures metabolites of DHEA and DHEA sulfate and thus correlates with adrenal androgen production. Androstenedione will contribute significant 17KS and, if an alkali extraction is not used, estrone will also contribute. The principal androgens, testosterone and dihydrotestosterone, have hydroxyl rather than keto groups on carbon 17; hence, their metabolic products are not measured as 17KS. A wide variety of drugs, including penicillin, nalidixic acid, spironolactone, and phenothiazines, as well as nonspecific urinary chromogens, can spuriously increase values of 17KS. Measurement of urinary 17KS remains a useful, inexpensive screening test, and some clinicians prefer to follow 17KS to monitor therapy of CAH, but measurements of plasma steroids have now replaced the use of urinary 17KS in most centers.

Urinary 17-ketogenic steroids (17KGS) are occasionally confused with urinary 17-ketosteroids because of the similarity of the names; however, 17KGS are used to measure urinary metabolites of glucocorticoids, not sex steroids. Urinary 17KGS are assayed by oxidation of a variety of C-21 steroids to C-19 17-ketosteroids, which are then measured by the Zimmerman reaction as 17KS. All 17OHCS plus a number of other urinary steroids, including the 17KS, are measured, but the basal 17KS values are subtracted out. In addition to all the various problems of specificity and drug interference described earlier for 17OHCS and 17KS, a major disadvantage of 17KGS is that they will also detect pregnanetriol, the principal urinary metabolite of 17-hydroxyprogesterone. This is the steroid that shows the greatest elevations in congenital adrenal hyperplasia. Although some laboratories continue to perform measurements of 17KGS, this obsolete assay no longer has a place in modern pediatric practice.

Plasma ACTH and Other POMC Peptides

Accurate routine immunoassay of plasma ACTH is now available in most centers, but its measurement remains more difficult and variable than the assays for most other pituitary hormones. Handling of the samples must be done with care; samples must be drawn into a plastic syringe containing heparin or ethylenediamine tetraacetic acid (EDTA) and quickly transported in plastic tubes on ice, as ACTH adheres to glass and is quickly inactivated. Thus, elevated plasma ACTH concentrations can be highly informative, but most assays cannot detect low or low-normal values, and such values can be spurious if the samples are handled badly. In adults and older children who have well-established diurnal rhythms of ACTH, normal 8 a.m. values can rarely exceed 50 pg/mL, whereas 8 p.m. values are usually undetectable. Patients with Cushing disease often have normal morning values, but the diagnosis can be suggested by consistently elevated afternoon and evening values; patients with the ectopic ACTH syndrome can have values anywhere from 100 to 1000 pg/mL.

Secretory Rates

The secretory rates of cortisol and aldosterone (or other steroids) can be measured by administering a small dose of tritiated cortisol or aldosterone and measuring the specific activity of one or more known metabolites in a 24-hour urine collection. This procedure permitted measurement of certain steroids, such as aldosterone, before specific immunoassays became available. These procedures have also provided much information about the normal rate of production of various steroids. Based on this procedure most authorities have agreed that children and adults secrete about 6 to 8 mg of cortisol per square meter of body surface area per day.[72,73]

Dexamethasone Suppression Test

Administration of dexamethasone, a potent synthetic glucocorticoid, will suppress secretion of pituitary ACTH and of adrenal cortisol; the dexamethasone suppression test is a very useful procedure for distinguishing whether glucocorticoid excess is due primarily to pituitary disease or adrenal disease. As dexamethasone also suppresses adrenal androgen secretion, this test is useful for distinguishing between adrenal and gonadal sources of sex steroids. A complete, formal dexamethasone suppression test requires the measurement of basal values and those obtained in response to both low- and high-dose dexamethasone. This is described in the section on the evaluation of Cushing syndrome. Variations of this test are commonly used, notably the single 1 mg dose in adults or 0.3 mg/m² in children. This is a useful outpatient screening procedure for distinguishing Cushing syndrome from exogenous obesity. It can be useful for the same purpose in adolescents and older children, but it is otherwise of limited utility in pediatrics. An overnight high-dose dexamethasone suppression test is probably more reliable than the standard 2-day, high-dose test in differentiating adults with Cushing disease from those with the ectopic ACTH syndrome. However, the utility of this test in pediatric patients has not been established.

Stimulation Tests

Direct stimulation of the adrenal with ACTH is a rapid, safe, and easy way to evaluate adrenocortical function. The original ACTH test consisted of a 4- to 6-hour infusion of 0.5 units/kg of ACTH(1-39). This will maximally stimulate adrenal cortisol secretion, and thus effectively distinguishes primary adrenal insufficiency (Addison disease), in which the adrenal is incapable of responding, from secondary adrenal insufficiency due to hypopituitarism. In secondary adrenal insufficiency, some steroidogenic capacity is present, therefore some cortisol is produced in

TABLE 13-4 **Responses of Adrenal Steroids to a 60-Minute ACTH Test**

	Infants		Prepubertal		Pubertal	
	BASAL	STIMULATED	BASAL	STIMULATED	BASAL	STIMULATED
17OH-Pregnenolone	6.8		1.7	9.6	3.6	24
17OHP	0.8	5.8	1.5	5.8	1.8	4.8
DHEA	1.4		2.4	4.3	9.0	19
11-Deoxycortisol	2.3		1.8	5.8	1.7	4.9
Cortisol	280	830	360	830	280	690
DOC	0.6	2.4	0.2	1.7	0.2	1.7
Progesterone	1.1	3.2	1.1	4.0	1.9	4.8

All values are mean values in nmol/L; to convert these values to ng/dL, multiply nmol/L by the following values: 17OH-Pregnenolone, 33.3; 11-deoxycortisol, 34.6; DOC, 33.1 androstenedione, 28.6; DHEA, 28.8; DHT, 29; E_1, 27; E_2, 27.2; Prog, 31.5; 17OHP, 33.1. To convert cortisol to μg/dL, multiply by 0.363.

Data adapted from Endocrine Sciences, Tarzana, California.

response to the ACTH; thus, cortisol secretion is less than normal but greater than the negligible values seen in primary adrenal insufficiency.

The 4- to 6-hour intravenous ACTH test has been replaced in clinical practice by the 60-minute test, wherein a single bolus of ACTH(1-24) is administered intravenously and cortisol and possibly other steroids are measured at 0 and 60 minutes. Normal responses to a 60-minute test are shown in Table 13-4.[74] Synthetic ACTH(1-24) (cosyntropin) is preferred, as it has a more rapid action and shorter half-life than ACTH(1-39). The usual dose is 15 μg/kg in children up to 2 years of age, and 0.25 mg for children older than 2 years and adults. All of these doses are pharmacologic. A very-low-dose (1 μg) test may be useful in assessing adrenal recovery from glucocorticoid suppression. Newer data show that maximal steroidal responses can be achieved after only 30 minutes, but the best available standards are for a 60-minute test. One of the widest uses of intravenous ACTH tests in pediatrics is in diagnosing congenital adrenal hyperplasia (CAH). Stimulating the adrenal with ACTH increases steroidogenesis, resulting in an accumulation of steroids proximal to the disordered enzyme. For example, Figure 13-3 shows that impaired activity of P450c21 (21-hydroxylase) should lead to the accumulation of progesterone and 17-hydroxyprogesterone (17OHP). However, progesterone does not accumulate in appreciable quantities, because it, too, is converted to 17OHP. In routine practice, measuring the response of 17OHP to a 60-minute challenge with intravenous ACTH is the single most powerful and reliable means of diagnosing 21-hydroxylase deficiency; genetic testing can provide a useful confirmation.[22] Comparing the patient's basal to ACTH-stimulated values of 17OHP against those from large numbers of well-studied patients usually permits the discrimination of normal persons, heterozygotes, patients with nonclassic CAH, and patients with classic CAH, although there inevitably is some overlap between groups (Figure 13-11).[22] Measurement of testosterone or Δ^4 androstenedione in response to ACTH can distinguish normal persons from patients with classic CAH, but heterozygotes and patients with cryptic CAH have values overlapping both normals and classic CAH.

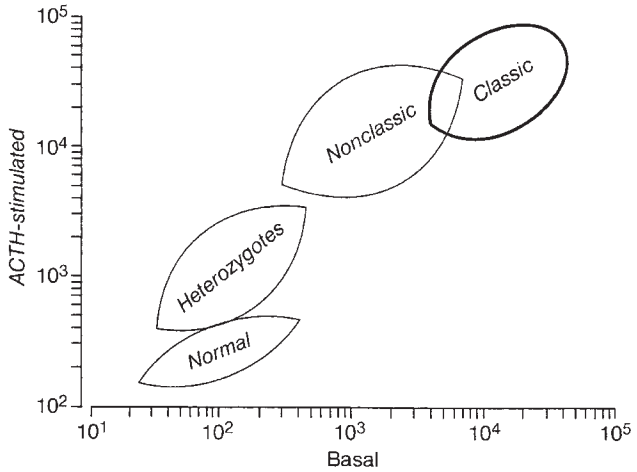

FIGURE 13-11 ■ 17OHP values (in ng/100 mL) before and after stimulation with ACTH in normals, patients with CAH, and heterozygotes.

Longer ACTH tests of up to 3 days have also been employed to evaluate adrenal function. It is important to remember that ACTH has both acute and chronic effects. Thus, short tests measure only the acute effects of ACTH—that is, the maximal stimulation of preexisting steroidogenic machinery. By contrast, a 3-day test will examine the more chronic effects of ACTH to stimulate increased capacity for steroidogenesis by increasing the synthesis of steroidogenic machinery. Few situations exist where a 3-day intramuscular ACTH test is indicated, although it is occasionally useful in diagnosing the rare syndromes of hereditary unresponsiveness to ACTH.[75]

Insulin-induced hypoglycemia is an effective but potentially risky test and hence is now rarely used. Insulin (0.1 U/kg/IV) is administered and blood is obtained at 0, 30, 45, and 60 minutes. The insulin-induced hypoglycemia will stimulate the release of "counter-regulatory" hormones that have actions to increase plasma glucose concentrations: ACTH and cortisol, growth hormone, epinephrine, and glucagon. Because of the inherent risk of convulsions as a result of hypoglycemia, an experienced physician must be in attendance (not merely

"available") throughout the course of the test. Blood glucose must fall to half of the initial value or to 45 mg/dL to achieve an adequate test, and it is wise to terminate the test after this level is reached. Most patients will experience hunger, irritability, diaphoresis, and tachycardia; when these are followed by drowsiness or sleep, blood sugar levels are likely below acceptable limits. If this occurs, a blood sample should be obtained and 2 mL/kg of 20% to 25% glucose given intravenously, to a maximum of 100 mL.

Metyrapone Test

Metyrapone blocks the action of P450c11β and, to a much lesser extent, P450scc. It is thus a chemical means of inducing a transient deficiency of 11-hydroxylase activity, which results in decreased cortisol secretion and subsequent increase in ACTH secretion. Metyrapone testing is done to assess the capacity of the pituitary to produce ACTH in response to a physiologic stimulus. This test is useful in evaluating the hypothalamic-pituitary axis in the presence of central nervous system lesions after neurosurgery or long-term suppression by glucocorticoid therapy.[76] Patients with a previous history of hypothalamic, pituitary, or adrenal disease or those who have been withdrawn from glucocorticoid therapy may be reevaluated with a metyrapone test. A normal response indicates recovery of the HPA axis and predicts that the patient will respond normally to the stress of surgery.

Metyrapone is generally given orally as 300 mg/m^2 every 4 hours for a total of six doses (24 hours). Unlike many other drugs, it is appropriate to continue to increase the dose in older or overweight patients, but the total dose should not exceed 3 g. Blood should be obtained for cortisol, 11-deoxycortisol and ACTH before and after the test, and a 24-hour urine collection should be obtained for 17OHCS before and during the test. In a normal response to metyrapone, cortisol decreases, ACTH increases, and 11-deoxycortisol (the substrate for P450c11β) increases greatly, to about 5 μg/dL. Metabolites of 11-deoxycortisol result in a doubling in urinary 17OHCS excretion. Adults and older children can be tested with the administration of a single oral dose of 30 mg/kg at midnight, given with food to reduce the gastrointestinal irritation. Blood samples are drawn at 8 a.m. the mornings before and after administering the drug.

GENETIC LESIONS IN STEROIDOGENESIS

Autosomal recessive genetic disorders disrupt each of the steps in the pathway shown in Figure 13-3. Most of these result in diminished synthesis of cortisol. In response to adrenal insufficiency, the pituitary synthesizes increased amounts of POMC and ACTH, which promotes increased steroidogenesis; ACTH and possibly other peptides derived from the amino terminal end of POMC also stimulate adrenal hypertrophy and hyperplasia. Thus, the term *congenital adrenal hyperplasia* refers to a group of diseases traditionally grouped together on the basis of the most prominent finding at autopsy.

In theory, the congenital adrenal hyperplasias are easy to understand. A genetic lesion in one of the steroidogenic enzymes interferes with normal steroidogenesis. The signs and symptoms of the disease derive from deficiency of the steroidal end product and the effects of accumulated steroidal precursors proximal to the blocked step. Thus, reference to the pathways shown in Figure 13-3 and knowledge of the biologic effects of each steroid should permit one to deduce the manifestations of the disease.

In practice, the congenital adrenal hyperplasias can be confusing, both clinically and scientifically. The key clinical, laboratory, and therapeutic features of each form of CAH are summarized in Table 13-5. Because each steroidogenic enzyme has multiple activities and many extra-adrenal tissues contain enzymes that have similar activities, the complete elimination of a specific adrenal enzyme may not result in the complete elimination of its steroidal products from the circulation. Furthermore, "partial deficiencies" in which some enzymatic activity remains are now recognized frequently, typically causing disease with later onset and milder clinical manifestations. The cloning of the genes for the steroidogenic enzymes has now permitted the direct study of these diseases, permitting an accurate understanding of their disordered physiology.

Congenital Lipoid Adrenal Hyperplasia

Lipoid CAH is the most severe genetic disorder of steroid hormone synthesis. This disorder is characterized by the absence of significant concentrations of all steroids, high basal ACTH and plasma renin activity, an absent steroidal response to long-term treatment with high doses of ACTH or hCG, and grossly enlarged adrenals laden with cholesterol and cholesterol esters.[77] These findings indicate a lesion in the first step in steroidogenesis—the conversion of cholesterol to pregnenolone. It was initially thought that the lesion was in an enzyme involved in this conversion, and, before the role of P450scc was understood, lipoid CAH was misnamed 20,22-desmolase deficiency. However, the gene for P450scc is normal in these patients, as are the mRNAs for adrenodoxin reductase and adrenodoxin.[77] Furthermore, placental steroidogenesis persists in lipoid CAH, permitting normal term gestation. The normal P450scc system plus the accumulation of cholesterol esters in the affected adrenal suggested that the lesion lay in an upstream factor involved in cholesterol transport into mitochondria. This factor was identified by cell biologic studies, cloned and named the steroidogenic regulatory protein (StAR)[13] and quickly found to be expressed in the adrenal and gonad, but not in the placenta, and then identified as the disordered step in lipoid CAH.[15,16]

Lipoid CAH is a StAR gene knockout experiment of nature, revealing the complex physiology of the StAR protein.[77] StAR promotes steroidogenesis by increasing the movement of cholesterol into mitochondria, but in the absence of StAR steroidogenic cells make steroids at about 14% of the StAR-induced level.[9,10,17] This observation led to the two-hit model of lipoid CAH[16] (Figure 13-12). The first hit is the loss of StAR itself,

TABLE 13-5 **Clinical and Laboratory Findings in the Congenital Adrenal Hyperplasias**

Enzyme Deficiency	Presentation	Laboratory Findings	Therapeutic Measures
Lipoid CAH (StAR or P450scc)	Salt-wasting crisis Male pseudohermaphroditism	Low/absent levels of all steroid hormones Decreased/absent response to ACTH Decreased/absent response to hCG in male pseudohermaphroditism ↑ ACTH and PRA	Glucocorticoid and mineralocorticoid replacement, salt supplementation Estrogen replacement at age > 12 years Gonadectomy of male pseudohermaphrodite and salt supplementation
3β-HSD	Salt-wasting crisis Male and female pseudohermaphroditism	↑ Δ^5 steroids before and after ACTH ↑ Δ^5/Δ^4 serum steroids Suppression of elevated adrenal steroids after glucocorticoid administration ↑ ACTH and PRA	Glucocorticoid and mineralocorticoid replacement Salt supplementation Surgical correction of genitalia Sex hormone replacement as necessary
P450c21	*Classic form:* Salt-wasting crisis Female pseudohermaphroditism Pre- and postnatal virilization *Nonclassic form:* Premature adrenarche, menstrual irregularity, hirsutism, acne, infertility	↑ 17OHP before and after ACTH ↑ Serum androgens and urine 17KS Suppression of elevated adrenal steroids after glucocorticoid Rx ↑ ACTH and PRA	Glucocorticoid and mineralocorticoid replacement Salt supplementation Surgical repair of female pseudohermaphroditism
P450c11β	Female pseudo-hermaphroditism Postnatal virilization in males and females	↑ 11-Deoxycortisol and DOC before and after ACTH ↑ Serum androgens and urine 17KS Suppression of elevated steroids after glucocorticoid administration ↑ ACTH and ↓ PRA Hypokalemia	Glucocorticoid administration Surgical repair of female pseudohermaphroditism
P450c11AS	Failure to thrive Weakness Salt loss	Hyponatremia, hyperkalemia ↑ Corticosterone ↓ Aldosterone ↑ PRA	Mineralocorticoid replacement Salt supplementation
P450c17	Male pseudohermaphroditism Sexual infantilism Hypertension	↑ DOC, 18-OHDOC, corticosterone, 18-hydroxycorticosterone Low 17α-hydroxylated steroids and poor response to ACTH Poor response to hCG in male pseudohermaphroditism Suppression of elevated adrenal steroids after glucocorticoid administration ↑ ACTH and ↓ PRA Hypokalemia	Glucocorticoid administration Surgical correction of genitalia and sex steroid replacement in male pseudohermaphroditism consistent with sex of rearing Estrogen replacement in female at >12 years Testosterone replacement if reared as male (rare)
POR	Male and female pseudohermaphroditism Antley-Bixler syndrome Infertility in adults	↑ ACTH, Prog, 17OHP ↓ DHEA, Andro, T Normal electrolytes	Glucocorticoid and sex steroid replacement Surgical correction of skeletal anomalies

ACTH, adrenocorticotropic hormone (corticotropin); DOC, deoxycorticosterone; hCG, human chorionic gonadotropin; PRA, plasma renin activity; 17OHP, 17-hydroxyprogesterone; 17KS, 17-ketosteroids; 18-OHDOC, 18-hydroxy deoxycorticosterone.

leading to a loss of most, but not all, steroidogenesis, leading to a compensatory rise in ACTH and LH. These hormones increase cellular cAMP, which increases biosynthesis of LDL receptors, their consequent uptake of LDL cholesterol, and de novo synthesis of cholesterol. In the absence of StAR, this increased intracellular cholesterol accumulates as in a storage disease, causing the second hit, which is the mitochondrial and cellular damage caused by the accumulated cholesterol, cholesterol esters, and their auto-oxidation products.[9,10,16]

The two-hit model explains the unusual clinical findings in lipoid CAH. In the fetal testis, which normally makes large amounts of testosterone in fetal life, the Leydig cells are destroyed early in gestation, eliminating testosterone biosynthesis; hence, an affected 46,XY fetus does not undergo normal virilization and is born with female external genitalia and a blind vaginal pouch. However, Wolffian duct derivatives are well developed, indicating the presence of some testosterone synthesis early in fetal life, as predicted by the two-hit model. The undamaged Sertoli cells produce Mullerian inhibitory hormone, so that the phenotypically female 46,XY fetus has no cervix, uterus, or fallopian tubes. The steroidogenically active fetal zone of the adrenal is similarly

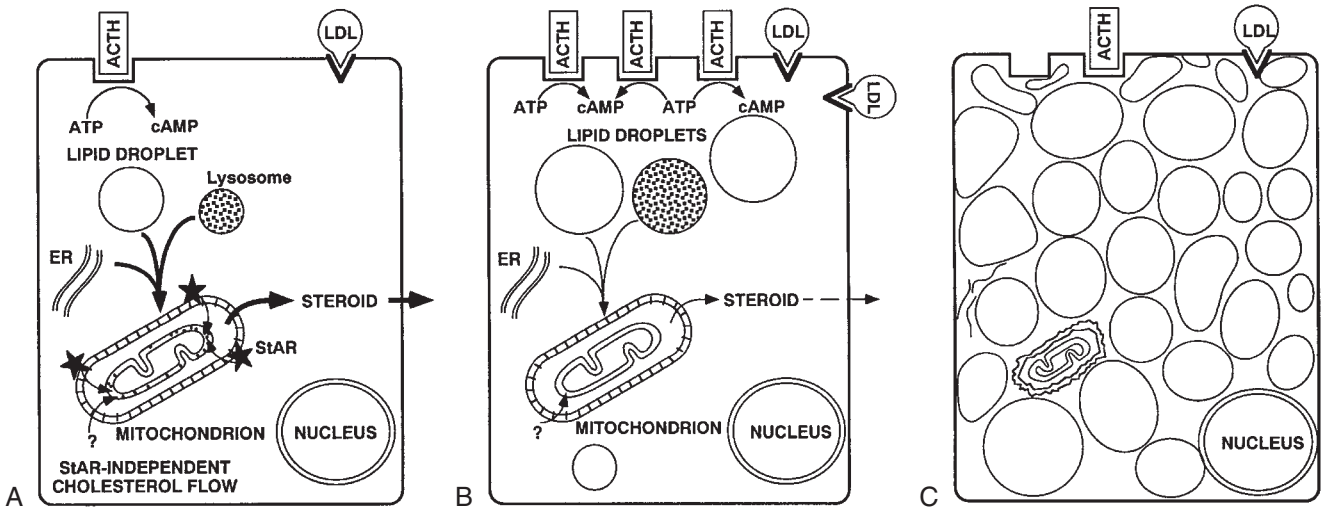

FIGURE 13-12 ■ Two-hit model of lipoid CAH. **A,** In a normal adrenal cell, cholesterol is primarily derived from LDL by receptor-mediated endocytosis and is processed in lysosomes before entering the cellular pool, but cholesterol can also be synthesized de novo from acetyl CoA. Cholesterol from both sources is stored as cholesterol esters in lipid droplets. Cholesterol reaches the mitochondria by poorly defined processes, then travels from the outer to inner mitochondrial membrane by both StAR-dependent and StAR-independent mechanisms. **B,** In early lipoid CAH, the absence of StAR reduces cholesterol flow and steroidogenesis, but some steroidogenesis persists via the StAR-independent pathway. The decreased secretion of cortisol leads to increased ACTH, which stimulates further cholesterol uptake and synthesis; this cholesterol accumulates in lipid droplets. **C,** Accumulating lipid droplets damage the cell, both through physical disruption of cytoarchitecture and by the chemical action of auto-oxidation products, eventually destroying all steroidogenic capacity. In the ovary, follicular cells remain unstimulated and undamaged until they are recruited at the beginning of each cycle. They can then produce small amounts of estradiol, as in panel **B,** leading to feminization and anovulatory cycles in affected females.

affected, eliminating most DHEA biosynthesis, and hence eliminating the fetoplacental production of estriol, so that midgestation maternal and fetal estriol levels are very low. The definitive zone of the fetal adrenal, which differentiates into the zonae glomerulosa and fasciculata, normally produces very little aldosterone, and as fetal salt and water metabolism are maintained by the placenta, stimulation of the glomerulosa by angiotensin II generally does not begin until birth. Consistent with this, many newborns with lipoid CAH do not have a salt-wasting crisis until after several weeks of life, when chronic stimulation then leads to cellular damage.[16,78]

The two-hit model also explains the spontaneous feminization of affected 46,XX females who are treated in infancy and reach adolescence.[9,10,16,79,80] The fetal ovary makes little or no steroids and contains no steroidogenic enzymes after the first trimester; consequently the ovary remains largely undamaged until it is stimulated by gonadotropins at the time of puberty, when it then produces some estrogen by StAR-independent steroidogenesis. Continued stimulation results in cholesterol accumulation and cellular damage, so that biosynthesis of progesterone in the latter part of the cycle is impaired. Because gonadotropin stimulation only recruits individual follicles and does not promote steroidogenesis in the whole ovary, most follicles remain undamaged and available for future cycles. Cyclicity is determined by the hypothalamic-pituitary axis and remains normal. With each new cycle, a new follicle is recruited and more estradiol is produced by StAR-independent steroidogenesis. Although net ovarian steroidogenesis is impaired, enough estrogen is produced (especially in the absence of androgens) to induce breast development, general feminization, monthly estrogen withdrawal, and cyclic vaginal bleeding.[16,79] However, progesterone synthesis in the latter half of the cycle is disturbed by the accumulating cholesterol esters so that the cycles are anovulatory. Measurements of estradiol, progesterone, and gonadotropins throughout the cycle in affected adult females with lipoid CAH confirm this model.[80] Similarly, examination of StAR-knockout mice confirms the two-hit model. Thus, examination of patients with lipoid CAH has elucidated the physiology of the StAR protein in each steroidogenic tissue.

Genetic analysis of patients with lipoid CAH has revealed numerous mutations in the StAR gene.[9,10] Lipoid CAH is common in Japan, and about 65% to 70% of affected Japanese alleles and virtually all affected Korean alleles carry the mutation Q258X. The carrier frequency for this mutation appears to be about 1 in 300 so that 1 in every 250,000 to 300,000 newborns in these countries is affected, for a total of about 500 patients in Japan and Korea. Other genetic clusters are found among Palestinian Arabs, most of whom carry the mutation R182L; in eastern Saudi Arabia, carrying R188C; and in Switzerland, carrying the mutation L260P. Deletion of only 10 carboxyterminal residues reduces StAR activity by half, and deletion of 28 carboxyterminal residues by the common Q258X mutation eliminates all activity. By contrast, deletion of the first 62 aminoterminal residues has no effect on StAR activity, even though this deletes the entire mitochondrial leader sequence and forces StAR to remain in the cytoplasm. Physical studies and partial proteolysis indicate that residues 63-193 of StAR (i.e., the domain that lacks most of the crucial residues identified by missense mutations) are protease-resistant and constitute a "pause-transfer" sequence, which permits

the bioactive loosely folded carboxyterminal molten globule domain to have increased interaction with the outer mitochondrial membrane.

The clinical findings in most patients with lipoid CAH are quite similar: an infant with normal-appearing female genitalia experiences failure to thrive and salt loss in the first weeks of life.[9,10,16,77] However, studies have revealed other clinical presentations, including apparent sudden infant death syndrome (SIDS) and late initial presentation of salt loss at about 1 year of age. An attenuated disease caused by mutations that retain about 20% to 25% of normal StAR activity has been described and is called "nonclassic lipoid CAH."[81] Those affected are usually children who first experience symptoms of adrenal insufficiency after several years, and the 46,XY patients have normal-appearing male external genitalia. Some patients have been diagnosed in adulthood and have been mistaken for having "familial glucocorticoid deficiency," a blanket term referring to disorders of ACTH action; most of these patients carry the R188C mutation in StAR.[82,83] Thus, the spectrum of clinical presentation of congenital lipoid adrenal hyperplasia is substantially broader than initially appreciated.

Treatment of lipoid CAH is straightforward if the diagnosis is made. Physiologic replacement with glucocorticoids, mineralocorticoids, and salt will permit survival to adulthood. The glucocorticoid requirement is less than in the virilizing adrenal hyperplasias because it is not necessary to oversuppress excess adrenal androgen production, so that growth in these patients should be normal. Severely affected 46,XY newborns have normal female external genitalia and may be advised to undergo orchiectomy later in life and be raised as females with sex hormone replacement therapy started at age of puberty. Affected 46,XX females typically have spontaneous pubertal feminization but anovulatory cycles and early secondary amenorrhea; they therefore also require sex hormone replacement therapy.

Disorders Resembling Lipoid CAH: P450scc Deficiency and SF1 Deficiency

Mutations in other genes can produce a clinical phenotype that is essentially indistinguishable from that caused by StAR mutations, but these disorders should not be called congenital lipoid adrenal hyperplasia. Beginning in 2001, several patients have been described with mutations in P450scc.[84] Their clinical and hormonal findings are indistinguishable from those with StAR mutations; however, to date no patient with a P450scc mutation has had the adrenal hyperplasia typically seen in lipoid CAH.[84,85] It would seem logical that elimination of all P450scc activity would be incompatible with term gestation, as the placenta, a fetal tissue, must produce progesterone in the second half of pregnancy to suppress maternal uterine contractions, thus preventing miscarriage. It is most likely that these few fetuses with P450scc mutations reached term gestation because of unusually protracted maintenance of the maternal corpus luteum of pregnancy, which normally involutes in the second trimester, but this has not been investigated directly. Nonclassic P450scc deficiency that is clinically and hormonally indistinguishable from nonclassic lipoid CAH has been reported in patients with P450scc mutations that retain 10% to 20% of wild-type activity.[86,87]

More than 50 patients have also been described carrying mutations in the gene for steroidogenic factor 1 (SF1), a transcription factor required for adrenal and gonadal, but not for placental, expression of genes for the steroidogenic enzymes.[88,89] There is broad phenotypic variability in SF1-deficient patients; some are 46,XY with a female phenotype and adrenal failure, thus resembling lipoid CAH, but in most cases the gonadal phenotype predominates and there is little if any impairment of adrenal steroidogenesis. SF1 mutations may be found in about 10% of 46,XY patients who have disordered sexual development. The Leydig cells may have lipid accumulation and progressive degeneration, similar to the findings in lipoid CAH.[89]

3β-Hydroxysteroid Dehydrogenase Deficiency

3βHSD deficiency is a rare cause of glucocorticoid and mineralocorticoid deficiency that is fatal if not diagnosed early in infancy. In its classic form, genetic females have clitoromegaly and mild virilization because the fetal adrenal overproduces large amounts of DHEA, a small portion of which is converted to testosterone by extra-adrenal 3βHSD1 and other enzymes. Genetic males also synthesize some androgens by peripheral conversion of adrenal and testicular DHEA, but the concentrations are insufficient for complete male genital development, so that these males have a small phallus and severe hypospadias.

There are two functional human genes for 3βHSD: the type 1 gene (*HSD3B1*) is expressed in the placenta and peripheral tissues, and the type 2 gene (*HSD3B2*) is expressed in the adrenals and gonads.[9] Genetic and endocrine studies of 3βHSD deficiency show that both the gonads and the adrenals are affected as a result of a single mutated 3βHSD2 gene that is expressed in both tissues. However, hepatic 3βHSD1 activity persists in the face of complete absence of adrenal and gonadal 3βHSD2 activity, thus complicating the diagnosis. Genetic studies have identified numerous mutations causing 3βHSD deficiency, all found in the type 2 gene.[90] Mutations have never been found in 3βHSD1, presumably because this would prevent placental biosynthesis of progesterone, resulting in a spontaneous first-trimester abortion.

The presence of peripheral 3βHSD activity complicates the hormonal diagnosis of this disease. One would expect that affected infants should have low concentrations of 17OHP, yet some newborns with 3βHSD deficiency have very high concentrations of serum 17OHP, approaching those seen in patients with classic 21-hydroxylase deficiency.[91] The high 17OHP concentrations are due to extra-adrenal 3βHSD1. The adrenal of a patient with 3βHSD2 deficiency will secrete very large amounts of three principal Δ^5 steroids, pregnenolone, 17-hydroxypregnenolone, and DHEA. Some of the secreted 17-hydroxypregnenolone is then converted to 17OHP by 3βHSD1. This 17OHP is not effectively picked up by the adrenal for subsequent conversion to cortisol because the circulating concentrations are

below the Michaelis constant (K_m) of P450c21 (1 μM 17OHP, or about 40,000 ng/dL). The ratio of the Δ^5 to the Δ^4 compounds remains high, consistent with the adrenal and gonadal deficiency of 3βHSD.[91] Thus, the principal diagnostic test in 3βHSD deficiency is intravenous administration of ACTH with measurement of the three Δ^5 compounds and the corresponding Δ^4 compounds. Unlike the case of 21-hydroxylase deficiency, where heterozygotes can be diagnosed by the response of 17OHP to ACTH, steroidal responses to ACTH cannot be used to identify carriers of 3βHSD deficiency.[92]

Mild or "partial" defects of adrenal 3βHSD activity have been reported on the basis of ratios of Δ^5 steroids to Δ^4 steroids following an ACTH test that exceed 2 or 3 standard deviations above the mean; these patients are typically young girls with premature adrenarche or young women with a history of premature adrenarche and complaints of hirsutism, virilism, and oligomenorrhea. However, these patients do not have 3βHSD deficiency as their 3βHSD2 genes are normal.[93] Patients with mild 3βHSD2 mutations have ratios of Δ^5 to Δ^4 steroids that exceed 8 standard deviations above the mean.[94] Thus ratios of Δ^5 to Δ^4 steroids are not reliable and cannot be used to diagnose 3βHSD deficiency; the diagnosis requires an ACTH test with a rise in Δ^5 steroids (typically a rise in 17OH-pregnenolone to $>$ 3000 ng/dL).[94] The basis of the mildly elevated ratios of Δ^5 to Δ^4 steroids in these hirsute individuals with normal 3βHSD genes is unknown. In adult women the hirsutism can be ameliorated and regular menses can be restored by suppressing ACTH with 0.25 mg of dexamethasone given orally each day, but such treatment is contraindicated in girls who have not yet reached their final adult height.

17α-Hydroxylase/17,20-Lyase Deficiency

P450c17 is the single enzyme that catalyzes both 17α-hydroxylase and 17,20-lyase activities.[9] 17-hydroxylase deficiency has been studied in detail at both clinical and genetic levels[95] and appears to be especially common in Brazil.[96] Deficient 17α-hydroxylase activity and deficient 17,20-lyase activity have been described as separate genetic diseases, but it is now clear that they represent different clinical manifestations of different lesions in the same gene.[21] Deficient 17α-hydroxylase activity results in decreased cortisol synthesis, overproduction of ACTH, and stimulation of the steps proximal to P450c17. These patients may have mild symptoms of glucocorticoid deficiency, but this is not life threatening, as the lack of P450c17 results in the overproduction of corticosterone, which also has glucocorticoid activity.[95] This is similar to the situation in rodents, whose adrenals lack P450c17 and consequently produce corticosterone as their glucocorticoid. Affected patients also typically overproduce DOC in the zona fasciculata, which causes sodium retention, hypertension, and hypokalemia and also suppresses plasma renin activity and aldosterone secretion from the zona glomerulosa, although the suppression of aldosterone is rather variable. When P450c17 deficiency is treated with glucocorticoids, DOC secretion is suppressed and plasma renin activity and aldosterone concentrations rise to normal.

The absence of 17α-hydroxylase and 17,20-lyase activities in complete P450c17 deficiency prevents the synthesis of adrenal and gonadal sex steroids. As a result, affected females are phenotypically normal but fail to undergo adrenarche and puberty and genetic males have absent or incomplete development of the external genitalia (male pseudohermaphroditism; 46,XY disorder of sexual development [DSD]). The classic presentation is that of a teenage female with sexual infantilism and hypertension. The diagnosis is made by finding low or absent 17-hydroxylated C-21 and C-19 plasma steroids, which respond poorly to stimulation with ACTH. Serum levels of DOC, corticosterone, and 18-OH-corticosterone are elevated, hyperresponsive to ACTH, and suppressible with glucocorticoids.

The *CYP17A1* gene encoding P450c17 is located on chromosome 10q24.3.[9] The molecular basis of 17α-hydroxylase deficiency has been determined in numerous patients by cloning and sequencing of the mutated gene identifying more than 50 distinct mutations. Four mutations appear recurrently: a duplication of four nucleotides causing a frameshift is found among descendants of Dutch Frieslanders, in-frame deletion of residues 487-489 is common in Asia, a deletion of phenylalanine at position 53 or 54, and the common W406R and R362C mutations, found among Brazilians of Spanish and Portuguese ancestry, respectively.[9,96] The genetic lesions identified include twelve mutations that cause frameshifts or premature translational termination; as expected, none of these mutants has any detectable 17α-hydroxylase or 17,20-lyase activity. Eleven missense and in-frame mutations have been found, most of which also eliminate all activity, whereas some others, such as P342T, reduce both activities by 80%.

Selective deficiency of the 17,20-lyase activity of P450c17 has been reported in some cases, which initially led to the incorrect conclusion that 17α-hydroxylase and 17,20-lyase are separate enzymes. One of the original patients was studied at the genetic level, showing two wholly inactivating mutations, which led to a corrected diagnosis of the patient as having complete 17α-hydroxylase deficiency.[21] Because both the 17α-hydroxylase and 17,20 lyase activities of P450c17 are catalyzed on the same active site, it was not clear that a syndrome of isolated 17,20 lyase deficiency could exist, until two patients with genital ambiguity, normal excretion of 17OHCS, and markedly reduced production of C_{19} steroids were studied at the molecular genetic level.[97] One patient was homozygous for the P450c17 mutation R347H, and the other was homozygous for R358Q; both mutations changed the distribution of surface charges in the redox-partner binding site of P450c17. When assayed in vitro, both mutants retained nearly normal 17α-hydroxylase activity but had no detectable 17,20 lyase activity, and enzymatic competition experiments showed that the substrate binding site remained normal. When an excess of P450 oxidoreductase and cytochrome b_5 was provided, some 17,20 lyase activity was restored, demonstrating that the loss in lyase activity was caused by impaired electron transfer. Several additional patients have been described with similar

mutations, and an active site mutation causing isolated 17,20 lyase deficiency has also been described.[21]

Computational modeling of P450c17 predicts the effects of all known mutations, including those with partial retention of both activities and those causing selective 17,20 lyase deficiency.[98] R347, R358, and several other arginine and lysine residues lie in the redox partner binding site; mutation of these residues cause varying degrees of selective loss of 17,20 lyase activity.[21,97,98]

P450 Oxidoreductase Deficiency

P450 oxidoreductase (POR) deficiency is a newly recognized form of CAH.[99,100] POR is the 2-flavin protein that transfers electrons from NADPH to all 50 microsomal forms of cytochrome P450, including P450c17, P450c21, and P450aro, as well as the drug-metabolizing P450 enzymes of the liver (see Fig 13-5).[12] Because POR participates in so many functions, its mutation might be expected to yield a severe phenotype, and POR-deficient mice die during fetal development. However, beginning in 1985, several patients were described with apparent combined deficiencies of P450c17 and P450c21, and it was suggested that a mutation in POR was responsible, but this was not proven until 2004.[99] A wide array of POR mutations has now been described, affecting various P450 enzymes to differing degrees, apparently explaining the great variability in the clinical and hormonal findings in POR deficiency.[99-103] The serum and urinary steroids indicate defects in both P450c17 and P450c21, and clinical findings vary from severely affected infants with ambiguous genitalia, cortisol deficiency, and the Antley-Bixler skeletal malformation syndrome (ABS) to mildly affected women who appear to have a form of polycystic ovary syndrome or mildly affected men with gonadal insufficiency. ABS is characterized by craniosynostosis, brachycephaly, radio-ulnar or radiohumeral synostosis, bowed femora, arachnodactyly, midface hypoplasia, proptosis, and choanal stenosis. When ABS is seen in association with abnormal steroids and ambiguous genitalia in either sex, the cause is an autosomal recessive mutation in POR[99,100,102]; by contrast, when ABS is seen without a lesion in steroidogenesis or genital development, the cause is an autosomal dominant, gain-of-function mutation in fibroblast growth factor receptor 2.[100] Thus, the term *Antley-Bixler syndrome* should be reserved for the phenotypic description of the skeletal malformations and should not be equated with POR deficiency, which may or may not be associated with ABS.[99,100]

Patients with POR deficiency will typically have normal electrolytes and mineralocorticoid function, nearly normal levels of cortisol that respond poorly to stimulation with ACTH, high concentrations of 17OHP that respond variably to ACTH, and low levels of C19 precursors to sex steroids. A remarkable feature of POR deficiency is that there is genital ambiguity in both sexes; females may be virilized and males may be underdeveloped, although there is considerable variation among individuals. As the 17,20 lyase activity of P450c17 is especially sensitive to perturbations in electron transport,[12,21,97] defects in fetal testicular steroidogenesis leading to incompletely developed external genitalia in 46,XY males is the predicted outcome. By contrast, the partial virilization seen in 46,XX genetic females appears to be due to two causes. First, placental aromatase (P450aro) requires POR. Pregnant women carrying a fetus with the POR mutation R457H (but not POR A287P) may experience virilization during pregnancy,[99-101] similar to that experienced by women carrying a fetus with P450aro deficiency.[39] The fetus normally disposes of large amounts of adrenal C19 steroids by excreting them through the placenta, which aromatizes them to the maternal estrogens of pregnancy (see Figure 13-7). A defect in this placental aromatase activity, either from mutation of POR or P450aro itself, will permit large amounts of fetal C19 steroids to enter and virilize the mother. This is evidenced by the low estriol values seen in women carrying a fetus with some POR mutations. Second, analysis of urinary steroids from patients with POR deficiency indicates that the alternative "backdoor pathway" of androgen production (see Figure 13-6) also contributes to the prenatal virilization of affected females.[101,104] The relative importance of these two distinct mechanisms for virilizing the fetus with POR deficiency remain unresolved. The mechanism linking defective POR activity to the ABS skeletal phenotype probably entails diminished activity of CYP26B1, the POR-dependent microsomal enzyme that degrades retinoic acid.[105] Studies of two families with CYP26B1 mutations and recreating such mutations in transgenic mice and zebrafish provides powerful evidence that retinoic acid must be degraded locally at embryonic sites that normally form skeletal joints and sutures; interference with this activity in POR deficiency appears to be the principal mechanism accounting for the skeletal phenotype.[105] Other mechanisms, including defective signaling by hedgehog proteins secondary to a POR-associated defect in cholesterol synthesis, may also play a role.[102]

Because the principal hepatic drug-metabolizing enzymes require POR, it is logical to expect impaired drug metabolism in POR-deficient patients. Although transgenic mice with liver-specific POR defects metabolize drugs poorly and accumulate hepatic lipids, similar problems have not yet been described in patients with POR deficiency. Although numerous studies of drug-metabolizing enzymes in vitro show major impairment by POR mutations,[106]only one study has found such an effect in a POR-deficient patient.[107] Much remains to be learned about POR deficiency.

The incidence of POR deficiency is unknown. Because the disorder is newly described, it may seem rare, but the rapid description of large numbers of patients and the potentially subtle clinical manifestations in individuals carrying mutations with partial activity suggest that POR deficiency may be fairly common. Two mutations are especially common: A287P, the predominant mutation in patients of European ancestry; and R457H, the predominant mutation in patients of Japanese ancestry. Because few patients have been studied in the newborn period, it has not been established whether newborn screening of 17OHP designed to detect 21-hydroxylase deficiency will also detect POR deficiency, although some reported POR patients were

initially misdiagnosed with 21-hydroxylase deficiency. Treatment of POR deficiency requires multidisciplinary management of craniosynostosis and other orthopedic problems, and DSD management including sex hormone replacement therapy starting at pubertal age in both sexes. Some patients may benefit from low-dose glucocorticoid replacement therapy, especially during severe illness; this should be determined individually by assessing the response of cortisol to ACTH.

Cytochrome b_5 Deficiency

Cytochrome b_5 is a small hemoprotein that acts as an allosteric factor to facilitate the interaction of P450c17 with POR, thus fostering 17,20 lyase activity.[20] Adrenal expression of b_5 is specific to the zona reticularis and coincides with the onset of adrenarche.[64] Cytochrome b_5 deficiency is a newly described form of androgen deficiency, apparently affecting both adrenal and testicular androgen synthesis. The first report of b_5 deficiency was a male pseudohermaphrodite with methemoglobinemia who was not evaluated hormonally.[108] Methemoglobinemia is an expected consequence of b_5 deficiency because the reduction of methemoglobin is the principal physiologic role of b_5, and the usual cause of methemoglobinemia is deficiency of cytochrome b_5 reductase. Two cases report male pseudohermaphroditism with elevated concentrations of methemoglobin, but not with clinical methemoglobinemia[109,110]; as the lesion only affects androgen synthesis, adrenal insufficiency is not part of this disorder, which is part of the syndrome of 17,20 lyase deficiency.[21]

21-Hydroxylase Deficiency

21-Hydroxylase deficiency, which is due to mutations in the *CYP21A2* gene encoding adrenal P450c21, is one of the most common inborn errors of metabolism and accounts for over 90% of all patients with CAH. Because of improved diagnosis and treatment in infancy, patients with severe 21-hydroxylase deficiency now routinely reach adulthood, so that the management of CAH concerns physicians dealing with all age groups.[22-24]

Pathophysiology

In severe 21-hydroxylase deficiency, there is an inability to convert progesterone to DOC, resulting in aldosterone deficiency that causes severe hyponatremia (Na+ often below 110 mEq/L), hyperkalemia (K+ often above 10 mEq/L), and acidosis (pH often below 7.1). The associated hypotension, shock and cardiovascular collapse may result in death in an untreated newborn. As the placenta and the mother's kidneys maintain the control of fluids and electrolytes in the fetus, this salt-losing crisis develops only after birth, usually during the second week of life. The inability to convert 17OHP to 11-deoxycortisol results in cortisol deficiency, which impairs postnatal carbohydrate metabolism and exacerbates cardiovascular collapse, because a permissive action of cortisol is required for full pressor action of catecholamines. High concentrations of cortisol in the adrenocortical capillary effluent that bathes the medulla are needed for the conversion of norepinephrine to epinephrine; hence, children with CAH have low epinephrine concentrations, which may exacerbate the hypoglycemia associated with cortisol deficiency.

Although the role of cortisol in fetal physiology is not well established,[51-53] cortisol deficiency is manifested prenatally. Low fetal cortisol stimulates ACTH secretion, which stimulates adrenal hyperplasia and transcription of the genes for all the steroidogenic enzymes, especially for P450scc, the rate-limiting enzyme in steroidogenesis. This increased transcription increases enzyme production and activity, with consequent accumulation of non-21-hydroxylated steroids. There are three pathways by which these steroids are diverted to androgens (see Figure 13-6). First, 17OH-pregnenolone may be converted to DHEA by the 17,20 lyase activity of P450c17; if not inactivated by sulfation to DHEAS, DHEA may be converted to androstenedione by 3βHSD2. Androstenedione may then be converted to testosterone in the fetal adrenal or in target tissues by 17βHSD5 (see Figure 13-3). Second, although 17OHP is not normally an effective substrate for the 17,20 lyase activity of P450c17, the very high levels of 17OHP characteristic of CAH will "force" some conversion to androstenedione by mass action. Third, there is an alternative or "backdoor pathway" to androgen, in which 17OHP is 5α and 3α reduced to 17OH-allopregnenolone, which is readily converted by P450c17 to androsterone and thence by 17βHSD and the oxidative action of 3αHSD to dihydrotestosterone, so that this most potent androgen is produced without DHEA, androstenedione, or testosterone as intermediates.[47] This pathway exists in the human fetus[49] and contributes substantially to the production of androgens in children with CAH.[50] The role of this pathway in virilizing the CAH fetus has not yet been established but is likely. Furthermore, as described previously (see "Fetal Adrenal Steroidogenesis"), fetal adrenal androgen synthesis is normally prevented during the time when the external genitalia may become virilized. The fetal adrenal transiently expresses 3βHSD2 at about 7 to 12 weeks, permitting cortisol synthesis, which in turn suppresses ACTH and hence suppresses fetal adrenal production of DHEA and other C-19 steroids.[51] In CAH, this transient production of cortisol is not possible, further driving the androgenization of female fetuses.

The fetal testes produce large amounts of testosterone in early to midgestation, which differentiates the pluripotent embryonic precursor structures into male external genitalia. In the male fetus with 21-hydroxylase deficiency, the additional testosterone produced in the adrenals has no phenotypic effect. By contrast, the fetal ovaries normally produce no sex steroids or other factors needed for differentiation of the female external genitalia. The testosterone inappropriately produced by the adrenals of the CAH female fetus causes varying degrees of external genital virilization, which can range from mild clitoromegaly with or without posterior fusion of the labioscrotal folds to complete labioscrotal fusion that includes a urethra traversing the enlarged clitoris (Figure 13-13). These infants have normal ovaries,

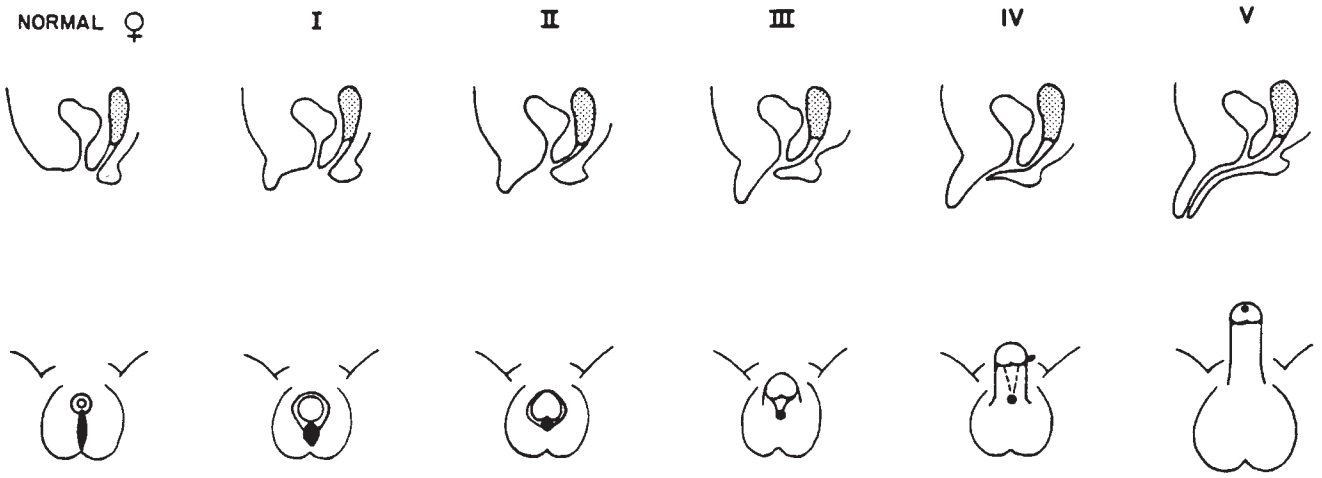

FIGURE 13-13 ■ Virilization of the external genitalia. A continuous spectrum is shown from normal female to normal male in both sagittal section (above) and perineal views (below), using the staging system of Prader. Disorders of external genitalia can occur either by the virilization of a normal female, as in congenital adrenal hyperplasia, or due to an error in testosterone synthesis in the male. In females with congenital adrenal hyperplasia due to 21-hydroxylase deficiency, the degree of virilization correlates poorly with the presence or absence of clinical signs of salt loss.

fallopian tubes, and a uterus, but they have "ambiguous" external genitalia or may be sufficiently virilized so that they appear to be male, resulting in errors of sex assignment at birth.

The diagnosis of 21-hydroxylase deficiency is suggested by genital ambiguity in females, a salt-losing episode in either sex, or rapid growth and virilization in males or females in infancy. Plasma 17OHP is markedly elevated (> 2000 ng/dL or 60 nmol/L and often exceeding 40,000 ng/dL or 1200 nmol/L) after 24 hours of age in an otherwise healthy full-term infant) and hyperresponsive to stimulation with ACTH (see Figure 13-11). It is important also to measure 11-deoxycortisol, DHEA, and androstenedione, both to distinguish among the forms of CAH and because adrenal or testicular tumors can also produce 17OHP. ACTH will also induce a substantial rise in serum 21-deoxycortisol in all forms of 21-hydroxylase deficiency, but not in normals, providing a useful adjunctive test when this steroid can be measured. High newborn 17OHP values that rise further after ACTH can also be seen in 3βHSD2 deficiency (because of the activity of hepatic 3βHSD1) and in P450c11 deficiency (because of end-product inhibition of P450c21).[91] 17OHP is normally high in cord blood but falls to normal newborn levels after 12 to 24 hours (Figure 13-14) so that assessment of 17OHP levels should not be made in the first 24 hours of life. Premature infants and term infants under severe stress (e.g., with cardiac or pulmonary disease) may have persistently elevated 17OHP concentrations with normal 21-hydroxylase. Newborn screening programs for CAH are now in place throughout the industrialized world, based on 17OHP measurements. The technologies employed and "cutoff" values used vary in different health care systems. When testing is done on full-term infants more than 24 hours after birth, the screening is reliable.[22] Endocrinologists and neonatologists must become familiar with local assays and the values found in the extremely premature,

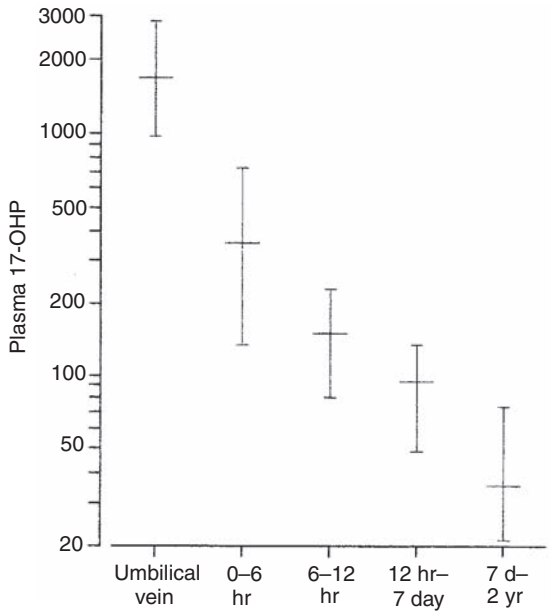

FIGURE 13-14 ■ Means and ranges of 17OHP in normal newborns (data are in ng/100 mL). Note that values can be very high and quite variable for the first 24 hours of life.

which may be read as false positives for CAH requiring repeat testing. Also, negative neonatal screening does not exclude milder 21-hydroxylase deficiency causing nonclassic CAH beyond the newborn period.

Clinical Forms of 21-Hydroxylase Deficiency

There is a broad spectrum of clinical manifestations of 21-hydroxylase deficiency, depending on the particular gene mutation. These different forms of 21-hydroxylase deficiency are not different diseases, as there is a continuous spectrum of manifestations, ranging from the severe

"salt-wasting" form to clinically inapparent forms that may be normal variants. Thus, the typical disease forms discussed in the following sections are mainly a clinical convenience.[22]

Salt-Wasting CAH. Salt-wasting CAH is caused by a nearly complete lack of P450c21 activity, effectively eliminating both glucocorticoid and mineralocorticoid synthesis. Females with this disorder are frequently diagnosed at birth because of virilization of the external genitalia; 21-hydroxylase deficiency is the most common form of 46,XX DSD. After appropriate resuscitation of the cardiovascular collapse, acidosis, and electrolyte disorders, if diagnosed late, the mineralocorticoids and glucocorticoids can be replaced orally and the ambiguous genitalia may be corrected with plastic surgical procedures. The steroidal replacement management is difficult because of the rapidly changing needs of a growing infant or child (see section on "Treatment," presented later in the chapter). Drug doses must be adjusted frequently, and there is also considerable individual variability in what constitutes "physiologic" replacement. As an underdosage of glucocorticoids can be life-threatening, especially during illness, most pediatricians have tended to err on the "safe side" and so these children usually receive inappropriately large doses of glucocorticoids. It is not possible to compensate for the growth lost during the first 2 years of life, when growth is fastest, so these children almost always end up shorter than predicted from their genetic potential. Adult females may have sexual dysfunction, marry with a low frequency, are more reluctant to form intimate relationships, and have decreased fertility. Prenatal androgens appear to affect behavior, but not sexual identity.[22] Males with this disorder are generally undiagnosed at birth and come to medical attention through the neonatal screening, during the salt-losing crisis that follows at day 5 to 15 of life, or die, invariably with an incorrect diagnosis. Adult males appear to have less steady heterosexual relationships and decreased fertility, especially with insufficient treatment, which promotes the occurrence of testicular adrenal rest tumors.[22]

Simple Virilizing CAH. Virilized females who have elevated concentrations of 17OHP but who do not suffer a salt-losing crisis have long been recognized as having the "simple virilizing" form of CAH. Unless detected by newborn screening, males with this disorder may escape diagnosis until age 3 to 7 years, when they come to medical attention because of early development of pubic, axillary, and facial hair; acne; and phallic growth. These signs may be mistaken for premature puberty, but the astute physician can readily differentiate such boys with sexual precocity from boys with true central precocious puberty, as the testes remain of prepubertal size in CAH, whereas gonadotropic stimulation in true precocious puberty results in pubertal-sized testes (≥ 4 mL). These children grow rapidly and are tall for age when diagnosed, but their epiphyseal maturation (bone age) advances disproportionately rapidly so that ultimate adult height is compromised. Untreated or poorly treated children with CAH may fail to undergo normal puberty, and boys may have small testes and azoospermia because of the feedback of the adrenally produced testosterone on pituitary gonadotropins. When treatment is begun at several years of age, suppression of adrenal testosterone secretion may remove tonic inhibition of the hypothalamus, occasionally resulting in true central precocious puberty, requiring treatment with a GnRH agonist. High concentrations of ACTH in poorly treated males may stimulate the enlargement of adrenal rests in the testes. These enlarged testes usually appear nodular by ultrasound, unlike the homogeneously enlarged testes in central precocious puberty. Because the adrenal normally produces 100 to 1000 times as much cortisol as aldosterone, mild defects (amino acid replacement mutations) in P450c21 are less likely to affect mineralocorticoid secretion than cortisol secretion. This is reflected physiologically by the increased plasma renin activity seen in these patients after moderate salt restriction.

Nonclassic CAH. Many people have very mild forms of 21-hydroxylase deficiency. These forms may be evidenced by mild to moderate hirsutism, virilism, acne, menstrual irregularities, and decreased fertility in adult women (so-called late-onset CAH), or there may be no phenotypic manifestations at all other than an increased response of plasma 17OHP to an intravenous ACTH test (so-called cryptic CAH).[22] Despite the minimal manifestations of this disorder, these individuals also have hormonal evidence of a mild impairment in mineralocorticoid secretion, evidenced by an unusually greater rise in PRA when dietary sodium is restricted.

There is some inconsistency in classifying patients into these three forms of CAH because each diagnostic category is not a separate disease but represents a typical picture in a continuous spectrum of disease, caused by a broad spectrum of genetic lesions. Furthermore, because some mutant P450c21 alleles are common in the general population, most patients are compound heterozygotes, carrying a different mutation on the allele inherited from each parent. Finally, factors other than the specific mutations found in P450c21 will influence the clinical phenotype, including the presence of extra-adrenal 21-hydroxylases, undiagnosed P450c21 promoter mutations, and variations in androgen metabolism and sensitivity. Thus, discordances between genotype and phenotype are to be expected.

Incidence of 21-Hydroxylase Deficiency

Perinatal screening for elevated concentrations of serum 17OHP in several countries has shown that the incidence of "classic" CAH (i.e., salt-wasting and simple virilizing CAH) is about 1 in 14,000, yielding a heterozygous carrier rate of 1 in 60. The screening of 1.9 million newborns in Texas yielded an overall incidence of 1 in 16,000, including incidences of 1 in 15,600 Caucasians, 1 in 14,500 Hispanics (primarily Mexican Americans of indigenous American ancestry), and 1 in 42,300 African Americans.[111] Because about 20% of the African-American gene pool is of European descent, the calculated incidence in individuals of wholly sub-Saharan African ancestry is about 1 in 250,000. Nonclassic CAH is clearly much

more common; its incidence varies substantially among ethnic groups, with the highest incidence among Ashkenazi Jews and Mediterranean peoples.[9,22,112] The high incidence, lack of mortality, and lack of decreased fertility in most individuals with nonclassic CAH suggest that this is a polymorphic variant and not a disease in the classic sense. Nevertheless, patients with nonclassic CAH may seek help for complaints of virilism, menstrual disorders, and fertility.[112]

Genetics of the 21-Hydroxylase Locus

21-Hydroxylase Genes. The functional 21-hydroxylase gene is formally termed *CYP21A2* and a nearby nonfunctional pseudogene is formally termed *CYP21A1P*. These genes, also termed P450c21B (functional gene) and P450c21A (pseudogene), are duplicated in tandem with the C4A and C4B genes encoding the fourth component of serum complement[9,23,24] (Figure 13-15). Although the P450c21A locus is transcribed, the resultant RNAs do not encode protein; only the P450c21B gene encodes 21-hydroxylase.[9] The P450c21 genes consist of 10 exons, are about 3.4 kb long, and differ in only 87 or 88 of these bases. This high degree of sequence similarity indicates that these two genes are evolving in tandem through intergenic exchange of DNA. The P450c21 genes of mice and cattle are also duplicated and linked to leukocyte antigen loci. However, whereas only the P450c21B gene functions in human beings, only the P450c21A gene functions in mice and both genes function in cattle.[9,23] Sequencing of the gene duplication boundaries show that the human locus duplicated after mammalian speciation, consistent with data that indicate that other mammals have single *CYP21* gene copies.[9,23]

HLA Linkage. The *CYP21* genes lie within the class III region of the human major histocompatibility complex (MHC) (see Figure 13-15). HLA typing has been used for prenatal diagnosis and to identify heterozygous family members but has been replaced by direct genetic analysis. Statistical associations (linkage disequilibrium) are well established between CAH and certain specific HLA types.[9,23,24] Salt-losing CAH is associated with HLA-B60 and HLA-40 in some populations, and HLA-Bw47 is strongly associated with salt-losing CAH. HLA-Bw51 is associated with simple virilizing CAH in some populations, and about 40% of haplotypes for nonclassic CAH carry HLA-B14. HLA-B14 is often associated with a duplication of the C4B gene, but all HLA-B alleles can be found linked to CAH. HLA-identical individuals

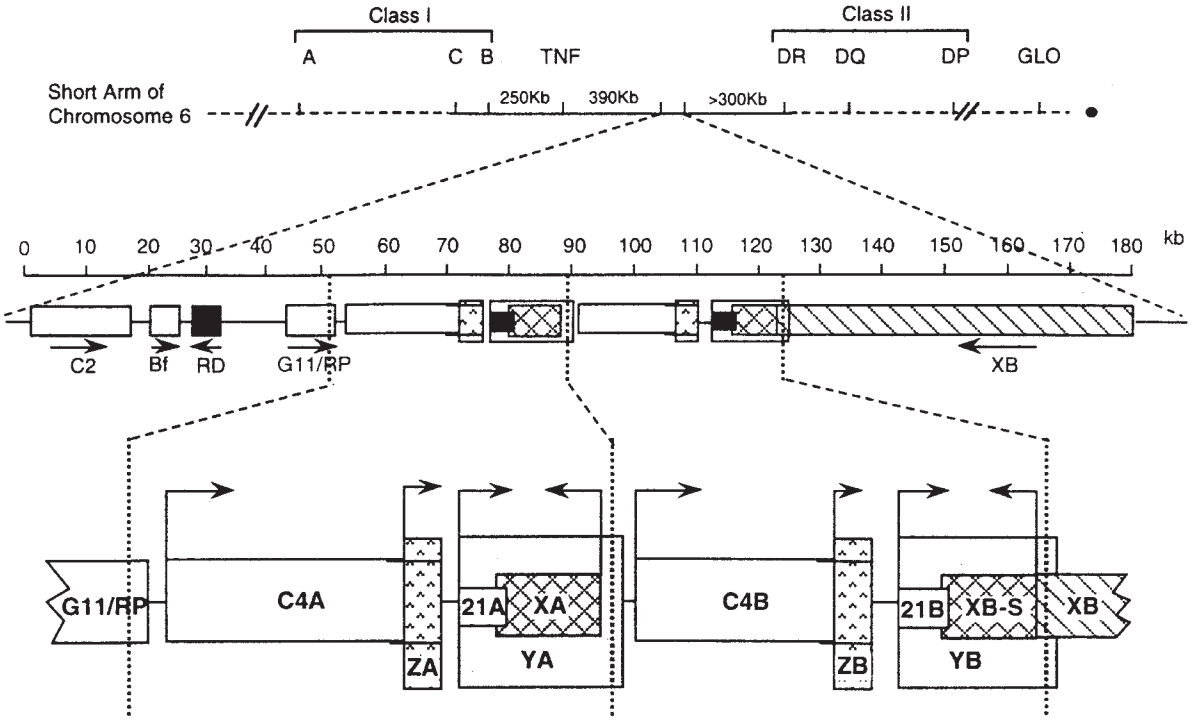

FIGURE 13-15 ■ Genetic map of the HLA locus containing the genes for P450c21. The top line shows the p21.1 region of chromosome 6, with the telomere to the left and the centromere to the right. Most HLA genes are found in the class I and class II regions; the class III region containing the P450c21 genes lies between these two. The second line shows the scale (in kilobases) for the diagram immediately below, showing (from left to right) the genes for complement factor C2, properdin factor Bf, and the RD and G11/RP genes of unknown function; arrows indicate transcriptional orientation. The bottom line shows the 21-hydroxylase locus on an expanded scale, including the C4A and C4B genes for the fourth component of complement, the inactive CYP21A gene (21A) and the active CYP21B gene (21B) that encodes P450c21. XA, YA, and YB are adrenal-specific transcripts that lack open reading frames. The XB gene encodes the extracellular matrix protein Tenascin-X; XB-S encodes a truncated adrenal-specific form of the Tenascin-X protein, whose function is unknown. ZA and ZB are adrenal-specific transcripts that arise within the C4 genes and have open reading frames, but it is not known if they are translated into protein; however, the promoter elements of these transcripts are essential components of the CYP21A and CYP21B promoters. The arrows indicate transcriptional orientation. The vertical dotted lines designate the boundaries of the genetic duplication event that led to the presence of A and B regions.

in a single family may have different clinical features of CAH despite HLA identity, possibly representing extra-adrenal 21-hydroxylation, de novo mutations, or multiple genetic crossover events.

Other Genes in the 21-Hydroxylase Locus. The tandemly duplicated C4A and C4B loci produce isoforms of complement component C4 that can be distinguished functionally and immunologically[9,23]; the C4B protein has greater hemolytic activity despite greater than 99% sequence identity with C4A. The C4A gene is always 22 kb long, but there are long (22 kb) and short (16 kb) forms of C4B due to a variation in one intron. The 3′ ends of the C4 genes are only 2466bp upstream from the transcriptional start sites of the P450c21 genes. Promoter sequences needed for the transcription of the human P450c21B gene lie within intron 35 of the C4B gene.[113] In addition to the P450c21 and C4 genes, there are several other genes within 100 kb of the P450c21 gene, including the genes for complement factor C2 and properdin factor Bf (see Figure 13-15). Lying just 3′ of the Bf gene on the opposite strand of DNA from P450c21 is the STK19 gene (also variously called RD, RP, and G11), which encodes a nuclear serine/threonine kinase.[110]

A pair of genes, termed XA and XB, is duplicated with the C4 and P450c21 genes.[9,23] These genes lie on the strand of DNA opposite from the C4 and P450c21 genes and overlap the 3′ end of P450c21. The last exon of XA and XB lies within the 3′ untranslated region of exon 10 in P450c21A and P450c21B, respectively. The XA gene was truncated during the duplication of the ancestral C4-P450c21-X genetic unit but is transcribed in the adrenal. The XB gene encodes a large extracellular matrix protein called Tenascin X that is expressed in most tissues, especially connective tissue.[115] The XB gene spans about 65kb of DNA and includes 43 exons encoding a 12kb mRNA. The XB gene also encodes a short truncated form of Tenascin-X having unknown function and arising from an intragenic promoter. Identification of a CAH patient with a "contiguous gene syndrome" comprising a deletion of both the P450c21B and XB genes demonstrated that Tenascin X deficiency results in Ehlers-Danlos syndrome (EDS).[116] Most forms of EDS are caused by autosomal dominant mutations in collagen genes; the recessive forms are caused by mutations in genes for collagen-modifying enzymes, including Tenascin-X, which is associated with and stabilizes collagen fibrils. Tenascin-X deficiency causes a clinically distinct, somewhat more severe, recessive form of EDS, either with or without associated 21-hydroxylase deficiency.[117]

P450c21 Gene Lesions Causing 21-Hydroxylase Deficiency

21-Hydroxylase deficiency can be caused by *CYP21A2* gene deletions, gene conversions, and apparent point mutations. The most common apparent point mutations are actually small gene conversion events,[9,23] so that gene conversions account for about 85% of the lesions in 21-hydroxylase deficiency. Each person has two *CYP21A2* alleles, one contributed by each parent. Most patients with 21-hydroxylase deficiency are compound heterozygotes, having different lesions on their two alleles. Because gene deletions and large conversions eliminate gene transcription, homozygosity for these lesions will cause salt-losing CAH. Some microconversions, such as those creating premature translational termination, are also associated with salt-losing CAH. Milder forms, such as simple virilizing and nonclassic CAH, are associated with amino acid replacements in the P450c21 protein caused by gene microconversion events. Patients with these forms of CAH are usually compound heterozygotes bearing a severely disordered allele and a mildly disordered allele so that the clinical manifestations are based on the nature of the mildly disordered allele.

Mapping of P450c21 Genes in Normals and in CAH. Although the P450c21B and P450c21A loci (*CYP21A2* and *CYP21A1P* genes) differ by only 87 or 88 nucleotides, they can be distinguished by restriction endonuclease digestion and Southern blotting. Two unusual and related features of the 21-hydroxylase locus complicate its analysis. First, the gene deletions in this locus are most unusual in that they extend 30 kb from one of several points in the middle of P450c21A to the precisely homologous point in P450c21B. Thus, the 15% of alleles that carry deletions do not yield a typical Southern blotting pattern with a band of a size different from that of one of the normal, unless one uses very rarely cutting enzymes and analyzes the resulting large DNA fragments by pulsed-field gel electrophoresis. The second unusual feature of this locus is that gene conversions are extremely common.[9,23]

Gene Conversions and Microconversions Causing CAH. If a segment of gene A replaces the corresponding segment of the related gene B, the structure of recipient gene B is said to be "converted" to that of donor gene A. The hallmark of gene conversion is that the number of closely related genes remains constant, whereas their diversity decreases. Two types of gene conversions commonly cause 21-hydroxylase deficiency: large gene conversions that can be mistaken for gene deletions and small microconversions that resemble point mutations. The relative frequency of large gene conversions versus gene deletions was formerly controversial, principally because initial studies used relatively small groups of patients from single locations or ethnic groups. A compilation of multiple studies shows that about 19% of mutant alleles have gene deletions, 8% have large gene conversions, 67% have microconversions, and 6% had other lesions[23] (Figure 13-16). Such numbers emphasize the more severely affected patients. About 75% of mutated P450c21B genes are grossly intact and appear to carry point mutations, but gene sequencing shows that most apparent point mutations are also found in the P450c21A pseudogene, indicating that they are actually representing micro gene conversion events (Table 13-6). Three changes in the pseudogene (8bp deletion, exon 3; T insertion, exon 7; Gly3 18Stop, exon 8) render its RNA product nonfunctional. Each change results in an altered reading frame or premature stop codon,

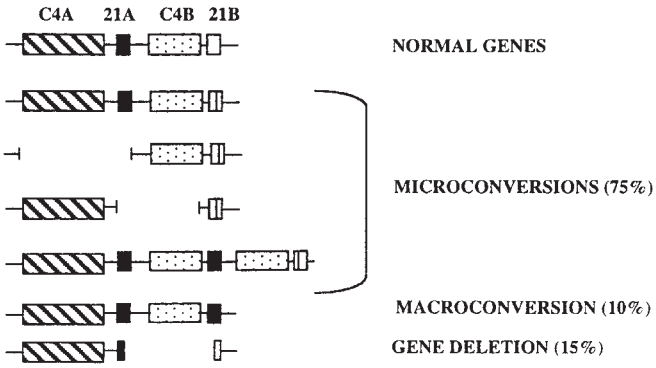

FIGURE 13-16 ■ Classes of genetic rearrangements causing 21-hydroxylase deficiency. Deletions or duplications of the C4A and C4B genes can occur with or without associated lesions in the P450c21B gene. Note that all "point mutations" in P450c21B are actually "microconversion." Many authors combine the "gene deletion" and "macroconversion" groups because these are difficult to distinguish by Southern blotting as both result in a loss of the P450c21B gene, but the genotypes are clearly distinct, as shown.

TABLE 13-6 **Microconversions in the *CYP21A2* Gene That Cause 21-Hydroxylase Deficiency**

Mutation	Location	Associated Phenotypes	Activity
Pro 30→Leu	Exon 1	NC/SV	30%-60%

Pro 453→Ser	Exon 10	NC	20%-50%
GG→C @ 484	Exon 10	SW	

eliminating all activity; all of these have been found in P450c21B alleles that cause severe salt-losing CAH. Three closely clustered base changes alter the normal amino acid sequence Ile-Val-Glu-Met at codons 236 to 239 in exon 6 to Asn-Glu-Glu-Lys in both P450c21A and in a small number of genes causing severe salt-losing CAH.

The most common lesion in classic CAH is an A→G change in the second intron, 13 bases upstream from the normal 3′ splice acceptor site of this intron; this is a microconversion found in over 25% of severely affected CAH alleles. This intronic mutation causes abnormal splicing of the encoded RNA, destroying activity. However, a small portion of this mRNA may be spliced normally in some patients so that the phenotypic presentation is variable; most such patients are salt losers, but some have non–salt-losing CAH. This intron 2 microconversion is often associated with the Ser/Thr polymorphism at codon 268; this is a true polymorphism, as S268T does not alter enzymatic activity. The microconversion R356W, which is found in about 10% of severely affected alleles, may retain slight activity and has been found in both salt-losing and simple virilizing CAH. A large number of rare mutations have been described in single individuals.

Mutations Causing Simple Virilizing and Nonclassic CAH. The microconversion I172N is the most common cause of simple virilizing CAH. When this residue is changed to Asn, Leu, Gln, or His and the resulting mutant P450c21 protein is assayed in vitro, it retains only 3% to 7% of normal 21-hydroxylase activity. The intron 2 microconversion is occasionally seen in simple virilizing CAH. The microconversion P30L is generally associated with classic CAH, but it is found in some patients with simple virilizing CAH.

The most common mutation causing nonclassic CAH is V281L, a microconversion linked to HLA-B14 and HLA-DR1 but also found in patients with other HLA types. The microconversion P30L is found in about 15% to 20% of nonclassic alleles, and the mutations R339H and P453S have been associated with nonclassic CAH; the P453S mutation is polymorphic in about 20% of P450c21A pseudogenes and hence also represents a microconversion event.

Prenatal Diagnosis of CAH

The prenatal diagnosis of 21-hydroxylase deficiency can be approached by measuring fetally produced 17OHP or Δ^4-androstenedione in amniotic fluid, but these steroids may not be elevated above the broad range of normal in non–salt-losing or nonclassic CAH. Second, HLA typing of fetal amniocytes can be informative if there is previous linkage analysis of an affected index case and parents. However, some HLA alleles are expressed weakly in cultured amniocytes, and the procedure is no longer widely used. Third, sequencing of the affected gene is now widely used, but the complex genetics of the CAH locus mean this procedure is reliable only when the genetic lesion in a previously affected sibling or the parents is known.

Diagnosis

In the absence of prenatal screening, genital ambiguity, neonatal screening or a salt-losing crisis will generally alert pediatricians to most cases of severe 21-hydroxylase deficiency. Salt-losing crises generally occur in the second week of life, and the child presents with vomiting, diarrhea, dehydration, hyperkalemia, and hyponatremia. Occasionally, such infants are thought to have viral syndromes or gastrointestinal obstructions; such a failure to make the diagnosis can result in the infant's death.

Similarly, boys with simple virilizing CAH may escape diagnosis until they are 3 to 7 years old, when they present with isosexual precocity, advanced bone age, and characteristically prepubertal testes. Teenage and adult females with nonclassic CAH may consult an internist, obstetrician, or dermatologist for virilism, hirsutism, menstrual irregularity, infertility, or acne.

The key diagnostic maneuver is to measure 17OHP and other steroids in response to intravenous synthetic ACTH. The usual doses are 15 μg/kg in children up to 2 years of age, and 0.25 mg in older children and adults. 17OHP and cortisol should be measured at 0 and 60 minutes. Individual patient responses must be compared to age- and sex-matched data from normal children. Normal responses are shown in Table 13-4 and Figure 13-11. Both basal and stimulated levels of 17OHP are markedly elevated in patients with salt-losing and simple virilizing forms of 21-hydroxylase deficiency. Basal levels are usually greater than 2000 ng/dL and increase to more than 5000 to 10,000 ng/dL after ACTH. Patients with the milder late-onset or cryptic forms typically have normal to mildly elevated basal levels but have supranormal responses to ACTH stimulation (i.e., 1500 to > 10,000 ng/dL). The cortisol response to ACTH is absent or subnormal in patients with the classic forms of CAH and is normal in patients with late-onset and cryptic forms. Basal plasma ACTH levels reflect the extent of 21-hydroxylase and cortisol deficiency (i.e., they are markedly elevated in severe forms and may be normal in patients with the milder forms who are not overtly adrenal insufficient).

Other ancillary tests are listed in Table 13-5. Urinary excretion of 17-ketosteroids will generally be elevated, but this test is no longer in general use and more useful for monitoring the efficacy of suppressive therapy than for initial diagnosis. When urinary steroids are measured, a complete 24-hour sample must be obtained, and a concomitant measurement of creatinine excretion is required to monitor the completeness of the collection. Less than 24 hour urine collections are not quantitatively accurate because of diurnal variations in steroid excretion. Measurements on spot urine samples may give some qualitative information when correlated to creatinine. Urine steroid profiling with mass-spectrometric methods (GC/MS or LC/MS-MS) typically shows elevated metabolites of 17OHP: pregnanetriol, 17-OH-pregnanolone, and pregnanetriolone.

Plasma renin activity and its response to salt restriction can be especially useful. Most patients with simple virilizing 21-hydroxylase deficiency have high plasma renin activity that increases further on sodium restriction, confirming that these patients are partially mineralocorticoid deficient and can maintain a normal serum sodium level only by hyperstimulation of the zona glomerulosa.

Treatment

The management of CAH remains difficult.[22] Overtreatment with glucocorticoids causes delayed growth, even when the degree of overtreatment is insufficient to produce signs and symptoms of Cushing syndrome. Undertreatment results in continued overproduction of adrenal androgens, which hastens epiphyseal maturation and closure, again compromising growth and other manifestations of androgen excess.

Doses of glucocorticoids should be based on the expected normal cortisol secretory rate. Several studies have established that the secretory rate of cortisol is about 6 to 8 mg/m^2 per day. However, effective suppression of ACTH and adrenal androgen production requires somewhat higher doses of about 10 to 15 mg/m^2 per day.[22] Newly diagnosed patients, especially newborns, require substantially higher initial dosages to suppress their hyperactive CRH-ACTH-adrenal axis. The glucocorticoid used is important. Most tables of glucocorticoid dose equivalencies are based on their equivalence in anti-inflammatory assays. However, the growth-suppressant equivalences of various glucocorticoids do not parallel their anti-inflammatory equivalencies: long-acting synthetic steroids such as dexamethasone have a disproportionately greater growth-suppressant effect and hence must be avoided in treating growing children and adolescents (Table 13-7). Most authorities favor the use of oral

TABLE 13-7 **Potency of Various Therapeutic Steroids (Set Relative to the Potency of Cortisol)**

Steroid	Anti-inflammatory Glucocorticoid Effect	Growth-Retarding Glucocorticoid Effect	Salt-Retaining Mineralocorticoid Effect	Plasma Half-Life (minutes)	Biologic Half-Life (hours)
Cortisol (hydrocortisone)	1.0	1.0	1.0	80-120	8
Cortisone acetate (oral)	0.8	0.8	0.8	80-120	8
Cortisone acetate (IM)	0.8	1.3	0.8		18

Triamcinolone	5		0		
Dexamethasone	30	80	0	150-300	36-54
9α-Fludrocortisone	15		200		
DOC acetate	0		20		
Aldosterone	0.3		200-1000		

hydrocortisone or cortisone acetate in three divided daily doses in growing children. However, adults and older teenagers who already have fused their epiphyses may be managed with prednisone or dexamethasone.[22]

Mineralocorticoid therapy in CAH patients returns plasma volume to normal and eliminates the hypovolemic drive to ACTH secretion. Thus, mineralocorticoid therapy often permits the use of lower doses of glucocorticoids in patients with simple virilizing CAH, optimizing growth in children and diminishing unwanted weight gain in adults. Only one oral mineralocorticoid preparation, fludrocortisone (9α-fluorocortisol), is generally available. When the oral route is not available in severely ill patients, mineralocorticoid replacement is achieved through intravenous hydrocortisone plus sodium chloride. About 20 mg of hydrocortisone has a mineralocorticoid effect of about 0.1 mg of 9α-fluorocortisol (see Table 13-7). Mineralocorticoids are unique in pharmacology in that their doses are not based on body mass or surface area. In fact, newborns are quite insensitive to mineralocorticoids as reflected by their high serum aldosterone concentrations (see Figure 13-17) and often require larger doses than do adults (0.15 to 0.30 mg/day, depending on the sodium supplementation). In older children, the replacement dose of 9α-fluorocortisol is 0.05 to 0.15 mg daily. It must be emphasized that a mineralocorticoid is essentially useless unless adequate sodium is presented to the renal tubules. Thus, additional salt supplementation, usually 1 to 2 g NaCl/day in the newborn, is also needed. Some adult patients with severe salt-losing CAH can discontinue mineralocorticoid replacement and salt supplementation; this probably reflects the increased mineralocorticoid sensitivity in adults, their free access to salty foods, and the induction of hepatic extra-adrenal 21-hydroxylating enzymes.[27]

Long-term management requires careful clinical and laboratory monitoring. Measurements of growth should be made at 3- to 4-month intervals in children, along with an annual assessment of bone age. Each visit should be accompanied by measurement of blood pressure, plasma renin activity and serum Δ^4-androstenedione, DHEA, DHEA sulfate, and testosterone. Plasma 17OHP is generally measured but may be difficult to interpret because of its variation as a function of the timing of glucocorticoid doses, its diurnal variation and its hyperresponsiveness to stress (e.g., clinic visits).

Experimental Prenatal Treatment of CAH

Because the treatment of CAH involves administering a glucocorticoid to suppress the HPA axis, this approach has been proposed for treating the affected fetus by administering glucocorticoids to the mother. Female fetuses affected with CAH begin to become virilized at about 6 to 8 weeks' gestation, the same time at which the testes of normal male fetuses produce testosterone, causing fusion of the labioscrotal folds, enlargement of the genital tubercle into a phallus, and the formation of the phallic urethra. The adrenals of female fetuses with CAH may produce concentrations of testosterone that approach those of a normal male, resulting in varying degrees of masculinization of the external genitalia. If fetal adrenal steroidogenesis is suppressed in a female fetus with CAH, the virilization can theoretically be reduced or eliminated. Thus, some have advocated administering dexamethasone to the mother as soon as pregnancy is diagnosed; however, such treatment remains experimental and requires approval by an institutional review board (IRB) and informed parental consent.[22] This treatment should be done only when the parents are known to be heterozygotes by having already had an affected child. However, even in such pregnancies, only one in four fetuses will have CAH. Furthermore, as no prenatal treatment is needed for male fetuses affected with CAH, only one in eight pregnancies of heterozygous parents would harbor an affected female fetus that might potentially benefit from prenatal treatment. However, treatment must be started at about 6 weeks postconception (8 weeks of amenorrhea). Prenatal diagnostics cannot begin until 6 to 8 weeks into pregnancy when fetal sexing may be performed from mother's blood, allowing nontreatment or early cessation of dexamethasone treatment in male fetuses. In female fetuses, chorion biopsy at 12 to 13 weeks will allow the diagnosis of CAH. Thus, seven of eight pregnancies will be treated needlessly to treat one affected female fetus.[22]

The ethics of such prenatal treatment remain highly controversial.[22,118,119] The rationale is that dexamethasone, which is not metabolized by placental 11βHSD2, will cross the placenta, suppress fetal ACTH, and consequently suppress adrenal steroidogenesis. However, it is not known precisely when the fetal hypothalamus begins to produce CRH, when the fetal pituitary begins to produce ACTH, whether all fetal ACTH production is regulated by CRH, or whether these hormones are suppressible by dexamethasone in the early fetus. Although there is evidence that pharmacologic doses of glucocorticoids do not harm pregnant women, few data exist for the fetus. Pregnant women with diseases such as nephrotic syndrome and systemic lupus erythematosus are generally treated with prednisone, which does not reach the fetus because it is inactivated by placental 11βHSD. Treatment of a fetus with CAH requires the use of fluorinated steroids that escape metabolism by these enzymes, and few data are available about the long-term use of such agents throughout gestation.

The usual protocol employs dexamethasone doses of 20 μg/kg of maternal body weight (with a maximum dose of 1.5 mg/day). For a 60-kg woman, this is 1.2 mg, which is about six times physiologic replacement. However, the fetus normally develops in the presence of very low cortisol concentrations of only about 20 to 60 nmol/L (0.7 to 2 μg/dL),[120,121] which is only about 10% of the corresponding maternal level. Thus, the doses used in prenatal treatment appear to achieve effective concentrations of active glucocorticoid that may be up to 60 times physiologic for the fetus. The potential benefits of prenatal treatment are reduction or elimination of virilization of external genitalia and brain, reducing the risk of gender confusion and the need for surgery. The advocates of prenatal treatment report modest cushingoid features in the mother and no untoward effects in the offspring, including the 7 of 8 fetuses in whom the treatment is stopped once the diagnosis is made. However, animal

studies indicate prenatally administered dexamethasone increases risks of palatal clefting; impairs brain, kidney, and islet cell development; decreases birth weight; and increases risks of hypertension.[22,119,122] Human studies have been limited in methodology or size, but clinical studies in Sweden found that prenatally treated children without CAH had poorer working memory and poorer self-perception of scholastic competence and increased self-rated social anxiety[123]; there were also mild effects on sociability[124] and gender role behavior in boys,[125] leading the Swedish investigators to discontinue further research on this treatment.[126] Alternative approaches, such as a preimplantation genetic diagnosis, also carry some risks. Thus, the risks of prenatal treatment appear to outweigh the benefits.[119]

Experimental Postnatal Treatment of CAH

Growth is compromised in most children with CAH. The use of short-acting glucocorticoids and mineralocorticoid supplementation help, but adult heights are typically at least 1 SD below predicted heights (based on parental heights).[22] The loss of height in CAH is partially due to the effect of sex steroids on epiphyseal closure and partially due to glucocorticoid-induced resistance to the action of growth hormone; the most crucial times when height is lost are during the first 2 years of life and during the pubertal growth spurt. Consequently, several research studies have addressed optimizing the final height of children with CAH.[22]

Antiandrogens and Aromatase Inhibitors. Antiandrogens and aromatase inhibitors have been tried in the presence of low-dose mineralocorticoids and lower doses of glucocorticoids.[22] Because estrogen, not androgen, is the key hormone in promoting epiphyseal fusion, inhibiting the conversion of androgen to estrogen with an aromatase inhibitor (testolactone) promotes growth, whereas the antiandrogen (flutamide) ameliorates virilization. The principal benefit of this approach is that it permits the use of physiologic replacement doses of glucocorticoids (8 mg/m^2/day of hydrocortisone), rather than the usual supraphysiologic doses of 12 to 15 mg/m^2/day, thus further promoting normal growth. The drugs are expensive and not approved for this use, long-term safety and efficacy are not established, and antiandrogens are potentially hepatotoxic. Thus, like all experimental therapies, this approach should only be pursued in controlled, prospective, IRB-approved trials.[22]

Adrenalectomy. Adrenalectomy has been proposed in severe CAH. As the adrenal carrying severe P450c21 mutations (e.g., gene deletions) cannot produce aldosterone or cortisol, it has been argued that these affected glands do more harm than good and should be removed. The advent of laparoscopic adrenalectomy has made this suggestion feasible without undue surgical trauma to the patient. Among 18 adrenalectomized patients, five had adrenal crises when therapy was suboptimal and two became hypoglycemic during intercurrent illnesses.[22] These risks are similar to those faced by children with CAH who do not receive stress-dose steroids. Adrenalectomy also removes the adrenal medulla, but it does not appear to predispose to hypoglycemia because children with CAH are already epinephrine deficient. Thus, although adrenalectomy is an extreme measure, it may be appropriate in selected cases.[22]

Growth Hormone and GnRH Agonist Therapy. Growth hormone and GnRH agonist therapy have been proposed in children near the age of puberty, as pharmacologic GH therapy may partially overcome the effects of higher doses of glucocorticoids, and GnRH agonists will delay the progression of puberty, permitting more time to grow. Small preliminary studies with these agents are promising, but both agents are expensive and neither is approved for this use; controlled prospective trials are needed.[22]

Lesions in Isozymes of P450c11

11β-Hydroxylase Deficiency

There are two distinct forms of 11-hydroxylase.[9] P450c11β, encoded by the *CYP11B1* gene, mediates the 11β-hydroxylation of 11-deoxycortisol to cortisol and that of DOC to corticosterone in the zonae fasciculata and glomerulosa. P450c11AS, or aldosterone synthase, encoded by the *CYP11B2* gene, is found only in the zona glomerulosa and mediates 11β-hydroxylation, 18-hydroxylation, and 18-oxidation; thus, it is the sole enzyme required to convert DOC to aldosterone. P450c11β is found in both the glomerulosa and fasciculata, and mediates 11β-hydroxylation and some 18-hydroxylation, but it has no 18-methyl oxidase activity. Deficient P450c11β activity causes about 5% of CAH in persons of European ancestry but is more common in both Moslem and Jewish Middle Eastern populations.[127,128] Severe deficiency of P450c11β decreases the secretion of cortisol, causing CAH and virilization of affected females. The defect in the pathway to cortisol results in accumulation of 11-deoxycortisol and the defect in the 17-deoxy pathway in the synthesis of corticosterone in the fasciculata may lead to overproduction of DOC. Because DOC is a mineralocorticoid, these patients can retain sodium. Although DOC is less potent than aldosterone, it is secreted at high levels in 11β-hydroxylase deficiency, so that salt is retained and the serum sodium remains normal. Overproduction of DOC frequently leads to hypertension; as a result, 11β-hydroxylase deficiency is often referred to as "the hypertensive form of CAH" when detected in older children. However, newborns often manifest mild, transient salt loss as a result of the normal newborn resistance to mineralocorticoids (Figure 13-17); this may lead to incorrect diagnosis and treatment. Thus, there may be a poor correlation between DOC concentrations, serum potassium, and blood pressure or between the degree of virilization in affected females and the electrolyte and cardiovascular manifestations. Newborns may also have elevated concentrations of 17OHP, presumably as a "backup" phenomenon of high concentrations of 11-deoxycortisol inhibiting P450c21, so that P450c11β deficiency may be detected in newborn screening for P450c21 deficiency.[111] The diagnosis is established by demonstrating elevated basal concentrations of DOC and

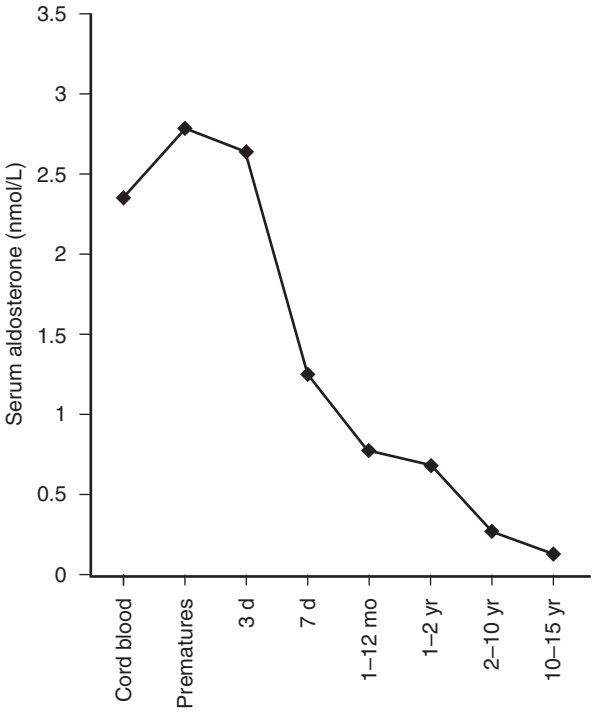

FIGURE 13-17 ■ Concentrations of aldosterone as a function of age.

11-deoxycortisol which hyperrespond to ACTH; a normal or suppressed plasma renin activity is also a hallmark of this disease.

The *CYP11B1* mutations causing 11β-hydroxylase deficiency have been reviewed; common mutations include R448H, which is common among Moroccan Jews, and Q356X and G379V found in Tunisian Arabs.[128] A milder, nonclassic form of 11β-hydroxylase deficiency, analogous to nonclassic 21-hydroxylase deficiency has been reported in otherwise asymptomatic women with hirsutism, virilism, and menstrual irregularities. However, true nonclassic 11β-hydroxylase deficiency is rare; only two of five hyperandrogenemic women who had 11-deoxycortisol values more than three times higher than the 95th percentile in response to stimulation with ACTH had mutations of P450c11β, all of which retained 15% to 37% of normal activity.[129] Repeated ACTH testing in two of the three women who lacked mutations showed much lower (but still elevated) 11-deoxycortisol values. Thus, just as in the case of nonclassic 3βHSD deficiency, an abnormal steroid response to ACTH is not sufficient to diagnose a genetic lesion.

Corticosterone Methyl Oxidase Deficiencies

P450c11AS, encoded by the CYP11B2 gene, has 93% amino acid sequence identity with P450c11β and is expressed exclusively in the zona glomerulosa, where it catalyzes 11β-hydroxylase, 18-hydroxylase, and 18 methyl oxidase activities. Disorders of P450c11AS cause the so-called corticosterone methyl oxidase (CMO) deficiencies, wherein aldosterone biosynthesis is impaired while the zona fasciculata continues to produce corticosterone and DOC. The absence of aldosterone biosynthesis will generally result in a salt-wasting crisis in infancy, at which time the normal secretory rate of DOC is insufficient to meet the newborn's mineralocorticoid requirements (similarly to the newborn with P450c11β deficiency). Thus, these infants typically present with hyponatremia, hyperkalemia, and metabolic acidosis, but the salt-wasting syndrome is typically less severe than in patients with 21-hydroxylase deficiency or lipoid CAH because of the persistent secretion of DOC. These patients may recover spontaneously and grow to adulthood without therapy. This probably reflects the increasing sensitivity to mineralocorticoid action with advancing age in childhood, as reflected by the usual, age-related decrease in serum aldosterone (see Figure 13-17). Consistent with this, plasma renin activity is markedly elevated in affected children but may be normal in affected adults.

CMOI deficiency results from a complete loss of P450c11AS activity so that no 18-hydroxylase or 18 methyl oxidase activity persists, eliminating the biosynthesis of 18OH-corticosterone and aldosterone, while preserving the biosynthesis of corticosterone by P450c11β. Thus, the diagnosis for CMOI deficiency is usually based on an increased ratio of corticosterone to 18OH-corticosterone. A frameshift mutation, a premature stop codon, and the missense mutation R384P are known to cause this disorder.[9]

CMOII deficiency results from amino acid replacement mutations in P450c11AS that selectively delete the 18 methyl oxidase activity while preserving the 18-hydroxylase activity. The diagnosis of CMOII deficiency requires an increased 18OH-corticosterone and very low aldosterone concentration. CMOII deficiency is common in Sephardic Jews of Iranian origin, where all affected individuals appear to be homozygous for two different mutations, R181W and V385A.[130] Family members who were homozygous for only one of these mutations were clinically unaffected; both mutations are required to cause disease.

The distinction between CMOI and CMOII is not precise, and these disorders should be regarded as different degrees of severity on a continuous clinical spectrum just as the various forms of 21-hydroxylase deficiency are part of a broad clinical spectrum. The close linkage and genetic similarity of the *CYP11B1* and *CYP11B2* genes is reminiscent of the P450c21A and P450c21B genes. However, gene conversion is rare, apparently due to the higher recombinational frequency in the HLA region carrying the P450c21 genes.

Glucocorticoid-Suppressible Hyperaldosteronism

Although *CYP11B* gene conversions are rare, an unusual gene duplication causes glucocorticoid-suppressible hyperaldosteronism. A homologous recombination event creates a third CYP11B gene that fuses the 5′ flanking DNA of the CYP11B1 gene for P450c11β onto the CYP11B2 gene for P450c11AS, thus placing the regulation of P450c11AS under the control of ACTH rather than the renin-angiotensin system, so that these patients make P450c11AS in response to physiology that should stimulate P450c11β.[131] The excess P450c11AS causes hyperaldosteronism and hypertension; this is then

suppressible by glucocorticoid suppression of ACTH, which normally suppresses P450c11β, hence the name "glucocorticoid-remediable hypertension"; this disorder appears to account for about 2% of hypertension.[132]

Lesions in Isozymes of 11β-Hydroxysteroid Dehydrogenase

Cortisone and prednisone are inactive prohormones that must be reduced to cortisol or prednisolone in order to bind to and activate the glucocorticoid receptor. The interconversion of these keto- and hydroxysteroids is catalyzed by the two isozymes of 11β-hydroxysteroid dehydrogenase, 11βHSD1 (encoded by *HSD11B1*) and 11βHSD2 (encoded by *HSD11B2*). Both enzymes are reversible in vitro, hence both can act as either an oxidase or reductase, depending on the availability of cofactors, but under physiologic situations 11βHSD1 generally acts to activate cortisone to cortisol whereas 11βHSD2 reverses this activation.[9,11,45] 11βHSD1 is primarily expressed in liver and fat, and 11βHSD2 is expressed in mineralocorticoid-responsive tissues where it inactivates cortisol, permitting low concentrations of aldosterone to activate mineralocorticoid receptors (which also bind cortisol); 11βHSD2 is inactive against aldosterone, DOC, and fluorocortisol. Interest in these enzymes extends far beyond their deficiency states, as they play central roles in metabolism[43-45]; this has stimulated interest in using inhibitors of 11βHSD1 to treat the metabolic syndrome, but such agents are not yet clinically available.[133]

Lesions in 11βHSD1: (Apparent) Cortisone Reductase Deficiency

Defective 11βHSD1 activity, diagnosed by reduced ratios of urinary metabolites of cortisol to those of cortisone, impairs cortisol feedback at the hypothalamic-pituitary axis, increasing the secretion of ACTH and consequently increasing adrenal C19 steroid secretion resulting in hyperandrogenism, sexual precocity, and polycystic ovaries. These patients may have heterozygous mutations (K187N, R137C) in the *HSD11B1* gene encoding 11βHSD1; because 11βHSD1 normally functions as a dimer, the presence of some mutant protein can exert dominant negative effects.[134] Alternatively, a genetic lesion may be found in the *H6PDH* gene,[135] which encodes hexose-6-phosphate dehydrogenase (H6PDH), the enzyme that generates the NADPH used by 11βHSD1 in the lumen of the endoplasmic reticulum. Although it was initially thought that mutations in both 11βHSD1 and H6PDH interacted to cause this disease,[136] mutations of H6PDH in patients appear to manifest with a more severe phenotype and are sufficient to cause this disorder.[134,135,137,138]

Lesions In 11βHSD2: Apparent Mineralocorticoid Excess (AME)

Patients with AME have hypervolemic hypertension, salt retention, and hypokalemic alkalosis—the classic picture of hyperaldosteronism—but with suppressed plasma renin activity and without measurable serum mineralocorticoids due to recessive mutations of 11βHSD2.[42] About 30 different mutations in 11βHSD2 have been described in about 60 patients with AME, and heterozygous carriers may have an increased risk of hypertension.[139] Typical features of children with AME include failure to thrive, delayed puberty, polydipsia, polyuria, muscle weakness, and hypertension. The hypertension is severe, often causing end-organ damage at an early age. Diagnosis is made from the high ratio of urinary metabolites of cortisol to cortisone. Treatment includes antagonism of the mineralocorticoid receptor with spironolactone, correction of the hypokalemia, low-salt diets, and diuretics, but it is only partially successful, and 10% of patients die from cerebrovascular accidents.[140]

ADRENAL INSUFFICIENCY

Many conditions cause adrenal insufficiency, including CAH, hypopituitarism with ACTH deficiency, and primary adrenal disorders. Primary adrenal insufficiency is commonly termed Addison disease, but this is a vague term that encompasses many disorders. Up to World War II, most patients with "Addison disease" had tuberculosis of the adrenal, but over 80% of contemporary adult patients have autoimmune adrenalitis, therefore, the term *Addison disease* is now widely used to indicate an autoimmune or idiopathic cause.

The spectrum of adrenal disorders presenting in infants, children, and adolescents differs from that presenting in adulthood (Box 13-1). CAH and autoimmune adrenal disease represent the largest proportions of cases, but some of the inherited developmental and metabolic causes of adrenal failure are also fairly common.[141,142] Diagnosing some of these disorders is important for assessing potential associated features, initiating long-term management, and instituting genetic counseling.[143] Adrenal disorders are typically divided into chronic and acute causes, but many acute presentations reflect an undiagnosed underlying chronic or developmental process (Box 13-2). Acute presentations may be triggered by intercurrent illness, trauma, or surgery, with poor fluid and sodium intake.

Acute Primary Adrenal Insufficiency

Acute adrenal crisis occurs most commonly in the child with undiagnosed chronic adrenal insufficiency who is subjected to an additional severe stress such as major illness, trauma, or surgery. The major presenting symptoms and signs include abdominal pain, fever, hypoglycemia with seizures, weakness, apathy, nausea, vomiting, anorexia, hyponatremia, hypochloremia, acidemia, hyperkalemia, hypotension, shock, cardiovascular collapse, and death. Treatment consists of fluid and electrolyte resuscitation, ample doses of glucocorticoids, chronic glucocorticoid and mineralocorticoid replacement, and treatment of the precipitating illness.

Massive adrenal hemorrhage with shock due to blood loss can occur in large infants who have had a traumatic delivery. A flank mass is usually palpable and can be distinguished from renal vein thrombosis by microscopic rather than gross hematuria; the diagnosis is then confirmed by

BOX 13-1 Causes of Adrenal Insufficiency

Primary Adrenal Insufficiency

- Congenital adrenal hyperplasia
  - Autoimmune disorders
  - Autoimmune adrenalitis
- Autoimmune polyglandular syndromes
- Adrenal hypoplasia congenita
  - X-linked adrenal hypoplasia
  - Other (*SF1*, IMAGe syndrome)
- ACTH resistance syndromes
  - Familial glucocorticoid deficiencies, types 1 and 2
  - Triple A (Allgrove) syndrome
- Metabolic disorders
  - Adrenoleukodystrophy
  - Peroxisome biogenesis disorders (e.g., Zellweger)
  - Cholesterol metabolism (Smith-Lemli-Opitz, Wolman)
  - Mitochondrial (Kearn-Sayers, mitochondrial deletions)
- Infectious disorders
  - Sepsis
  - Tuberculosis
  - Fungal infections
  - Viral
- Infiltrative/destructive causes
  - Hemorrhage
  - Amyloidosis, sarcoidosis, metastases
- Drugs inhibiting steroid biosynthesis

Secondary Adrenal Insufficiency

- Hypothalamic tumors, radiation, or surgery
- Hypopituitarism
- Isolated ACTH insufficiency
- Defects in POMC synthesis and processing
- Withdrawal from glucocorticoid therapy

BOX 13-2 Signs and Symptoms of Adrenal Insufficiency

Features Shared by Acute and Chronic Insufficiency

- Anorexia
- Apathy and confusion
- Dehydration
- Fatigue
- Hyperkalemia
- Hypoglycemia
- Hyponatremia
- Hypovolemia and tachycardia
- Nausea and vomiting
- Postural hypotension
- Prolonged neonatal jaundice
- Salt craving
- Weakness

Features of Acute Insufficiency (Adrenal Crisis)

- Abdominal pain
- Fever

Features of Chronic Insufficiency (Addison Disease)

- Decreased pubic and axillary hair
- Diarrhea
- Hyperpigmentation
- Low-voltage electrocardiogram
- Small heart on x-ray
- Weight loss

computed tomography or ultrasonography. Massive adrenal hemorrhage is more commonly associated with meningococcemia (Waterhouse-Friderichsen syndrome). Meningitis is often, but not always, present. The characteristic petechial rash of meningococcemia can progress rapidly to large ecchymoses; the blood pressure drops and respirations become labored, frequently leading rapidly to coma and death. Immediate intervention with intravenous fluids, antibiotics, and glucocorticoids is not always successful. A similar adrenal crisis may also occur rarely with septicemia from *Streptococcus*, *Pneumococcus*, *Pseudomonas*, diphtheria, and methicillin-sensitive and resistant isolates of *Staphylococcus aureus*.[144] Adrenal hemorrhage has also been reported with the antiphospholipid syndrome and in patients on anticoagulant therapy.

Chronic Primary Adrenal Insufficiency

Autoimmune Disorders

Autoimmune adrenalitis is most commonly seen in adults 25 to 45 years old, about 60% to 70% of whom are women, with an adult prevalence of about 1 in 25,000.[145] Autoimmune destruction of other endocrine tissues is frequently associated with autoimmune adrenalitis. Chronic adrenal insufficiency is suggested by poor weight gain or weight loss, weakness, fatigue, anorexia, hypotension, hyponatremia, hypochloremia, hyperkalemia, frequent illnesses, nausea, and vague gastrointestinal complaints (see Box 13-2), reflecting chronic deficiency of both glucocorticoids and mineralocorticoids. Early in the course of autoimmune adrenalitis one may see signs of glucocorticoid deficiency (weakness, fatigue, weight loss, hypoglycemia, anorexia) without signs of mineralocorticoid deficiency (hyponatremia, hyperkalemia, acidosis, tachycardia, hypotension, low voltage on EKG, small heart on chest x-ray) or evidence of mineralocorticoid deficiency without glucocorticoid deficiency. Thus, an initial clinical presentation that spares one category of adrenal steroids does not mean it will be spared in the long run. The symptoms listed in Box 13-2 can be seen in chronic adrenal insufficiency that is either primary or secondary. In primary chronic adrenal insufficiency, the low concentrations of plasma cortisol stimulate the hypersecretion of ACTH and other POMC peptides, including the various forms of melanocyte-stimulating hormone (MSH); consequently, chronic primary adrenal insufficiency is also characterized by

hyperpigmentation of the skin and mucous membranes, whereas secondary adrenal insufficiency is not. Such hyperpigmentation is most prominent in skin exposed to sun and in flexor surfaces such as knees, elbows, and knuckles. The diagnosis is suggested by the previously listed signs and symptoms, verified by a low morning cortisol level with a high ACTH, and confirmed by a minimal response of cortisol to a 60-minute intravenous ACTH test. Hyponatremia, hyperkalemia, low aldosterone, and elevated PRA suggest a disturbance in mineralocorticoid production. Associated findings may include the appearance of a small heart on chest x-ray, anemia, azotemia, eosinophilia, lymphocytosis, and hypoglycemia. Treatment of chronic primary adrenal insufficiency consists of physiologic glucocorticoid and mineralocorticoid replacement therapy.

Autoimmune adrenalitis is strongly associated with specific HLA haplotypes and with polymorphisms in the gene for cytotoxic T lymphocyte–associated antigen 4 (CLTA 4), which may be broadly involved in susceptibility to autoimmune disease.[146,147] The diagnosis of autoimmune chronic adrenal insufficiency is based largely on finding circulating antibodies directed against adrenal cells or adrenal cellular contents. In many cases the adrenal antigens are steroidogenic cytochrome P450 enzymes, especially P450scc, P450c17, and P450c21.[145] It is not clear how these enzymes reach immune cells to elicit an antibody response, but autopsy studies show infiltration of the adrenal cortex.[141] Thus, it is likely that cell-mediated immunity is responsible for destruction of adrenocortical cells, resulting in a secondary discharge of cellular contents (including P450 enzymes) into the circulation, with the subsequent development of secondary "marker" antibodies against these P450s. About half of adult patients with lymphocytic adrenalitis will also have autoimmune disease of another endocrine tissue with high titers of antibodies directed against specific contents of the affected tissue. This finding has led to the definition of specific autoimmune polyendocrine syndromes (APS), some of which are more prevalent in childhood.

Type 1 Autoimmune Polyendocrine Syndrome. Type 1 autoimmune polyendocrine syndrome (APS1), also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dysplasia (APECED), is characterized by chronic mucocutaneous candidiasis, autoimmune Addison disease, and hypoparathyroidism. At least two of these features must be present to make the diagnosis, and their age of onset can be highly variable. In general, chronic mucocutaneous candidiasis appears in early childhood and affects the mouth and nails. Acquired hypoparathyroidism can present with clinical hypocalcemia during middle or late childhood, although in some cases hypocalcemia may be masked by untreated adrenal insufficiency. The adrenal disorder usually presents in childhood or adolescence; autoimmune adrenal disease may be a presenting feature in about 5% of cases.[148] Additional autoimmune features of this condition include alopecia and vitiligo; gastritis, chronic diarrhea, and malabsorption with or without pernicious anemia; hypergonadotropic hypogonadism, especially in women; and less commonly hepatitis, thyroiditis, interstitial nephritis, myositis, dental enamel hypoplasia, acquired asplenia, and type 1 diabetes mellitus. Keratoconjunctivitis is an important associated feature that requires careful monitoring and treatment to prevent blindness. Oral or esophageal squamous cell carcinoma occurs in 10% of individuals as adults.[148] APS1 is rare in most populations but is common among people of Finnish (1:15,000), Sardinian, and Iranian Jewish (1:9,000) ancestry.[141] APS1 is caused by recessively inherited mutations in a 58-kilodalton transcription factor called AIRE ("autoimmune regulator").[149,150] More than 50 different mutations in the *AIRE* gene have been described, although the homozygous or compound heterozygous R257X change is especially common in the Finnish population. The *AIRE* gene is widely expressed in developing tissues of the immune system. The specific mechanisms by which these mutations result in the pleiotropic findings of APS1 are not yet clear, although deletion of AIRE in mice results in ectopic expression of peripheral tissue antigens in thymic medullary epithelial cells, resulting in the development of an autoimmune disorder similar to APS1/APECED.[151]

Type 2 Autoimmune Polyendocrine Syndrome. Type 2 autoimmune polyendocrine syndrome (APS2), also known as Schmidt syndrome, refers to the relatively common association of autoimmune adrenalitis with thyroiditis or type 1 diabetes.[145] APS2 is more common in females (3:1 ratio), is HLA-linked, and is generally seen in young or middle-aged adults but can present at almost any age. Primary (hypergonadotropic) ovarian failure is seen in up to one quarter of postpubertal females with APS2, but primary testicular failure is rare.[141] Pernicious anemia, hepatitis, vitiligo, and alopecia may also be seen, but the hypoparathyroidism and mucocutaneous candidiasis typical of APS1 are not seen in APS2. APS2 is associated with the same HLA markers as idiopathic autoimmune adrenalitis, which may simply be a form of APS2.

Adrenal Hypoplasia Congenita

Adrenal hypoplasia congenita, also known as congenital adrenal hypoplasia, is a disorder of adrenal development resulting in primary adrenal insufficiency. This condition can occur with several different inheritance patterns and with a variety of associated or syndromic features.

X-linked Adrenal Hypoplasia Congenita. X-linked adrenal hypoplasia congenita (AHC) is caused by mutations of the *NR0B1* gene encoding DAX1 on chromosome Xp21. In this most common form of primary adrenal hypoplasia, the definitive zone of the fetal adrenal does not develop, and the fetal zone is vacuolated and cytomegalic. About half of boys with AHC present with salt loss and glucocorticoid insufficiency in early infancy; the rest present more insidiously with chronic adrenal insufficiency throughout childhood.[142] Hypogonadotropic hypogonadism and incomplete pubertal development are associated features, although early puberty with subsequent pubertal arrest has been reported in rare cases. An underlying defect in spermatogenesis may also be present.

DAX1 is a nuclear transcription factor involved in adrenal and testicular development, as well as being expressed in pituitary gonadotropes. About two thirds of boys with AHC have point mutations,[142] the other one third have *NR0B1* gene deletions either in isolation or as part of a contiguous gene deletion syndrome involving a telomeric X-linked mental retardation locus (*IL1RAPL1*) or centromeric genes for glycerol kinase deficiency (*GKD*) and sometimes ornithine transcarbamylase (*OTC*) and Duchenne muscular dystrophy (*DMD*). An adult-onset form of AHC due to point mutations has also been described.[152]

Boys with AHC respond well to glucocorticoid and mineralocorticoid replacement therapy. Testosterone treatment to induce secondary sexual characteristics is needed in adolescence; spontaneous fertility is rare and attempts to induce spermatogenesis with gonadotropins are rarely successful. Female carriers are unaffected, but half of their sons will be affected. Close monitoring and genetic counseling can help to prevent life-threatening adrenal crises in other family members or future pregnancies. Thus, a family history of adrenal failure, unexplained death, or pubertal abnormalities in the male relatives of a boy with adrenal insufficiency should suggest AHC; indeed, a substantial proportion of boys with sporadic adrenal hypoplasia have DAX1 mutations.[142]

Autosomal Forms of Adrenal Hypoplasia. In addition to X-linked AHC, autosomal recessive forms of adrenal hypoplasia have been reported and are yielding to genetic analysis. Mutations in steroidogenic factor-1 (SF1, *NR5A1*), which were discussed earlier as a disorder of steroidogenesis that resembles lipoid CAH, are sometimes classified as a form of adrenal hypoplasia. However, SF1 mutations affect the gonad more severely than the adrenal and have not been reported in phenotypic males with adrenal hypoplasia.[142] Primary adrenal failure has also been associated with Pena-Shokeir syndrome type 1, pseudotrisomy 13, Meckel syndrome, and Pallister-Hall syndrome (*GLI3*), and with defects in *WNT3*.[4]

IMAGe Syndrome. Primary adrenal hypoplasia and neonatal adrenal crisis are also part of the IMAGe syndrome (*I*ntrauterine growth retardation, *M*etaphyseal dysplasia, *A*drenal hypoplasia, *Ge*nitourinary anomalies).[153] A large, multigenerational family with multiple, well-characterized individuals[154] has now been studied by linkage analysis, identifying a dominant missense mutation in the *CDKN1C* gene as the cause of this disorder.[155] In addition, four other unrelated patients had four different missense mutations in *CDKN1C*.[155] The *CDKN1C* gene encodes the Wilms tumor supressor p57KIP2, which inhibits several cyclin-dependent kinases. This gene lies in the imprinted region of chromosome 11p15.5, so that only the maternal allele is expressed. Different mutations in this same gene cause Beckwith-Wiedemann syndrome.[156] The Beckwith mutations inhibit cell cycle, whereas the IMAGe mutations do not, and, when expressed in *Drosophila*, the Beckwick mutations have no effect on eye development, but the IMAGe mutations cause restricted growth.[155] Thus, mutations in the same gene cause both the IMAGe adrenal hypoplasia syndrome and the Beckwith-Wiedemann adrenal hyperplasia syndromes.

ACTH Resistance Syndromes

Hereditary unresponsiveness to ACTH, also termed familial glucocorticoid deficiency (FGD), can present as an acute adrenal crisis precipitated by an intercurrent illness in an infant or with the signs and symptoms of chronic adrenal insufficiency in childhood. Several different recessively inherited causes of FGD have been identified. Unlike individuals with autoimmune adrenalitis, adrenal hypoplasia, or other forms of destruction of adrenal tissue, patients with hereditary unresponsiveness to ACTH typically continue to produce mineralocorticoids, because production of aldosterone by the adrenal zona glomerulosa is regulated principally by the renin-angiotensin system. Thus, the presenting picture consists of failure to thrive, lethargy, pallor, hyperpigmentation, and hypoglycemia, often associated with seizures. Rare cases may also entail electrolyte abnormalities or increased plasma renin activity, leading to misdiagnosis as a different form of adrenal insufficiency.

MC2R Mutations: Familial Glucocorticoid Deficiency Type 1 (FGD1). The ACTH receptor is a 7-transmembrane, G-protein–coupled member of the family of melanocortin receptors termed MC2R.[157] *MC2R* mutations appear to be the most common cause of ACTH resistance, with several dozen reported cases, but the statistical distribution of these cases is unclear, as many different clinical criteria have been applied.[82] These patients present with glucocorticoid deficiency and hyperpigmentation, often around 2 years of age; hypoglycemia is common and ACTH levels are grossly elevated, accounting for the hyperpigmentation. Tall stature and increased head circumference has been reported in several cases. Treatment with replacement doses of glucocorticoids typically prevents adrenal crises but may not suppress elevated ACTH levels completely; nevertheless, the use of supraphysiologic doses of steroids to suppress ACTH should be avoided.

MRAP Mutations: Familial Glucocorticoid Deficiency Type2 (FGD2). The melanocortin 2 receptor accessory protein, MRAP, is a small transmembrane protein that forms unusual antiparallel dimers and serves two functions: it facilitates trafficking of MC2R from the endoplasmic reticulum to the cell membrane, and it interacts with MC2R on the cell surface to facilitate receptor action.[158] Both MRAP and the related MRAP2 protein serve similar functions with other members of the MCR family, but MRAP2 mutations have not yet been reported. MRAP mutations apparently are the second-most common cause of FGD, but MRAP mutations are clinically indistinguishable from MC2R mutations.[159]

Other Forms of Familial Glucocorticoid Deficiency. Mild mutations in StAR that cause nonclassic lipoid CAH[81] may be mistaken for familial glucocorticoid deficiency.[82] Linkage analysis in families with apparent FGD has identified mutations in *NNT*, the gene encoding

nicotinamide nucleotide transhydrogenase, as another cause of this disease.[160] The NNT protein is located on the inner mitochondrial membrane, where it participates in the generation of NADPH, which is necessary for the action of P450scc to convert cholesterol to pregnenolone and for responses to oxidative stress. In the Irish Traveller population, the *MCM4* gene encoding minichromosome maintenance complex component 4 has also been found to be associated with FGD; patients with MCM4 mutations also presented with growth failure, increased chromosomal breakage, and natural killer cell deficiency.[161]

Triple A (Allgrove) Syndrome. Triple A (Allgrove) syndrome consists of (1) ACTH-resistant *a*drenal (glucocorticoid) deficiency (80% of individuals), (2) *a*chalasia of the cardia (85%), and (3) *a*lacrima (90%). The alacrima is the earliest and most consistent symptom, and the achalasia and adrenal insufficiency develop over the first two decades, although the achalasia is usually noted first. Mineralocorticoid insufficiency is reported in about 15% of cases, and up to 60% of patients develop progressive neurologic symptoms such as intellectual impairment, sensorineural deafness, peripheral and cranial neuropathies, optic atrophy, Parkinsonism, and autonomic dysfunction.[75] About 80% of affected patients have autosomal recessive mutations in *AAAS*, which encodes a WD-repeat protein termed ALADIN[162,163]; the basis of the disease in patients lacking AAAS mutations is not yet known. ALADIN co-localizes to the cytoplasmic side of the nuclear pore, where it interacts with and participates in the nuclear translocation of ferritin heavy chain protein, FTH1, thus rendering cells progressively susceptible to oxidative damage.[164] Clinical findings can be quite variable even within the same family. Adrenal insufficiency is rarely the presenting feature. Thus, a detailed family history of achalasia, alacrima, or neurologic disorders is important when evaluating a patient with primary adrenal failure.

Metabolic Disorders

Metabolic disorders can also cause chronic primary adrenal insufficiency, including adrenoleukodystrophy (Schilder disease), peroxisome biosynthesis disorders (e.g., Zellweger syndrome spectrum), disorders of cholesterol synthesis and metabolism (e.g., Wolman disease, cholesterol ester storage disease, Smith-Lemli-Opitz syndrome), and mitochondrial disorders (e.g., Kearns-Sayre syndrome).

Adrenoleukodystrophy (ALD). This peroxisomal disease is the most common metabolic cause of adrenal failure. Most cases are caused by mutations in the peroxisomal membrane protein ALDP encoded by the *ABCD1* gene on chromosome Xq28[165,166]; ALDP belongs to the superfamily of ATP-binding cassette transporters. There are many clinical forms of ALD, including the childhood cerebral form (CCALD) with cerebral demyelination, the adolescent cerebral form, the adult cerebral form, adrenomyeloneuropathy with axonopathy of the pyramidal and somatosensory tracts and peripheral neuropathy, the olivo-ponto-cerebellar form, and a form presenting only with Addison disease.[167] CCALD is the most common phenotype. The prevalence of this condition is generally reported to be between 1:20,000 to 100,000, although the overall frequency may be as high as 1:17,000.[168] A rare autosomal recessive form of this condition also exists, which usually presents in infancy (discussed later).

ALDP imports activated acyl-CoA derivatives of very long chain fatty acids (VLCFA) into peroxisomes where they are shortened by β-oxidation.[169,170] Consequently, ALD is characterized by high ratios of C26 to C22 VLCFA in plasma and tissues, permitting the diagnosis of individual patients and affected fetuses.[171] Carriers can usually be detected by VLCFA screening, although genetic analysis may be necessary in some cases. Symptoms of X-linked CCALD commonly develop in mid-childhood; adrenomyeloneuropathy presents in adulthood.[172] The same ALDP mutation can cause both adrenoleukodystrophy and adrenomyeloneuropathy, hence it is likely that other genetic loci are also involved.[173] The earliest findings in CCALD are associated with the central nervous system leukodystrophy and include behavioral changes, poor school performance, dysarthria, and poor memory progressing to severe dementia. Symptoms of adrenal insufficiency usually appear after symptoms of white matter disease, but adrenal insufficiency may be the initial finding in up to 20% of children or young adults.[168,174,175] By contrast, adrenomyeloneuropathy typically begins with adrenal insufficiency in childhood and adolescence, and signs of neurologic disease follow 10 to 15 years later. About 1% to 3% of female carriers of X-linked ALD may develop neurologic symptoms or adrenal dysfunction. Because screening is accurate and the diagnosis has long-term implications, VLCFA should be analyzed in all boys presenting with adrenal failure where the diagnosis is not clear.

Dietary therapy with so-called Lorenzo's oil (a 4:1 mixture of glyceryl-trioleate and glyceryl-trierucate) improves VLCFA levels, but it has been ineffective for the treatment of established cerebral disease, although a role in preventing the onset of cerebral disease has been evaluated.[168,173] Other therapeutic options include hematopoietic stem cell transplantation,[168,170] which is most successful for early cerebral disease with a reported 5- to 8-year survival rate of 56%.[176] Lovastatin treatment decreases plasma C24:0 and C26:0 but is no longer recommended because it has no effect on C26:0 in cells or on VLCFAs.[177]

Peroxisome Biogenesis Disorders. Peroxisome biogenesis disorders (PBDs) are a group of autosomal recessive conditions caused by mutations in PEX proteins. Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease form the "Zellweger spectrum" and are clinically distinct from rhizomelic chondrodysplasia punctata due to PEX7 gene mutations.[178,179] These disorders are characterized by developmental delay, hypotonia, neurosensory deafness, optic atrophy, and dysmorphic facial development. Patients often develop seizures, especially those with neonatal adrenoleukodystrophy. The diagnosis can be confirmed by the presence of C26:1, increased

C26:0, and an increased ratio of C26:C22 and C24:C22 VLCFA. Most children with the severe forms of Zellweger syndrome and neonatal adrenoleukodystrophy do not survive past 2 years, although other variants of the Zellweger spectrum are associated with longer survival.[180]

Wolman Disease. Most cellular cholesterol derives from the uptake of circulating lipoproteins that contain cholesterol esters; these esters are cleaved to free cholesterol by lysosomal acid lipase (cholesterol esterase), encoded by the *LIPA* gene on chromosome 10q23.31.[10] Mutations of *LIPA* cause Wolman disease (primary xanthomatosis) and its milder variant, cholesterol ester storage disease.[181-186] In Wolman disease, cholesteryl esters and triglycerides accumulate in the liver, spleen, lymph nodes, and other tissues. In the adrenal, there is insufficient free cholesterol available for steroidogenesis, causing adrenal insufficiency. The disease is less severe than congenital lipoid adrenal hyperplasia with respect to steroidogenesis, and patients may survive for several months after birth. However, the disease affects all cells, not just steroidogenic cells, as all cells must store and utilize cholesterol; hence, the disorder is relentless and fatal. Vomiting, steatorrhea, failure to thrive, hepatosplenomegaly, jaundice, and anemia are the usual presenting findings, sometimes beginning in the first week of life, leading to developmental delay and malabsorptive malnutrition. Characteristic bilateral subcapsular adrenal calcification that outlines the adrenals may be seen on pre- or postnatal ultrasound scan. The diagnosis is established by bone marrow aspiration yielding foam cells containing large lysosomal vacuoles engorged with cholesterol esters, and it is confirmed by finding absent cholesterol esterase activity in fibroblasts, leukocytes, bone marrow cells, or cultured amniocytes (for prenatal diagnosis). Treatment by transplanting bone marrow or other hematopoietic cells appears to ameliorate the course of the disease in about half of cases, but the mechanism of this effect is unclear.[187,188] Wolman disease is rare, causing about 3% of cases of primary adrenal insufficiency in one large series.[141] Cholesterol ester storage disease appears to be a milder defect in the same enzyme, generally presenting in childhood or adolescence.[186] Hypercholesterolemia is typical, and accumulated neutral fats and cholesterol esters in the arteries predispose to atherosclerosis. Massive hepatomegaly and hepatic fibrosis may lead to esophageal varices.

Smith-Lemli-Opitz Syndrome. Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive defect in cholesterol biosynthesis resulting from abnormalities in the sterol Δ-7-reductase gene, *DHCR*7.[189] The incidence of SLOS is estimated from 1:80,000 to 1:13,000. More than 100 mutations have been described, but two predominate: the c.964G>C mutation is mostly found in North America and Western Europe, whereas the W151X mutation is frequently found in Central and Eastern Europe, suggesting founder effects for these two mutations.[190] The clinical features of SLOS include microcephaly, developmental delay, a typical facial appearance, proximal thumbs and syndactyly of the second and third toes, cardiac abnormalities, and underdeveloped genitalia in males. Adrenal insufficiency is present in some cases, especially during times of stress or when LDL-derived cholesterol sources are inadequate (e.g., dietary insufficiency/bile salt depletion).[191] The clinical spectrum of SLOS is extremely broad, likely reflecting differences in residual intrauterine cholesterol biosynthesis or differences in the transplacental supply of cholesterol supporting fetal development.[190] Biochemical analysis of sterol Δ-7-reductase activity, coupled with genetic analysis, can confirm the diagnosis. Alternatively, LC-MS/MS is a good method for sterol detection that can be used for diagnostic confirmation of SLOS. This approach may be adopted for newborn screening for SLOS via dried blood samples in the future. Life expectancy varies with disease severity. Dietary cholesterol supplementation, ranging from 20 to 300 mg/kg/day, has become an established therapeutic intervention. Beneficial effects include providing cholesterol to tissues outside the CNS and down-regulating HMG-CoA reductase, probably suppressing 7-DHC synthesis. Although this may result in amelioration of the extra-CNS phenotype, a beneficial effect on brain is unlikely, as plasma cholesterol does not cross the blood-brain barrier. Adding simvastatin to cholesterol supplementation is of uncertain benefit.[190]

Mitochondrial Disorders. Mitochondrial disorders can be associated with primary adrenal dysfunction.[192] Typical clinical features include lactic acidosis, cataracts, sensorineural deafness, and myopathy/ophthalmoplegia. Adrenal failure is rare in childhood, but subclinical adrenocortical insufficiency may be found in adults with multisystem disease, and is a poor prognostic factor. The Kearns-Sayre syndrome results from large-scale deletions of mitochondrial DNA and can be associated with additional endocrinopathies such as hypothyroidism, hypogonadism, diabetes, growth failure, and hypoparathyroidism.

Other metabolic disorders have also been reported to cause adrenal insufficiency, including Niemann-Pick disease type B, a lysosomal lipid storage disease due to mutations in the sphingomyelin phosphodiesterase 1 (SMPD1) gene manifesting with hepatosplenomegaly and pulmonary disease.

Other Causes

Chronic adrenal insufficiency may result from other causes. Hemorrhage and infections, discussed earlier as causes of acute primary adrenal insufficiency, may spare some adrenal tissue, leaving severely compromised, rather than totally absent, adrenal function. The result, as with autoimmune adrenalitis, is a chronic disorder with insidious onset of the broad range of nonspecific findings described earlier. Tuberculosis, fungal infections (e.g., histoplasmosis, coccidioidomycosis), viral infections (e.g., HIV, CMV), metastases, amyloidosis, and sarcoidosis may cause a similar clinical picture. Drugs such as aminoglutethimide, etomidate, suramin, and ketoconazole can also inhibit cortisol biosynthesis; these drugs can cause adrenal insufficiency and must be used with caution.

Secondary Adrenal Insufficiency

ACTH is required for adrenal cellular growth and for transcription of genes for steroidogenic factors, hence any impairment of ACTH synthesis or release can cause secondary adrenal insufficiency. Examples include hypothalamic defects, hypopituitarism, disorders of POMC synthesis and processing, and suppression of the hypothalamic-pituitary axis following exogenous steroid treatment.

Most forms of secondary adrenal insufficiency affect glucocorticoid and androgen synthesis rather than mineralocorticoid release, as angiotensin II is the primary drive to the zona glomerulosa. However, the clinical and biochemical assessment may be complicated as glucocorticoids are necessary for renal free water clearance and concomitant vasopressin (AVP, ADH) insufficiency may be present. In fact, treatment of secondary adrenal insufficiency can unmask a previously inapparent deficiency of antidiuretic hormone and thus precipitate diabetes insipidus, so close attention must be given to fluid and electrolyte balance when steroid replacement is introduced. Conversely, the hypothyroidism resulting from TSH deficiency will result in slowed metabolism of the small amount of cortisol produced and, therefore, protects the patient from the symptoms of adrenal insufficiency. Treatment of hypothyroidism with thyroxine will accelerate metabolism of these small amounts of cortisol, thus unmasking adrenal insufficiency due to ACTH deficiency and, on occasion, can precipitate an acute adrenal crisis. Therefore, careful evaluation of the pituitary-adrenal axis is required in hypopituitarism with secondary hypothyroidism. Many clinicians will choose to "cover" a patient with small doses of glucocorticoids (one fourth to one half of physiologic replacement) during initial treatment of such secondary hypothyroidism. Finally, it is important to appreciate that combined deficiency of growth hormone and ACTH will strongly predispose the patient to hypoglycemia, as both hormones act to raise plasma glucose. This effect is especially important in infancy and early childhood, when children are vulnerable to hypoglycemia during periods of prolonged fasting.

Hypothalamic Causes

Hypothalamic causes of ACTH insufficiency include tumors and radiotherapy. Tumors, such as craniopharyngioma, are associated with ACTH deficiency in about 25% of patients.[193,194] The frequency may be higher in tumors such as germinoma and astrocytoma. Adrenal insufficiency is rarely the presenting complaint but may contribute to the clinical picture. After surgery or radiation therapy, the great majority of patients with hypothalamic tumors will have ACTH deficiency as part of their surgical or radiation-induced hypothalamic-pituitary damage. Therefore, all such patients should receive glucocorticoid coverage during treatment, irrespective of the status of the HPA axis at the time the tumor is identified. Because treatment of secondary adrenal insufficiency can precipitate diabetes insipidus, close attention to water balance is essential. ACTH insufficiency can also result following whole-brain irradiation for brain tumors and other central malignancies. This may involve both hypothalamic and pituitary mechanisms. The frequency of ACTH insufficiency in such cases is much lower than following the treatment of hypothalamic tumors, but may manifest some years after treatment.[195]

ACTH Deficiency

ACTH may be deficient as part of a multiple pituitary hormone deficiency (MPHD, panhypopituitarism) or as isolated ACTH insufficiency. MPHD can result from pituitary surgery or radiotherapy, from an infiltrative process (e.g., Langerhans cell histiocytosis), or from a poorly understood form of hypothalamic dysfunction. In most cases, growth hormone secretion is lost first, followed in order by gonadotropins, TSH, and ACTH, so ongoing vigilance and assessment of these patients is required for many years. MPHD can also result from disorders of hypothalamic-pituitary development involving transcription factors such as HESX1, LHX4, and SOX3. Associated features such as optic nerve hypoplasia (HESX1) and cerebellar abnormalities (LHX4) may help to focus the diagnosis. Impaired ACTH secretion has also been described in individuals with PROP1 mutations, one of the most frequent genetic causes of MPHD. This finding can occur many years after presentation with GH, TSH, and gonadotropin deficiency, highlighting the importance of long-term follow-up of patients with pituitary disorders.[196,197]

Patients with MPHD often have a relatively mild form of adrenal insufficiency. Mineralocorticoid secretion is normal, whereas cortisol secretion is reduced but not absent. However, adrenal reserve is severely compromised by the chronic understimulation of steroidogenic enzyme biosynthesis. Because some cortisol synthesis continues, the diagnosis may not be apparent unless a CRF or metyrapone test of pituitary ACTH production capacity and an intravenous ACTH test of adrenal reserve are performed. This can be especially true when TSH deficiency is a component of hypopituitarism, as outlined earlier; treatment of secondary hypothyroidism with thyroxine will accelerate metabolism of these small amounts of cortisol, thus unmasking adrenal insufficiency due to ACTH deficiency, and, on occasion, can precipitate an acute adrenal crisis.

Isolated ACTH insufficiency is a rare condition that can be caused by recessively inherited mutations in the *TPIT* gene. *TPIT* encodes a T-box factor (TBX19) that regulates transcription of the POMC promoter in corticotropes.[198] These patients usually present with severe, early-onset ACTH insufficiency.[199,200] Hypoglycemia and prolonged jaundice are frequently present, and neonatal death may result.[201] As this defect is confined to POMC synthesis in the corticotropes, the additional features of generalized POMC deficiency are not present. TPIT mutations are not found in approximately half of patients with isolated ACTH insufficiency, suggesting that other causes are yet to be found.[202] Hypocortisolemia due to isolated ACTH insufficiency has also been described with hippocampal (memory) defects and hair abnormalities (alopecia) as part of the "triple H syndrome," a possible autoimmune association.[203]

Disorders of POMC

Defects in POMC synthesis and processing can also cause abnormal ACTH production and action. In patients with POMC mutations, plasma ACTH and cortisol concentrations are usually extremely low, but depending on the genetic defect, plasma ACTH concentrations may also be elevated reflecting the production of an immunoreactive but bioinactive protein.[204] Recessively inherited mutations or deletion of the POMC gene will affect multiple POMC peptides, including MSH and β-endorphin. Thus, red hair, pale skin, and obesity are associated features of this form of secondary adrenal insufficiency.[205] These clinical signs may be more subtle in individuals with naturally dark hair and pigmented skin, or red hair may darken in adulthood.[206] Mutations in prohormone convertase 1 (PC1, *PCSK1*), which is required for the processing of POMC to ACTH, cause abnormal cleavage and processing of several hormone systems, including the generation of bioactive ACTH from POMC.[207] Patients with this rare recessive disorder can have hypocortisolemia together with abnormal glucose metabolism, obesity, hypogonadotropic hypogonadism, and persistent malabsorptive diarrhea.[207,208]

Long-Term Steroid Therapy

Long-term glucocorticoid therapy can suppress POMC gene transcription and the synthesis and storage of ACTH. Furthermore, long-term therapy apparently decreases the synthesis and storage of CRF and diminishes the abundance of receptors for CRF in the pituitary. Therefore, recovery of the hypothalamic-pituitary axis from long-term glucocorticoid therapy entails recovery of multiple components in a sequential cascade and, hence, often requires considerable time (see the section on "Glucocorticoid Therapy and Withdrawal," presented later in the chapter). Patients successfully withdrawn from glucocorticoid therapy or successfully treated for Cushing disease may exhibit a fairly rapid normalization of plasma cortisol values while continuing to have diminished adrenal reserve for over 12 months. Inhaled steroids, nasal sprays, and even steroid eye drops can cause suppression of the adrenal axis, so vigilance may be needed following their withdrawal or at time of additional stress (e.g., surgery, intercurrent illness).[209-211] Although treatment with cortisone and prednisone during pregnancy will result in minimal suppression of the fetal adrenal, because of the protective effects of placental 11βHSD, dexamethasone treatment in pregnancy can affect fetal adrenal steroidogenesis.

ADRENAL EXCESS

Cushing Syndrome

The term *Cushing syndrome* describes any form of glucocorticoid excess; *Cushing disease* designates hypercortisolism due to pituitary overproduction of ACTH. The related disorder caused by ACTH of nonpituitary origin is termed the *ectopic ACTH syndrome*. The term *Cushing syndrome* is sometimes used to refer specifically to hypersecretion of cortisol from adrenal tumors, but this is ambiguous and should be avoided. Other causes of Cushing syndrome include adrenal adenoma, adrenal carcinoma, and multinodular adrenal hyperplasia. All of these are distinct from *iatrogenic Cushing syndrome*, which is the similar clinical constellation resulting from administration of supraphysiologic quantities of ACTH or glucocorticoids.

Although generally described in great detail and illustrated with striking photographs in endocrine texts, Cushing disease is fairly rare in adults.[212] Furthermore, about 25% of patients referred to large centers for Cushing disease are children, thus it is becoming increasingly clear that pediatric Cushing disease is more common than previously recognized. Many patients first seen as adults actually experience the onset of symptoms in childhood or adolescence. Harvey Cushing's original patient was a young woman of only 23 years whose history and clinical features indicated long-standing disease. Hence, many patients with Cushing syndrome can be detected in the pediatric age group. In adults and children over 7 years of age, the most common cause of Cushing syndrome is true Cushing disease (adrenal hyperplasia due to hypersecretion of pituitary ACTH).[213] Boys are more frequently affected than girls in the prepubertal period, although the sex ratios are equal during adolescence and women have a higher incidence of Cushing disease in adulthood.[214] In infants and children under 7 years, adrenal tumors predominate. Among 60 infants under 1 year of age with Cushing syndrome, 48 had adrenal tumors[215] (Table 13-8).

Clinical Findings

The physical features of Cushing syndrome are familiar to virtually all physicians. Central obesity, "moon facies," hirsutism, and facial flushing are seen in over 80% of adults with Cushing syndrome. Striae, hypertension, muscular weakness, back pain, "buffalo hump" fat distribution, psychological disturbances, acne, and easy bruising are also commonly described (35% to 80%). However, these

Data from Miller, W. L., Townsend, J. J., Grumbach, M. M., & Kaplan, S. L. (1979). An infant with Cushing's disease due to an adrenocorticotropin-producing pituitary adenoma. J Clin Endocrinol Metab, 48, *1017–1025.*

are the signs and features of advanced Cushing disease. When annual photographs of such patients are available, it is often apparent that these features can take 5 years or longer to develop. Thus, the classic cushingoid appearance will usually not be the initial picture seen in the child with Cushing syndrome. The earliest, most reliable indicators of hypercortisolism in children are weight gain and growth arrest[216] (Table 13-9). Cumulative data from three large studies of pediatric Cushing disease identified weight gain at presentation in 91/97 (94%) cases and growth failure in 82/95 (86%) cases.[216-218] Thus, any overweight child who stops growing should be evaluated for Cushing syndrome. Glucocorticoids suppress growth by increasing hypothalamic secretion of somatostatin, suppressing growth hormone secretion and IGF-1 production, and by acting directly on the epiphyses to inhibit sulfation of cartilage, inhibit mineralization, and inhibit cell proliferation. By contrast, children with simple dietary obesity often grow more rapidly and are tall for their age (presumably due to chronic secondary hyperinsulinism). The obesity of Cushing disease in children is initially generalized rather than centripetal, and a "buffalo hump" is evidence of long-standing disease. Psychological disturbances, especially compulsive overachieving behavior, are seen in about 40% of children and adolescents with Cushing disease [216] and are distinctly different from the depression typically seen in adults.[219] Emotional lability has been described in approximately 30% of cases.[217] An underappreciated aspect of pediatric Cushing disease is the substantial degree of bone loss and undermineralization in these patients.[216,220,221] It is likely that Cushing disease is generally regarded as a disease of young adults because the diagnosis was missed, rather than absent, during adolescence. Rarely, Cushing syndrome caused by adrenal carcinoma or the ectopic ACTH syndrome can produce a rapid fulminant course.

Data from Devoe, D. J., Miller, W. L., Conte, F. A., et al. (1997). Long-term outcome in children and adolescents after transsphenoidal surgery for Cushing's disease. J Clin Endocrinol Metab, 82, *3196–3202.*

Cushing Disease

Among adults, over 90% of patients with Cushing disease have identifiable pituitary microadenomas.[219,222] These tumors are generally 2 to 10 mm in diameter, are not encapsulated, have ill-defined boundaries, and are frequently detectable with a contrast-enhanced pituitary MRI. These tumors are often identifiable only by minor differences in their appearance and texture from surrounding tissue, thus the frequency of surgical cure is correlated with the technical skill of the surgeon.

Among children and adolescents, about 80% to 85% of those with Cushing disease have surgically identifiable microadenomas.[216,223,224] Although removal of the tumor usually appears curative, 20% of such "cured" patients suffer relapse and again manifest Cushing disease within about 5 years so that the net cure rate is 65% to 75%.[216-218,225,225] Transsphenoidal surgery offers the best initial approach for rapid and complete cure of most patients, but alternative approaches may be necessary in younger children if sphenoid sinus aeration has not yet occurred. Control of hypercortisolemia is important in the perioperative period. Careful monitoring for recovery of the HPA axis is necessary over several months, as stress responses may be diminished despite normal basal cortisol secretion. Short-term consequences of transsphenoidal surgery include transient diabetes insipidus and cerebrospinal fluid rhinorrhea.[217,218,227] Persistent panhypopituitarism is rare, but the effects of hypercortisolism on growth hormone secretion may remain for 1 to 2 years after treatment, and growth hormone deficiency can occur even in those children who have not received irradiation.[217,218,227] Final height may be reduced by 1.5 to 2 SD by the long-term hypercortisolism.[216,228] Treatment with growth hormone may ameliorate this growth loss in patients with GH insufficiency.[229,230]

The high cure rate of transsphenoidal microadenomectomy in Cushing disease indicates that the majority of such patients have primary disease of the pituitary itself, rather than secondary hyperpituitarism resulting from hyperstimulation of the pituitary by CRF or other agents. Careful follow-up studies of these patients confirm this.[216,224,225] In most postoperative patients, the circadian rhythms of ACTH and cortisol return to normal, ACTH and cortisol respond appropriately to hypoglycemia, cortisol is easily suppressed by low doses of dexamethasone, and the other hypothalamic-pituitary systems return to normal.

However, some patients with Cushing disease have no identifiable microadenoma, and some "cured" patients relapse. This suggests that this smaller population of patients may have a primary hypothalamic disorder, or that some of the pituitary tissue responsible for ACTH-hypersecretion was not excised. Effective treatment of Cushing disease with cyproheptidine, a serotonin antagonist, has been reported in adults, further suggesting a hypothalamic disturbance. Thus, present clinical

investigation suggests that Cushing disease is usually caused by a primary pituitary adenoma, but that sometimes it is caused by hypothalamic dysfunction. Microsurgery can be curative in the former, but not the latter. Unfortunately, no diagnostic maneuver is available to distinguish the two possibilities; thus, transsphenoidal exploration remains the preferred initial therapeutic approach to the patient with Cushing disease.

The management of nonresponsive or relapsed Cushing disease is challenging. Repeat transsphenoidal surgery is typically the first approach, especially if there is evidence of a distinct lesion or lateral hypersecretion of ACTH identified by petrosal sinus sampling. Second-line approaches include hypophysectomy, gamma-knife irradiation, cyproheptadine, cabergoline, adrenalectomy, and drugs that inhibit adrenal function. All have significant disadvantages, especially in children. Hypophysectomy also eliminates pituitary secretion of growth hormone, TSH, and gonadotropins, causing growth failure, hypothyroidism, and failure to progress in puberty, respectively. Although hypothyroidism is easily treated with oral thyroxine replacement, growth hormone deficiency requires very expensive replacement therapy. Sex steroid replacement can be used to achieve secondary sexual characteristics at the age of puberty; however, gonadotropin replacement or pulsatile gonadotropin-releasing hormone therapy will be needed to achieve fertility. Pituitary irradiation has been touted to avoid many of these problems and is effective in treating Cushing disease, but growth-hormone deficiency occurs in most cases and additional endocrinopathies can occur with time.[231] The interval from radiotherapy to cure can be more than 1 year, during which time therapeutic blockage of hypercortisolemia is necessary to prevent the ongoing effects of Cushing disease on growth, weight, and bone mineralization. Furthermore, large doses of radiation increase the risk of cerebral arteritis, leukoencephalopathy, leukemia, glial neoplasms, and bone tumors involving the skull; stereotactic radiotherapy may reduce these potential effects, but few data exist yet in children. Cyproheptadine has met with virtually no success in pediatric Cushing disease, in part due to the unacceptable side effects (weight gain, irritability, hallucinations) often seen with the needed doses.

Laparoscopic adrenalectomy is the preferred approach in our centers when two transsphenoidal procedures fail. In addition to the obvious effects of eliminating normal production of glucocorticoids and mineralocorticoids, removal of the adrenal eliminates the physiologic feedback inhibition of the pituitary. In some adults, this results in the development of pituitary macroadenomas, producing large quantities of ACTH. These can expand and impinge on the optic nerves and can produce sufficient POMC to yield enough MSH to produce profound darkening of the skin (Nelson syndrome), but this is rarely seen in children. There is relatively little pediatric experience with ketoconazole and other drugs that inhibit steroidogenesis, but these may provide a useful form of therapy for selected patients or for controlling hypercortisolemia in the short term.[232] Metyrapone is not useful for long-term therapy; ortho, para-DDD (mitotane), an adrenolytic agent, may be used to effect a "chemical adrenalectomy," but its side effects of nausea, anorexia, and vomiting are severe. Etomidate may be useful in the acute setting for severe or life-threatening Cushing disease prior to surgery.[233,234]

Other Causes of Cushing Syndrome

Ectopic ACTH Syndrome. The ectopic ACTH syndrome is commonly seen in adults with oat cell carcinoma of the lung, carcinoid tumors, pancreatic islet cell carcinoma, and thymoma. Ectopically produced POMC and ACTH are derived from the same gene that produces pituitary POMC, but they are not sensitive to glucocorticoid feedback in the malignant cells. This phenomenon permits distinction between pituitary and ectopic ACTH by suppressibility of the former by high doses of dexamethasone. Although the ectopic ACTH syndrome is rare in children, it has been described in infants younger than 1 year of age. Associated tumors have included neuroblastoma, pheochromocytoma, islet cell carcinoma of the pancreas, and neuroendocrine tumors of the thymus.[235] The ectopic ACTH syndrome is typically associated with ACTH concentrations 10 times higher than those seen in Cushing disease. However, both adults and children with this disorder may show little or no clinical evidence of hypercortisolism, probably due to the typically rapid onset of the disease and to the general catabolism associated with malignancy. Unlike patients with Cushing disease, adults and children with the ectopic ACTH syndrome frequently have hypokalemic alkalosis, presumably because the extremely high levels of ACTH stimulate the production of DOC by the adrenal fasciculata and may also stimulate the adrenal glomerulosa in the absence of hyperreninemia.

Adrenal Tumors. Adrenal tumors, especially adrenal carcinomas, are the more typical cause of Cushing syndrome in infants and small children (see Table 13-8). These tend to occur with much greater frequency in girls; the reason for this is unknown. Adrenal adenomas almost always secrete cortisol with minimal secretion of mineralocorticoids or sex steroids. By contrast, adrenal carcinomas tend to secrete both cortisol and androgens and are often associated with progressive virilization.[236,237] Adrenal adenoma or carcinoma may be associated with congenital bodily asymmetry (hemihypertrophy), sometimes as part of the Beckwith-Wiedemann syndrome, or with germline mutations or loss-of-heterozygosity of the tumor suppressor gene p53, sometimes as part of the Li-Fraumeni syndrome.[238] CT and MRI are useful in the diagnosis of adrenal tumors, and steroid analysis can be informative at the time of presentation and for monitoring for potential relapse. The treatment for both adenoma and carcinoma is surgical, and complete resection is needed for cure. In some cases, the histologic differentiation of adrenal adenomas and carcinomas is difficult, but a worse prognosis is associated with increased tumor size, capsular or vascular invasion, retroperitoneal lymph nodes, metastases, or failure to normalize hormonal values postoperatively.[237,239-241] Although a few patients with residual or metastatic disease have done well with

adjunctive therapy with ortho, para-DDD (mitotane), or other chemotherapeutic strategies, the general prognosis remains poor. To improve outcome for such rare diseases, therapeutic strategy now follows international protocols, which are linked to registries for controlled trials to monitor short and- long-term outcome.[241]

ACTH-Independent Multinodular Adrenal Hyperplasias. ACTH-independent multinodular adrenal hyperplasias comprise benign adrenal hyperplasia such as ACTH-independent macronodular adrenocortical hyperplasia (also known as massive macronodular adrenocortical disease) and micronodular hyperplasias, mostly primary pigmented nodular adrenocortical disease (PPNAD). Macronodular disorders are histologically associated with nodules larger than 1 cm and micronodular disorders encompass nodules that are smaller than 1 cm. In childhood, bilateral macroadenomatous hyperplasia is mostly seen with McCune-Albright syndrome due to somatic mutations in the gene encoding guanine nucleotide–binding protein, alpha-stimulating polypeptide GNAS1. Patients typically present with the triad of polyostotic fibrous dysplasia, café-au-lait skin spots with irregular margins and gonadotropin-independent sexual precocity. However, as the disorder is caused by somatic cell mutations, rather than germline mutations, its manifestations are clinically heterogeneous and may include other endocrine disorders such as Cushing syndrome, thyrotoxicosis, hyperparathyroidism, pituitary gigantism, and hyperprolactinemia. Cushing syndrome is rare in McCune-Albright syndrome and usually presents before 6 months of age. Most cases of macronodular adrenocortical hyperplasia are sporadic, isolated, and occur in middle age, although some cases are associated with MEN 1.

The group of micronodular benign adrenal hyperplasias comprises PPNAD and isolated micronodular adrenocortical disease. PPNAD is a rare entity characterized by the secretion of both cortisol and adrenal androgens.[242,243] It is seen in infants, children, and young adults, with females affected more frequently. It is usually seen as part of the "Carney complex," which is a form of multiple endocrine neoplasia (MEN), consisting of pigmented lentigines and blue nevi on the face, lips, and conjunctiva, and a variety of tumors including schwannomas and atrial myxomas, and occasionally GH-secreting pituitary adenomas, Leydig cell tumors, calcifying Sertoli cell tumors (which may secrete estrogens), and medullary carcinoma of the thyroid.[243,244] Typical features of Cushing syndrome are often seen in the pediatric population.[245] The adrenals are not truly hyperplastic but consist of discrete pigmented nodules surrounded by atrophic tissue, which permits their identification by MRI or CT. Because the hypercortisolism is resistant to suppression with high doses of dexamethasone and because both glucocorticoids and sex steroids are produced, this entity is clinically difficult to distinguish from the ectopic ACTH syndrome, but plasma ACTH assays are usually diagnostic. Complete adrenalectomy is usually indicated, although some successes have been reported with subtotal resections.

Carney complex, like other MEN disorders, is typically autosomal dominant. Loss of heterozygosity and mutations in a regulatory subunit of protein kinase (PRKAR1A) on chromosome 17q22-24 have been found in 73% of patients with Carney complex,[246-250] or as sporadic germline or somatic events in isolated adrenal tumors (isolated PPNAD).[251] In general, patients with Carney complex harboring PRKAR1A mutations manifest at a younger age and have more myxomas, schwannomas, thyroid tumors, and gonadal tumors than patients without PRKAR1A mutations. Patients with isolated PPNAD typically carry the PRKAR1A mutations c.709-7del6 or c.1A>G / p.M1V, which is important for genetic counseling and screening.[250]

Patients with micronodular benign adrenal hyperplasia without Carney complex and PRKAR1A mutations may harbor mutations in other cAMP signaling proteins. Mutations in the gene encoding phosphodiesterase 11A4 (PDE11A) have been reported in individuals with isolated micronodular adrenocortical disease and PPNAD and mutations in phosphodiesterase 8B (PDE8B) in isolated micronodular adrenocortical disease.[250,252] Both PDE11A and PDE8B catalyze the hydrolysis of cAMP and cGMP and are expressed in several endocrine tissues including the adrenals. Thus, it is becoming clear that abnormalities in signaling pathways play an important role in adrenal hyperplasia and tumorigenesis.[253]

Differential Diagnosis

Cushing syndrome in children is usually suggested by weight gain, growth arrest, mood change, and change in facial appearance (plethora, acne, hirsutism). The diagnosis in children may be subtle and difficult when it is sought at a relatively early point in the natural history of the disease. For initial screening, three laboratory investigations are recommended: (1) diurnal ACTH and cortisol profiles from blood (the latter may be performed on saliva); (2) 24-hour urinary free cortisol measurements, and (3) the overnight 1 mg dexamethasone suppression test.[243] Absolute elevations above the "upper limits of normal" for concentrations of plasma ACTH and cortisol are often absent. Rather than finding morning concentrations of cortisol $>$ 20 μg/dL or of ACTH $>$ 50 pg/mL, it is more typical to find mild, often equivocal elevations in the afternoon and evening values. This loss of the diurnal rhythm, evidenced by continued secretion of ACTH and cortisol throughout the afternoon, evening, and nighttime, is usually the earliest reliable laboratory index of Cushing disease. A single plasma cortisol measurement obtained at midnight from an indwelling venous catheter while the patient remains asleep should be less than 2 μg/dL in normal individuals and more than 2 μg/dL in Cushing disease.[254] By contrast, the values for ACTH and cortisol are typically extremely high in the ectopic ACTH syndrome, whereas cortisol is elevated but ACTH is suppressed in adrenal tumors and in multinodular adrenal hyperplasia (Table 13-10). In all forms of Cushing syndrome, monitoring of the 24-hour urinary free cortisol (UFC) assists in deciding whether further investigations are warranted. A normal 24-hour UFC value is generally $<$ 70 μg/m^2/day (with radioimmunoassays). Several repeat collections may be necessary, and it is important to use normal ranges adjusted for size

TABLE 13-10 **Diagnostic Values in Various Causes of Cushing Syndrome**

ACTH concentration in pg/mL.
17OHCS in mg/24 hours.

as well as age, as children with simple obesity have higher cortisol secretion rates. Another baseline test is the low-dose (1 mg) dexamethasone overnight suppression test with a cutoff for cortisol < 1.8 μg/dL (50 nmol/L). If both the 24-hour UFC and the low-dose dexamethasone overnight suppression test are normal, the diagnosis of Cushing syndrome is usually excluded. Exceptions are patients with intermittent or periodic cortisol hypersecretion who need longer follow-up and repeat testing for diagnosis of Cushing syndrome.

Once the diagnosis Cushing syndrome is established, further investigations may be needed to find the origin of disease. Low- and high-dose dexamethasone suppression tests can be useful when done with care. To achieve reliable results in pediatric patients, children should be hospitalized, preferably on a pediatric clinical research ward. Two days of baseline (control) data should be obtained. Low-dose dexamethasone (20 μg/kg/day, up to a maximum of 2 mg) should be given, divided into equal doses given every 6 hours for 2 days followed by high-dose dexamethasone (80 μg/kg/day) given in the same fashion. Eight a.m. and 8 p.m. (or midnight) values for ACTH and cortisol and 24-hour urine collections for 17OHS, 17KS, free cortisol, and creatinine (to monitor the completeness of the collection) should be obtained on each of the 6 days of the test. Measurements of either urinary free cortisol or 17OHCS are probably equally reliable if the laboratory has established good pediatric standards. Because of variations due to episodic secretion of ACTH, the 8 a.m. and 8 p.m. blood values should be drawn in triplicate at 8:00, 8:15, and 8:30. In patients with exogenous obesity or other non-Cushing disorders, cortisol, ACTH, and urinary steroids will be suppressed readily by low-dose dexamethasone. Plasma cortisol should be less than 5 μg/dL, ACTH less than 20 pg/mL, and 24-hour urinary 17OHS less than 1 mg/g of creatinine. Patients with adrenal adenoma, adrenal carcinoma, or the ectopic ACTH syndrome will have values relatively insensitive to both low- and high-dose dexamethasone, although some patients with multinodular adrenal hyperplasia may respond to high-dose suppression and a paradoxical rise in cortisol following dexamethasone has been reported with the Carney complex.[255,256] Patients with Cushing disease classically respond with a suppression of ACTH, cortisol, and urinary steroids during the high-dose treatment but not during the low-dose treatment. However, some children, especially those early in the course of their illness, may exhibit partial suppression in response to low-dose dexamethasone. Thus, if the low dose that is given exceeds 20 μg/kg/day or if the assays used are insufficiently sensitive to distinguish partial from complete suppression, false-negative tests may result.

Petrosal sinus sampling is widely used in adults with Cushing disease, to distinguish pituitary Cushing disease from the ectopic ACTH syndrome. The smaller vascular bed in children increases the risk of this procedure, but inferior petrosal venous sampling has been used with some success in adolescents in an attempt to localize pituitary adenomas prior to surgery.[257] Such approaches should only be undertaken in specialist centers; jugular

venous sampling may provide an alternative approach, although extensive data in the pediatric population are not available.[258] In general, the diagnosis of Cushing disease is considerably more difficult to establish in children than in adults. In addition to laboratory tests, imaging studies may help in establishing the exact diagnosis of Cushing syndrome. An adrenal CT scan or MRI may visualize an adrenal cortex tumor or a macro-/micronodular adrenal hyperplasia, whereas adrenal ultrasound often fails and therefore should not be trusted as a diagnostic tool for adrenal disorders. MRI is also the preferred method for visualizing the hypothalamus and the anterior pituitary for lesions.

Virilizing and Feminizing Adrenal Tumors

Most virilizing adrenal tumors are adrenal carcinomas producing a mixed array of androgens and glucocorticoids; virilizing and feminizing adrenal adenomas are quite rare. Virilizing tumors in boys have a presentation similar to that of simple virilizing congenital adrenal hyperplasia. There will be phallic enlargement, erections, pubic and axillary hair, acne, increased muscle mass, deepening of the voice, acne, and scrotal thinning, but the testicular size will be prepubertal. Elevated concentrations of testosterone in young boys alter behavior, with increased irritability, rambunctiousness, hyperactivity, and rough play, but without evidence of libido. Diagnosis is based on hyperandrogenemia that is non-suppressible by glucocorticoids. The treatment is surgical; all such tumors should be handled as if they are malignant, with care exerted not to cut the capsule and seed cells onto the peritoneum. The pathologic distinction between adrenal adenoma and carcinoma is difficult, especially in pediatric patients.

Feminizing adrenal tumors are extremely rare in either sex. P450aro, the enzyme aromatizing androgenic precursors to estrogens, is not normally found in the adrenals but is found in peripheral tissues such as fat and is also found in some adrenal carcinomas. It is not known whether most feminizing adrenal tumors exhibit ectopic adrenal production of this enzyme, whether some other enzyme mediates aromatization in the tumor, or whether these are truly androgen-producing, virilizing tumors occurring in a setting where there is unusually effective peripheral aromatization of adrenal androgens. Feminizing adrenal (or extra-adrenal) tumors can be distinguished from true (central) precocious puberty in girls by the absence of increased circulating concentrations of gonadotropins and by a prepubertal response of luteinizing hormone to an intravenous challenge of gonadotropin releasing hormone (LRF, GnRH). In boys, such tumors will cause gynecomastia, which will resemble the benign gynecomastia that often accompanies puberty. However, as with virilizing adrenal tumors, testicular size and the gonadotropin response to LRF testing will be prepubertal. The diagnosis of a feminizing tumor in a pubertal boy can be extremely difficult, but it is usually suggested by an arrest in pubertal progression and can be proved by the persistence of circulating plasma estrogens after the administration of testosterone.

Other Disorders

Primary Hyperaldosteronism: Conn Syndrome

Conn syndrome, characterized by hypertension, polyuria, hypokalemic alkalosis, and low plasma renin activity due to an aldosterone-producing adrenal adenoma, is well described in adults but is rare in children. The diagnostic task is to differentiate primary aldosteronism from physiologic secondary hyperaldosteronism occurring in response to another physiologic disturbance. Any loss of sodium, retention of potassium, or decrease in blood volume will result in hyperreninemic secondary hyperaldosteronism. Renal tubular acidosis, treatment with diuretics, salt-wasting nephritis, or hypovolemia due to nephrosis, ascites, or blood loss are typical settings for physiologic secondary hyperaldosteronism. Primary aldosteronism is characterized by hypertension and hypokalemic alkalosis. The cause is a small adrenal adenoma, usually confined to one adrenal. Laparoscopic surgery permits both adrenals to be explored surgically because adrenal vein catheterization is not possible in children and is difficult in adults. Aldosterone is normally produced in glomerulosa cells in response to intravascular volume depletion via the renin-angiotensin system or high plasma potassium. In primary aldosteronism the adrenal constitutively produces aldosterone in the absence of angiotensin II and hyperkalemia. Somatic mutations in the gene encoding the K+ channel KCNJ5 (also known as Kir3.4) have been found in tumor tissue of some adult patients with aldosterone producing adenomas and have also been found as germ line mutations in four unrelated families with severe hypertension, aldosteronism, and adrenal hyperplasia.[259-262] These KCNJ5 mutations affect the ion selection filter of the K+ channel, causing an increase in Na+ influx and permanent depolarization of the cell membrane.[259] Membrane depolarization then activates voltage-gated Ca2+ channels, which increases intracellular Ca2+ thus providing the normal signal for aldosterone production and glomerulosa cell proliferation. Somatic mutations of KCNJ5 are found in 34% of aldosterone producing adenomas; such mutations are more prevalent in females and at a younger age, and they manifest with higher preoperative aldosterone levels.[263] By contrast, germ line KCNJ5 mutations appear to be rare and are more likely to be associated with bilateral adrenal hyperplasia than with aldosterone producing adenomas.

Familial Glucocorticoid Resistance

Familial glucocorticoid resistance is a rare disorder caused by mutations in the α-isoform of the glucocorticoid receptor. Decreased glucocorticoid action results in grossly increased ACTH secretion, which, in addition to stimulating the production of cortisol, also stimulates the production of other adrenal steroids. Thus, these patients may present with fatigue, hypertension, and hypokalemic alkalosis, suggesting a mineralocorticoid excess syndrome, and they also have symptoms of hyperandrogenism.[264,265] By contrast, they typically lack cushingoid features with biochemical hypercortisolism.

Circadian rhythmicity of the HPA axis is maintained, and resistance to dexamethasone suppression is observed. Patients have been described who are homozygous for missense mutations,[266] heterozygous for a gene deletion,[267] or homozygous for a wholly null mutation.[53] Heterozygous point mutations with incomplete dominant negative activity or multiple effects on GRα action have also been described.[268] Point mutations may interfere with GRα-dependent transcriptional regulation through altered DNA binding, impaired ligand binding, delayed nuclear localization, abnormal nuclear aggregation, and disrupted interaction with coactivators, depending on the position of the mutation.[264] Thus, familial glucocorticoid resistance is usually a syndrome of partial resistance to the action of glucocorticoids. Treatment consists of supraphysiologic doses of dexamethasone that will elicit a physiologic response with the poorly functioning receptor, usually starting with 0.25 to 0.5 mg/day at bedtime and titrating to the suppression of morning ACTH and thus androgens, blood pressure, and serum potassium levels.[265] The dose of dexamethasone may be reduced to a minimum according to individual needs. Hypertension may require additional treatment with aldosterone antagonists.

Pseudohypoaldosteronism

Pseudohypoaldosteronism (PHA) is a rare salt-wasting disorder of infancy characterized by hyponatremia, hyperkalemia, and increased plasma renin activity in the face of elevated aldosterone concentrations reflecting aldosterone resistance.[269] The more common, more severe, systemic, autosomal recessive form of PHA ("pseudohypoaldosteronism type 2") is caused by inactivating mutations in any of the three subunits (α, β, γ) of the amiloride-sensitive sodium channel, ENaC (encoded by the *SCNN1A*, *B*, and *G* genes).[270] This condition is often associated with lower respiratory tract disease consisting of chest congestion, cough, and wheezing (but not pulmonary infections) as ENaC mutations increase the volume of pulmonary fluid.[271] This disease persists into adulthood, requiring vigorous salt-replacement therapy throughout life. Gain-of-function mutations due to carboxyterminal truncation of β-ENaC cause Liddle syndrome, an autosomal dominant form of salt-retaining hypertension.[270]

Autosomal dominant renal type 1 pseudohypoaldosteronism ("PHA type 1") is caused by inactivating mutations in the mineralocorticoid receptor (encoded by the *NR3C2* gene).[272] More than 50 different mutations have been found in this receptor, which interfere with mineralocorticoid binding and gene transcription.[273] This disease is milder than the recessive forms of PHA caused by ENaC mutations and remits with age, but it requires sodium replacement therapy in infancy and childhood. Rarely, point mutations in the mineralocorticoid receptor have been found in association with an autosomal dominant form of severe hypertension, which begins in adolescence and worsens in pregnancy.[274] In these cases, alterations in the structure of the ligand-binding domain of the mineralocorticoid receptor result in mild constitutive activation and permit binding and activation of the receptor by progesterone.

An acquired, transient form of PHA is often seen in infants with obstructive uropathy, especially shortly following surgical relief of the obstruction or with urinary tract infections. The lesion is renal tubular,[275] so that mineralocorticoid treatment is generally ineffective; salt replacement generally suffices while the renal lesion resolves.

GLUCOCORTICOID THERAPY AND WITHDRAWAL

Since their introduction into clinical medicine in the early 1950s, glucocorticoids have been used to treat virtually every known disease. At present their rational use falls into two broad categories: replacement in adrenal insufficiency and pharmacotherapeutic use. The latter category is largely related to the anti-inflammatory properties of glucocorticoids but also includes their actions to lyse leukemic leukocytes, lower plasma calcium concentrations, and reduce increased intracranial pressure. Virtually all of these actions are mediated through glucocorticoid receptors, which are found in most cells. Because there appears to be only one major type of glucocorticoid receptor, clearly all glucocorticoids will affect all tissues containing such receptors. Thus, with the exception of the distinction between glucocorticoids and mineralocorticoids, tissue-specific, disease-specific, or response-specific analogs of naturally occurring glucocorticoids cannot be produced. The only differences among the various glucocorticoid preparations are their ratio of glucocorticoid to mineralocorticoid activity, their capacity to bind to various binding proteins, their molar potency, and their biologic half-life. Dexamethasone is commonly used to reduce increased intracranial pressure and brain edema. Neurosurgical experience indicates that the optimal doses are 10 to 100 times those that would thoroughly saturate all available receptors, suggesting that this action of dexamethasone may not be mediated through the glucocorticoid receptor.

Glucocorticoids are so termed because of their major actions to increase plasma concentrations of glucose. This occurs by their induction of the transcription of the genes encoding the enzymes of the Embden-Meyerhof glycolytic pathway and other hepatic enzymes that divert amino acids, such as alanine, to the production of glucose. Thus, the coordinated action to increase the transcription of these genes can result in increased plasma concentrations of glucose, obesity, and muscle wasting. The other features of Cushing syndrome are similarly attributable to the increased transcriptional activity of specific glucocorticoid-sensitive genes.

In the normal population, there is a wide interindividual variation in glucocorticoid sensitivity, which is at least in part explained by genetic variants of the glucocorticoid receptor (GR) gene.[265] Several single nucleotide polymorphisms have been associated with changes in glucocorticoid sensitivity. A3669G (rs6198) is associated with glucocorticoid insensitivity and a more active immune system with an increased risk for autoimmune disease; it is present in about 35% of the normal population. ER22/23EK polymorphism (rs6189 and rs6190)

present in about 7% of the population is associated with mild glucocorticoid resistance and a healthier metabolic profile. By contrast, polymorphisms N363S (rs1695) and Bcl1 (rs41423247), present in about 8% and 45% of people, respectively, are associated with mild glucocorticoid hypersensitivity yielding a less fortunate metabolic profile (more body fat, less lean mass, increased cholesterol and insulin resistance, etc.).[265] Some of the variability in glucocorticoid sensitivity is explained by a large number of GR subtypes arising from alternative processing of the GR gene. Various GR isoforms may be generated through alternative splicing and alternate sites of translational initiation. These isoforms may then also be subjected to tissue-specific posttranslational modifications such as phosphorylation, ubiquitination, sumoylation, and acetylation. These processes allow cells to generate a broad range of glucocorticoid responsiveness to specifically regulate glucocorticoid-dependent genes.[276] Thus, individual glucocorticoid sensitivity plays a role in modulating the risk for diseases (cardiovascular, autoimmune, metabolic) and may also affect responsiveness to glucocorticoid treatment.

Replacement Therapy

Glucocorticoid replacement therapy is complicated by undesirable side effects with even minor degrees of overtreatment or undertreatment. Overtreatment can cause the signs and symptoms of Cushing syndrome; and even minimal overtreatment can impair the growth of children. Undertreatment will cause the signs and symptoms of adrenal insufficiency (see Box 13-2) only if the extent of undertreatment (dose and duration) is considerable. However, undertreatment may impair the individual's capacity to respond to stress. Glucocorticoid replacement therapy is most commonly employed in congenital adrenal hyperplasia due to 21-hydroxylase deficiency; however, in this setting, undertreatment will lead to overproduction of adrenal androgens, which will hasten epiphyseal maturation and closure, thus compromising ultimate adult height. Therefore, when formulating a program of adrenal replacement therapy for the growing child, it is crucial to mimic the normal endogenous production of glucocorticoids.

To optimize pediatric glucocorticoid replacement therapy, astute physicians have gauged their therapy to resemble the endogenous secretory rate of cortisol. Several studies indicate that the cortisol secretory rate is 6 to 8 mg/m^2/day in children and adults,[72,73] but data are not available for infants and children under 5 years. The range of normal values varies considerably, indicating that therapy must be tailored and individualized for each patient to achieve optimal results. The management of this delicate balance between overtreatment and undertreatment of the child requiring replacement therapy is thus confounded by considerable variation in the "normal" cortisol secretory rate among different children of the same size and the probability that most conventional guidelines err on the side of overtreatment. However, several additional factors must be considered in tailoring a specific child's glucocorticoid replacement regimen.

The specific form of adrenal insufficiency being treated significantly influences therapy. When treating autoimmune adrenalitis or any other form of "Addison disease," it is prudent to err slightly on the side of undertreatment. This will eliminate the possibility of glucocorticoid-induced iatrogenic growth retardation and will permit the pituitary to continue to produce normal to slightly elevated concentrations of ACTH. This ACTH will continue to stimulate the remaining functional adrenal steroidogenic machinery and also provide a fairly convenient means of monitoring the effects of therapy. By contrast, when treating severe, virilizing congenital adrenal hyperplasia, the adrenal should be suppressed more completely, as essentially all adrenal steroidogenesis will result in the production of unwanted androgens, with their consequent virilization and rate of advancement of bony maturation that is more rapid than the rate of advancement of height. However, overtreatment will also compromise growth.

The presence or absence of associated mineralocorticoid deficiency is an important variable. Children with mild degrees of mineralocorticoid insufficiency, such as those with "simple virilizing" congenital adrenal hyperplasia, may continue to have mildly elevated ACTH values, suggesting insufficient glucocorticoid replacement in association with elevated PRA. In some children, the ACTH is elevated in response to chronic, compromised hypovolemia, attempting to stimulate the adrenal to produce more mineralocorticoid. In these children, who do not manifest overt signs and symptoms of mineralocorticoid insufficiency, treatment with mineralocorticoid replacement may permit one to decrease the amount of glucocorticoid replacement needed to suppress plasma ACTH and urinary 17KS. This reduction in glucocorticoid therapy reduces the likelihood that adult height will be compromised.

The specific formulation of glucocorticoid used is also of great importance. Extremely potent, long-acting glucocorticoids, such as dexamethasone or prednisone, may be used in the treatment of adults but are rarely appropriate for replacement therapy in children. As children are continually growing and changing their weights and body surface areas, it is necessary to adjust their dose frequently. Small, incremental changes are more easily done with relatively weaker glucocorticoids. The use of short-acting steroids permits the patient to have physiologically low nighttime glucocorticoid activity, facilitating rest, growth, and pituitary stimulation. The efficacy of attempting to mimic the physiologic diurnal variation in steroid hormone secretion remains controversial. As ACTH and cortisol concentrations are high in the morning and low in the evening, it is intellectually and logically appealing to attempt to duplicate this circadian rhythm in replacement therapy. However, the results do not clearly indicate that better growth is achieved by giving relatively larger doses in the morning and lower doses at night. This probably reflects the fact that ACTH and cortisol secretion are episodic throughout the day and that this well-established circadian variation is not smooth. The pattern of high in the morning and low in the evening is only an averaged result. Furthermore, the adrenal releases cortisol episodically throughout the day in response to various physiologic demands

(hypoglycemia, exercise, stress, etc.); thus, under normal circumstances the plasma concentrations are high when the clearance and disposal rates are also high. A planned program of replacement therapy cannot possibly anticipate these day-to-day variations.

Finally, *dosage equivalents among various glucocorticoids can be misleading*. Virtually all handbooks of therapy publish tables of equivalency for the most commonly used pharmaceutical preparations of glucocorticoids. A similar set of equivalencies is shown in Table 13-7. Because most preparations of glucocorticoids are intended for pharmacotherapeutic use rather than replacement therapy, and because the most common indication for pharmacologic doses of glucocorticoids is for their anti-inflammatory properties, virtually all tables of glucocorticoid equivalencies are based on anti-inflammatory, immunosuppressive equivalencies. However, the differences in the plasma half-life and ability to bind to plasma proteins result in different biologic equivalencies when one assesses, for instance, anti-inflammatory versus growth-suppressant equivalencies. For example, dexamethasone is widely reported as being about 30 times more potent than cortisol when its anti-inflammatory capacities are measured, but the growth suppressant activity of dexamethasone is about 80 times that of cortisol (Table 13-7). Thus, all of the variables discussed earlier explain why there is little unanimity in recommendations for designing a glucocorticoid replacement regimen. However, an understanding of these variables will permit appropriate monitoring of the patient and encourage the physician to vary the treatment according to the responses and needs of the individual child.

Commonly Used Glucocorticoid Preparations

Numerous chemical derivatives and variants of the naturally occurring steroids are commercially available in a huge array of dosage forms, vehicles, and concentrations. Choosing the appropriate product can be simplified by considering only the most widely used steroids listed in Table 13-7.

There are four relevant considerations in the choice of which drug to use. First, the glucocorticoid potency of the various drugs is generally calculated and described according to the anti-inflammatory potency, but this may not be the appropriate consideration in many cases. Second, the growth-suppressant effect of a glucocorticoid preparation may be significantly different from its anti-inflammatory effect. This is due to differences in half-life, metabolism and protein binding, and receptor affinity (potency). Third, the mineralocorticoid activity of various glucocorticoid preparations varies widely. Both glucocorticoid and mineralocorticoid hormones can bind to both glucocorticoid (type 1) and mineralocorticoid (type 2) receptors, and most authorities now regard these as two different types of glucocorticoid receptors. Mineralocorticoid activity is intimately related to the activity of 11βHSD2, which metabolizes glucocorticoids but not mineralocorticoids to forms that cannot bind the receptor. Thus, the relative mineralocorticoid potency of various steroids is determined by both their affinity for the type 2 receptor and their resistance to the activity of 11βHSD2. An understanding that some commonly used glucocorticoids, such as cortisol, cortisone, prednisolone, and prednisone, have significant mineralocorticoid activity is especially important when large doses of glucocorticoids are used as "stress doses" in a patient on replacement therapy. Such stress doses of the glucocorticoid preparation may provide sufficient mineralocorticoid activity to meet physiologic needs; therefore, mineralocorticoid supplementation is not needed. Fourth, the plasma half-life and biologic half-life of the various preparations may be discordant and will vary widely. This is mainly related to binding to plasma proteins, hepatic metabolism, and hepatic activation. For example, cortisone and prednisone are biologically inactive (and even have mild steroid antagonist actions) until they are metabolized by hepatic 11βHSD1 to their active forms, cortisol and prednisolone. Thus, the relative glucocorticoid potency of these preparations will also be affected by hepatic function. Cortisone and prednisone are cleared more rapidly in patients receiving drugs such as phenobarbital or phenytoin, which induce hepatic enzymes, and are cleared more slowly in patients with liver failure.

In addition to these chemical considerations in the choice of glucocorticoid, the route of administration is important. Glucocorticoids are available for oral, intramuscular, intravenous, intrathecal, intra-articular, inhalant, and topical use; topical preparations include those designed for use on skin, mucous membranes, and conjunctiva. Each preparation is designed to deliver the maximal concentration of steroid to the desired tissue while delivering less steroid systemically. However, all such preparations are absorbed to varying extents, so that the widely used inhalant preparations used to treat asthma can, in sufficient doses, cause growth retardation and other signs of Cushing syndrome. In general, and in contradistinction to many other drugs, orally administered steroids are absorbed rapidly, but incompletely, whereas intramuscularly administered steroids are absorbed slowly, but completely. Thus, if the secretory rate of cortisol is 8 mg/m^2 of body surface area, the intramuscular or intravenous replacement dose of cortisol (hydrocortisone) would be 8 mg/m^2. The efficiency of absorption of glucocorticoids can vary considerably depending on diet, gastric acidity, bowel transit time, and other individual factors. This emphasizes that the dosage equivalents listed in Table 13-7 and similar tables are only approximations, and doses must be tailored to the clinical response.

ACTH can also be used for glucocorticoid therapy by its action to stimulate endogenous adrenal steroidogenesis. Although intravenous and intramuscular ACTH are extremely useful in diagnostic tests of adrenal function, the use of ACTH as a therapeutic agent is no longer favored, principally because it will stimulate synthesis of mineralocorticoids and adrenal androgens as well as glucocorticoids. Furthermore, the need to administer ACTH parenterally further diminishes its usefulness. Intramuscular ACTH 1-39 in a gel form is recommended for and is the treatment of choice for infantile spasms and possibly also for other forms of epilepsy in infants resistant to conventional anticonvulsants.

Whether this action is mediated by ACTH itself, by other peptides in the biologic preparation, by ACTH-induced adrenal steroids, or by ACTH-responsive synthesis of novel "neurosteroids"[277] in the brain has not been determined. When pharmacologic doses of ACTH are used therapeutically, as in infantile spasms, the patient should be given a low-sodium diet to ameliorate steroid hypertension. Although greatly elevated concentrations of ACTH, as in the ectopic ACTH syndrome, will cause pituitary suppression, treatment with daily injections of ACTH results in less hypothalamic-pituitary suppression than does treatment with equivalent doses of oral glucocorticoids, presumably because the effect on the adrenal is transient. Also, adrenal suppression obviously does not occur in ACTH therapy. Because the effects of ACTH on adrenal steroidogenesis are highly variable, it is even more difficult to determine dosage equivalencies for ACTH and oral steroid preparations than it is among the various steroids, as discussed previously. A very rough guide from studies in adults is that 40 units of ACTH(1-39) gel is approximately equivalent to 100 mg of cortisol.

Pharmacologic Therapy

Pharmacologic doses of glucocorticoids are used in a variety of clinical situations including immune suppression in organ transplantation, tumor chemotherapy, treatment of "autoimmune" collagen vascular and nephrotic syndromes, regional enteritis, and ulcerative colitis. Asthma, pseudotumor cerebri, dermatitis, certain infections, neuritis, and certain anemias are also often treated with glucocorticoids. The choice of glucocorticoid preparation to be used is guided by the pharmacologic parameters described previously and in Table 13-7 and by custom (e.g., the use of betamethasone rather than dexamethasone to induce fetal lung maturation in impending premature deliveries). There is substantial variation in the relative glucocorticoid and mineralocorticoid activities of each steroid, depending on the assay used,[278] hence Table 13-7 is an integration of multiple studies and can only be taken as a rough guide.

Pharmacologic doses of glucocorticoids administered for more than 1 or 2 weeks will cause the signs and symptoms of iatrogenic Cushing syndrome. These are similar to the glucocorticoid-induced findings in Cushing disease, but they may be more severe because of the high doses involved (Table 13-11). Iatrogenic Cushing syndrome is also not associated with adrenal androgen effects, and mineralocorticoid effects are rare. Alternate-day therapy can decrease the toxicity of pharmacologic glucocorticoid therapy, especially suppression of the HPA axis and suppression of growth. The basic premise of alternate-day therapy is that the disease state can be suppressed with intermittent therapy, whereas there is significant recovery of the HPA axis during the "off" day. Thus, alternate-day therapy requires the use of a relatively short-acting glucocorticoid administered only once in the morning of each therapeutic day to ensure that the "off" day is truly "off." Long-acting glucocorticoids, such as dexamethasone, should not be employed for alternate-day therapy; results are best with oral prednisone or methylprednisolone.

TABLE 13-11 **Complications of High-Dose Glucocorticoid Therapy**

Short-Term Therapy	Long-Term Therapy
Gastritis	Gastric ulcers
Growth arrest	Short stature
↑ Appetite	Weight gain
Hypercalciuria	Osteoporosis, fractures
Glycosuria	Slipped epiphyses
Immune suppression	Ischemic bone necrosis
Masked symptoms of infection, especially fever and inflammation	Poor wound healing
	Catabolism
	Cataracts
Toxic psychoses	Bruising (capillary fragility)
	Adrenal/pituitary suppression
	Toxic psychosis

Withdrawal of Glucocorticoid Therapy

Withdrawal of glucocorticoid therapy can be difficult and can lead to symptoms of glucocorticoid insufficiency. When glucocorticoid therapy has been used for only 1 week or 10 days, therapy can be discontinued abruptly, even if high doses have been used.[279] Although only one or two doses of glucocorticoid are needed to suppress the HPA axis, this axis recovers very rapidly from short-term suppression. When therapy has persisted for 2 weeks or longer, recovery of HPA function is slower, and tapered doses of glucocorticoids are indicated. Acute discontinuation of therapy in such patients will lead to symptoms of glucocorticoid insufficiency, the so-called steroid withdrawal syndrome. This symptom complex does not include salt loss, as adrenal glomerulosa function, regulated principally by the renin-angiotensin system, remains normal. However, blood pressure can fall abruptly, as glucocorticoids are required for the action of catecholamines in maintaining vascular tone. The most prominent symptoms of the steroid withdrawal syndrome include malaise, anorexia, headache, lethargy, nausea, and fever. In reducing pharmacologic doses of glucocorticoids, it might appear logical to reduce the dosage precipitously to "physiologic" replacement doses. However, this is rarely successful and occasionally disastrous. Even when given "physiologic" replacement, patients who have been receiving pharmacologic doses of glucocorticoids will experience steroid withdrawal. Long-term pharmacologic glucocorticoid therapy inhibits synthesis of glucocorticoid receptors, so that physiologic concentrations of glucocorticoids will elicit subphysiologic cellular responses, resulting in the steroid withdrawal syndrome. Thus, it is necessary to taper gradually from the outset. The duration of glucocorticoid therapy is a critical consideration in designing a glucocorticoid withdrawal program. Therapy for a couple of months

will completely suppress the HPA axis but will not cause adrenal atrophy. Therapy that continues for years may result in almost total atrophy of the adrenal fasciculata/reticularis and hence may require a withdrawal regimen that takes months.

Procedures for tapering steroids are empirical. Their success is determined by the length and mode of therapy and by individual patient responses. Patients who have been on alternate-day therapy can be withdrawn more easily than those receiving daily therapy, especially daily therapy with a long-acting glucocorticoid such as dexamethasone. In patients on long-standing therapy, a 25% reduction in the previous level of therapy is generally recommended weekly. A patient with a body surface area of 1 m^2 will have a secretory rate of cortisol of about 9 mg/day. If the patient has been on daily therapy equivalent to 100 mg of cortisone for many months, a tapering protocol over 8 to 10 weeks may be needed. A protocol of 75% of the previous week's dose would thus be 75 mg/day for the first week, 56 mg/day for the second, then 42, 31.5, 24, 18, 13.5, 10, 7.5, 5.5 mg/day, then off treatment. A more practical regimen based on the sizes of tablets available would be 75, 50, 37.5, 25, 17.5, 12.5, 10, 7.5, and 5 mg/day. Most patients can be tapered more rapidly, but all patients need to be followed closely. When withdrawal is done with steroids other than cortisone or cortisol, measurement of morning cortisol values can be a useful adjunct. Morning cortisol values of 10 μg/dL or more indicate that the dose can be reduced safely.

Even after the successful discontinuation of therapy, the HPA axis is not wholly normal. Just as in the patient successfully treated for Cushing disease, the HPA axis may be incapable of responding to severe stress for 6 to 12 months after successful withdrawal from long-term, high-dose glucocorticoid therapy. Thus, evaluation of the hypothalamus and pituitary by a CRF or metyrapone test, and evaluation of adrenal responsiveness to pituitary stimulation with an intravenous low-dose ACTH test, should be done at the conclusion of a withdrawal program and 6 months thereafter. The results of these tests will indicate if there is a need for "steroid coverage" in acute surgical stress or illness.

Stress Doses of Glucocorticoids

The cortisol secretory rate increases significantly during physiologic stress such as trauma, major surgery, or severe illness. Patients receiving glucocorticoid replacement therapy or those recently withdrawn from pharmacologic therapy need coverage with "stress doses" of steroids in such situations. However, the specific indications for this coverage and the appropriate dosage are controversial and difficult to establish; most practitioners prefer to err on the "safe" side of steroid overdosage. This is the safest tactic in the short term, but it can have a significant effect on growth over a period of years.

It is generally said that doses 3 to 10 times physiologic replacement are needed for "the stress of surgery." The stress accompanying a surgical procedure can vary greatly. Modern techniques of anesthesiology, better anesthetic, analgesic, and muscle-relaxing drugs, and increased awareness of the particular needs of children in managing intraoperative fluids and electrolytes have greatly reduced the stress of surgery. In the past, a significant portion of such stress had to do with pain and hypovolemia, but when managed appropriately on contemporary pediatric services, minor surgical procedures elicit minimal changes in cortisol levels.[58]. Similarly, part of the stress of acute illness is fever and fluid loss, factors now familiar to all pediatricians. Although it remains appropriate and necessary to give about three times physiologic requirements during such periods of stress, it is probably not necessary to give much higher doses. Similarly, it is not necessary to triple a child's physiologic replacement regimen during simple colds, upper respiratory infection, otitis media, or after immunizations.

The preparation of the hypoadrenal patient on replacement therapy for surgery requires coordination with the anesthesia team. The best approach is to place a stress dose of 25 mg hydrocortisone per m^2 in the intravenous fluid, so that the glucocorticoid is delivered continuously during surgery, rather than being given a single bolus at the beginning of the procedure. It appears that the greatest stress is at the time of anesthesia reversal, rather than at the time of anesthesia induction.[57] Regular therapy at two to three times physiologic requirements can then be reinstituted on the day after the surgical procedure.

Mineralocorticoid Replacement

Replacement therapy with mineralocorticoids is indicated in salt-losing congenital adrenal hyperplasia and in syndromes of adrenal insufficiency that affect the zona glomerulosa. Only one mineralocorticoid, 9α-fluorocortisol (Florinef), is currently available. There is no parenteral mineralocorticoid preparation so that hydrocortisone plus salt must be used.

Because of increasing mineralocorticoid sensitivity with age (see Figure 13-17), mineralocorticoid doses are similar in children and adults. Newborns are quite insensitive to mineralocorticoids and typically require substantially larger doses than adults. The adult replacement dose of 9α-fluorocortisol is usually 0.05 to 0.1 mg daily, but newborns with CAH may require up to 0.4 mg. Sodium must be available to the nephrons for mineralocorticoids to promote reabsorption of sodium, thus, the newborn with salt-losing congenital adrenal hyperplasia must be treated with both mineralocorticoids and sodium chloride. Similarly, mineralocorticoids will cause hypertension only by retaining sodium.

Cortisol has significant mineralocorticoid activity: approximately 20 mg of cortisol or cortisone intravenously has a mineralocorticoid action equivalent to 0.1 mg of 9α-fluorocortisol. Thus, when cortisol or cortisone is given in stress doses, each provides adequate mineralocorticoid activity, and mineralocorticoid replacement can be interrupted. This is frequently seen when patients with salt-losing congenital adrenal hyperplasia undergo surgery: the stress doses of intramuscular cortisone acetate and the intravenous saline solutions administered during and after surgery suffice for the patient's mineralocorticoid requirements. Additional 9α-fluorocortisol

is not needed until the supraphysiologic stress doses of cortisol are decreased. Because 9α-fluorocortisol can be administered only orally, and because this may not be possible in the postoperative period, the appropriate drug for glucocorticoid replacement is cortisol or cortisone, both of which have mineralocorticoid activity, rather than synthetic steroids such as prednisone or dexamethasone, which have little mineralocorticoid activity.

CONCLUDING REMARKS

Because the adrenal cortex is principally concerned with steroid synthesis, most of its disorders reflect genetic lesions in adrenal development and steroidogenesis. Overproduction and underproduction of steroids having varied and complex physiologic actions lead to complex phenotypes and clinical presentations. These primary, genetic disorders typically present themselves in infancy and childhood. By contrast, secondary disorders, such as Cushing disease (usually a disorder of the pituitary) and Addison disease (usually a disorder of cellular immunity) may be seen at any age. Thus, the pediatric endocrinologist must have a detailed understanding of the cell biology, genetics, and biochemistry of steroid hormone biosynthesis. Improvements in the speed, efficiency, accuracy, and economy of DNA sequencing now permit direct genetic diagnosis of many genetic diseases. However, it is unlikely that measurements of steroid hormones will become obsolete in the foreseeable future, and an understanding of steroid physiology will always be needed to comprehend clinical presentations, formulate differential diagnoses, choose genes for study, and monitor therapy. Thus, genetics will continue to enhance clinical physiology but will not replace it.

QUESTIONS

1. A newborn 46,XX baby was born after a normal term pregnancy and left the nursery with the mother at 2 days of life after having been checked and declared healthy by a pediatrician. The newborn screening reveals a 17OH progesterone of 1986 ng/dl (60 nmol/L). On recall at 2 weeks of age, the screening test reveals a similar value. The child is now referred to a pediatric endocrine center. What could be the cause of this elevated 17OH progesterone?
   a. Defect in HSD3B2
   b. Defect in P450 oxidoreductase
   c. Defect in CYP11B1
   d. Defect in either b or c
   e. Defect in a, b, or c

Answer: e

2. An 8-year-old boy is referred for precocious puberty and overgrowth. At 5 years of age he had two small soft tissue tumors of the skin removed by the dermatologist and has a remarkable amount of freckles characterizing his face. Otherwise he is a healthy, smart second grader. Physical exam reveals a height of +2 SD and weight of +2 SD; pubertal stage Tanner 3-4 with pubic hair 3-4, penis length 7 cm (90th percentile), and testes R 4 ml, L 6 ml with palpable tumor (confirmed by ultrasound). Bone age is 12 years. What is the likely diagnosis?
   a. Central precocious puberty
   b. Late-onset CAH with TART
   c. Leydig cell tumor
   d. Carney complex
   e. Leopard syndrome

Answer: d

3. The following genes have been associated with familial glucocorticoid deficiency (FGD), also termed *hereditary unresponsiveness to ACTH*, *except* which one?
   a. MRAP
   b. NNT
   c. MC2R
   d. PRKAR1A
   e. StAR

Answer: d

4. A 9-year-old obese girl is referred for possible Cushing syndrome. Which of the following clinical findings is strongest to support this hypothesis and prompt further workup?
   a. Early morning serum cortisol 23.6 ug/dl (= 650 nmol/L)
   b. Exaggerated weight gain in the past 2 to 3 years
   c. Growth arrest
   d. Visceral adiposity
   e. Acne and pubic hair Tanner 3

Answer: c

5. Which of the following genetic defects of steroid biosynthesis may cause both 46,XY DSD and 46,XX DSD at birth?
   a. HSD3B2
   b. POR
   c. HSD17B3
   d. Both b and c
   e. Both a and b

Answer: e

6. The following statements are true for the alternative steroid "backdoor" pathway to dihydrotestosterone, *except* which one?
   a. Was first described in the tammar wallaby
   b. Contributes to androgen production in 21-hydroxylase deficiency
   c. Genetic defects in this pathway cause 46,XY DSD and adrenal insufficiency
   d. Shares the involvement of the CYP17 gene/enzyme with the classic pathway for its functionality
   e. Is involved in the virilization of a 46,XX fetus with P450 oxidoreductase deficiency during pregnancy

Answer: c

CHAPTER 14

Pheochromocytoma and Multiple Endocrine Neoplasia Syndromes

Steven G. Waguespack, MD • Anita K. Ying, MD

CHAPTER OUTLINE

INTRODUCTION

Endocrine neoplasms comprise a variety of benign and malignant tumors that arise from the endocrine glands or neuroendocrine tissues. Although most childhood endocrine neoplasms are sporadic, without an identifiable germline mutation, others are hereditary and are secondary to mutations in one of many known tumor-predisposing genes. Catecholamine-producing tumors and medullary thyroid carcinoma (MTC) are major examples of tumors that, when diagnosed during childhood, typically occur within the context of a broader tumor-predisposition syndrome such as von Hippel-Lindau (VHL) disease and the multiple endocrine neoplasia (MEN) type 2 syndromes, respectively. Advances in genetic testing and research have led to the discovery of new hereditary endocrine neoplasia syndromes and tumor-predisposing genes as well as a better understanding of underlying pathophysiology in these disorders. Knowledge regarding genotype-phenotype relationships has evolved, as has clinical practice regarding the age of genetic testing, presymptomatic screening for endocrine tumors, and the timing of therapeutic intervention. Given the rapidly changing field, it has become imperative for pediatric patients with an endocrine tumor to be evaluated in programs with known multidisciplinary expertise for such problems. In addition, formal genetic counseling and results of genetic testing should be fully incorporated into treatment planning and long-term follow-up. This chapter reviews the pathophysiology, diagnosis, and management of pediatric neuroendocrine tumors and the most common genetic syndromes associated with their diagnosis.

GENETIC COUNSELING AND TESTING

A diagnosis of an endocrine tumor in a child should always raise concern for an underlying hereditary condition, which can subsequently have medical, reproductive, psychological, or social consequences for the patient and family. Genetic counseling is a process of communication that promotes understanding, decision making, and coping related to the impact of genetic disease.[1] It should be incorporated into all stages of care, both at diagnosis and

during long-term follow-up, because patients' counseling and information needs change over time and also because genetic testing and management recommendations are likely to evolve. Genetic testing, best exemplified in MEN2,[2] is a multistep process that begins with an affected patient. MEN2 is one of few hereditary cancer syndromes for which predictive genetic testing is clearly indicated during childhood because an intervention (i.e., early thyroidectomy) can prevent future morbidity and possible mortality due to incurable metastatic MTC. In other disorders, such as MEN1 and VHL, genetic testing and early presymptomatic screening of an asymptomatic child may lead to an earlier diagnosis of disease but not disease that can be prevented by a prophylactic intervention. In all cases, despite the anticipated medical benefits afforded from an early diagnosis, genetic testing in children also has the potential for psychosocial harm: alteration of the child's self-image and of the parents' perception of the child, modification of the patient's outlook on life, worry about the potential for genetic discrimination, early "medicalization" of an otherwise healthy child, changes in family relationships, and concerns regarding future reproductive issues. Online resources for genetic counseling and testing include the National Society of Genetic Counselors (www.nsgc.org), the National Cancer Institute "Cancer Genetics" website (www.cancer.gov/cancertopics/genetics), and "Gene Tests" (www.genetests.org), a publicly funded project that provides current and authoritative information on genetic disease and testing.

PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Pheochromocytomas (PHEO) and paragangliomas (PGL) are uncommon neuroendocrine tumors that arise from neural crest–derived cells. PHEO (Figure 14-1) is the term used for a catecholamine-producing paraganglioma that occurs in the adrenal medulla, whereas PGL (Figure 14-2) refers to extra-adrenal tumors that arise from both sympathetic and parasympathetic paraganglia located outside the cerebrospinal axis.[3-5] The term *PHEO* is often used interchangeably with PGL, but it is best to maintain a distinction between these two neoplasms due to underlying differences in genetics, clinical presentation, and malignant potential (Table 14-1).

PHEO/PGL represent < 7% of tumors that arise from the sympathetic nervous system and have an estimated incidence of 0.3 cases/million/year or less.[6,7] Up to

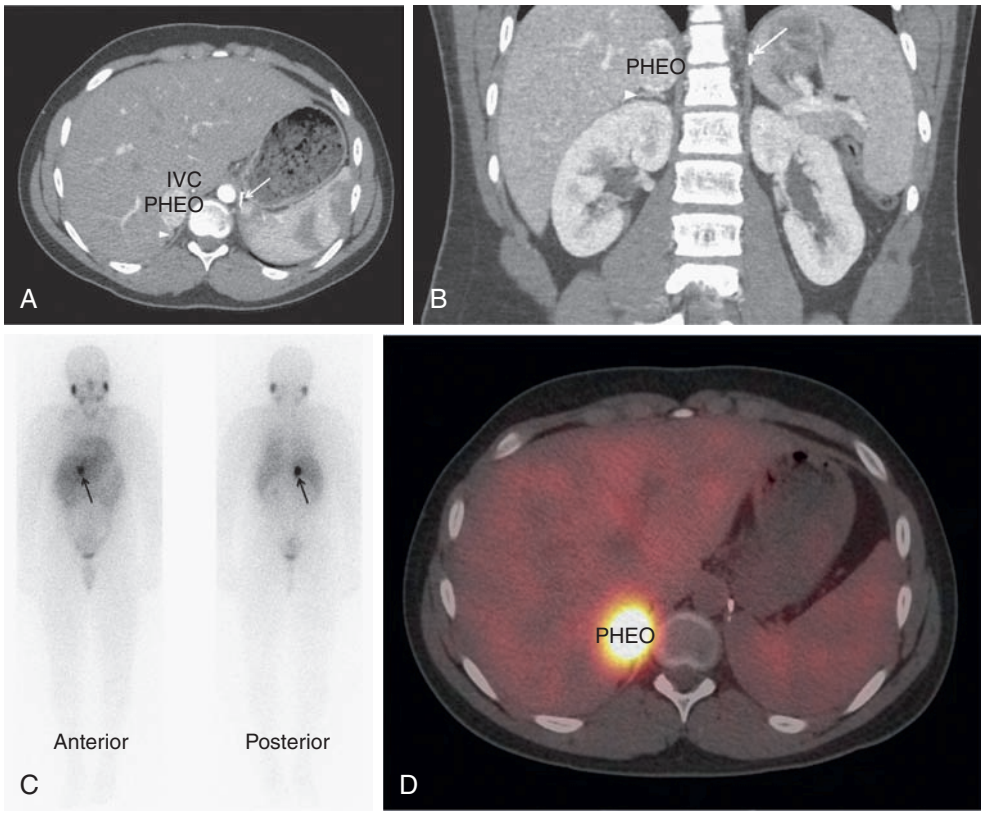

FIGURE 14-1 ■ Pheochromocytoma. A normotensive 14-year-old male with von Hippel-Lindau disease and a history of a left pheochromocytoma and abdominal paraganglioma diagnosed at the age of 7 was found to have elevated norepinephrine and normetanephrine levels after screening with a 24-hour urine collection. Axial CT postcontrast (**A**) and coronal reconstruction (**B**) identified a vascular neoplasm (PHEO) arising from the superior right adrenal gland. IVC, inferior vena cava; arrowhead, normal adrenal gland; arrow, surgical clips from previous adrenalectomy. MIBG scan confirmed the functional nature of the tumor and ruled out other sites of disease. Planar (**C**) and fused SPECT/CT axial images (**D**) in the same patient, 24 hours after the administration of ^{123}I MIBG. *(This image can be viewed in full color online at ExpertConsult.)*

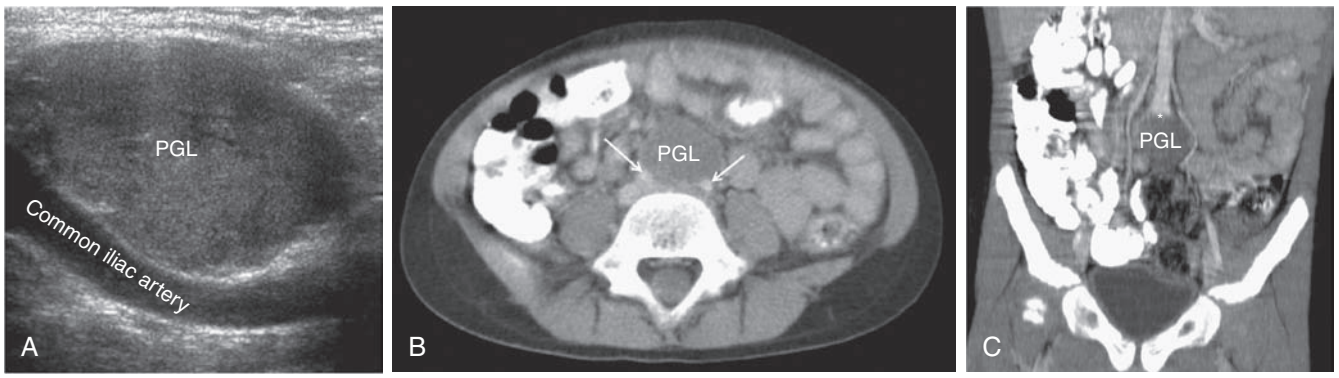

FIGURE 14-2 ■ Paraganglioma. A 6-year-old female with a malignant paraganglioma (PGL) and an *SDHB* mutation presented with severe hypertension during a well-child examination. **A,** Abdominal ultrasound (sagittal view) revealed a homogeneous, hypervascular 3.3 cm mass at the level of the aortic bifurcation. **B,** Axial CT postcontrast confirmed a low attenuation tumor (arrows refer to common iliac arteries); **C,** Coronal reconstruction detailed the location of the neoplasm at the aortic bifurcation (∗) in the organ of Zuckerkandl.

TABLE 14-1 **Major Disorders and Genes Associated with Pheochromocytoma and Paraganglioma**

	Gene (Chromosome)	Type of Tumor	Clinical Phenotype[a]	Earliest Age of DX[b]	Screening Guidelines[c]
Multiple endocrine neoplasia type 2A (MEN2A)	*RET* (10q11.2)	PHEO/rare PGL	Adrenergic Malignancy very rare Background of adrenal medullary hyperplasia	5-8[d141,153] 12[e168,455]	Start by age 8 years in codon 634 mutations; by age 20 years in lower risk codons
Multiple endocrine neoplasia type 2B (MEN2B)	*RET* (10q11.2)	PHEO	Adrenergic Malignancy rare Background of adrenal medullary hyperplasia	12[350]	Start by age 8 years
Neurofibromatosis type 1 (NF1)	*NF1* (17q11.2)	PHEO/PGL Rare composite PHEO[f]	Adrenergic Malignancy uncommon PHEO usually in adults (mean age 42[427])	7[456]	Screen any NF1 patient with HTN or other signs/symptoms of catecholamine excess or an incidental adrenal or para-aortic mass Consider testing in young women of child-bearing age who plan to become pregnant and in any patient prior to an elective surgical procedure
Familial paraganglioma syndrome 1 (PGL1)	SDHD (11q23)	PGL/PHEO	Primarily nonfunctional malignancy rare	5[9]	Start by age 10 years
Familial paraganglioma syndrome 3 (PGL3)	*SDHC* (1q21)	Primarily head and neck PGL	Primarily nonfunctional malignancy rare	13[457]	Start by age 10 years
Familial paraganglioma syndrome 4 (PGL4)	*SDHB* (1p36.1-p35)	PGL (primarily abdominal)/PHEO	Noradrenergic Malignancy common	3[458]	Start by age 5 years
von Hippel-Lindau disease (VHL)	*VHL* (3p25.3)	PHEO/PGL	Noradrenergic Malignancy uncommon	2[393]	Start by age 5 years

[a]**Noradrenergic** tumors almost exclusively secrete norepinephrine and normetanephrine whereas **adrenergic** tumors secrete epinephrine and metanephrine, in addition to norepinephrine and normetanephrine.
[b]Earliest age of diagnosis of PHEO/PGL and reference(s).
[c]In the opinion of the authors and based on review of the literature, age at which annual screening for PHEO/PGL should be initiated for patients with a known gene mutation.
[d]Ages of earliest PHEO onset reported in consensus guidelines via personal communication.
[e]Age of earliest PHEO onset published in the medical literature.
[f]A composite PHEO is a mixed tumor comprised of PHEO and neuroblastoma, ganglioneuroma, or ganglioneuroblastoma.
DX, diagnosis; HTN, hypertension; PGL, paraganglioma; PHEO; pheochromocytoma.
Adapted from Waguespack, S. G., Rich, T., Grubbs, E., et al. (2010). A current review of the etiology, diagnosis, and treatment of pediatric pheochromocytoma and paraganglioma. J Clin Endocrinol Metab, 95, *2023–2037.*

20% of PHEO/PGL are identified during childhood at an average age of 11 years; there is a slight predominance in boys, particularly when diagnosed under the age of 10.[7-15] Less than 2% of children diagnosed with hypertension will harbor a catecholamine-producing neoplasm.[16,17]

All functional PHEO/PGL produce and metabolize catecholamines and contain chromaffin tissue, which refers to the brown-black color resulting from the oxidation of catecholamines after staining with chromium salts. PGL occur in all locations where paraganglia are found (from the skull base to the pelvis) and are either functional (sympathetic) or nonfunctional (parasympathetic) neoplasms, depending on the site of origin and underlying pathophysiology[18-20] (see Table 14-1). PGL arising in the head and neck region are almost exclusively nonfunctional, whereas most intra-abdominal PGL (most commonly occurring within the organ of Zuckerkandl) (see Figure 14-2) are secretory tumors. The majority of these tumors diagnosed during childhood are PHEO, which synthesize and secrete catecholamines (dopamine, norepinephrine, or epinephrine) and their metabolites (including 3-methoxytyramine, normetanephrine, and metanephrine, respectively)[18,21,22] (Figure 14-3). Multicentric tumors are more common in childhood presentations of PHEO/PGL.[8,10,23]

Biosynthesis and Actions of Catecholamines

Dopamine, norepinephrine, and epinephrine (collectively known as "catecholamines") are chemical neurotransmitters and hormones that play important roles in the regulation of numerous physiologic processes and the development of neurologic, psychiatric, endocrine, and cardiovascular diseases.[24-27] The catecholamines are composed of a catechol (1,2-dihydroxybenzene) moiety and a side-chain amine group. They are synthesized from the amino acid tyrosine, which is converted to 3,4-dihydroxyphenylalanine (dopa) by the enzyme tyrosine hydroxylase, the rate-limiting step in catecholamine biosynthesis (see Figure 14-3). Subsequent enzymatic decarboxylation and hydroxylation of dopa yields dopamine and norepinephrine, respectively, and norepinephrine is subsequently converted to epinephrine via the cytosolic enzyme phenylethanolamine N-methyltransferase (PNMT).

The catecholamines are synthesized and stored in granules within the adrenal medulla, where they are released via exostosis into the systemic circulation in response to stressful stimuli. Dopamine and norepinephrine are also produced by postganglionic neurons in the sympathetic nervous system. Epinephrine is made only in the adrenal medulla, where it represents the predominant catecholamine (~80%) because PNMT expression is dependent on and regulated by high local concentrations of glucocorticoids (as occurs only in the adrenal medulla, surrounded by the cortisol-synthesizing cortex with a distinct concentration gradient toward the adrenal medulla).[24,28,29] The effects of catecholamines are terminated via rapid reuptake into nerve terminals by the norepinephrine transporter and via metabolism by two major enzymes: monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT)[18,24,27] (see Figure 14-3).

The complex actions of norepinephrine and epinephrine are mediated by the G protein–coupled α- and β-adrenergic receptors, whereas dopamine binds to a different class of G protein–coupled dopamine receptors (five distinct receptors that are divided into two families: D1-like and D2-like)[24-26] (Table 14-2). The initial classification of adrenergic receptors was based on epinephrine's ability to both excite (α-receptor) and inhibit (β–receptor) smooth muscle. Specific agonists and antagonists characterize the adrenergic receptor subtype (α_1, α_2, β_1, β_2, and β_3) and can be used as therapeutic agents. The D2 receptor is the primary dopamine receptor that is targeted for drug therapy.

Clinical Presentation

The clinical presentation of pediatric PHEO/PGL is highly variable. Children with these tumors can come to attention due to symptomatic catecholamine hypersecretion, symptoms due to tumor mass effect (e.g., pain), an incidental radiographic finding, or because of screening for one of the associated hereditary tumor syndromes[7,30,31] (see Table 14-1). PHEO/PGL may also arise in the setting of cyanotic congenital heart disease.[32,33] Given their neuroendocrine origin, PHEO/PGL can very rarely co-secrete other hormones that result in a clinical syndrome of ectopic hormone excess, such as gigantism (growth hormone-releasing hormone), Cushing syndrome (corticotropin-releasing hormone or adrenocorticotropic hormone), hypercalcemia (parathyroid hormone–related peptide), the syndrome of inappropriate antidiuretic hormone secretion, or secretory diarrhea (vasoactive intestinal peptide).[18,34]

The clinical presentation of a functional PHEO/PGL depends on differences in catecholamine secretion and release as well as individual patient sensitivities to catecholamines.[35] Signs and symptoms of catecholamine excess include hypertension, which is typically sustained in the majority of pediatric cases; severe headaches; paroxysmal episodes with the classic triad of headaches, palpitations, and diaphoresis (less common in children); orthostatic hypotension and syncope; pallor; tremor; or anxiety.* PHEO/PGL in children can also cause nonspecific signs and symptoms such as blurred vision; abdominal pain, diarrhea, and other gastrointestinal symptoms; weight loss; hyperglycemia; polyuria and polydipsia; low-grade fever; and behavioral problems/decline in school performance.† Bladder PGL can present with hematuria and paroxysmal symptoms during micturition.[34,39]

Complications of catecholamine excess can include hypertensive crisis, cardiomyopathy (*takotsubo* cardiomyopathy), arrhythmias, pancreatitis, severe constipation and intestinal pseudo-obstruction, stroke, seizures, and

*See references 3, 8, 12, 14, 16, 18, 19, 30, and 36.
†See references 8, 12, 14, 16, 18, 19, and 36-38.

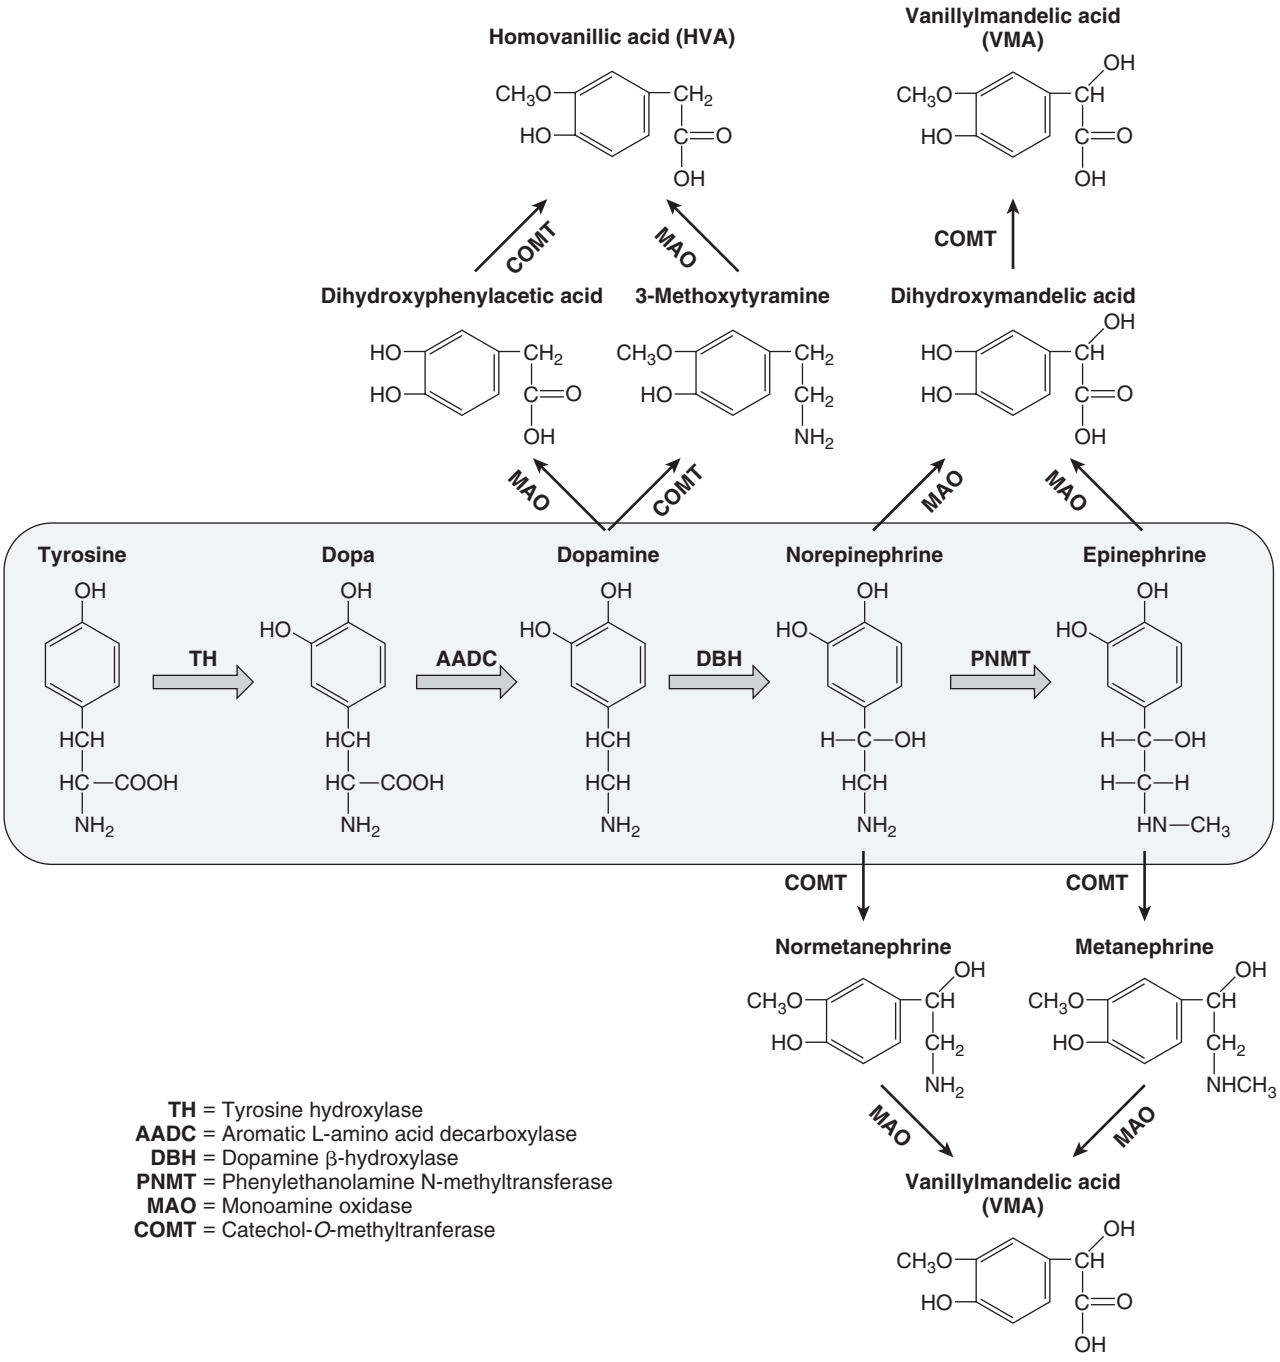

FIGURE 14-3 ■ Catecholamine synthesis and metabolism. The catecholamines are synthesized from the amino acid tyrosine, which is converted to 3,4-dihydroxyphenylalanine (Dopa) by the enzyme tyrosine hydroxylase (TH), the rate-limiting step in catecholamine biosynthesis. Subsequent enzymatic decarboxylation (aromatic L-amino acid decarboxylase; AADC) and hydroxylation (dopamine β-hydroxylase; DBH) yields dopamine and norepinephrine, respectively, and norepinephrine is subsequently converted to epinephrine via the cytosolic enzyme phenylethanolamine N-methyltransferase (PNMT). The catecholamines are metabolized by two major enzymes: monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT).

even multisystem crisis and death.[19,34,36,38,40-42] Symptoms of parasympathetic PGL include hearing loss, pulsatile tinnitus, neck mass and other symptoms of mass effect such as voice hoarseness, pharyngeal fullness, and dysphagia.[43]

Compared with sporadic disease, PHEO/PGL identified during the course of prospective presymptomatic screening within the context of a familial disorder are smaller and less symptomatic (frequently asymptomatic) tumors.[44-46] Although this type of clinical presentation is becoming more commonplace, there is currently no consensus as to how to approach such patients with small asymptomatic tumors, particularly in clinical settings where the risk for malignancy is low.

TABLE 14-2 **Catecholamine Receptor Classification, Function, and Pharmacology**

Receptor Type	Primary Pharmacologic Agonist(s)	Primary Pharmacologic Antagonist(s)	Major Biologic Effects
α_1	Phenylephrine, midodrine	Doxazosin, prazosin, terazosin, etc.	Vasoconstriction; promotes cardiac growth and structure
α_2	Clonidine, methyldopa, tizanidine	Yohimbine	Inhibition of norepinephrine release; vasoconstriction; inhibits adrenal catecholamine release and modulates CNS dopamine neurotransmission
β_1	Dobutamine	Atenolol, bisoprolol, esmolol, metoprolol	Increases heart rate and contractility
β_2	Albuterol, levalbuterol, salmeterol, terbutaline, etc.	Propranolol (prototypic β_2 antagonist that is also a β_1 antagonist) and others	Smooth muscle relaxation (arteriolar and venous dilation; relaxation of tracheobronchial muscles)
β_3	Investigational	Investigational	Metabolic effects in adipose tissue and skeletal muscle
D1-like (D_1 and D_5)	L-DOPA	No primary agents	Vasodilation; increased renin secretion; promotes norepinephrine and epinephrine release; various CNS functions
D2-like (D_2, D_3, and D_4)	Bromocriptine, cabergoline, pramipexole, ropinirole	Aripiprazole, chlorpromazine, haloperidol, metoclopramide, prochlorperazine, etc.	Decreases prolactin secretion; decreases renin secretion; inhibits norepinephrine and epinephrine release; various CNS functions

Evaluation

Biochemical Diagnosis

The diagnosis of PHEO/PGL has been simplified by advances in the assays used to detect and quantify levels of catecholamines and their metabolites in blood and urine. The measurement of fractionated plasma or urine metanephrines (metanephrine and normetanephrine) is the most sensitive test (approaching 100% sensitivity) for the diagnosis of a sympathetic chromaffin tumor and should be the primary diagnostic test in the initial evaluation of suspected PHEO/PGL[3,18,47-54] (Figure 14-4).

The high sensitivity of metanephrine testing is based on the fact that there is continuous intratumoral metabolism of catecholamines, a process that occurs independently of catecholamine release, which can occur intermittently or at low rates.[50] An elevation of metanephrines greater than fourfold above the reference range is associated with almost 100% probability of the presence of a catecholamine-secreting tumor.[55] Any drugs known to interfere with these assays (e.g., acetaminophen, tricyclic antidepressants, phenoxybenzamine, and decongestants, among others[3]) should be discontinued prior to testing. Dietary restrictions need not be routinely employed but should be considered if the assay utilized measures only deconjugated normetanephrines or if a dopamine-secreting tumor is suspected.[56] The measurement of the catecholamine metabolites vanillylmandelic acid (VMA) and homovanillic acid (HVA) is no longer recommended for the evaluation of PHEO/PGL. However, testing for HVA and VMA in spot urine samples remains a critical component of the evaluation of neuroblastoma, where these analytes have a high sensitivity and specificity for tumor detection.[57]

In patients with mildly elevated metanephrine levels in whom a false-positive test result is suspected, consideration should be given to measuring these analytes in the supine position, 30 minutes after an indwelling needle or catheter is inserted into the vein.[3,53] Clonidine suppression and glucagon stimulation tests[58-60] have been a component of the diagnostic algorithm in adults but are rarely required and, in the case of the glucagon stimulation test, have been largely abandoned due to insufficient diagnostic sensitivity.[61] Furthermore, these tests have not been validated in the diagnosis of childhood PHEO/PGL and are not currently recommended.

Catecholamine-producing tumors can be subclassified as being either noradrenergic or adrenergic based uon their pattern of catecholamine release.[62,63] Noradrenergic PHEO/PGL secrete norepinephrine and normetanephrine, as seen in VHL disease and in tumors associated with the familial PGL syndromes.[15,62,64-66] Adrenergic tumors secrete both epinephrine and norepinephrine and their metabolites, and these tumors are more commonly PHEO that arise sporadically or within the clinical context of MEN2 or NF1.[50,62,64,66] This differential secretion of catecholamines is due to decreased expression of PNMT in noradrenergic tumors.[64]

Dopamine-secreting tumors are rare and are typically extra-adrenal *SDHx*-mediated paragangliomas.[67-69]

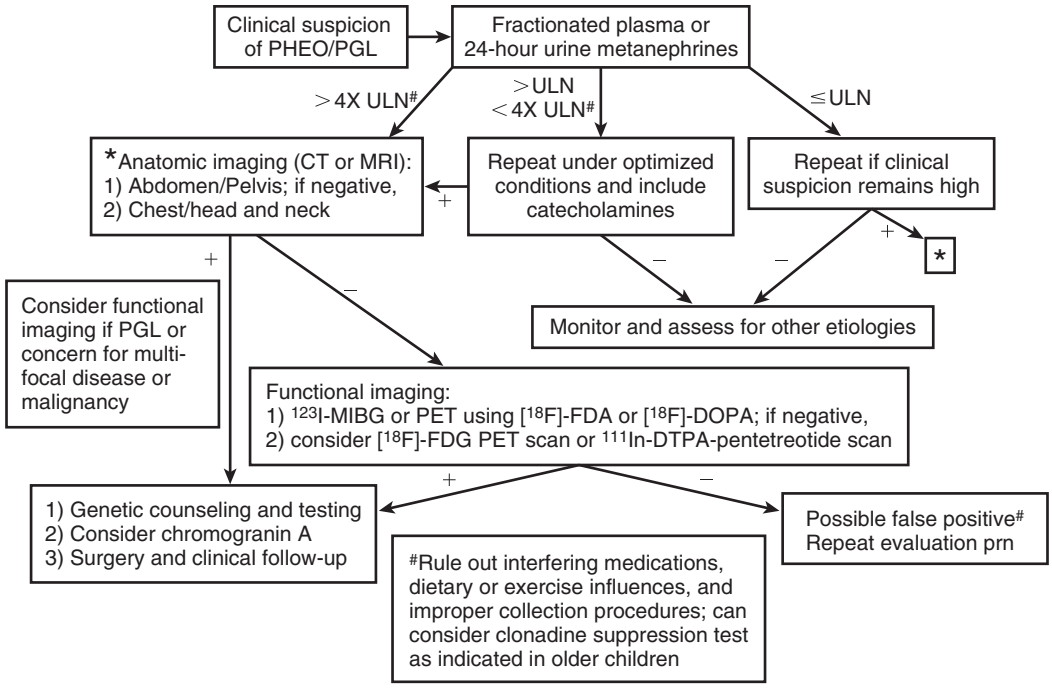

FIGURE 14-4 ■ **Diagnosis of pediatric pheochromocytoma/paraganglioma.** (Adapted from Waguespack, S. G., Rich, T., Grubbs, E., et al. (2010). A current review of the etiology, diagnosis, and treatment of pediatric pheochromocytoma and paraganglioma. *J Clin Endocrinol Metab, 95*, 2023–2037.)

The measurement of plasma methoxytyramine (see Figure 14-3) may help to identify such a tumor, particularly in the context of an *SDHx* mutation,[70] but this test is not widely available. A dopamine-secreting tumor should be considered in normotensive patients identified to have a mass that appears consistent with a PHEO/PGL, in which case dopamine and its metabolites, homovanillic acid and methoxytyramine (if available), should also be measured.[68,70-72] For prospective screening in patients with an *SDHx* mutation, total catecholamines should also be checked in addition to metanephrines due to this possibly.

Chromogranin A is a major secretory protein present in the soluble matrix of chromaffin granules that serves as an effective tumor marker that may correlate with PHEO/PGL size and malignant potential.[15,47,73-75] Chromogranin A also appears to be a useful marker in the biochemically silent, *SDHB*-related paraganglioma,[20,69] making it a potentially useful test in the screening of asymptomatic *SDHx* mutation carriers.

Radiographic Studies

Once a diagnosis of catecholamine excess is established from biochemical testing, radiographic studies should be undertaken to identify the location of the tumor(s)[19,53] (see Figures 14-1, 14-2, and 14-4). These tests include both anatomic imaging using computed tomography (CT) or magnetic resonance imaging (MRI) and functional nuclear scintigraphy obtained concomitantly with single-photon emission computed tomography (SPECT)/CT, chiefly using radiolabeled meta-iodobenzylguanidine (MIBG).[76] Initial radiographic studies should include anatomic cross-sectional imaging of the abdomen and pelvis, followed by imaging of the neck and chest if the initial studies are unrevealing[18,50] (see Figure 14-4). CT and MRI have similar diagnostic sensitivities, and so the imaging test of choice is best determined by local practices and patient preference.[53,77] Abdominal ultrasound may also be considered in young children, if local expertise permits (see Figure 14-2). Catecholamine-producing tumors are highly vascular (and hence enhancing) neoplasms that commonly contain necrotic, cystic, or hemorrhagic areas; on MRI, they may exhibit a classic hyperintense appearance on T2-weighted images.[18,78]

MIBG, a synthetic compound that bears structural similarity to norepinephrine (except it also has a guanidine side chain that resists metabolism), accumulates preferentially in adrenergic tissues, namely due to reuptake via the norepinephrine transporter system.[79,80] MIBG utilized for diagnostic purposes is radiolabeled with either ^{123}I or ^{131}I, although ^{123}I-MIBG is the agent of choice because of its superior imaging properties and substantially lower radiation dose.[76] ^{123}I-MIBG scanning is a sensitive and specific test (94% and 92%, respectively[76]) that can confirm the catecholamine-producing nature of a tumor, localize tumors not seen with cross sectional imaging, and potentially identify other sites of disease, although its use is more limited in malignant disease.[50,51,81-84] Whether or not MIBG scintigraphy is required in all cases where tumor is located by CT or MRI remains an area of debate,[53] but it should be considered in known syndromic disease where there is a higher risk of multifocal disease. Prior to ^{123}I-MIBG scanning, care should be taken to ensure that the patient is not taking medications (decongestants, calcium channel blockers, or labetalol) that are known to decrease MIBG uptake, and potassium iodide should be administered to

block thyroid uptake of radioactive iodine.[80,85] Because of the limitations of MIBG testing, other nuclear imaging modalities have been studied: somatostatin receptor scintigraphy using ^{111}In-DTPA-pentetreotide (octreotide), [^{18}F] fluoro-dihydroxyphenylalanine (^{18}F-DOPA) positron emission tomography (PET), [^{18}F]-fluorodopamine (^{18}F-FDA) PET, or [^{18}F] fluorodeoxyglucose (FDG) PET.[50,77,86-88] Although some of these functional studies, particularly ^{18}F-DOPA and ^{18}F-FDA PET, are likely to be superior to scanning with MIBG,[89-91] not all centers can perform these studies. [^{18}F]FDG PET appears to be superior in the evaluation and workup of malignant PHEO/PGL, particularly in *SDHB* mutation carriers.[91-94]

Genetic Issues

The majority of apparently-sporadic PHEO/PGL that present in children and young adults are due to an identifiable germline mutation in one of several tumor-predisposing genes[9,15] (see Table 14-1). The most commonly associated syndrome is VHL followed by the familial paraganglioma syndromes (PGL1-4) and MEN2 (see separate sections presented later in the chapter). In all cases, synchronous or metachronous tumors can occur in both adrenal glands as well as extra-adrenal sites, underscoring the need for lifelong follow-up testing and appropriate genetic counseling and testing. Table 14-1 lists the major hereditary syndromes associated with PHEO/PGL in children. Knowledge regarding the genetic causes of catecholamine-producing tumors is rapidly expanding and genes associated with the development of PHEO/PGL include egl nine homolog 1 [*C. elegans*] (*EGLN1* also known as *PHD2*)[95]; kinesin family member 1B (*KIF1B*)[96]; transmembrane protein 127 (*TMEM127*)[97]; succinate dehydrogenase complex, subunit A (SDHA)[98]; MYC associated factor X (*MAX*)[99]; and succinate dehydrogenase complex assembly factor 2 (*SDHAF2*), the cause of PGL2.[100] Most recently, gain-of-function germline and somatic mutations in HIF-1 alpha-like factor (*HIF2A*; also known as *EPAS1*) have been associated with the development of PGL in individuals with congenital polycythemia.[101,102]

Family history, clinical presentation of the patient, and differences in the biochemical phenotype help to prioritize genetic testing.[31,103] PHEO/PGL that arise in the context of VHL or the familial paraganglioma syndromes occur at younger ages and are typically noradrenergic tumors, producing almost exclusively norepinephrine and normetanephrine.[15,66] Adrenergic tumors (which secrete epinephrine and metanephrine, in addition to norepinephrine and normetanephrine), are seen in MEN2, NF1, and sporadic cases. In general, *VHL* is the major gene of interest in children with PHEO and *SDHB* is the suspected gene in patients with PGL or malignant disease.[9,15] Evaluation for *RET* proto-oncogene germline mutations is recommended only in the rare case of a child with an apparently sporadic PHEO who exhibits an adrenergic phenotype, because medullary thyroid carcinoma usually presents before PHEO in most individuals with MEN2.[2,31] NF1 is usually clinically diagnosed and therefore testing for mutations in the *NF1* gene in the context of an apparently sporadic tumor will be of very low yield and therefore is not recommended.

Management

Surgical Therapy

Surgical resection is the mainstay in the treatment of PHEO/PGL. A preoperative biopsy is not indicated and potentially dangerous.[104] The procedure of choice for most PHEO is laparoscopic adrenalectomy, either using transperitoneal or retroperitoneal approaches.[4,105-111] Laparotomy should be contemplated in patients with large PHEO or a concern for underlying malignancy based on the clinical presentation, genetic background, or radiographic appearance of the tumor.[4] In the setting of bilateral PHEO or known hereditary PHEO, a cortical-sparing procedure should be performed to minimize the risk of the lifelong glucocorticoid and mineralocorticoid replacement and the attendant risks of primary adrenal insufficiency.[4,107,112-114] Because it is extremely difficult to preserve a vascularized portion of adrenal cortex sufficient to prevent corticosteroid dependence without also leaving some residual adrenal medulla, there is a risk for recurrent PHEO in the remnant; limited data suggest that recurrence rates in this setting are between 10% and 38%.[10,30,112,115] The surgical approach for removal of a PGL depends on the location of the tumor but in selected cases of abdominal disease can also be performed laparoscopically.[19,108] Head and neck PGL can be expectantly monitored or treated with surgery or radiation.[4]

It is important that the anesthesiologist have experience with the intraoperative management of PHEO/PGL, because dysrhythmias can occur and blood pressures can be quite labile.[116,117] Both intravenous antihypertensive medications (esmolol, labetalol, nitroprusside, phentolamine, etc.) and vasopressors (e.g., phenylephrine and norepinephrine) should be readily available for intraoperative use. The greatest risk for hypertension occurs during anesthesia induction and manipulation of the tumor, whereas hypotension is most likely to occur after ligation of the adrenal vein, when the abrupt decline in catecholamine concentrations leads to vasodilation.[4] Postoperatively, the patient should be monitored for the two major complications of hypotension and hypoglycemia.[3,4,116,117] Hypertension may persist for days to weeks following surgery. In patients who have had a cortical-sparing adrenalectomy in the context of bilateral PHEO resection, stress glucocorticoids should be provided and a high-dose cosyntropin stimulation test obtained prior to hospital discharge to determine the need for adrenal steroid replacement.

Medical Preparation for Surgery

Once the diagnosis of a PHEO/functional PGL has been confirmed, medical therapy to normalize the blood pressure and mitigate the signs and symptoms of catecholamine excess should be initiated (Table 14-3). If surgery

TABLE 14-3 **Preoperative Medical Management of Pheochromocytoma/Sympathetic Paraganglioma**

Drug Class	Drug	Mechanism of Action	Initial Pediatric Dose
α-adrenergic receptor blockers	Doxazosin	α_1-antagonist	0.5-1 mg daily
	Phenoxybenzamine	α_1- and α_2-antagonist	0.2-0.5 mg/kg/day divided BID (max 10 mg BID)
	Prazosin	α_1-antagonist	0.05-0.1 mg/kg/day divided TID (max 1 mg TID)
β-adrenergic receptor blockers	Atenolol	β_1- antagonist	0.5-1 mg/kg/dose daily (max 50 mg daily)
	Metoprolol	β_1- antagonist	1-2 mg/kg/day divided BID (max 50 mg BID)
	Propranolol	β_1- and β_2-antagonist	0.5-1 mg/kg/day divided BID (max 40 mg BID)
Calcium channel blockers	Nifedipine (sustained release)	Calcium channel blocker	0.25-0.5 mg/kg/day daily or BID (max 60 mg total daily dose)
Inhibitors of catecholamine synthesis	Metyrosine	Tyrosine hydroxylase inhibitor	125-250 mg divided BID-TID

is planned, medical treatment should be taken for at least 1 to 2 weeks prior to surgery. This is done to minimize the potential complications that may arise from acute catecholamine surges during the induction of anesthesia and manual manipulation of the tumor.[11,19,116,118] No universal algorithm exists for the medical management of a PHEO/PGL prior to surgery. Nevertheless, blockade of α-adrenergic receptors is usually the therapy of choice and effective α-receptor blockade improves symptoms, lowers blood pressure, and expands the vascular bed and blood volume. The primary agent used in children is the nonselective α-blocker phenoxybenzamine.[7,18,19,116] Side effects of phenoxybenzamine can include nasal congestion, symptomatic orthostasis, and tachycardia. Due to its long half-life, it may also increase the risk of postoperative hypotension.[3,11,51,60] Selective α_1-blockers such as prazosin and doxazosin and calcium channel blockers such as nifedipine can also be utilized.[11,60,119-121] Although labetalol and carvedilol, drugs with both α- and β-antagonist activity, are attractive options for preoperative blockade, they are not universally recommended for primary medical treatment because of their lower α-adrenergic receptor blockade relative to their β-antagonist activity.[121] Metyrosine is a competitive inhibitor of tyrosine hydroxylase, the rate-limiting step of catecholamine biosynthesis (see Figure 14-3), and it can also be utilized as part of the preoperative preparative regimen.[121,122] However, not all centers use metyrosine routinely due to its potential significant side effects (sedation, diarrhea, and extrapyramidal manifestations) and unclear benefit in most cases.[4,18,31] Symptomatic postural hypotension may be seen at the beginning of medical therapy, particularly with large biochemically active tumors, so it is imperative to start at low doses and increase the dose or frequency every few days until the blood pressure is normal for age and height and the patient is minimally orthostatic. Phenoxybenzamine is only supplied as a single dose (10-mg capsule), so it will need to be compounded by the pharmacy to allow for the administration of the lower doses needed in younger children. Phenoxybenzamine is also an expensive drug, which makes the selective α_1-blockers a more attractive option in many cases.

Once alpha blockade has been established, a β-blocking agent (see Table 14-3) is typically added to control reflex tachycardia.[121] A β-blocker should not be used as a single agent because of the possibility of worsening symptoms and hypertension due to unopposed catecholamine effects at α-adrenergic receptors.[3] A few days prior to surgery, oral salt loading (either via increased dietary intake or with sodium chloride tablets) is recommended to expand the blood volume in order to mitigate postoperative hypotension. Some centers also routinely admit patients for intravenous fluids prior to PHEO/PGL resection,[121] and this should be considered for very symptomatic children with large tumors.

Prognosis and Follow-up

The prognosis of children diagnosed with PHEO/PGL is excellent with 5- and 10-year survival rates of 98% and a 20-year survival rate of 84%.[15] Based on data from a British tumor registry, the incidence of malignant disease in children is estimated to be 0.02 per million per year.[7] Approximately 12% of pediatric PHEO/PGL are malignant,[8] although some referral centers report a malignancy rate in tumors diagnosed during childhood as high as 65%.[14,15,30] The high rate of malignancy from some studies may in part reflect a referral bias. On the other hand, the latency period between diagnosis and confirmation of metastatic disease is 9 years on average[15]; thus, the true rate of malignancy may be higher than previously recognized because it can only be identified during long-term systematic follow-up of patients diagnosed with PHEO/PGL during childhood. Children with metastatic disease typically demonstrate a more indolent clinical course with average overall survival $>$ 6 years after the diagnosis of metastatic disease.[15]

There is no single histologic feature or immunohistochemical profile that is independently able to predict metastatic potential in a resected PHEO/PGL, but features noted more frequently in malignant tumors include extra-adrenal location, confluent tumor necrosis, absence of hyaline globules, coarse nodularity of the primary tumor, high proliferative index, and size greater than 5 cm, among others.[22,123-125] Malignancy is therefore only established by the identification of distant metastases in a site where paraganglia are not normally located (primarily bones but also lymph nodes, liver, or lungs).[15,22,123] The risk of

malignant disease is greater for extra-adrenal sympathetic PGL than for PHEO or nonsecretory head and neck PGL, and overall prognosis is worse for these patients.[15,125] The highest risk for malignancy and death is in SDHB-related sympathetic PGL, which represents 50% or more of malignant tumors.[15,65,69,126-130]

Because PHEO/PGL can have unpredictable behavior and because children are at risk for the development of metachronous primary tumors, delayed metastasis from previously treated neoplasms, and local recurrence (in the case of cortical-sparing procedures), long-term follow-up with biochemical screening and intermittent imaging studies is required, particularly for children with a PGL or a known *SDHB* mutation.[3,7,10,15,19,22,30,112,115] For asymptomatic children with an identified genetic mutation predisposing them to the development of a PHEO/PGL, annual biochemical screening is advised, with the age of initial screening determined by the specific gene mutation (see Table 14-1). Furthermore, occasional cross-sectional imaging, typically MRI because of the lack of radiation exposure, is recommended periodically for follow-up of patients at high risk of recurrence or malignant disease (e.g., abdominal paragangliomas) or at risk for developing a PHEO/PGL that may not be identified on biochemical testing alone (e.g., familial paraganglioma syndromes), although the optimal screening strategy has yet to be determined.[131]

MEDULLARY THYROID CARCINOMA

MTC is a malignant neuroendocrine tumor that arises from the neural crest–derived, calcitonin-producing parafollicular C cells of the thyroid gland.[132,133] It comprises only a small minority of thyroid malignancies diagnosed in patients under the age of 21 years, although it is the most common thyroid malignancy diagnosed at less than age 5 years.[134] The overall age-adjusted incidence of MTC during childhood is < 0.5 cases per million per year, with a fairly equal female:male ratio, unlike the differentiated thyroid carcinomas, which are more frequent in girls than boys.[134-136]

When diagnosed during childhood, MTC primarily results from a dominantly inherited or de novo activating mutation in the multiple endocrine neoplasia (MEN) type 2A or type 2B or familial MTC (FMTC). FMTC is more commonly being recognized as a phenotypic variant of MEN2A with decreased penetrance or delayed onset of the other neoplastic manifestations.[141,142] *RET* is a member of the cadherin superfamily and encodes a receptor tyrosine kinase that has an extracellular binding domain and an intracellular tyrosine kinase (Figure 14-5). The endogenous ligands (which activate RET via a high-affinity ligand-binding coreceptor, GFRα) are members of the glial cell–derived neurotrophic factor (GDNF) family, which

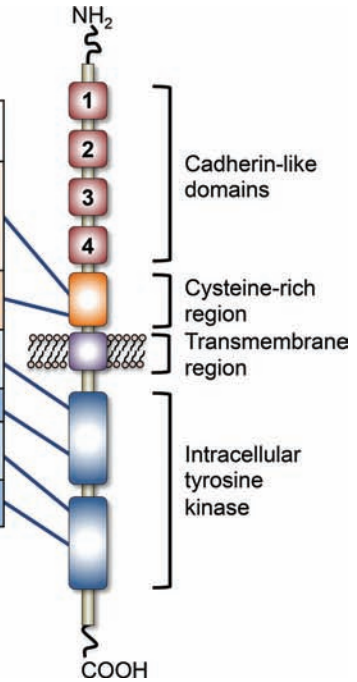

FIGURE 14-5 ■ The RET receptor and commonly mutated codons and associated phenotypes in the MEN2 syndromes, including the recent ATA risk stratification. [a]Age of testing refers to the age at which clinical testing with thyroid ultrasound and basal calcitonin levels would be appropriate. It is not meant to indicate the age of testing for the presence of a *RET* mutation, which may be done earlier after appropriate genetic counseling, or the absolute age for early thyroidectomy. [b]Although a case of very aggressive MTC in a child diagnosed at age 6 years has been reported, an older age of disease onset is generally observed with this *RET* mutation. [c]Only rare cases of MEN2B secondary to the A8883F mutation have been published, and the MTC phenotype of this mutation remains largely unknown. MTC, medullary thyroid carcinoma; PHEO, pheochromocytoma; PHPT, primary hyperparathyroidism; CLA, cutaneous lichen amyloidosis; HSCR, Hirschsprung disease. (*This image can be viewed in full color online at ExpertConsult.*) (From Waguespack, S. G., Rich, T. A., Perrier, N. D., et al. (2011). Management of medullary thyroid carcinoma and MEN2 syndromes in childhood. *Nat Rev Endocrinol, 7*, 596–607.)

are involved in the regulation of neural tissue development.[143] The RET protein therefore plays a crucial role in the development of neural crest–derived cells, the urogenital system, and the central and peripheral nervous systems, notably the enteric nervous system.[144,145]

Although sporadic nonheritable tumors account for up to 75% of adult cases of MTC,[141] such tumors are rare in children. In contrast to sporadic MTC, hereditary MTC is typically multifocal, bilateral, and located in the middle to upper regions of the thyroid lobes (Figure 14-6), an area where C cells are the most highly concentrated.[133,146,147] Microscopic examination and calcitonin staining of the thyroid will often identify C-cell hyperplasia, which is the initial stage in an oncologic cascade that leads to the development of microscopic noninvasive MTC and ultimately lymph node and distant metastatic disease due to frankly invasive carcinoma (Figure 14-6).[133,148] Patients with hereditary MTC have an age-related progression of malignant disease, with lymph node and distant metastases typically occurring years after the onset of C-cell hyperplasia.[2,148] The cervical and mediastinal lymph node basins are the most common sites of metastatic disease,

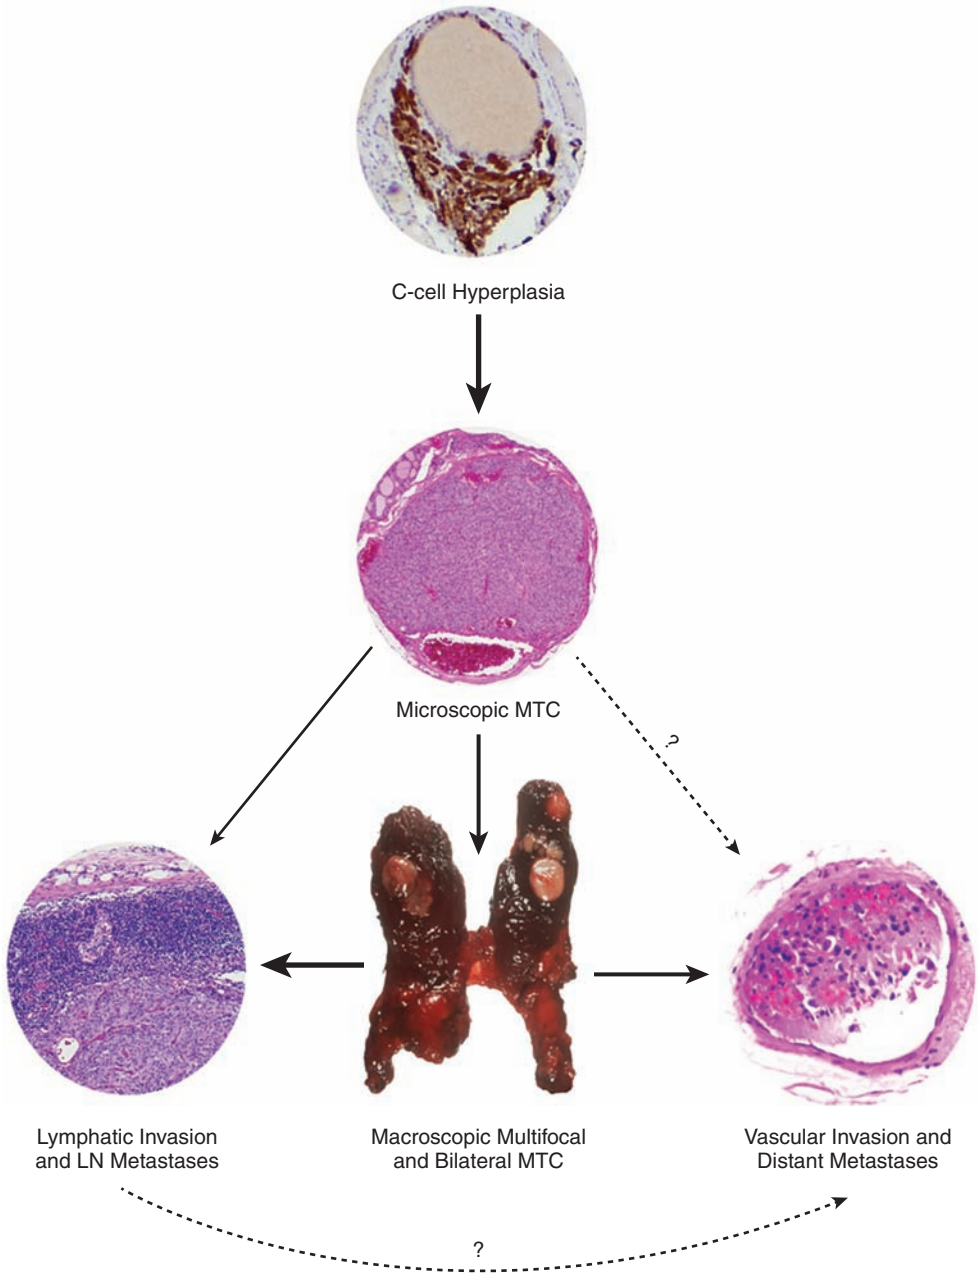

FIGURE 14-6 ■ The development and progression of hereditary MTC in childhood. C-cell hyperplasia is the initial stage in an oncologic cascade that ultimately leads to the development of microscopic noninvasive MTC and ultimately lymph node and distant metastatic disease due to frankly invasive carcinoma. The weight of the arrows denotes the hypothetical probability of the event occurring in the typical pediatric patient with a *RET* codon 634 mutation. LN, lymph node; MTC, medullary thyroid carcinoma. *(This image can be viewed in full color online at ExpertConsult.)* (From Waguespack, S. G., Rich, T. A., Perrier, N. D., et al. (2011). Management of medullary thyroid carcinoma and MEN2 syndromes in childhood. *Nat Rev Endocrinol, 7*, 596–607.)

whereas distant sites for MTC spread typically include the lungs, liver, and bone or bone marrow. Positive lymph node status and higher stage at diagnosis predict lower disease-free survival and higher mortality.[136,149-151]

Clinical Presentation

Children with sporadic MTC present similar to other thyroid malignancies, typically with a palpable thyroid nodule or cervical lymphadenopathy. They do not have the characteristic facial or other features found in MEN2B as described later. On the other hand, children with hereditary disease due to a *RET* mutation rarely present with overt clinical disease, outside of the newly identified MEN2A kindred or MTC associated with MEN2B, a diagnosis that remains uniformly delayed.[152] Therefore, in the 21st century, the predominant clinical presentation of MTC during childhood is one of the presymptomatic identification of a positive *RET* mutation and the ultimate identification of microscopic MTC after early thyroidectomy.

Evaluation and Management

Several guidelines and review papers are available to assist the clinician in the specific evaluation and management of the child with suspected or proven MTC.[2,141,153-156] As with all pediatric thyroid malignancies, surgery is the cornerstone of therapy. Given the potential higher complication rates in children than adults,[157] children should be operated on by a surgeon skilled in thyroid surgery and with "high volume" experience for this procedure.[158] Apart from the decision of when to intervene, the thyroid surgeon must also consider the patient's *RET* genotype and clinical data and incorporate this knowledge into the decision-making process to determine the optimal surgical approach.[2] Meticulous and safe removal of all thyroid tissue, including the posterior capsule, is the goal of the prophylactic thyroidectomy.[154] Routine central compartment (level VI) neck dissection[159] is not performed in the setting of a purely prophylactic thyroidectomy because lymph node metastases are quite rare in that setting.[141,148-150,154,160,161] However, if the operation is for a clinically evident hereditary tumor or for sporadic MTC, thyroidectomy and a concomitant central neck dissection should be performed. Dissection of the lateral cervical lymph node compartments (levels IIA to V) is generally performed only in cases where there is clinical evidence of lateral neck involvement.

Fortunately, life-threatening MTC rarely occurs during childhood and typically only in the clinical context of MEN2B. MTC is not sensitive to standard cytotoxic chemotherapy, which historically has incorporated the agent dacarbazine.[142] Targeted molecular therapies that inhibit RET and other receptor tyrosine kinases known to be involved in angiogenesis have shown great promise in the treatment of metastatic MTC.[162-164] The drug vandetanib became the first such agent approved by the U.S. Food and Drug Administration (FDA) for the treatment of adults with MTC, and preliminary results from a phase I/II trial in children with MTC have been encouraging.[165]

Prognosis

The prognosis of MTC diagnosed during childhood is generally excellent, with 5-year and 15-year survival rates of 95% and 86%, respectively.[134] Mean survival after diagnosis is 28.3 years and the presence of distant disease at diagnosis, compared with locoregional disease, portends a worse prognosis.[134,166,167] As the tumor stage increases, the risk of both locoregional and distant metastatic disease rises,[136,166] although lymph node metastases may still occur when the tumor is < 1 cm in size.[168-171] Many children who present with clinical MTC already have metastatic disease at diagnosis. Consequently, the majority of cases of childhood MTC that are not diagnosed before lymph node metastases occur represent incurable, albeit indolent, cancers. The aggressiveness of the clinical course can be predicted by the presence of certain *RET* mutations (see MEN2 section), the child's clinical presentation, and the use of calcitonin and carcinoembryonic antigen (CEA) as tumor markers. The loss of calcitonin expression, a CEA level out of proportion to calcitonin, and a rapid CEA or calcitonin doubling time are all harbingers of an aggressive disease course.[141,151,172,173]

HEREDITARY ENDOCRINE NEOPLASIA SYNDROMES

Carney Complex

The Carney complex (CNC) is a genetically and clinically heterogeneous disorder with autosomal dominant inheritance first described in 1985.[174] It is characterized by spotty skin pigmentation affecting the lips, conjunctiva, and other mucosal surfaces (Figure 14-7); myxomas of the breast, heart, and skin; endocrine tumors or overactivity, classically primary pigmented nodular adrenocortical disease (PPNAD)[175] and growth hormone/prolactin hypersecretion; and psammomatous melanotic schwannoma, among other clinical manifestations.[174,176,177] Two or more distinct genetic loci are associated with CNC: the gene *PRKAR1A*[178,179] on chromosome 17q23-q24 and an unknown gene on chromosome 2p16.[180] *PRKAR1A* encodes for the RI-α subunit of protein kinase A, the major mediator of intracellular cAMP signaling. Most *PRKAR1A* mutations are inactivating point mutations, and about 30% of CNC patients have de novo disease.[176,181] In patients with CNC, the overall *PRKAR1A* mutation detection rate is 62%.[181]

The major endocrine phenotype of the CNC is PPNAD, occurring either alone or with other CNC manifestations, in 60% of cases.[181] PPNAD is a rare form of ACTH-independent hypercortisolism pathologically associated with multiple small (< 1 cm) black or brown nodules (containing lipofuscin) in an otherwise atrophic cortex[175,182,183] (see Figure 14-7). The median age of onset is 34 years (with about 20% of cases occurring during childhood), and there is a female predilection after puberty.[181] The hypercortisolism is typically insidious in

FIGURE 14-7 ■ Carney complex and primary pigmented nodular adrenocortical disease (PPNAD). **A,** A 10-year-old female with ACTH-independent Cushing syndrome and the Carney complex demonstrates facial rounding, plethora, and the classic distribution of facial lentigines. **B,** Gross pathologic specimen of the right adrenal gland in another patient with PPNAD and the Carney complex. *(This image can be viewed in full color online at ExpertConsult.)*

its onset, and a classic finding in PPNAD-related Cushing syndrome is the paradoxical increase in glucocorticoid excretion during high-dose dexamethasone administration for the Liddle test.[184] Adrenal imaging is of limited value for the confirmation of PPNAD, but it can suggest diffuse micronodular disease on high-resolution studies.[182,183,185] The treatment of symptomatic PPNAD is bilateral adrenalectomy.

Growth-hormone hypersecretion (causing gigantism or acromegaly, depending on the age of onset) is the primary pituitary phenotype of the CNC, occurring in 10% to 12% of CNC patients.[174,181,186] Pathologically, this may be associated with an adenoma or hyperplasia.[186,187] Concomitant hyperprolactinemia is prevalent and is similarly caused by underlying hyperplasia or frank adenomas in rare cases.[187,188] Subtle abnormalities in growth hormone and prolactin secretion may be identified in up to 75% of patients with CNC.[186] Thyroid neoplasia occurs in 25% of CNC patients and differentiated thyroid carcinoma (both papillary and follicular carcinomas) have been identified in 2.5% of cases.[181] Males with CNC are at risk for testicular tumors, primarily bilateral large-cell calcifying Sertoli cell tumors (LCCSCT), clinically identified in 33% to 41% of patients.[181,186] Similar to the Peutz-Jeghers syndrome (discussed later), gynecomastia or palpable mass(es) may be a clinical presentation of LCCSCT, which can also be malignant in rare cases.[186,189]

Once CNC is diagnosed clinically or an asymptomatic child is found to harbor a germline *PRKAR1A* mutation, prospective monitoring for the development of the tumors and endocrine disorders characteristic of the syndrome can be undertaken,[176,186] although optimal screening strategies remain largely unknown.

Familial Isolated Pituitary Adenomas

Hereditary pituitary adenomas can occur within families outside of the context of MEN1 and other autosomal dominant, heritable endocrine neoplasia syndromes. The term *familial isolated pituitary adenomas (FIPA)* was first proposed in 2006.[190] Pituitary tumors occurring within FIPA families clinically present similar to sporadic pituitary adenomas and all hormonal subtypes are represented. The disorder was ultimately identified in a subset of FIPA kindreds to be caused by germline mutations in the aryl hydrocarbon receptor-interacting protein (*AIP*) gene.[191,192]

Mutations in *AIP* represent about 15% of FIPA cases (50% of kindreds with familial somatotropinomas), and more than 50 AIP mutations have been described to date.[192,193] Penetrance is incomplete and is estimated to be around 30%.[193] Median age of diagnosis is 23 years (range 8 to 74 years) and half of cases present during childhood or adolescence.[194] In patients < age 18 years presenting with an apparently-sporadic pituitary macroadenoma, 20% may harbor a germline *AIP* mutation.[195] FIPA individuals with *AIP* mutations have tumors that are larger (overwhelmingly macroadenomas) and diagnosed at a much younger age compared with *AIP*-negative patients.[192,194] The majority of *AIP*-mutated adenomas are somatotroph or mammosomatotroph adenomas, which typically present with gigantism in males.[192,194] These AIP-mutated growth-hormone secreting tumors are more recalcitrant to the typical therapies prescribed for gigantism/acromegaly.[194]

Given the identification of *AIP*-related FIPA, there are no consensus guidelines as to the timing of genetic testing

for *AIP* mutations in sporadic pituitary adenoma cases or at-risk members of an affected kindred. Recommendations for prospective clinical screening in asymptomatic *AIP*-mutation carriers are also not well established. However, some authors have proposed an approach to care of such patients that includes an annual hormonal and auxologic evaluation.[193,196]

Familial Paraganglioma Syndromes

The familial paraganglioma syndromes, also referred to as the familial paraganglioma and pheochromocytoma syndromes (FPPS),[131] are characterized primarily by the development of parasympathetic and sympathetic PGL and PHEO.[197] Four autosomal dominantly inherited FPPS syndromes (PGL1-4) have been described (see Table 14-1) and are due to germline mutations in discrete genes encoding either the subunits of the succinate dehydrogenase (SDH) enzyme gene (*SDHB*, *SDHC*, and *SDHB*) or a protein necessary for the flavination of SDHA: PGL1(*SDHD*),[198] PGL2(*SDHAF2*),[100] PGL3 (*SDHC*),[199] and PGL4 (*SDHB*).[200] The *SDHx* genes constitute the subunits for complex II of the mitochondrial respiratory chain that, when mutated, lead to stabilization of hypoxia inducible factor 1 with a subsequent state of pseudohypoxia.[131] The clinical phenotype differs among the four syndromes and remains poorly characterized in some cases, such as PGL2. As an example, mutations in *SDHC* primarily cause benign parasympathetic head and neck PGL (also referred to as "glomus tumors" or "chemodectomas"), whereas mutations in *SDHB* are associated more with abdominal PGL and a high risk of malignancy (see Table 14-1, Figure 14-2). In all cases, penetrance of the clinical phenotype is less than 100% and increases with age.[127,197,201,202] Mutations in *SDHD* (and possibly also *SDHAF2*) demonstrate parent-of-origin effects, with disease generally occurring only when the mutation is inherited from the father.[197,203] *SDHx*-related tumors are associated with gastrointestinal stromal tumors (GIST), a finding that has also been referred to as the Carney-Stratakis syndrome or dyad.[204,205] Other non-paraganglial malignancies described (chiefly in patients with *SDHB* mutations) include renal cell carcinoma and papillary thyroid carcinoma.[201,206,207] A patient with an *SDHD* mutation was identified to have a growth hormone-secreting pituitary macroadenoma, suggesting a possible role of SDH defects and pituitary tumorigenesis.[208]

Hyperparathyroidism-Jaw Tumor Syndrome

The hyperparathyroidism-jaw tumor (HPT-JT) syndrome is a heritable disorder primarily characterized by parathyroid neoplasia and primary hyperparathyroidism associated with ossifying fibromas of the maxilla or mandible. First reported in 2002, *CDC73* (formerly known as *HRPT2*) is the only known gene in which mutations cause HPT-JT, and *CDC73* mutations are identified in about 60% of HPT-JT syndrome kindreds.[209] Primary hyperparathyroidism due to a single benign parathyroid adenoma is the most common clinical manifestation, but parathyroid carcinomas are quite prevalent in the syndrome, representing up to 15% of HPT cases.[210] The youngest age of diagnosis of HPT has been seven years.[211] Ossifying fibromas, also known as cemento-ossifying fibromas, can be quite aggressive and occur in 30% to 40% of individuals with HPT-JT syndrome.[210] They are chiefly treated with surgical extirpation. Other clinical manifestations of the HPT-JT syndrome include renal lesions (cysts, hamartomas, and nephroblastoma) and uterine tumors.[212,213] Prospective clinical monitoring of individuals with a *CDC73* mutation includes periodic biochemistries, dental imaging, and ultrasonography of the kidney and uterus.[210]

Multiple Endocrine Neoplasia 1 (MEN1)

MEN1 is an autosomal dominantly inherited tumor syndrome characterized by the occurrence of glandular hyperplasia and benign or malignant neoplasia in two or more specific endocrine glands, chiefly the parathyroids, pituitary, and neuroendocrine cells of the duodenum and pancreas[153,214-217] (Table 14-4). The tumors can be hormonally active or inactive and multifocality is common, except for pituitary tumors. Some patients also develop adrenocortical adenomas, carcinoid tumors, benign tumors of the skin (angiofibromas, collagenomas, lipomas), central nervous system (CNS) tumors (meningiomas and ependymomas), or uterine leiomyomas.[216,217]

The hereditary nature of MEN1 was first recognized by Wermer in 1954.[218] Genetic linkage analysis among families with a clinical diagnosis of MEN1 initially localized the inherited abnormality to chromosome 11q13,[219,220] which ultimately led to the identification in 1997 of germline mutations in several families with MEN1.[221,222] The MEN1 gene is a tumor suppressor gene that encodes a nuclear protein (menin), which in turn plays a role in transcriptional regulation, genome stability, cell division, and proliferation.[215,223,224] Advances in genetic testing have made it possible to establish a specific molecular diagnosis and screen unaffected relatives. The challenge for pediatric physicians, other caregivers, and parents is determining when to perform appropriate clinical surveillance and intervention for patients known to harbor an MEN1 gene mutation.

Epidemiology and Pathogenesis

The prevalence of MEN1 is estimated at 1 to 10 per 100,000 individuals.[225,226] The "two-hit" mechanism of disease, first described by Knudson in hereditary retinoblastoma,[227] is illustrated in Figure 14-8. Patients with MEN1 carry one wild-type and one inactive mutant allele of the *MEN1* gene (a germline mutation) in all cells. This in itself is insufficient to induce tumor formation. Subsequently, a somatic mutation (the "second hit") in a single cell deletes the only normally functioning *MEN1* gene, leads to a loss of heterozygosity at the *MEN1* locus in tumor DNA, and attenuates the ordinary constraints on cell growth by menin. Thus, tumor formation is initiated from a single clone of cells.

Most patients with MEN1 inherit the mutant allele from an affected parent, but about 10% of individuals

TABLE 14-4 **Characteristic Tumors and Associated Abnormalities in MEN1**

Organ System	Tumors	Estimated Penetrance[a]	Earliest Age of Onset (References)	Product Hypersecreted
Parathyroid	Hyperplasia/adenoma	90%-100%	8y[226]	Parathyroid hormone (PTH)
Anterior pituitary		15%-50%		
	Prolactinoma	20%	5y[†129]	Prolactin (PRL)
	Somatotropinoma	10%	9y[230]	Growth hormone (GH)
	Corticotropinoma	<5%	12y[459]	Adrenocorticotropic hormone (ACTH)
	Nonfunctioning	< 5%	12y[460]	
Enteropancreatic neuroendocrine		30%-80%		
	Insulinoma	10%	8y[461]	Insulin
	Gastrinoma	40%	10y[230]	Gastrin
	Glucagonoma	< 1%		Glucagon
	VIP producing	< 1%		Vasoactive intestinal polypeptide
	Nonfunctioning and PPoma	40%-80%	12y[460]	Pancreatic polypeptide
Stomach	Type II gastric carcinoid	10%	31y[230]	None
Thymus	Carcinoid	2%	16y[254]	ACTH, GH-releasing hormone, or none
Bronchus	Carcinoid	2%	15y[230]	None
Adrenal	Adrenocortical adenoma	40%	25[230]	Cortisol, aldosterone, or none
	Pheochromocytoma	< 1%		Metanephrines/ catecholamines
Skin	Angiofibromas	85%		
	Collagenomas	70%		
	Lipomas	30%		
CNS	Meningiomas	8%		
	Ependymomas	1%		
Uterus	Leiomyomas	Rare

†This patient had a mammosomatotroph tumor, co-secreting prolactin, and growth hormone.

with MEN1 represent de novo mutations.[222,224,228] More than 90% of tumors from MEN1 patients have loss of heterozygosity due to a subchromosomal rearrangement or deletion of the entire chromosome; other mechanisms for the second hit include point mutations, small deletions or insertions within the *MEN1* gene.[214,215,224] There have been more than 1100 germline mutations of the *MEN1* gene characterized thus far, and these mutations occur via multiple mechanisms and are distributed throughout the *MEN1* gene.[214,215,222,224,228] Testing by direct DNA sequencing identifies most MEN1 mutations, but approximately 5% to 10% of people with MEN1 do not have a mutation in the coding region or splicing sites of *MEN1*.[217,224] Such patients may represent a phenocopy (see the section on MEN4), or they may harbor a mutation in untranslated regions or introns or a large gene deletion, which requires other technologies such as multiplex ligation-dependent probe amplification (MLPA) to detect.[229]

Clinical Presentation and Management

The clinical presentation of MEN1 is highly variable, even among members of the same kindred, and will depend on the location and functionality of the underlying tumor(s). Not surprisingly, functional tumors typically present 5 to 10 years earlier than nonsecretory neoplasms.[230] There is almost complete penetrance of the phenotype, so MEN1 clinical and biochemical manifestations will generally develop in 80% and > 98% of patients, respectively, by the fifth decade of life.[153,228,230] An age-related progression of the various endocrine tumors exists in MEN1.[228,230] Penetrance of the phenotype in children with MEN1 is estimated to be < 1% before age 5 years, 7% by age 10 years, 28% by age 15, and 52% by age 20 years[228] (Figure 14-9). Prospective screening of asymptomatic *MEN1* mutation carriers leads to an earlier age of diagnosis,[228,230-235] and thus penetrance rates are likely to increase as clinical practice evolves. In contrast to MEN2, as described in the subsequent section, there are no clear genotype-phenotype correlations in MEN1, so a physician cannot rely on the specific mutation or family history to predict the age of onset, severity, or type of an MEN1 manifestation.[215,228,230]

In the absence of treatment, MEN1-associated endocrine tumors are associated with higher mortality (50% probability of death by the age of 50 years), and the cause of death in 50% to 70% of patients with MEN1 is usually

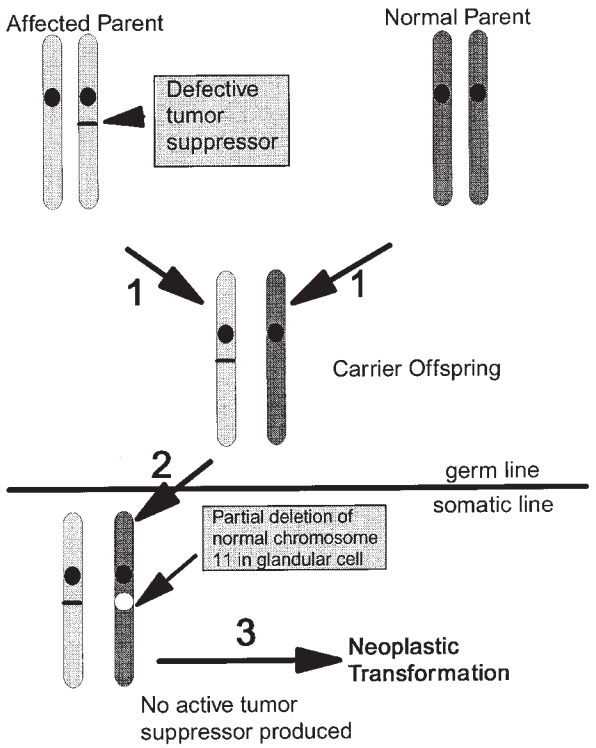

FIGURE 14-8 ■ "Two-hit hypothesis" of tumorigenesis in MEN1.[1] An affected parent passes a mutated *MEN1* gene to an offspring, who inherits a normal gene from the other parent.[2] Loss of heterozygosity in a somatic cell (a "second hit" that typically occurs via a subchromosomal rearrangement or deletion of the entire chromosome) deletes the remaining normal *MEN1* gene.[3] The absence of menin tumor suppressor activity in a cell leads to tumor formation.

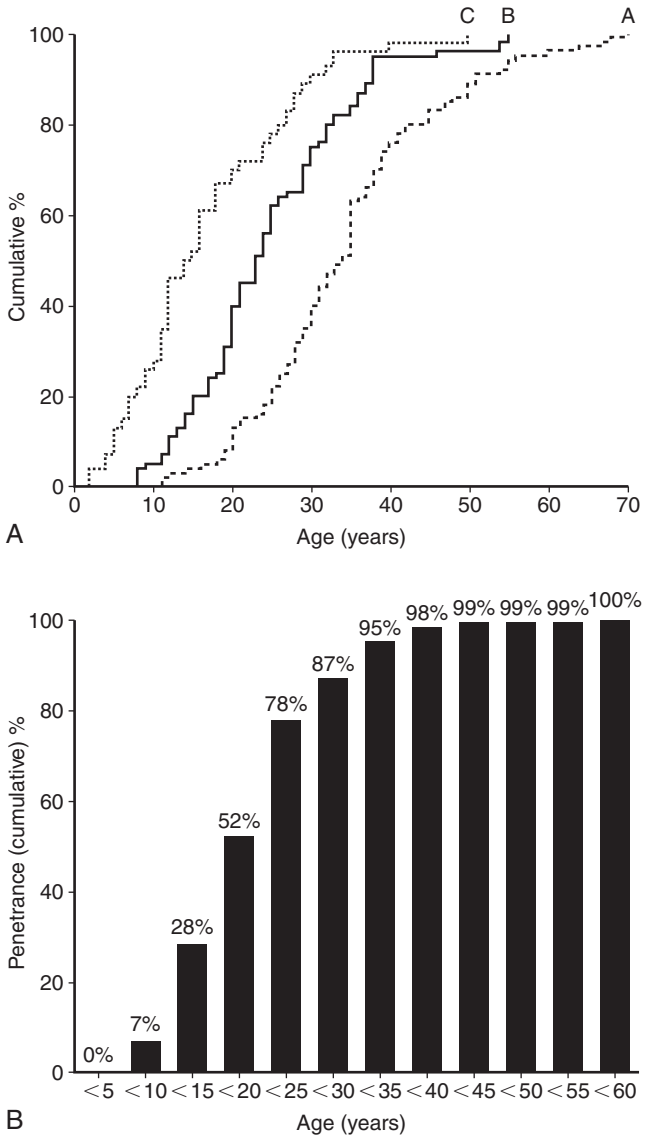

FIGURE 14-9 ■ Penetrance of the MEN1 phenotype. Age distributions (**A**) and age-related penetrance (**B**) of MEN1 clinical manifestations in 201 carriers of a mutated *MEN1* gene. Group A patients presented with clinical symptoms at the age depicted. Group B patients were asymptomatic but had positive biochemical screening at the age depicted. Group C patients were asymptomatic with negative biochemical screening with the age of their last biochemical testing shown. Groups B and C were significantly younger than Group A patients ($P < .001$). The age-related penetrance (B) is the proportion of mutation carriers who have developed a clinical manifestation by a given age. (From Bassett, J. H., Forbes, S. A., Pannett, A. A., et al. (1998). Characterization of mutations in patients with multiple endocrine neoplasia type 1. *Am J Hum Genet, 62,* 232–244.)

a malignant tumor process or sequelae of the disease.[216,236,237] In the current era, when medical management can effectively treat symptomatic gastrinoma, mortality due to the Zollinger-Ellison syndrome has declined. Currently, the greatest risk of mortality in MEN1 is chiefly from malignant enteropancreatic tumors and thymic carcinoids.[216,230,236]

The specific treatment for each type of MEN1-associated endocrine neoplasm is generally similar to that for the respective sporadic tumors occurring in patients without MEN1. This section will therefore focus more on the unique aspects of these disorders as they relate to MEN1 patients. As with most hereditary tumor syndromes, patients with MEN1 and their families should be managed by a multidisciplinary team consisting of relevant specialists with experience in the management of endocrine tumors.[216]

Primary Hyperparathyroidism

Primary hyperparathyroidism (PHPT) is the most common and earliest endocrine manifestation of MEN1.[216,226,230] MEN1 patients usually have multigland hyperplasia rather than single-gland adenomas. Symptoms of PHPT are due to the underlying hypercalcemia and can be nonspecific in children, including polyuria, difficulty concentrating, fatigue, headache, poor appetite, weight loss, abdominal pain, constipation, nausea, or emesis. Similar to adults, children can have end-organ damage (nephrolithiasis, nephrocalcinosis, acute pancreatitis, and bone involvement). Children with PHPT have been shown to have more severe symptoms, with 70% to 90% symptomatic compared with 20% to 50% of their adult counterparts.[238-240] Prolonged exposure to elevated PTH levels increases osteoclast activity, which can cause demineralization of bone, fractures, and eventually osteitis fibrosa cystica, the most severe skeletal manifestation of PHPT.[241] Compared with patients who

have sporadic PHPT, patients with MEN1 have lower bone density, a 1:1 male:female ratio (versus 1:3), lower PTH levels, and earlier age of onset (average age 20 to 25 years versus 55 years).[153,242,243] The youngest reported age of MEN1-associated PHPT is 8 years.[216]

The diagnosis of PHPT is based on an elevated calcium level in the setting of an inappropriately normal or frankly elevated PTH level. Because all parathyroid glands may be affected in MEN1 patients, preoperative imaging is generally not utilized.[244] However, in the case of reoperation, localization studies can be helpful to the surgeon.[245,246] Imaging modalities primarily include ultrasound, nuclear scintigraphy using technetium (^{99m}Tc) sestamibi, and CT/MRI.[247,248] Technetium (^{99m}Tc) sestamibi scans have a sensitivity of 85% to 100% in detecting single adenomas.[246] Sestamibi-SPECT imaging has a sensitivity of 90% for single adenomas, but only 55% for hyperplastic glands.[249] CT (sensitivity 50% to 70%), 4D-CT, or less commonly MRI, imaging can also help the surgeon preoperatively in those cases of reoperation.[246,250]

Surgical removal of the overactive parathyroid glands is the definitive treatment of PHPT in MEN1 patients, but the surgical approach remains controversial.[251] Subtotal (3.5 gland) parathyroidectomy with thymectomy or total (four gland) parathyroidectomy with thymectomy and parathyroid autotransplantation to the forearm are the primary options for surgical therapy. Resection of less than three glands results in the highest risk of persistent and recurrent disease (OR 3.11, 95% CI = 2.00 to 4.84).[252,253] A meta-analysis found that there was no significantly higher risk for persistent or recurrent HPT with a subtotal versus total procedure, but there was a significantly lower risk for permanent hypoparathyroidism with subtotal parathyroidectomy.[252,254] In studies that followed MEN1 patients beyond 10 years, the recurrence rates for either procedure range from 40% to 60%[255]; recurrent hypercalcemia can be as high as 50% in autotransplanted tissue.[216] Concomitant transcervical thymectomy is recommended to remove any potential ectopic parathyroid glands and to prophylactically remove the bulk of the thymus, which is at risk for the development of a thymic carcinoid.[252,253,255,256]

Surgical indications for treatment of asymptomatic PHPT in children with MEN1 are not clear,[251] especially given the potential for permanent hypoparathyroidism. Factors such as surgical experience, patient or parent preference, and availability of long-term monitoring of calcium levels should be considered in the timing of surgery.[216] In select MEN1 patients with PHPT, medical treatment with the calcimimetic agent, cinacalcet, appears to be effective.[257]

Gastroenteropancreatic-Neuroendocrine Tumors (GEP-NETs)

Gastroenteropancreatic neuroendocrine tumors (GEP-NETs) arise from neuroendocrine cells found in the pancreas, the gut, and its embryologic derivatives, including the thymus and bronchial tree. The term *carcinoid* is typically used to describe GEP-NETs arising in the gastrointestinal tract, lung, or thymus. Pancreatic NETs (pNETs), also known as pancreatic endocrine tumors (PETs), are GEP-NETs that originate in the neuroendocrine pancreas. The GEP-NETs most commonly encountered in MEN1 arise from the duodenum (gastrinomas) and the pancreatic islet cells (insulinoma, nonfunctioning tumors).[216,230]

GEP-NETs are the second most common manifestation of MEN1, occurring in 30% to 80% of patients.[153,216,230,258] GEP-NETs can be functional or nonfunctional. Gastrinomas primarily occur in the duodenum (within the so-called gastrinoma triangle), whereas other hormonally active tumors (such as insulinomas and VIPomas) arise from the pancreatic islet cells.[259-261] Nonfunctional pNETs are not associated with clinical symptoms caused by hypersecretion, but they can overproduce clinically silent hormones, such as pancreatic polypeptide and chromogranin A.[5,260,262-264]

Imaging modalities are similar for all GEP-NETs. Because GEP-NETs are often small and grow slowly, localization can be challenging and often multiple techniques are employed. Guidelines from the National Comprehensive Cancer Network (NCCN) recommend multiphasic CT or MRI as the first line for evaluation of pNETs, and MEN1 guidelines add endoscopic ultrasound as another modality.[216,262,265] The sensitivity for CT/MRI for pNET is 14% to 77% versus endoscopic ultrasound at 79% to 100%.[266] Endoscopic ultrasound (EUS) is especially helpful in the preoperative setting.[267] GEP-NETs generally possess somatostatin receptors. Thus, somatostatin receptor scintigraphy (i.e., an "octreotide scan") can be used as a second-line procedure.[262,268] FDG-PET is not routinely recommended due to the low proliferation rate of these neoplasms, but poorly differentiated tumors can be localized with FDG-PET.[262,269,270] Selective arterial injection of calcium or secretin with angiography or hepatic venous sampling can be helpful in tumor localization prior to surgery or identifying a functioning tumor among multiple nonfunctioning GEP-NETs. [271-273] A diagnosis of a malignant GEP-NET would be extraordinarily rare in childhood; guidelines regarding therapeutic approaches to malignant disease are available. [262]

Gastrinoma. Nearly 50% of GEP-NETs in MEN1 are gastrinomas, and 60% to 95% arise in the duodenum.[216,274] Gastrinomas are usually multiple, small (< 1 cm) tumors that result in elevated gastric acid production and recurrent peptic ulcer disease, referred to as the Zollinger-Ellison syndrome (ZES). Other symptoms can include diarrhea and steatorrhea.[216,266] The risk of malignancy to peripancreatic lymph nodes or, rarely, the liver is 50% to 60%.[255,266] The youngest reported age of diagnosis is 10 years old, but usually patients are older than 30 years, which is a decade earlier than sporadic cases.[230,275,276]

The diagnosis is established by an increased serum fasting gastrin concentration (usually > 1000 pg/mL) and elevated basal gastric acid secretion (gastric pH < 2).[5,262,277,278] Patients with borderline hypergastrinemia should be considered for the secretin stimulation test; after a 2 U/kg intravenous bolus,[279] a rise in gastrin ≥ 120 pg/mL from baseline affords the highest diagnostic sensitivity and specificity.[280] False-positive elevations of gastrin can occur due to use of proton pump inhibitors

or antacids, conditions of autoimmune chronic atrophic gastritis with achlorhydria, or chronic renal insufficiency.[281,282] Patients should therefore be off proton-pump inhibitors for at least 1 week, but this may not be possible in highly symptomatic patients.[262,278] Hypercalcemia can also stimulate gastrin secretion.[278]

Medical therapy with a potent oral proton pump inhibitor is the primary treatment of gastrinoma in MEN1 patients. Higher doses are generally needed compared with standard peptic ulcer disease.[216,273,283] Some patients may also require the addition of an H_2 receptor antagonist. The role of surgery in treating MEN1 patients with gastrinoma is controversial. Tumors are generally multiple and in the duodenum, so cure is less likely. If surgery is performed, both duodenal inspection and lymph node dissection are required.[259] For pancreatic gastrinomas or lesions > 2 cm, surgery should be considered to reduce risk of lymph node or hepatic metastasis.

Insulinoma. Insulinomas, β-islet cell tumors that oversecrete insulin, are the second most frequent functioning GEP-NET in MEN1. Most insulinomas are benign and occur in younger individuals as compared with sporadic cases.[216,275,284,285] Patients present with hypoglycemic symptoms that improve with glucose intake. The gold standard diagnostic test is a 72-hour fast. Diagnosis is established if serum glucose < 55 mg/dL with a concomitant insulin ≥ 3 μU/ml by immunochemiluminescent assay [ICMA], C-peptide ≥ 0.2 nmol/L and no detectable oral hypoglycemia in the blood.[286] One third of insulinoma patients will develop hypoglycemia at 12 hours, 80% at 24 hours, 90% at 48 hours, and 100% by 72 hours.[287]

Medical treatment with frequent carbohydrate meals, diazoxide, or octreotide is not always successful. Surgery is therefore considered the standard treatment.[287-289] In 10% of MEN1 patients, concomitant nonfunctioning pNETs are present, so preoperative localization can improve the success of surgery.[289] In addition to imaging modalities noted earlier for all GEP-NETs, intraoperative direct pancreatic ultrasonography is also likely to improve surgical success.[287] In contrast to other functioning GEP-NETs, insulinomas have a lower malignant potential, ranging from 0% to 20%.[275]

Glucagonoma. Glucagonomas secrete glucagon and are malignant in more than 70% of cases.[153] The syndrome produced is characterized by a skin rash in the groin and extremities (necrolytic migratory erythema) in 70% of patients, mild diabetes mellitus in 87%, weight loss in almost all patients, stomatitis, and anemia.[263] Glucagonomas commonly occur in the tail of the pancreas with liver metastases in 90% and lymph node metastases in 30% of cases.[262,263] Surgical resection is the treatment of choice but can be challenging given a metastatic presentation at diagnosis in 50% to 80% of cases.[284]

VIPoma. VIPomas are very rare tumors that secrete vasoactive intestinal peptide (VIP) and are associated with the Verner-Morrison syndrome of watery diarrhea, hypokalemia, and achlorhydria (i.e., pancreatic cholera).[263,290] Less frequent symptoms include glucose intolerance, hypercalcemia with normal parathyroid hormone levels, and episodes of cutaneous flushing. There can be co-secretion of VIP with calcitonin, serotonin, substance P, and some of the prostaglandins.[5] VIPomas are diagnosed by confirming plasma VIP levels > 60 pmol/L and stool volume > 0.5 to 1 L/day during a fast.[216] VIPomas are located usually in the tail of the pancreas. Surgical resection can be curative. However, VIPomas are often > 3 cm at presentation and metastatic spread to liver more than lymph nodes is present in about 50% at diagnosis, which may require systemic therapy or hepatic embolization.[5,291]

Nonfunctioning Pancreatic Neuroendocrine Tumors (NFpNETs). Nonfunctioning PETs (NFpNETs) were previously reported to occur in approximately 20% to 40% of MEN1 patients, but a prospective endoscopic ultrasound study found an incidence of almost 55%.[5,292] Thus, NFpNETs are becoming recognized as the most frequent GEP-NET in MEN1 patients. They are often sporadic with numerous microadenomas spreading throughout the pancreas,[293] and they have a significant potential for malignancy, especially with larger tumor size. Epidemiologic studies have shown as high as 27% of patients with NFpNETs between 2.1 to 3 cm have metastasis, compared with 11% of those ≤ 2 cm.[294] More important, NFpNETs are now reported to confer increased risk of death in MEN1 patients, comparable to thymic tumors and functioning NETs, except insulinomas.[236,237,295]

There is controversy on indications for surgical treatment. General consensus is that tumors ≥ 2 to 3 cm should be considered for resection because of increased risk of death and metastasis. Life expectancy of patients with NFpNETs ≤ 2 cm compared to MEN1 patients without pNET is not clearly different, so surgery may not be beneficial for smaller lesions.[294]

Pituitary Adenomas

Pituitary tumors occur in 15% to 50% of patients with MEN1.[296,297] The earliest reported age is 5 years old with a mean age of onset being 38 ± 15.3 years.[297,298] The clinical manifestations and treatment of pituitary tumors in MEN1 patients are similar to that for non-MEN1 patients. In MEN1, however, there does seem to be higher prevalence in women, higher rate of invasiveness and macroadenomas, more pluripotent tumors, and an overrepresentation of prolactinomas.[296,297,299] Approximately 60% of pituitary tumors in MEN1 patients secrete prolactin, < 25% secrete GH, < 10% are co-secreting, 5% secrete ACTH, and the remaining are nonfunctioning.[297,299] There is no increased prevalence of pituitary carcinoma or increased risk of death from having pituitary tumor.[236,299] Hypersecreting MEN1-associated pituitary tumors are reported to be more resistant to standard medical therapies.[297,299]

Other Clinical Manifestations

Carcinoid Tumors. In MEN1 patients, carcinoid tumors may be located in the bronchi, gastrointestinal (GI) tract,

or thymus. Carcinoids are generally diagnosed in the fifth decade of life, but the youngest reported case of thymic carcinoid in an MEN1 patient occurred in a patient who was 16 years old.[256] Thymic carcinoids are more prevalent in smokers and males (male:female ratio 20:1), whereas bronchial carcinoids are more prevalent in women (male:female ratio 1:4).[243,300] Bronchial carcinoids tend to behave indolently, whereas thymic carcinoids carry a significant increased risk for death in MEN1 patients.[236] Thymic carcinoids can still occur despite previous prophylactic transcervical thymectomy, presumably because the entire thymus is not removed via a cervical approach.[256]

Patients with thymic and bronchial carcinoids are generally asymptomatic at presentation, although thymic carcinoids have been associated with ectopic growth hormone releasing hormone and ACTH secretion.[301,302] CT (95% sensitivity) and MRI (100% sensitivity) are generally used for prospective screening, and MRI may be the preferred modality to avoid excessive exposure to ionizing radiation in a population already prone to tumor development.[256,303,304] Surgical resection is the treatment of choice.[303,305]

Type II gastric carcinoids are well-differentiated tumors with malignant potential that arise secondary to hypergastrinemia.[306-308] The incidence in patients with MEN1/ZES is as high as 30%.[309,310] Lesions are usually multiple, < 1 cm, and found by endoscopic surveillance. Treatment can include high doses of proton-pump inhibitors, removal of the gastrinoma as indicated, somatostatin analogs, and endoscopic excision for lesions < 1 cm or surgical resection for larger tumors.[306,311,312,306-308,310-314]

Adrenocortical Tumors. Unilateral and bilateral adrenocortical tumors are reported in 20% to 40% of MEN1 patients.[217,315,316] Adrenal hyperplasia, cortical adenomas, multiple adenomas, cysts, and adrenocortical carcinoma are the types of adrenal lesions reported. Most of these tumors are nonfunctioning, with 8% to 15% presenting with hypersecretion of aldosterone or cortisol.[315] The incidence of adrenocortical carcinoma is approximately 1% in MEN1 patients, but it increases to 13% for tumors larger than 1 cm.[254,315,316]

Cutaneous Manifestations. Often underappreciated as a component of the MEN1 phenotype, skin manifestations commonly occur in older MEN1 patients[317,318] (Figure 14-10). Multiple facial angiofibromas, benign tumors of blood vessels and connective tissue similar to those seen in tuberous sclerosis, occur in up to 88% of patients; other common cutaneous manifestations include collagenomas in 72% and lipomas in 34%.[317] Collagenomas are skin-colored cutaneous nodules, arranged symmetrically on the trunk, neck, and upper limbs. In general, these lesions do not require treatment, although lipomas can grow quite large and may need to be resected due to local symptoms.

Genetic Testing and Presymptomatic Screening

Many centers employ an integrated program of both genetic counseling and testing of at-risk individuals and clinical screening to detect the development of tumors in presymptomatic *MEN1* mutation carriers, with the hope that earlier diagnosis and treatment of these tumors may help to reduce morbidity and mortality.[216,319] However, at the present time, there is no specific treatment that will prevent an MEN1-associated disease, nor do any prophylactic therapies appear to be warranted. In addition, earlier identification of asymptomatic disease may potentially lead to earlier, possibly unnecessary treatment that may in fact have a negative long-term

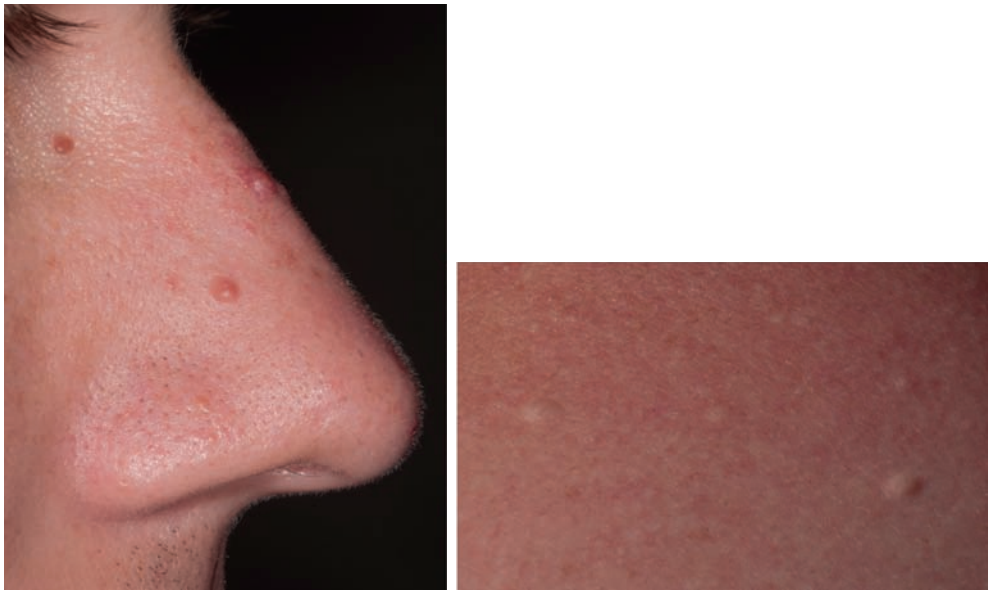

FIGURE 14-10 ■ Skin manifestations of MEN1. Angiofibromas (left panel) and collagenomas (right panel) are identified in the majority of adults with MEN1. Angiofibromas are telangiectatic papules characterized by fibrous tissue and vascular proliferation and distributed primarily on the nose and adjacent cheeks. Collagenomas are cutaneous stromal lesions that represent areas of excess collagen and tend to occur on the upper torso, neck, and shoulders. *(This image can be viewed in full color online at ExpertConsult.)*

impact. Thus, the goal of screening in MEN1 is primarily to detect a clinical manifestation at an earlier stage, specifically so that treatment can be rendered before malignancy develops in high-risk organs or serious ramifications from excess hormone secretion occur. Because of the long latency for disease manifestations, many unaffected individuals will potentially undergo years of episodic testing, which may have psychosocial and financial consequences, and this must be kept in mind as a prospective screening program is planned for any given MEN1 patient.

MEN1 germline mutation testing through an accredited clinical genetics laboratory should be offered to all index patients and first-degree relatives of those individuals with a known *MEN1* gene mutation, regardless of symptomatology.[216] Because relevant MEN1 disease has been diagnosed in children as young as 5 years of age (see Table 14-4), current practice is to offer testing at the earliest opportunity, but only after extensive genetic counseling. Mutational testing is also beneficial for the family members who do not end up carrying the mutation, so they can avoid unnecessary surveillance and relieve the burden of disease from their progeny.

Once an *MEN1* mutation is identified, the optimal ages to begin screening for disease have not been clearly established. MEN1 clinical practice guidelines based on systematic reviews of the medical literature and expert opinions were initially introduced in 2001 and updated in 2012.[153,216] Table 14-5 summarizes a suggested MEN1 screening program derived from the medical literature. Although most clinical centers employ annual laboratory evaluation, not all centers order radiographic screening for presymptomatic children and young adults as the guidelines have proposed, and the frequency of prospective radiographic imaging is an important area that warrants further research. In all cases, patient/parent preference, risk of screening (e.g., radiation exposure with CT), local resources, and clinical judgment should be considered.

Multiple Endocrine Neoplasia 2 (MEN2)

The original description of MEN2A is attributed to Sipple, when he reported the case of a 33-year-old man who died of intracranial hemorrhage and was found on autopsy to have bilateral pheochromocytomas, bilateral MTC, and probable parathyroid hyperplasia.[320] In 1962, Cushman proposed an association between these endocrine tumors,[321] and MEN2 was subsequently named as a distinct clinical syndrome.[322] Linkage analysis studies in large MEN2 kindreds led to the localization of the putative gene to chromosome 10.[323,324] Ultimately, mutations in the *RET* proto-oncogene were found to cause MEN2A.[137,138]

The original characterization of the MEN2B phenotype in the English literature was made by Williams and Pollock in 1966,[325] and MEN2B was further distinguished as a variant of hereditary MTC with a mucosal neuroma phenotype.[326] In 1994, MEN2B was reported to also be secondary to activating mutations in *RET*.[139,140]

As a result of the initial collaborative efforts of the International *RET* Mutation Consortium, it quickly became apparent that only a limited number of mutations were associated with MEN2 and that strong genotype-phenotype correlations were present[327](see Figure 14-5). Because of the high penetrance of MTC in individuals with a *RET* mutation, there was a rapid incorporation of genetic testing into management algorithms for patients with MTC and their families. Predictive genetic testing thus ushered in the era of performing total prophylactic thyroidectomies for presymptomatic individuals carrying a high-risk *RET* germline mutation.[146] As a result, much of the decision making and counseling of affected children and their families falls into the hands of the pediatric provider.[328,329]

TABLE 14-5 **Suggested Biochemical and Radiologic Screening for Asymptomatic MEN1 Patients (derived from references 216, 230, 256)**

Tumor	Age to Begin (years)	Biochemical Test Annually	Imaging Test*
Parathyroid	8	Intact PTH, calcium	None
Pituitary	5	Prolactin, IGF-1	MRI (every 3-5 years)
Enteropancreatic NET			
Gastrinoma	20	Gastrin	None
Insulinoma	5	Fasting glucose, insulin	None
Other pNETs	< 10	Chromogranin-A, pancreatic polypeptide, glucagon, VIP	MRI, CT, or EUS (every 1-3 years)
Carcinoid			
Gastric	NA	None	Gastric endoscopy (every 3 years if ZES present)
Thymic	15	None	CT or MRI chest (every 1-3 years)
Bronchial	15	None	CT or MRI chest (every 1-3 years)
Adrenal	< 10	If symptoms of functioning tumor or > 1 cm on imaging	CT or MRI abdomen (every 3 years)

*If available, MRI is the preferred screening modality to decrease lifetime exposure to ionizing radiation. Some centers will image less frequently than the above published recommendations and use individual risk factors for rarer MEN1 manifestations to guide imaging frequency.

MEN2A

MEN2A accounts for 90% to 95% of MEN2 cases and is a highly penetrant, autosomal-dominant endocrine tumor syndrome characterized by the development of MTC in > 90% of *RET* mutation carriers. Depending on the specific mutation, pheochromocytoma or primary hyperparathyroidism occurs in 0% to 50% and 0% to 20% of individuals with MEN2A, respectively.[330] Furthermore, activating mutations in *RET* are also associated with Hirschsprung disease[331-333] and cutaneous lichen amyloidosis,[334,335] a dermatologic disorder of intense pruritus and secondary skin changes that is typically located in the interscapular region of the back.

In MEN2A, mutations are located mostly in the extracellular cysteine-rich domain of the *RET* proto-oncogene, usually in exon 10 (codons 609, 611, 618, or 620) or exon 11 (codon 634)[160,327,336,337] (see Figure 14-5). Mutations in *RET* codon 634 account for ~50% of *RET*-positive MEN2A cases, whereas exon 10 mutations account for about 16%.[160,336] As molecular testing becomes widespread in patients with MTC, more *RET* mutations and DNA variants are being identified, which is contributing to an everchanging spectrum of the MEN2A genotype and phenotype.[338,339]

MTC in MEN2A. MEN2A-related MTC, when identified during childhood, is usually diagnosed after early thyroidectomy directed by genetic testing results and is usually a microcarcinoma < 1 cm in size.[150,169,170] Most children with MEN2A will have a positive family history; de novo *RET* mutations represent only 2% to 9% of cases.[340,341] A strong genotype-phenotype relationship is present, such that the rapidity with which a mutation carrier will develop MTC can be estimated.[2,327,330,339,342,343] Patients with mutations in *RET* codon 634 have the highest risk of malignant C-cell disease followed by those with mutations in codons 609, 611, 618, 620, or 630, whereas mutations in codons 768, 790, 804, or 891 impart the lowest risk for clinically aggressive MTC.[141,330] However, the natural history of MTC in MEN2A remains highly variable.

Pheochromocytoma in MEN2A. PHEO arising within the context of MEN2A is an adrenergic tumor that usually arises within a background of adrenal medullary hyperplasia.[147,344-347] The risk for PHEO is highest in codon 634 mutations and to a much lesser degree with mutations in codons 609, 611, 618, and 620. [327,348-350,351,352] Diagnosis is most likely during the fourth and fifth decades of life,[66,344,348,353,354] but PHEO have been rarely reported to occur in children < 10 years of age.[141,153] Typically, a PHEO develops only after MTC is identified or is diagnosed at the same time as the MTC, but in up to 30% of cases, it may be the initial clinical presentation.[344,347,352,354,355] Guidelines published in 2009 have given clear recommendations for screening of pheochromocytoma in children with MEN2,[141] but some centers screen children with high-risk *RET* mutations annually starting at the age of 5 years.[2,31]

Primary Hyperparathyroidism in MEN2A. Patients with MEN2A are at risk of developing PHPT due to parathyroid adenomas and hyperplasia. PHPT is chiefly associated with codon 634 mutations and less commonly described in other *RET* mutations (see Figure 14-1).[141,356,357] Onset during childhood is extraordinarily rare but has been described in children as young as 5 years of age.[358]

MEN2B

MEN2B is a highly penetrant disease with an autosomal dominant pattern of inheritance that accounts for 5% to 10% of MEN2 cases.[160] MEN2B is almost always (> 95%) due to a single mutation in exon 16 (M918T, which results in an amino acid substitution from methionine to threonine at codon 918) that is located in the intracellular tyrosine kinase domain of RET[327,336,337] (see Figure 14-5). Rare MEN2B cases can be attributed to double *RET* mutations involving codon 804[359] or a mutation in codon 883 (Ala883Phe, exon 15), which may be less aggressive than the Met918Thr mutation.[360] Unlike MEN2A, most cases of MEN2B arise as a result of a de novo mutation, with the child having unaffected parents.[152,361] For this reason and due to the rarity of the syndrome, the diagnosis of MEN2B is almost always delayed, even in the presence of obvious clinical features.[152]

MEN2B is characterized by the development of MTC (100% of cases), PHEO (up to 50% of cases), and a highly penetrant and characteristic clinical phenotype (100% of cases).[141,362-371] Although the clinical phenotype is present in all patients, individual manifestations have a variable presentation and are age dependent.[366] Ganglioneuromas are a major clinical manifestation and occur on the lips, tongue (Figure 14-11), or conjunctiva ("mucosal neuromas"), in addition to the urinary system and gastrointestinal tract. The symptoms of intestinal ganglioneuromatosis include constipation and feeding problems in infancy and the development of megacolon. A second component of the MEN2B phenotype is the presence of musculoskeletal abnormalities, including a Marfanoid body habitus (Figure 14-12), narrow long facies, pes cavus, pectus excavatum, high-arched palate, scoliosis, or slipped capital femoral epiphysis. Other clinical features include joint laxity, hypotonia or proximal muscle weakness, thickened lips, ophthalmologic findings (inability to make tears in infancy; thickened and everted eyelids; mild ptosis and prominent corneal nerves), and pubertal delay. The oral manifestations of MEN2B (see Figure 14-11) are highly penetrant and often lead to the clinical diagnosis. Primary hyperparathyroidism is not a feature of MEN2B.

MTC in MEN2B. MTC that occurs in MEN2B is a highly aggressive malignancy with very early onset of metastasis (lymph node metastases have been documented within the first year of life[171]), a high cancer stage (defined by the TNM classification system) at diagnosis, and an average age of MTC onset (second decade of life) that is about 10 years earlier than that observed in MEN2A cases.[150,153,348,366,372] Earlier MTC onset is observed in children with MEN2B who have severe intestinal manifestations, who also seem to have a poorer prognosis than those without these intestinal manifestations.[367] Morbidity and mortality rates are much higher in MEN2B, although the

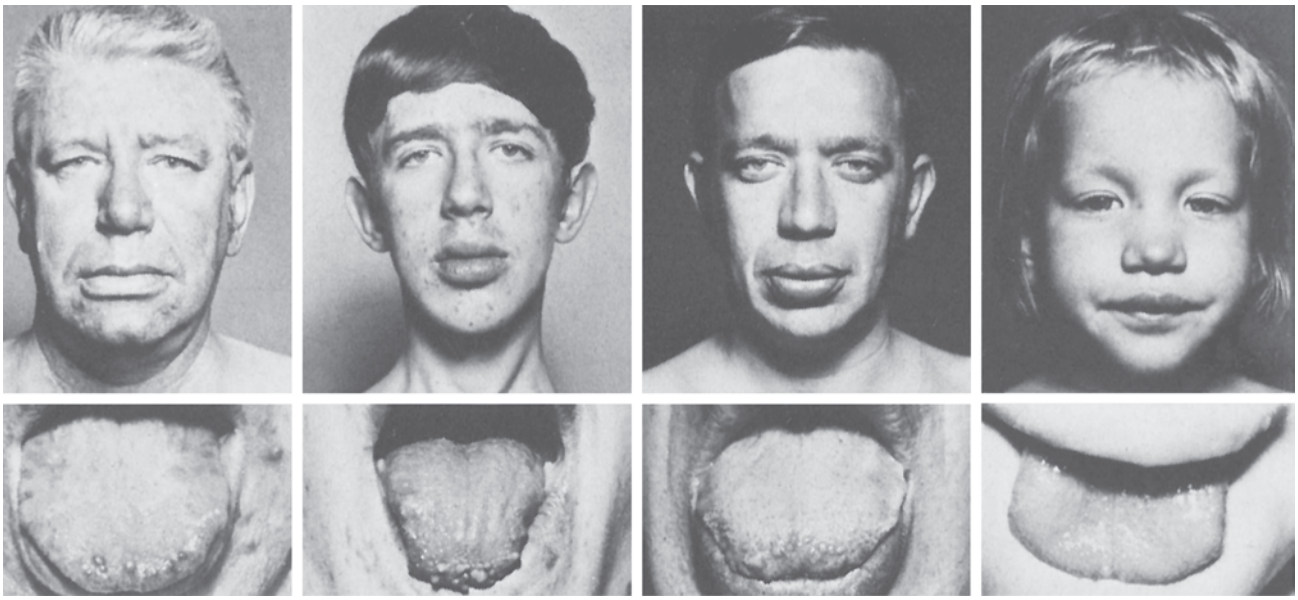

FIGURE 14-11 ■ Typical MEN2B facies. The typical MEN2B facies includes a narrow long face, eyelid eversion, thickened lips, and oral mucosal neuromas as demonstrated in several affected members of a single kindred. (From Sizemore, G. W., Health, H., 3rd, & Carney, J. A. (1980). Multiple endocrine neoplasia type 2. *Clin Endocrinol Metab, 9*, 299–315.)

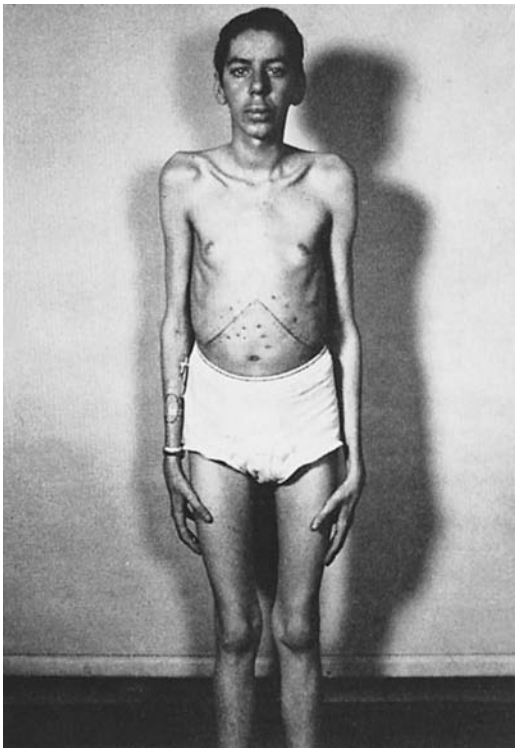

FIGURE 14-12 ■ Patient with typical features of MEN2B. Note the Marfanoid body habitus, thickened lips, and abdominal scars that reflect surgery for pheochromocytoma. (From Melvin, K. E., Tashjian, A. H., Jr, & Miller, H. H. (1972). Studies in familial (medullary) thyroid carcinoma. *Recent Prog Horm Res, 28*, 399–470.)

higher mortality rate may reflect the more advanced tumor stage at presentation rather than an intrinsically more aggressive carcinoma.[141,151]

Pheochromocytoma in MEN2B. Compared with the more heterogenous MEN2A population, patients with MEN2B have a higher lifetime risk (50%) of developing pheochromocytoma.[352] The clinical phenotype of the disease is not different than that seen in MEN2A. Despite an aggressive MTC phenotype and a constitutively activated RET tyrosine kinase, the rate of the development of malignant pheochromocytoma in patients with MEN2B does not seem higher,[125] nor does the age of onset seem different from patients with MEN2A, although some studies have suggested an earlier age of diagnosis.[347] Two notable differences between MEN2A and MEN2B are that PHEO is even less likely to be diagnosed before MTC and that historical mortality from PHEO is lower compared with death from MTC.[344,352]

Timing of Thyroidectomy in MEN2

The use of genetic testing to determine the timing of thyroid surgery in MEN2 has become increasingly complicated due to an improved understanding of the variable aggressiveness of MTC, even among family members with the same *RET* mutation.[373] Furthermore, novel and rare *RET* DNA variants that have not yet been fully established as pathogenic (the so-called variants of unknown significance) have been identified.[339,374,375] These considerations, plus the addition of routine ultrasonography and calcitonin screening,[141] have led to the contemporary dilemma of determining the optimal timing of prophylactic thyroidectomy for any individual patient. In any event, it is imperative for providers who care for children with MEN2 to recognize who needs early intervention to prevent morbidity and mortality from MTC and not to overtreat those children who are unlikely to develop clinically relevant disease over the short term.

In general, there is widespread agreement that the therapeutic goal in a child with MEN2 is to remove the at-risk thyroid before incurable MTC metastasis occurs

while minimizing potential medical and surgical morbidity. In experienced surgeons' hands, children who have a total thyroidectomy performed prior to the onset of metastatic disease have an excellent chance of remaining disease-free.[149,150,169,170,376-378] Cure is also possible even for children with high risk MEN2 despite surgery not being performed at the earliest prescribed ages.*

In the era before RET genetic testing, calcitonin response to the intravenous administration of potent calcitonin secretagogues (calcium, pentagastrin)[173,380] was used to identify mutation carriers and determine the timing of surgery. After the identification of RET as the gene responsible for MEN2, recommendations regarding the appropriate age for surgery were made on the basis of the specific *RET* mutation and the earliest age at which clinically relevant disease had been described for that particular mutation.[146,153] Arising from the 7th International Workshop on MEN in 1999, a consensus statement published in 2001 was the first to classify *RET* proto-oncogene mutations into three risk levels.[153] In 2009, the American Thyroid Association (ATA) published guidelines that expanded the previous consensus document, incorporating updated data on *RET* mutations and phenotypes and recognizing codon 634 mutations within a separate risk level (see Figure 14-5).[141] The ATA guidelines stratified all known *RET* mutations into one of four risk levels (ATA risk levels A through D), and the concept of safely delaying prophylactic thyroidectomy while offering careful expectant monitoring in children with lower risk level A and B mutations was introduced. The approach to care is evolving to incorporate knowledge regarding the RET genotype and clinical data such as thyroid ultrasound and calcitonin levels.[2,377,381,382]

Multiple Endocrine Neoplasia 4 (MEN4)

Multiple endocrine neoplasia type 4 (MEN4) is a newly recognized syndrome of multiple endocrine tumors that is caused by germline mutations in the *CDKN1B* gene on chromosome 12p13, which encodes the cell cycle inhibitor p27 and plays a critical role in regulating cell proliferation.[383] Homozygous mutations in *CDKN1B* were originally identified to cause MENX, a multitumor syndrome in the rat that has phenotypic features of both MEN1 and MEN2.[383,384] Subsequently, studies in humans without a proven MEN1 mutation confirmed that heterozygous mutations in the human homologue *CDKN1B* are also associated with an MEN1-like phenotype, subsequently called MEN4. Individuals with a germline *CDKN1B* mutation are at risk for developing tumors of the pituitary, parathyroid glands, adrenals, or GI neuroendocrine system, among others.[383-386] Although MEN4 is a rare cause of multiple endocrine neoplasia, mutational screening of the *CDKN1B* gene should be considered in patients with a clinical diagnosis of MEN1 but negative *MEN1* genetic testing.[216]

*See references 149, 150, 168-170, 329, 360, 366, 371, 377, and 379.

Von Hippel-Lindau Disease

VHL is an autosomal dominantly inherited disorder caused by germline mutations in the *VHL* tumor suppressor gene, first identified in 1993[387] and characterized by a clinical phenotype with variable penetrance that includes hemangioblastomas of the retina (also called retinal angiomas) and central nervous system; renal cysts and clear cell renal cell carcinoma; noradrenergic PHEO/PGL; pancreatic cysts, cystadenomas, and pancreatic NETs; endolymphatic sac tumors; and cystadenomas of the epididymis in males and broad ligament of the uterus in females.[388,389,390] About 20% of patients with VHL harbor a de novo mutation, and genetic testing is highly reliable, identifying a germline mutation in almost all clinically affected individuals.[390,391] The majority of VHL mutations are small deletions/insertions or point mutations, but about 25% are due to partial or whole gene deletion of the *VHL* gene, underscoring the importance of utilizing both sequence analysis and deletion/duplication analysis when performing genetic testing for VHL.[390]

PHEO/PGL occur in 10% to 20% of VHL patients,[388] (see Figure 14-1) primarily in individuals with missense mutations of the VHL gene.[388,389,392] PHEO/PGL can be one of the earliest clinical manifestations of VHL, having been diagnosed in patients as young as age 2 years,[393] and it can also be the sole clinical manifestation of VHL, as seen in VHL type 2C.[388,390,394] Prospective screening is generally recommended to commence by the age of 5 years in children with missense mutations or a family history of PHEO/PGL.[31,390,395] Although almost all VHL-related PHEO/PGL are functional noradrenergic tumors (see the previous section on PHEO and PGL), nonfunctional parasympathetic PGL occurring in the context of VHL have been described.[43,396,397]

Pancreatic NETs (pNETs) develop in 15% of VHL patients.[398] These tumors are clinically nonfunctional, although they can be malignant, especially with lesions > 3 cm, a mutation in exon 3, or a fast tumor doubling rate.[399,400] Prospective screening for pNET is performed as a component of screening for other intra-abdominal manifestations and includes intermittent ultrasound or MRI starting at age 16.[389,390,394]

Finally, testosterone-secreting lipid cell tumors have been described and so should be considered in women with VHL who present with an adnexal mass, amenorrhea, or hirsutism.[401]

OTHER TUMOR SYNDROMES ASSOCIATED WITH ENDOCRINE NEOPLASIA

APC-Associated Polyposis

The *APC*-associated polyposis disorders result from dominantly inherited germline mutations in the *APC* (adenomatous polyposis coli) tumor suppressor gene and include the clinical syndromes of familial adenomatous polyposis (FAP), attenuated FAP, Gardner syndrome, and Turcot syndrome.[402] Patients with an *APC* mutation are at greatest risk for colon cancer but may also develop endocrine neoplasia. Adrenocortical tumors (ACT) are two to four times as high in the *APC*-associated polyposis

syndromes compared with the general population.[403,404] Similar to sporadic adrenal neoplasia, *APC*-associated ACTs may be hormonally active or nonfunctioning and may rarely be malignant.[405] Patients with an *APC* mutation also have a 1% to 2% lifetime risk for thyroid malignancy,[403] with some studies suggesting a prevalence in FAP patients as high as 12%.[406] The primary subtype is papillary thyroid carcinoma, typically the cribriform-morular histologic variant, and it is a diagnosis almost exclusively made in young women during the third decade of life.[406-409]

Beckwith-Wiedemann Syndrome

The Beckwith-Wiedemann syndrome (BWS) is a congenital overgrowth disorder associated with abnormal regulation of gene transcription in an imprinted domain on chromosome 11p15.5 (also known as the BWS critical region).[410,411] Major findings include macrosomia and hemihyperplasia, macroglossia, visceromegaly, embryonal tumors (e.g., Wilms tumor, hepatoblastoma, neuroblastoma, pancreatoblastoma, and rhabdomyosarcoma), omphalocele, neonatal hypoglycemia, ear creases/pits, adrenocortical tumors/cytomegaly, and renal abnormalities (e.g., medullary dysplasia, nephrocalcinosis, medullary sponge kidney, and nephromegaly) (see Chapter 6). A variety of benign and malignant tumors, typically restricted to childhood onset, have been associated with BWS and occur in up to 7.5% of all cases.[411] ACTs, both benign and malignant, are among the more common neoplasia identified in BWS, representing up to 8% of benign and 7% of malignant tumors.[412] Fetal adrenocortical cytomegaly (a component of the underlying visceromegaly) and adrenal cystic lesions also occur.[412,413] Pheochromocytoma and thyroid carcinoma have also been reported,[412] but given only isolated cases, it remains unclear if these are truly associated with BWS.

Carney Triad

The Carney triad was originally described in 1977 as the association of gastric epithelioid leiomyosarcoma (later renamed GIST), paraganglioma, and pulmonary chondroma.[414] Over time, the phenotype has expanded to include clinically nonfunctioning adrenocortical tumors and esophageal leiomyomas.[415,416] The Carney triad affects primarily young women (85%) with a mean age of onset of 20 years.[7-48,416] Although it has been accepted to be a genetic disorder, the responsible gene(s) remains unknown. Due to incomplete expression of the phenotype, PGL is not present in all patients suspected to have the Carney triad.[415] When it occurs, PGL presents with catecholamine excess or due to tumor mass effects. PHEO can occur in a minority of patients, and the aortopulmonary body is a common site for development of PGL, although instances of PGL occur equally in the head and neck, thorax, and abdomen.[416]

Li-Fraumeni Syndrome

Li-Fraumeni syndrome (LFS) is a highly penetrant cancer-predisposition syndrome caused by dominantly inherited germline mutations in the tumor suppressor gene *TP53* (tumor protein p53).[417] Soft tissue and bone sarcomas, premenopausal breast cancer, adrenocortical carcinoma, and brain tumors represent the core tumors of LFS.[418,419] The major endocrine tumor associated with LFS is ACT, although several cases of thyroid carcinoma have also been reported.[420] The adrenal cortex is the third most common site of neoplasia development in LFS.[418,421] ACT have a very early age of onset, with the diagnosis most common in young children, who may represent the proband for a LFS kindred.[418,422,423] In southern Brazilian families, the *TP53* mutation Arg337His is associated with a higher susceptibility to isolated ACT in children (median age of diagnosis 3 years; range 4 months to 13.5 years).[424] Young children with an ACT typically present with virilization,[422,424] but at all ages, these tumors can present with other signs/symptoms of adrenocortical hyperfunction (such as Cushing syndrome) or with symptoms due to tumor mass effect, particularly in the case of nonfunctioning tumors.

Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder caused by mutations in the *NF1* gene, a tumor suppressor gene located on chromosome 17.[425] Café-au-lait macules, neurofibromas, axillary and inguinal freckling, optic pathway gliomas, skeletal dysplasia, and Lisch nodules of the iris are the main clinical features.

NF1 patients are at an increased risk of developing PHEO/PGL and GEP-NETs. A catecholamine-producing tumor is diagnosed in 2% to 6% of NF1 patients.[275,426] PHEO (10% bilateral) represent the majority of NF1-associated cases, but intraabdominal and pelvic PGL are diagnosed in up to 6%.[426,427] Onset is typically in adulthood (mean age of presentation 41.6 years[427]), and NF1-associated PHEO are characterized by an adrenergic phenotype.[428] Malignancy is uncommon but does occur in about 10% of cases.[427] Rarely, a composite PHEO (a mixed tumor comprised of PHEO and neuroblastoma, ganglioneuroma, or ganglioneuroblastoma) may occur in the setting of NF1.[429] GEP-NET occur in $<$ 10% of NF-1 patients and are almost exclusively duodenal somatostatinomas that occur in the periampullary region.[275,430] NF1-associated somatostatinomas are typically diagnosed during the fifth decade of life.[430] Other types of GEP-NETs that have been reported in NF1 patients include insulinomas, gastrinomas, and nonfunctioning pancreatic endocrine tumors.[275,431,432]

Several case reports of primary hyperparathyroidism due to benign and malignant parathyroid tumors and adrenocortical tumors have also been reported to occur in NF1.[405,433,434] However, it is unclear if mutations in the *NF1* gene are directly involved in the pathogenesis of these tumors. Finally, a unique endocrinopathy associated with NF1 in children with infiltrating optic pathway gliomas is the clinical syndrome of gigantism due to unregulated growth hormone secretion.[435]

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome (PJS) is an autosomal dominant syndrome characterized by hamartomatous polyps in the gastrointestinal tract and mucocutaneous hyperpigmentation.[436,437] It is caused primarily by inactivating mutations in the *STK11* (*LKB1*) gene. Individuals with PJS are at an increased risk for various malignancies over the course of their lives,[438] chiefly luminal gastrointestinal cancers and breast cancer, followed by pancreatic cancer, cervical and ovarian malignancies, and lung cancer. Several case reports of differentiated thyroid cancer have been reported,[439] but it remains unclear if this is a random occurrence or a direct association with PJS.

Patients with PJS are at risk for unique gonadal tumors that may clinically present with an endocrinopathy during childhood: Sertoli cell tumors of the testis in males and ovarian sex cord tumors with annular tubules (SCTATs) in females. Testicular Sertoli cell tumors in PJS are clinically benign lesions that typically occur in prepubertal boys (mean age 6.8 years) who present with gynecomastia and bilateral (rarely unilateral) testicular enlargement.[189] The microscopic findings are distinctive and the term *intratubular large cell hyalinizing Sertoli cell neoplasia* has been proposed.[189] Calcifications are unusual and not extensive in these lesions, although large-cell calcifying Sertoli cell tumors (similar to those identified in the Carney complex) can also occur within the PJS spectrum.[440] The gynecomastia is due to estrogen overproduction secondary to high levels of aromatase activity,[189] making the use of an aromatase inhibitor a rational approach to medically treating the gynecomastia in such cases.[441] SCTAT is a distinctive neoplasm that has morphologic features that lie between those of a Sertoli cell tumor and a granulosa cell tumor.[442] When occurring in the PJS, these tumors are typically small, calcified, multifocal and bilateral lesions, as compared with non-PJS SCTATs. SCTAT is almost always a benign neoplasm with a mean age of diagnosis of 27 years (range 4 to 57 years).[442] Clinical presentation is often due to estrogen overproduction and manifested by menstrual irregularity in postmenarchal women and sexual precocity in prepubertal girls. Abdominal pain and a palpable adnexal mass can also be presenting features, and SCTAT can also be an incidental finding.[442]

PTEN Hamartoma Tumor Syndrome

The *PTEN* hamartoma tumor syndrome (PHTS) results from germline mutations in the *PTEN* (phosphatase and tensin homologue) tumor suppressor gene and is inherited in an autosomal dominant manner. The PHTS encompasses the clinical phenotypes of Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome, *PTEN*-related Proteus syndrome, and Proteus-like syndrome.[337,443,444] Cowden syndrome (CS), the most common PHTS phenotype, is a multiple hamartoma syndrome with an increased risk for both benign and malignant tumors arising from the thyroid follicular cell and, in women, the breast and endometrium.[337] Macrocephaly is a consistent finding, occurring in 94% of patients with a *PTEN* mutation,[445] and common skin manifestations include papillomatous papules, trichilemmomas, and acral keratoses. Thyroid neoplasia occurs in the majority of individuals with CS and primarily includes multiple adenomatous nodules, follicular adenomas, and differentiated thyroid carcinoma (papillary and follicular thyroid carcinomas).[446-448] Follicular thyroid carcinoma appears to be overrepresented in *PTEN* mutation positive patients, but papillary carcinomas are also common.[447-449] The risk of thyroid neoplasia begins during early childhood, with a reported case of follicular thyroid carcinoma as young as age 7 years.[447]

Tuberous Sclerosis Complex

The tuberous sclerosis complex (TSC) is an autosomal dominant, multiorgan hamartomatous disorder characterized by abnormalities of the skin (hypomelanotic macules, facial angiofibromas, shagreen patches, fibrous facial plaques, ungual fibromas); brain (cortical tubers, subependymal nodules and subependymal giant cell astrocytomas, seizures, intellectual disability/developmental delay); kidney (angiomyolipomas, cysts, renal cell carcinomas); heart (rhabdomyomas, arrhythmias); and lungs (lymphangioleiomyomatosis).[450] The two known genes that cause the TSC include *TSC1* and *TSC2*, which encode for the proteins hamartin and tuberin, respectively.[451,452] Various endocrine neoplasms occurring within the context of the TSC have been reported, including functional pituitary adenomas, parathyroid hyperplasia and adenomas, GEP-NETs, and a single case report of a PHEO.[453] The pNETs can be benign or malignant and functioning or nonfunctioning, with a large proportion of cases associated with *TSC2* gene mutations.[454] Insulinomas appear to be overrepresented in TSC patients, so a low threshold should exist for clinical evaluation in those with classic signs or symptoms of hypoglycemia or worsening neurologic symptoms.[453]

SUMMARY AND FUTURE DEVELOPMENTS

Although rare, neuroendocrine tumors diagnosed during childhood, especially PHEO and MTC, are frequently associated with a known tumor predisposition syndrome. Advances in genomic medicine have improved our understanding of the etiology and pathophysiology of these disorders, which in turn has changed the way physicians manage patients with the diseases discussed in this chapter. Because it is a rapidly evolving field, the reader should continue to seek the most current information for important clinical decisions regarding individual patient care. Future research will add to our knowledge regarding genotype-phenotype correlations, optimal screening strategies for asymptomatic children known to carry a disease-causing mutation, timing of interventions such as early thyroidectomy in MEN2 and parathyroidectomy in MEN1, and the treatment of advanced or inoperable disease with newer targeted therapies.

QUESTIONS

1. A previously healthy 2-year-old boy presents with gonadotropin-independent precocious puberty. Pubic hair is Tanner 3, penis is enlarged, and testes are prepubertal.Congenital adrenal hyperplasia is ruled out with cosyntropin stimulation testing, and there is no known exogenous testosterone exposure. Adrenal neoplasia is suspected. Which of the following statements is correct?
   a. Adrenal imaging is likely to be negative.
   b. Ophthalmologic examination might reveal retinal angiomas.
   c. Genetic testing for a *TP53* mutation should be undertaken.
   d. A GnRH agonist is the treatment of choice.
   e. There is likely to be a family history of thyroid cancer.

Answer: c

2. A 10-year-old boy presents for evaluation of thyroid nodules:

Which of the following statements is *incorrect*?
   a. The lifetime chance of developing primary hyperparathyroidism is ~20%.
   b. Postoperative ileus may be problematic in this patient.
   c. His parents are unlikely to have the same diagnosis.
   d. The patient may have a history of failure to make tears and feeding difficulties.
   e. The patient is likely to have an activating mutation in codon 918 (M918T) of the *RET* proto-oncogene.

Answer: a

3. A 15-year-old girl is diagnosed with primary hyperparathyroidism (PHPT). Family history is positive for PHPT and prolactinoma in the mother and a maternal uncle with PHPT, a nonfunctioning pituitary adenoma, and a gastroenteropancreatic neuroendocrine tumor (GEP-NET). Which of the following statement is *incorrect?*
   a. The patient has a higher likelihood of developing a GEP-NET than a pituitary tumor.
   b. The chance of finding a mutation is > 80%.
   c. She should be screened for other endocrine neoplasia, even if asymptomatic.
   d. An activating mutation in *MEN1* is likely responsible.
   e. Her children have a 50% chance of having the same condition.

Answer: d

4. An 8-year-old boy with a history of ADHD is found to be hypertensive at a routine office visit. A pheochromocytoma is diagnosed after elevated plasma metanephrines are documented and a 3-cm left adrenal mass is identified on imaging. Which of the following genes is most likely to be mutated in this patient's case?
   a. *MEN1*
   b. *SDHB*
   c. *NF1*
   d. *RET*
   e. *VHL*

Answer: e

5. The management of a child with a pheochromocytoma includes all of the following *except*:
   a. Consultation with a genetic counselor
   b. Biopsy to confirm the diagnosis prior to surgery
   c. Long-term follow-up to assess for recurrence and the development of metachronous tumors
   d. Fluid expansion via salt loading prior to surgery
   e. Treatment with an α-adrenergic receptor blocker prior to surgery

Answer: b

6. The management of a child with medullary thyroid carcinoma includes all of the following *except*:
   a. Consultation with a genetic counselor
   b. Surgery performed by an experienced thyroid cancer surgeon
   c. Thyroid-stimulating hormone (TSH)-suppressive therapy
   d. Periodic assessment of calcitonin and CEA levels
   e. Testing for a germline mutation in the *RET* proto-oncogene

Answer: c

7. Which of the following hereditary tumor syndromes are associated with endocrine neoplasia?
   a. Beckwith-Wiedemann syndrome
   b. Tuberous sclerosis complex
   c. Neurofibromatosis type 1
   d. None of the above
   e. All of the above

Answer: e

CHAPTER 15

Puberty and its Disorders in the Female

Robert L. Rosenfield, MD • David W. Cooke, MD • Sally Radovick, MD

CHAPTER OUTLINE

INTRODUCTION

Puberty is the stage of development during which secondary sexual characteristics appear and there is a transition from the sexually immature to the sexually mature stage. *Adolescence* is widely used as a generally synonymous term for puberty, but it is often used to convey an added cultural connotation as a psychosocial coming of age.

By the mid-1960s, a general concept of the major factors involved in the initiation of puberty was established (Figure 15-1).[1,2] A decrease in sensitivity of the brain "gonadostat" to sex hormone negative feedback was thought to be the primary event. This signaled the hypothalamus to discharge neurohumors (then unidentified), which in turn stimulated the pituitary to release gonadotropins. The resultant rise in secretion of the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), was thought to account directly for increased estrogen production by the ovary. A mature relationship was thought to develop in which the blood levels of estrogen and gonadotropins were regulated reciprocally via the gonadostat,[3] much as a furnace is regulated by a thermostat. The pineal was identified as having gonadal suppressive properties. The increased adrenocortical secretion of 17-ketosteroids (17-KS), which becomes apparent at about the time of puberty ("adrenarche"), was thought to be due to a pituitary factor stimulating adrenal androgens in synergism with adrenocorticotropic hormone (ACTH).[4]

The rapid scientific advances since 1965 have permitted this concept to be tested in increasingly sophisticated ways. In the subsequent decade, radioimmunoassay (RIA), originally developed by Yalow and Berson, was applied to the measurement of gonadotropins and sex steroids; the gonadotropin-releasing hormone (GnRH) for both LH and FSH was isolated, identified, and synthesized by Guillemin's and Schally's groups. Cyclic adenosine-3′,5′-monophosphate (cAMP), postulated by Sutherland to mediate the action of peptide hormones, was found to mediate gonadotropin effects on the ovarian follicle. Jensen, Gorski, and their groups defined the initial steps in the mechanism of action of steroid hormones. The awarding of Nobel Prizes in medicine to Sutherland in 1971 and to Yalow, Schally, and Guillemin in 1977 marked the recognition of the landmark nature of many of these discoveries.

Our present view of the mechanisms controlling puberty is more refined and complex than it once was, although the previously discussed schema is correct in a general sense. The gonadostat is a patently oversimplistic concept for a complex system that regulates the hypothalamic GnRH pulse generator, a functionally interconnected and synchronized network of GnRH neurons.[5] The gonadostat setting seems to change throughout childhood in a biphasic

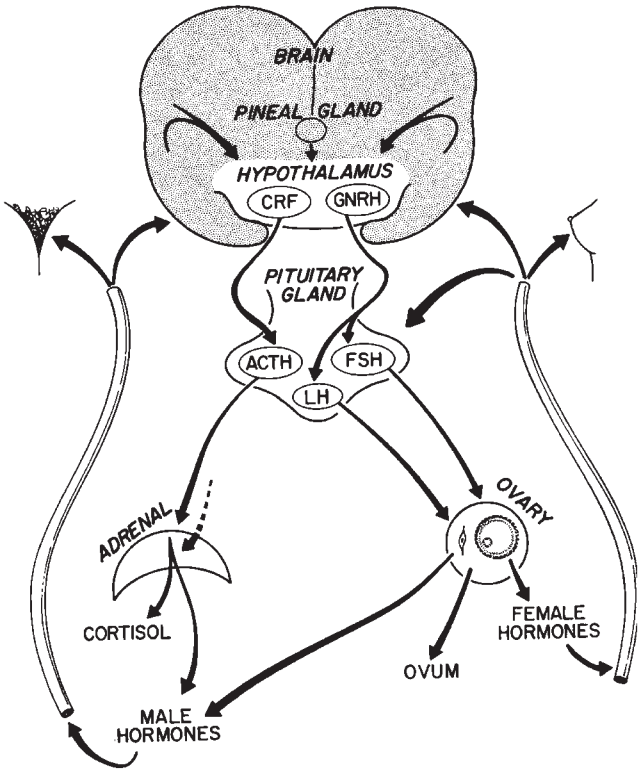

FIGURE 15-1 ■ Schematic representation of the neuroendocrine-ovarian axis involved in normal pubertal development. ACTH, adrenocorticotropic hormone; CRF, corticotropin-releasing factor; GnRH, gonadotropin-releasing hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone.

manner. This concept is illustrated in Figure 15-2.[6,7] During fetal and perinatal life, the gonadostat is insensitive to negative feedback by sex steroid hormones; at this time the nascent neuroendocrine-gonadal axis functions at a pubertal level. The gonadostat becomes increasingly sensitive to negative feedback during infancy, but it does not become highly sensitive until mid-childhood, at which time GnRH pulse generator activity is minimal. During late prepuberty the gonadostat begins to relinquish its inhibition. This permits the onset of puberty. The changing set point initially permits increasing, episodic secretion of GnRH. Increasing sensitivity of the pituitary gonadotropic cells to GnRH follows. The change in LH and FSH secretion is first detectable during sleep. Gradually the gonads become increasingly sensitized to gonadotropin stimulation, grow at an increased rate, and bring about sustained rises in plasma sex steroid hormone levels. Some of these phenomena synergize with others, so that autoamplification occurs and the pace of change accelerates. Eventually the set point for gonadotropin release comes to vary sufficiently to encompass a positive feedback mechanism.

The data on which this model is based are presented here. The most recent data on the hormonal milieu and accompanying physical stages of normal puberty are then presented. Abnormal puberty is subsequently discussed: the causes, differential diagnosis, and management.

DEVELOPMENT OF THE FEMALE REPRODUCTIVE SYSTEM

Maturation of the Neuroendocrine-Ovarian Axis

Fetus

Neuroendocrine Unit. The anterior lobe of the pituitary gland, of stromal ectodermal origin, and the posterior lobe, of neural origin, differentiate by 11 weeks' gestational age.[8] By this time, GnRH neurons have migrated from the olfactory placode into place in the medial basal hypothalamus.[9] Hypothalamic GnRH subsequently rises in parallel with fetal pituitary and serum LH and FSH.[10] All peak at about 20 to 24 weeks, as the connections of the pituitary portal system become complete, to levels not again seen until menopause.[11]

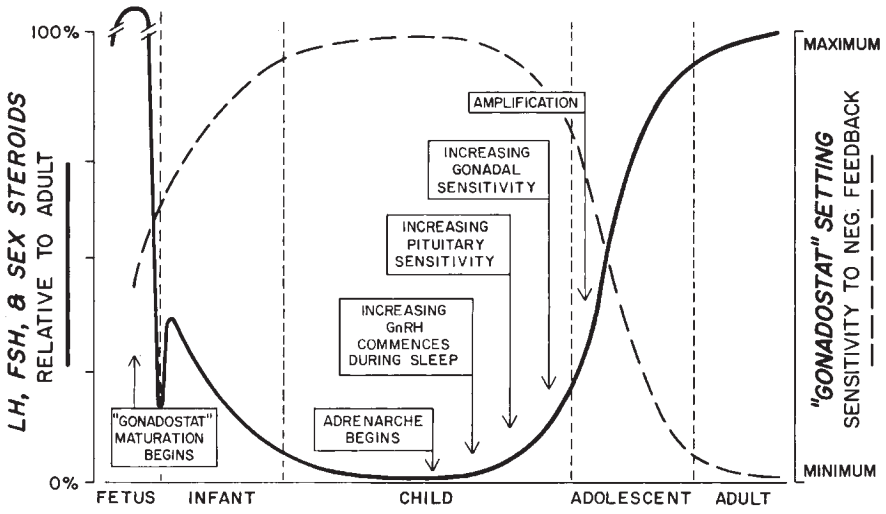

FIGURE 15-2 ■ The changing pattern of serum gonadotropins and sex hormones from fetal life to maturity in relationship to the apparent sensitivity of the central nervous system "gonadostat" to the negative feedback effect of sex hormones and the underlying hormonal events. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone. (Modified from M. Grumbach, C. Grave, & F. Mayer (Eds.), *The control of the onset of puberty.* New York: John Wiley & Sons.)

Serum LH and FSH levels are higher in human female than male fetuses.[11] In rats, GnRH-containing neurons develop earlier in females than in males,[12] and there are sexual dimorphisms in the degree of synapsing of specific tracts with dendritic spines in the preoptic nucleus, one of the major GnRH-containing areas of the hypothalamus.[13,14] These differences may be determined by gonadal sex steroid hormone output. In all species studied, fetal secretion of LH, particularly LH pulse frequency, is permanently desensitized to estradiol (E2)-progesterone negative feedback by fetal virilization.[15] In the rat this has been demonstrated to be mediated by permanent impairment of estradiol-induced progesterone receptor gene expression.[16]

In late gestation, fetal hypothalamic GnRH and pituitary gonadotropin secretion fall to low levels. These changes are likely explicable by the negative feedback effect of the high sex steroids produced by the fetoplacental unit. Meanwhile, maturation of the central nervous system (CNS) tracts that inhibit hypothalamic GnRH secretion and mediate gonadal negative feedback signals appears to progress throughout gestation.[17,18]

The production of gonadotropins by the fetal pituitary seems to facilitate normal ovarian development. Hypophysectomy of rhesus fetuses has been reported to reduce the number of germ cells and oocytes as well as the integrity of the rete ovarii.[19] Therefore, it seems that the survival of gametes depends on the secretions of the fetal pituitary.

Ovary. The ovaries differentiate in the urogenital ridge adjacent to the anlage of the adrenal cortex and the kidney. The granulosa cells are the homologues of the Sertoli cells of the testes. The theca, interstitial, and hilus cells are the homologues of the Leydig cells; hilus cells may even contain crystalloids like Leydig cells. Adrenocortical rests occasionally have been found in the hilus of the ovary.[20] Conversely, ovarian rests have been identified in the adrenal glands.[21]

The primitive germ cells migrate into the ovary from the yolk sac endoderm during the first month of gestation. The ovaries begin to become distinguishable from testes by 8 weeks of gestation[22] in the absence of testicular development being switched on by signaling cascade initiated by the *SRY* gene on the Y chromosome.[23] *Wnt-4* and forkhead (*Fox*) family transcription factor signaling by germ cells are critical for ovarian differentiation by sustaining oocyte and granulosa cell development and suppressing Sertoli and Leydig cell differentiation; they also support later aspects of follicle develoment.[24] Steroidogenic factor-1 (*SF-1*) *WT-1*, *LIM-1*, and possibly *DAX-1* genes play roles in the formation of the ovaries.[25] Germ cell bone morphogenetic proteins (BMPs) are necessary for primordial germ cell proliferation. Mitotic division of oogonia is maximal before the third month and comes to an end by the seventh month. Oogonia then undergo oogenesis, entering the prophase of meiosis to become primary oocytes during the final 5 to 6 months of gestation.[26] The number of oocytes reaches a peak at the fifth month when there are 6.8 million germ cells, of which 80% appear to be viable (Figure 15-3).[27] When oocytes enter the diplotene stage of meiotic prophase, they must be furnished with granulosa cells to form a primordial follicle, or else they undergo atresia.[28]

Primordial follicles appear in the fourth month, when the epithelium of the secondary sex cords provides granulosa cells to the oocytes, and they peak in number between the fifth and ninth months. They become primary follicles when the encircling granulosa cells become cuboidal. Primordial and small primary follicles (Figure 15-4)[29,30] are resting follicles, which are the major repository of germ cells.[31] This stock of germ cells is depleted only very slowly during childhood (see Figure 15-3). Secondary follicles and preantral follicles, characterized, respectively, by organization of theca and a larger granulosa cell population, then appear successively. After the seventh month, antral (graafian) follicles appear and those granulosa cells enveloping the oocyte become the cumulus.[30,32,33] Typically one or two antral follicles of 1 to 2 mm in diameter are present in the ovary by term, at which time the number of small

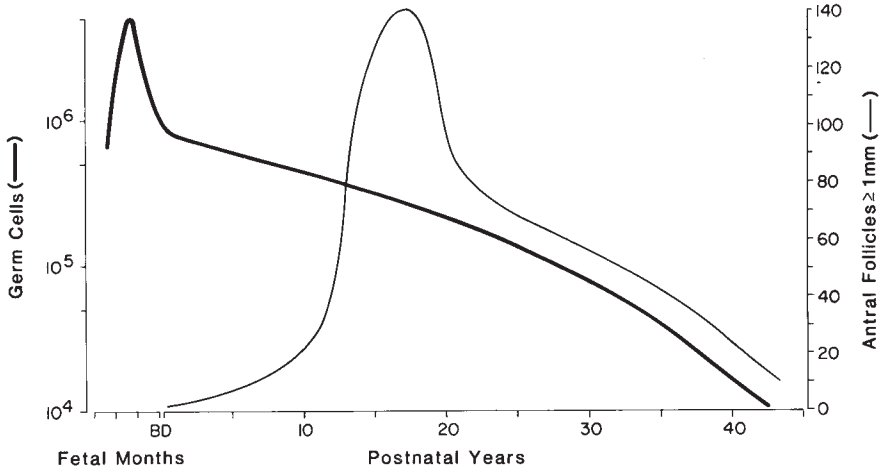

FIGURE 15-3 ■ The development of ovarian follicles from fetal life to maturity. Curves for total number of viable germ cells (thick line) and large antral follicles (thin line) smoothed from the data of Baker and Block. The number of germ cells is maximal at the fifth month of fetal life. The loss of germ cells is exponential throughout postnatal life. At puberty, a marked shift occurs in the pattern of development of follicles. An increased fraction grows to large antral size.

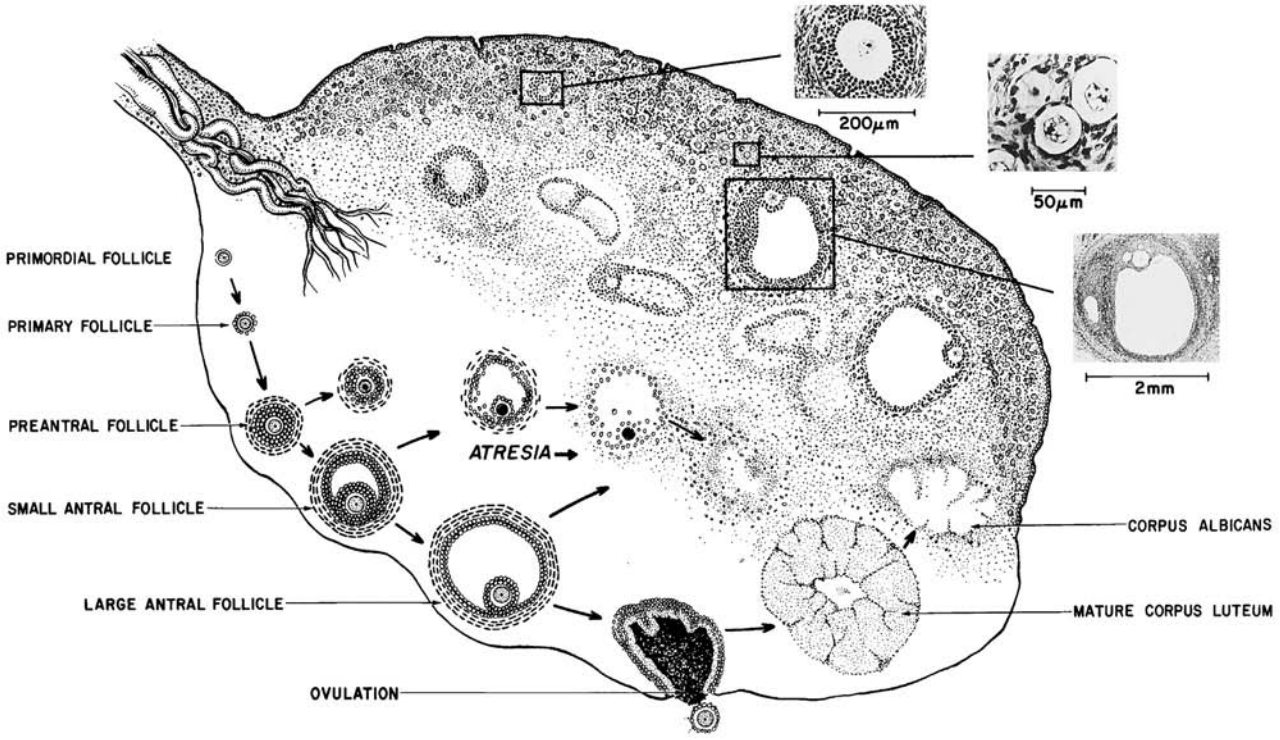

FIGURE 15-4 ■ The human ovary. The lower portion of the figure shows the classification of follicles. Preantral follicles contain as many as 300 granulosa cells, and their diameter ranges from 50 to 200 μm. The oocyte diameter increases from 25 or less to 80 μm. Antral (graafian, tertiary, or vesicular) follicles have a fluid-filled antrum and a full-grown oocyte, are lined with more than 300 granulosa cells, and have a well-developed theca. They are greater than 200 μm in diameter. The dimensions of the mature ovary are approximately 1.25 × 2.75 × 4 cm. The upper portion of the figure illustrates the histologic appearance of the perimenarcheal ovary. (Photomicrographs of ovarian details are reproduced from Peters, H. (1979). The human ovary in childhood and early maturity. *Eur J Obstet Gynecol Reprod Biol, 9,* 137; modified from Ross, G. T., Schreiber, J. R. (1978). The ovary. In S. S. C. Yen, & R. Jaffe (Eds.), *Reproductive endocrinology* (p. 63). Philadelphia: WB Saunders.)

preantral follicles is at its peak. At term, ovarian follicle development is complete,[30,32,33] and the complement of ova is greater than at any other time during postnatal life (see Figure 15-3), totaling 2 million, of which half appear atretic.[27,34]

Both X chromosomes are active in oocytes,[35] and these are necessary for the induction of the granulosa cell layer necessary for oocyte survival.[32,36] Several oocyte transcription factors then mediate the transition from primordial to primary follicles.[24] Growth differentiation factor-9 is critical for signaling the granulosa cells of primary follicles to induce the theca cell layer. Other autosomally determined paracrine factors, prominently involving TGF-β superfamily signaling, are necessary for the survival of oocytes and the further differentiation and growth of follicles. The forkhead transcription factor FOXL2, expressed specifically in granulosa cells, both mediates the GDF9 effect and restrains it from prematurely activating oocytes.[37]

Follicle number is determined by the balance between the number of ovarian germ cells and the rate of atresia. The endowment of ovarian germ cells has been thought to be determined during fetal life, as the germ cells of the ovary, unlike those of the testes, seem to be a non-renewing population; however, this concept has been challenged by research with germline stem cells that suggests a process of slow neogenesis.[38] Regardless, the regulation of atresia by the balance of cell survival and programmed cell death signals is a critical determinant of follicle number.[39] The endowment of follicles may be influenced by environmental factors, such as toxins,[40] thymic factors,[41] and placental insufficiency.[42] Fetal undernutrition has been suspected of temporarily or permanently altering ovarian follicular development.[43-45]

Theca-interstitial cells of the fetal primordial follicle form androstenedione and dehydroepiandrosterone as early as 3 months gestation in humans, but E2 formation probably does not occur until antral follicular development begins at 34-38 weeks gestation.[18,22,46] Thus, the contribution of the ovaries to fetal sex steroid levels is probably relatively low.

Placenta. The fetoplacental unit becomes the major source of sex hormones in the female fetus in the latter half of pregnancy: the fetal adrenal gland provides 17-ketosteroids as substrate for the formation of potent sex steroids by the placenta. Excess androgen, from any source, in the female fetus masculinizes genital differentiation, as discussed in other chapters. This also programs for LH elevation and insulin resistance in adult life.[15] Placental insufficiency, via hypoxemia and the resultant overactivation of fetal prostaglandin production and cortisol secretion, is another factor predisposing to postnatal insulin resistance.[47]

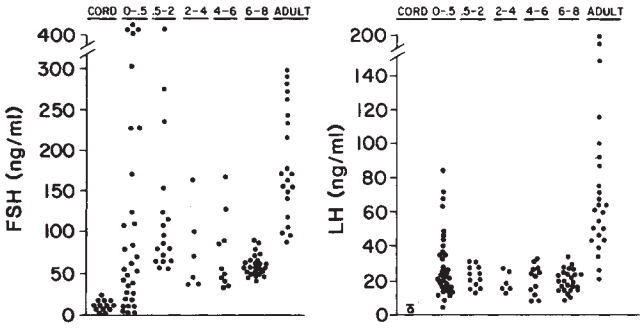

FIGURE 15-5 ■ The distribution of serum gonadotropin levels according to early generation radioimmunoassays from birth to adulthood (age in years) Left, Follicle-stimulating hormone (FSH). Right: Luteinizing hormone (LH). Umbilical cord level of LH measured by beta-subunit-specific radioimmunoassay. Standard LER-907: 100 ng equivalent to 2 mIU FSH and 6 mIU LH of the First International Reference Preparation of human pituitary gonadotropin for bioassay. (Data from Winter, J., Faiman, C., Hobson, W., et al. (1975). Pituitary-gonadal relations in infancy: I. Patterns of serum gonadotropin concentrations from birth to four years of age in the human and the chimpanzee. *J Clin Endocrinol Metab, 40*, 545; from Kaplan, S., Grumbach, M., & Aubert, M. (1976). The ontogenesis of pituitary hormones and hypothalamic factors in the human fetus. *Recent Prog Horm Res, 32*, 161.)

Infant and Child

Neuroendocrine Unit. The hypothalamic-pituitary-gonadal axis is transiently active during the neonatal period. This is sometimes termed the *minipuberty of the newborn*; unlike true puberty the clinical manifestations are only nascent and do not progress. The regulation of neonatal gonadotropin secretion, like that during puberty, is incompletely known.

Serum FSH and LH are low in cord blood and remain low until estrogen concentrations fall from inhibitory levels upon disruption of the fetoplacental unit at birth. Then the LH and FSH levels of neonates promptly begin to rise in pulsatile fashion to early pubertal levels in the first week of life (Figure 15-5).[7,11,48-51] This pituitary activity wanes in older infants, which may be related to the maturation of neural tracts that conduct inhibitory signals from the CNS.

Serum LH and FSH levels rise higher in female than male premature infants, reaching into the postmenopausal range.[17,52] This sexual dimorphism seems to be related to a lack of negative feedback due to lagging ovarian follicular development: antral follicle development begins near term gestational age.[18] There is parallel hyperprolactinemia without sexual dimorphism.[53]

By 40 weeks' gestational age, serum gonadotropins and LH/FSH ratios fall to lower levels in girls than in boys,[17] apparently because girls lack androgen-programmed accentuation of GnRH pulsatility.[16,54,55] Responses to GnRH and GnRH agonist are similar to those of early puberty (Figure 15-6).[56-59] In congenital agonadism, gonadotropins reach postmenopausal levels during the neonatal period.[60]

After about 4 months of age, gonadotropin and prolactin levels gradually begin to fall into the prepubertal range (see Figure 15-5). FSH is higher in girls than in boys, a tendency that tends to persist into early childhood.[48,61] This appears in part related to negative feedback by the higher activin-A and lower inhibin-B serum levels of girls than boys.[62] GnRH secretion also appears to be greater in girls than in boys at this time.[63]

The subsequent decline in gonadotropins may be related to an increase in hypothalamic sex steroid receptors. Hypothalamic estrogen receptors increase in a pattern reciprocal to the fall in serum gonadotropins in the rat (Figure 15-7),[64] as do hypothalamic dihydrotestosterone (DHT) receptors.[65] Increasing sensitivity of the hypothalamus to sex steroid hormone negative feedback could account for the inhibitory effect of the small amounts of circulating E2 and testosterone.

A nadir in both serum gonadotropins occurs by about 6 years of age (see Figures 15-2 and 15-5). At this age the LH and FSH response to GnRH is minimal, apparently

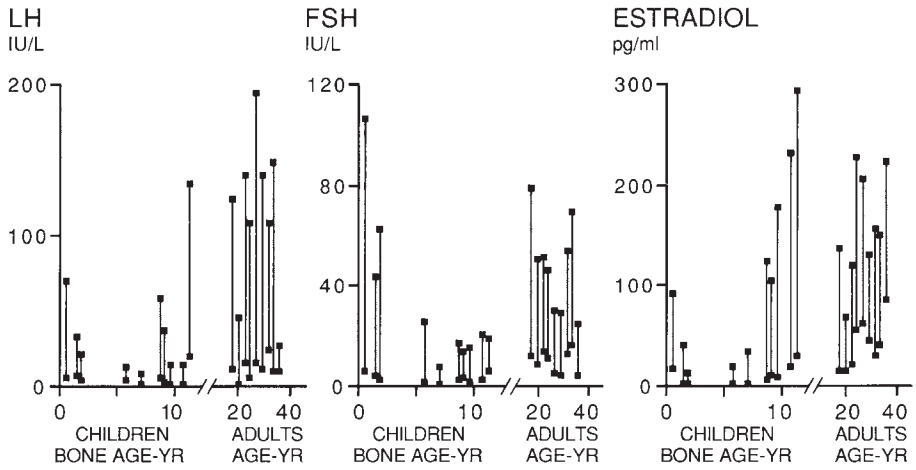

FIGURE 15-6 ■ Basal and peak responses to the gonadotropin-releasing hormone agonist nafarelin (1 μg/kg subcutaneously) during development. Lines connect the basal and peak responses in control children. The responses are related to bone age in children and chronologic age in adults. Note the biphasic pattern of the responses. They are high in infancy, lower in mid-childhood, and rise again during puberty. The peak gonadotropin responses occur at approximately 4 hours, and peak estradiol responses occur at 20 hours. FSH, follicle-stimulating hormone; LH, luteinizing hormone. (From Rosenfield, R. L., Burstein, S., Cuttler, L., et al. (1989). Use of nafarelin for testing pituitary-ovarian function. *J Reprod Med, 34*, 1044.)

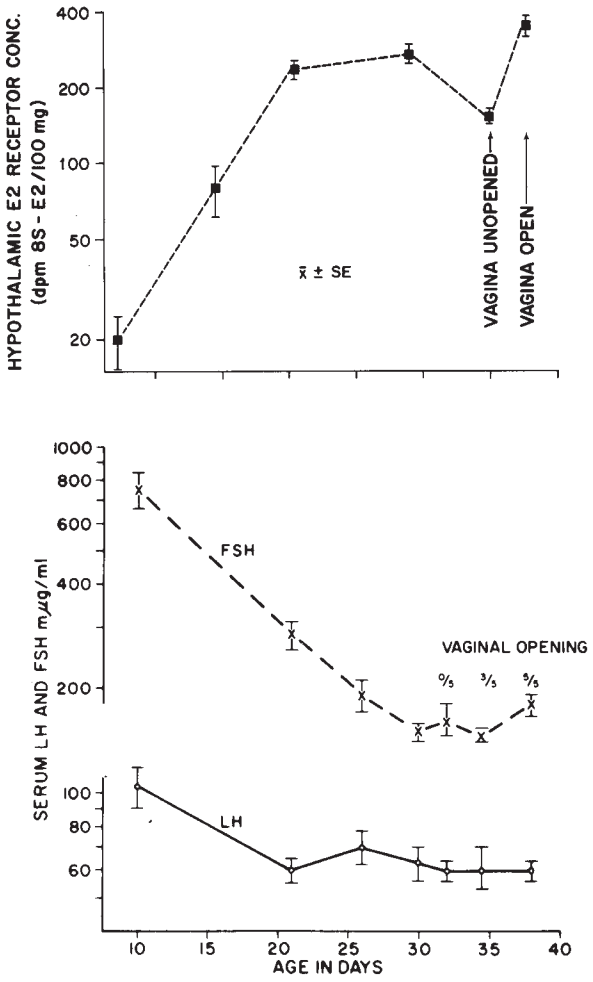

FIGURE 15-7 ■ Relationship of maturation of hypothalamic estrogen receptors (top) to serum gonadotropin levels (bottom) in the developing female rat. FSH, follicle-stimulating hormone; LH, luteinizing hormone. (From Rosenfield, R. L. [1977]. Hormonal events and disorders of puberty. In J. R. Givens (Ed.), *Gynecologic endocrinology*. Chicago: Year Book Medical. By permission of Mosby-Year Book.)

from lack of GnRH stimulation. Furthermore, at this stage agonadism is seldom reflected in a rise in serum gonadotropins or gonadotropin reserve.[60]

However, gonadotropin production is not completely suppressed in mid-childhood. Gonadotropins have been detected in the urine of young prepubertal children, at the limits of sensitivity of classic bioassays: LH excretion averaged 3% and FSH 15% of the adult amounts.[66] Specific monoclonal antibody-based assays have revealed that LH falls to less than 0.2 U/L during the day, whereas FSH remains detectable, and that the gonadotropins produced at this stage are secreted in micropulses that approximately double in association with sleep.[67] The gonadotropins also appear to be bioactive judging from their sensitivity to E2 negative feedback in the primate[68] and the active formation of antral follicles during childhood, which indicates gonadotropin stimulation, as discussed in the following section on the adult.

Between 7 and 10 years of age, even prepubertal girls experience subtle but significant increases in gonadotropin levels.[69] This change corresponds with rising secretion of GnRH.[63] These data indicate that the hormonal secretory pattern of the prepubertal 10-year old child is different from that of the 7-year old and indicate that the hormonal changes signaling the development of puberty are found late in the first decade of life, antedating by some time the development of secondary sex characteristics.

Ovary. The ovary of the infant and child is not quiescent. Initiation of growth and development of resting follicles occurs throughout childhood. The neonatal ovary typically contain an antral follicle with thecal luteinization,[70,71] and the number of antral follicles approximately doubles over that in infancy by 7 years and quadruples by 9 years (see Figure 15-3).[28] All these antral follicles normally undergo atresia in childhood, and this augments the amount of stroma.[28] As a result, by mid-childhood the ovaries of normal girls have up to 5 antral follicles 4 to 9 mm in diameter, and ovarian volume increases up to approximately 3.5 cc. Ovarian morphologic development begins to accelerate just before the onset of puberty.[28,72-76] Small follicle growth is reflected in serum anti-Müllerian hormone (AMH), which achieves adult levels by the time puberty begins.[77]

During the first few months of life, early pubertal blood levels of ovarian hormones are found as part of the transient activation of the hypothalamic-pituitary-gonadal axis that occurs in the newborn. Serum E2 and inhibin-B levels parallel those of FSH. In the neonatal period they begin rising to early pubertal levels, remain there for the first few months of life, and fall gradually thereafter (Figure 15-8).[56,59] In premature infants ovarian function is delayed until near term gestational age, and it is then exaggerated and prolonged.[18] The high gonadotropins of prematurity sometimes cause ovarian hyperstimulation in preterm infants.[78] Breast diameter peaks at 2 to 4 weeks of age in term infants, later in premature infants, and commonly persists for several months.[79] According to an ultrasensitive recombinant

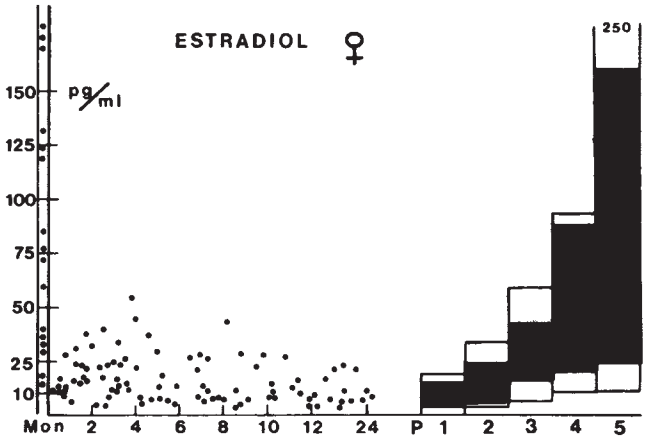

FIGURE 15-8 ■ The distribution of plasma estradiol levels in infant females compared with pubertal and adult female levels. The columns represent the normal ranges for the various stages of puberty. The area between 10th and 90th percentiles is dark. Stage P1 includes all prepubertal girls older than 2 years. The values between the ordinates were found between 2 and 5 days of age. (From Bidlingmeier, F., & Knorr, D. (1978). Oestrogens: physiological and clinical aspects. *Pediatr Adolesc Endocrinol, 4,* 43.)

cell bioassay, girls' estrogen levels in late infancy are several-fold greater than those of boys, averaging 1 pg/mL and ranging up to 3 pg/mL.[80] On occasion there may be subclinical but detectable estrogen effects on urogenital cytology.[81]

In mid-childhood, gonadotropin secretion in response to GnRH agonist testing elicits a prompt small rise in E2 secretion.[82,83] As girls begin to experience increasing diurnal production of gonadotropins in late prepuberty, E2 levels rise in diurnal fashion to approximate 10 pg/mL in midmorning.[69,84]

Adolescent

The endocrinologic changes of puberty actually begin in late preadolescence before secondary sex characteristics appear, as just reviewed. The underlying basic event is increasing secretion of hypothalamic GnRH. Puberty is the consequence of the hypothalamus releasing GnRH with increasing frequency and amplitude, first only at night, then gradually throughout the day.

Increased GnRH secretion in humans was initially deduced when Kastin, Job, Grumbach, and their collaborators demonstrated that preadolescent children had GnRH-releasable pituitary stores of LH and FSH (Figure 15-9; see Figure 15-6).[85] Subsequently, it was

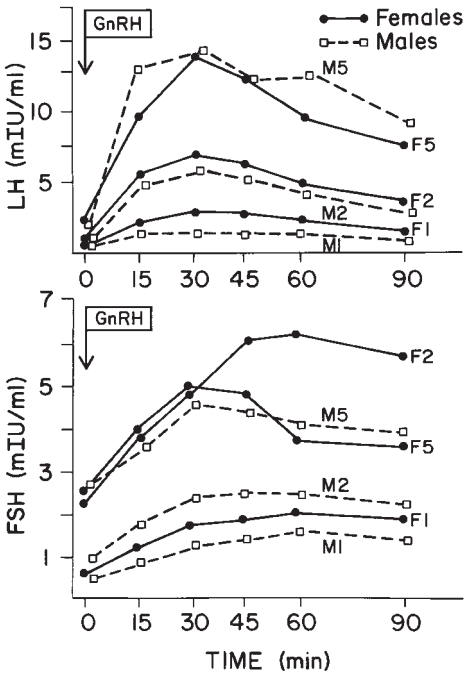

FIGURE 15-9 ■ The luteinizing hormone (LH) and follicle-stimulating hormone (FSH) responses to gonadotropin-releasing hormone (GnRH) bolus (50 μg/kg/day) in males (M) and females (F) in prepuberty (age 5 to 6 years: F1, M1), early puberty (F2, M2), and later puberty (F5, M5). The responses to GnRH tend to progress with advancing puberty. However, early pubertal girls have a readily releasable FSH pool that is greater than that of more advanced adolescents. The peak responses of girls tend to be somewhat greater than those of boys at comparable stages. (Data from Dickerman, Z., Prager-Lewin, R., & Laron, Z. (1976). Response of plasma LH and FSH to synthetic LHRH in children at various pubertal stages. *Am J Dis Child, 130,* 634.)

reported that in humans the output of an immunoreactive fragment of GnRH increases to adult levels during puberty.[63,86] Studies in the rat suggest that hypothalamic GnRH increases through puberty.[87]

Knobil subsequently showed that puberty can be induced in the immature female rhesus monkey by administering GnRH in hourly pulses that yield blood levels of about 2000 pg/mL.[88] Prolonged administration of GnRH according to this regimen first gradually brings about transient increases in LH and FSH. This then induces cyclic follicular development. The resultant moderate E2 surge is of such magnitude as to result in menarche due to withdrawal menstrual bleeding in an anovulatory cycle (Figure 15-10). Continuation of the same GnRH regimen leads to the development of normal monthly ovulatory menstrual periods. Physiologic pulses of GnRH in humans probably attain lower concentrations (200 pg/mL) and occur at slightly wider intervals than in monkeys.[89] Consequently, LH pulses in mature women occur at intervals of approximately 1 to 1.5 hour during the follicular phases, slowing during the luteal phase.[90]

Puberty begins when GnRH secretion increases. Serum LH then begins to rise disproportionately to FSH; this LH-FSH disparity is particularly evident during sleep, which is reflected in responses to GnRH or GnRH agonist (Table 15-1). Puberty becomes clinically apparent as thelarche when E2 levels are sustained $>$ 10 pg/mL.[83] It seems likely that a rise in inhibin-B as increasing ovarian follicles develop plays a key negative-feedback role in limiting further increase in FSH levels during puberty. FSH levels become less GnRH dependent during puberty.[67] The mechanisms for differential regulation of FSH and LH are discussed later in this chapter.

Pubertal gonadotropin cycles seem to develop well before menarche[7,91] and are capable of inducing cyclic estrogen production.[81,91] Our working model of the nature of pituitary-ovarian dynamics in early puberty is illustrated in Figure 15-11.

Puberty progresses as LH rises. Whereas serum FSH levels rise about 2.5-fold over the course of puberty, LH levels rise 25-fold or more.[67] The initial change in LH secretion at the beginning of puberty is a nightly increase in LH secretion that begins within 20 minutes of the onset of sleep. Subsequently, LH increases more with the onset of sleep, stays up longer, and falls less during waking hours. As the child approaches menarche, the daytime LH levels continue to increase until the diurnal rhythm is typically lost. FSH levels follow a similar pattern, although the FSH changes are less striking. The gonadotropin diurnal rhythm during puberty seems entirely related to sleep, unlike the cortisol circadian rhythm.[92] There is a delay of about 12 hours between the peak LH level during sleep and the E2 zenith, such that E2 levels are maximal between late morning and early afternoon.[84,93] The gonadotropin and E2 rhythms in an early pubertal girl are shown in Figure 15-12.[93]

Augmentation of the bioactivity of serum LH occurs during pubertal progression. Plasma LH bioactivity rises nearly fivefold more during the course of puberty than does LH as measured by polyclonal RIA (Figure 15-13).[94,95]

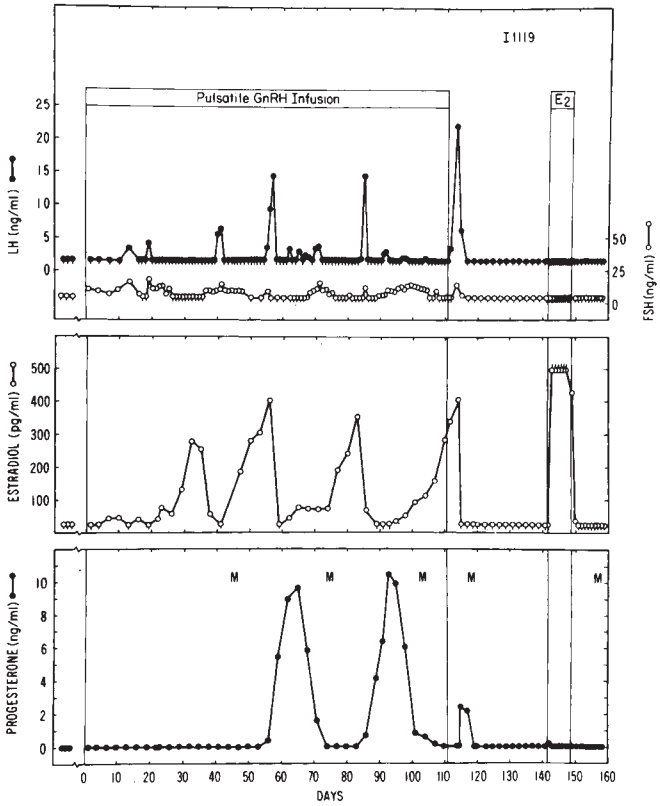

FIGURE 15-10 ■ Induction of puberty in a 13-month-old prepubertal rhesus monkey by an unvarying pulsatile gonadotropin-releasing hormone (GnRH) regimen (1 μg/min × 6 min hourly). Luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol (E2), and progesterone were undetectable before the GnRH infusion. On GnRH infusion, a rise in FSH was the first change detectable by midmorning sampling midway between GnRH pulses. A substantial E2 surge occurred approximately 1 month later. The subsequent LH surge was too modest to elicit ovulation, but menses (M) occurred a few days after subsidence of the week-long E2 surge—menarche resulting from an anovulatory cycle. Continuation of the GnRH led to the sustained occurrence of ovulatory menstrual cycles at 28-day intervals. An identical outcome results if an arcuate-lesioned adult animal undergoes this GnRH regimen. The third of the LH surges occurred 2 days after GnRH was discontinued. Progesterone secretion from the corpus luteum was blunted and transient in the absence of sustained LH secretion. A subsequent increase in plasma E2 produced by E2 implantation subcutaneously failed to elicit a gonadotropin surge, indicating that the animal had reverted to an immature state. Menarche eventually spontaneously recurred in such animals at the usual age (approximately 27 months). Small vertical lines beneath data points indicate values below the sensitivity of the assay. Note that gonadotropins and E2 were often undetectable (prepubertal range) during the induced puberty. (From Knobil, E. (1980). The neuroendocrine control of the menstrual cycle. *Recent Prog Horm Res, 36*, 53.)

The change in bioactive LH is mirrored well by the "third generation" monoclonal antibody-based immunometric ("pediatric") assays that have very high specificity for bioactive LH epitopes. However, disparities in the ratio of bioactive to immunoreactive LH (B/I) persist with these assays, for reasons related to the molecular microheterogeneity of gonadotropins, which is discussed later. Serum FSH rises during puberty according to immunoassay more so than by bioassay.[96]

E2 output increases rapidly in the year approaching menarche.[97] This seems to be the result of a variety of autoamplification phenomena that facilitate puberty, maturation of the dominant follicle, and ovulation. These are summarized in Box 15-1.[98-111] These phenomena occur at all levels of the axis. The CNS is stimulated by preovulatory levels of E2 to increase GnRH pulse amplitude. At the pituitary level there is the self-priming effect of GnRH, whereby a pulse of GnRH sensitizes the pituitary to have a greater LH response to a subsequent identical GnRH pulse. Critical patterns of E2 and progesterone secretion enhance the pituitary LH and FSH responsiveness to GnRH. At the gonadal level, the cascade of events is augmented by the FSH induction of aromatase activity and progestin production in granulosa cells, phenomena in which androgens play a synergistic role. Furthermore, FSH stimulates granulosa cell mitosis and induces LH receptors, phenomena in which E2 may play a synergistic role. Subsequently, LH is able to further enhance the aromatase and progesterone effects. Progesterone itself plays a synergistic role in stimulating granulosa cell progesterone and prostaglandin synthesis in concert with both FSH and LH. In the rat, ovarian GnRH receptor sites also diminish just before ovulation,[112] and at about this time the ovary changes its pattern of metabolism so that the secretion of androstanediol-3β-monosulfate decreases to levels that are no longer inhibitory to LH secretion.[113]

The preovulatory gonadotropin surge occurs when all these cascading processes culminate in activation of

BOX 15-1 Autoamplification Processes Involved in Pubertal Progression, Follicle Maturation, and Ovulation

Central nervous system GnRH secretion increases[98,99] via the following:
- E2-induced progesterone receptors[100]
- Progesterone synergization with E2[101]

Pituitary LH and FSH responsiveness to GnRH increases via:
- GnRH self-priming[102]
- Critical patterns of E2 secretion-stimulating LH/FSH responsiveness[103-105]
- Progesterone synergization with E2[104-106]
- LH bioactivity increases[94]

Gonadal responsiveness to FSH and LH increases via:
- FSH-induced aromatase and progesterone in granulosa cells: androgens and progesterone synergization with this effect[107-109]
- FSH-stimulated granulosa meiosis[31]and FSH-induced granulosa LH receptors; IGF-1 synergization[110,111]

E2, estradiol; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; IGF-1, insulin-like growth factor-1; and LH, luteinizing hormone.

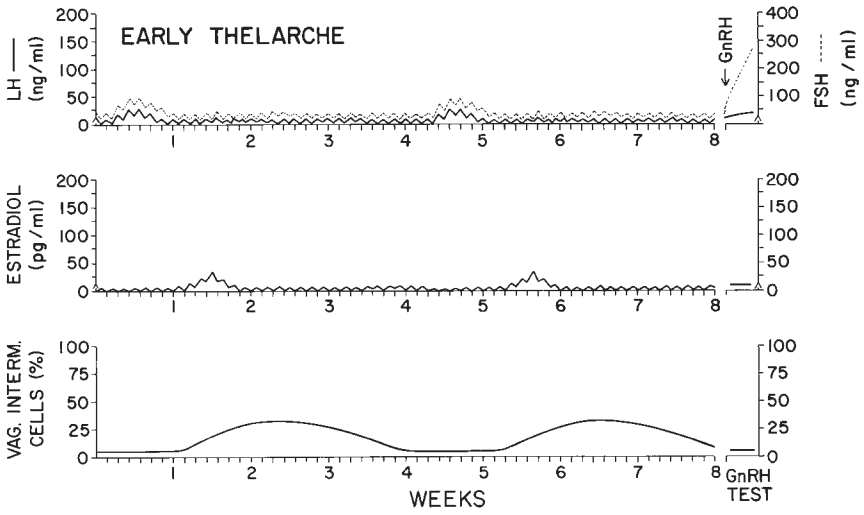

FIGURE 15-11 ■ Diagram depicting our working hypothesis of the hormonal patterns in girls during very early puberty. We conceptualize this pattern as occurring both cyclically in the earliest stage of normal puberty and occasionally in unsustained sexual precocity (i.e., most U.S. cases of idiopathic premature thelarche). Daytime and nighttime serum concentrations of hormones (gonadotropins relative to the LER-907 standard) and the percentage of intermediate cells on vaginal smear are shown. The typical response to a gonadotropin-releasing hormone (GnRH) test is illustrated. Subclinical hormonal cycles lasting approximately 1 month result from a few days of increased follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion. Because the drive to gonadotropin release is relatively weak, FSH and LH production are suppressed promptly and for long periods of time by the resultant modest amounts of estradiol (E2) secretion. Estradiol is detectable in plasma for only a few days a month. Maturation of the vaginal mucosa, however, is detectable for approximately 2 weeks after E2 production has waned.

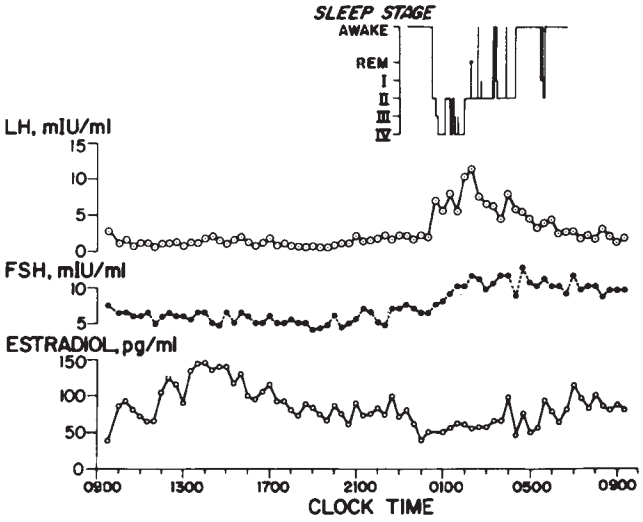

FIGURE 15-12 ■ The patterns of serum luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol (E2) typical of early female puberty. Note that daytime gonadotropin levels are in the prepubertal range. Note also the episodic nature of LH release at intervals of 1 to 3 hours. Estradiol levels are seen to fluctuate considerably in the course of the daytime, rising to peak levels about 12 hours after the maximum nocturnal gonadotropin surges. (From Boyar, R. M., Wu, R. H. K., Roffwarg, H., et al. (1976). Human puberty: 24-hour estradiol patterns in pubertal girls. *J Clin Endocrinol Metab*, *43*, 1418.)

the positive feedback mechanism, the hallmark of sexual maturity in the female. "Positive feedback" refers to the neuroendocrine system acquiring the ability to secrete a midcycle surge of LH when the ovary signals via increasing estrogen secretion that it is prepared for ovulation.

Menarche does not necessarily indicate full maturation of the neuroendocrine-ovarian axis. As the studies of Knobil illustrate (see Figure 15-10), menarche can be due to estrogen-withdrawal bleeding—and it is about half of the time—but ovulatory cycles may follow in short order. General characteristics of the mature ovary are shown in Figure 15-4.

The morphology of the normal adolescent ovary has long been considered polycystic, and histologic examination typically has shown thecal luteinization.[70,114] In the perimenarcheal period, the combination of a high number of follicles and mature gonadotropin stimulation leads to a greater number of large antral follicles than at any other stage (see Figure 15-3),[27] which often leads to a "multifollicular" ultrasonographic appearance.[72,115,116] By 1 year after menarche, at approximately 14 years of age, the ovaries normally achieve adult functional and anatomic characteristics. Many exceed normal adult ultrasonographic size or follicle count criteria, the largest reaching approximately a volume of 10.8 to 11.8 mL with 10-17 small (2-9 mm) antral follicles in the maximum plane.[73,116-119] Thus, many eumenorrheic normal postmenarcheal adolescents meet current ultrasonographic criteria for polycystic ovary morphology (see the "polycystic ovary syndrome" section),[120] often transiently.[121]

Adult

The follicular phase of each menstrual cycle recapitulates puberty in many respects. Gonadotropin and sex hormone levels are low during the premenstrual phase of the mature cycle (Figure 15-14A).[122,123] Gonadotropin concentrations then increase at the time of menstruation, FSH predominating in the early follicular phase while nocturnal LH pulsation is slow[124] (Figure 15-14B). Luteinizing hormone pulsation increases to a circhoral pattern around a stable baseline, and E2 production slowly begins as antral follicles

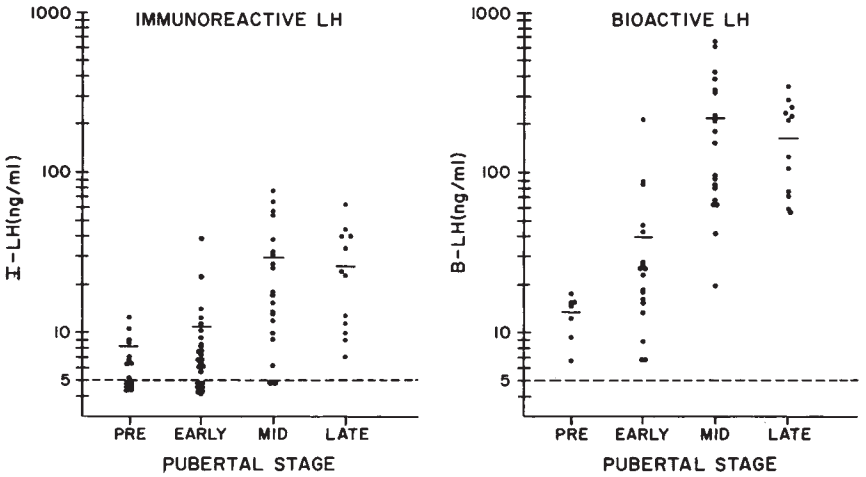

FIGURE 15-13 ■ Bioactive luteinizing hormone (B-LH) (right) and immunoreactive LH (I-LH) (left) in the same daytime serum samples of girls 10 to 16 years of age at various pubertal stages. The dashed lines indicate the limit of sensitivity of the assays. B-LH rises relatively more than I-LH in the course of puberty. The peak in the apparent biopotency of LH, estimated from the ratio of B-LH to I-LH, occurs at about the time of menarche. Late indicates early follicular phase normally menstruating postmenarcheal girls. Standard LER-907: 100 ng equivalent to 6 mIU LH of First International Reference Preparation (IRP) of human pituitary gonadotropin. The disparity between immunoreactivity and bioactivity is principally due to the presence of different proportions of immunoreactive and bioactive LH moieties in serum and standards. The ratio of bioactivity to immunoreactivity is closer to unity when sera are assayed against highly purified standards (like the first and second IRP of human luteinizing hormone), which have about fivefold higher specific activity and yield dose response relationships with serum LH that are more linear. (Data from Lucky, A. W., Rich, B. H., Rosenfield, R. L., et al. (1980). LH bioactivity increases more than immunoreactivity during puberty. *J Pediatr*, *97*, 205; Rosenfield, R. L., Helke, J. (1992). Is an immunoassay available for the measurement of bioactive LH in serum? *J Androl*, *13*, 1.)

develop (Figure 15-14C). E2 levels gradually increase and serum FSH levels fall reciprocally (Figure 15-14D). Upon formation of a dominant follicle, serum E2 concentrations increase geometrically. This selectively begins to amplify the pituitary's LH response to GnRH as E2 reaches about 90 pg/mL for over 3 days[104,105,125] (Figure 15-14E).

When the serum estradiol rises to over 200 to 300 pg/mL for 36 hours, the positive feedback mechanism is activated and the midcycle gonadotropin surge commences (Figure 15-14F). E2 then appears to induce progesterone receptor (PR) expression in the hypothalamus and pituitary.[126] An increase in progesterone to 100 ng/dL facilitates the LH surge, shortens the duration of time over which E2 is required for the surge to 24 hours, and brings about an FSH surge. The mechanism of progesterone action involves inhibition of GnRH cleavage.[106] Androgens may also play a role in facilitating FSH and GnRH release.[127,128] The LH surge is then primarily responsible for luteinizing the preovulatory ovarian follicle (see Figure 15-14F). At this time, LH pulses become larger in amplitude but slower in frequency and their apparent bioactivity increases. Ovulation then results.

As the follicle is disrupted by ovulation, estrogen levels fall (Figure 15-14G). As the corpus luteum begins to form, progesterone increases steadily to be sustained at very high levels for several days, along with lesser but substantial increases in E2 and 17-hydroxyprogesterone levels.[122,123,129] In response to the high progesterone level, LH pulses become slow and large.[124,129] In the absence of increasing human chorionic gonadotropin (hCG) from a conceptus, the corpus luteum's life span is exhausted and its production of progesterone and E2 wanes. Subsequently, FSH begins to rise out of

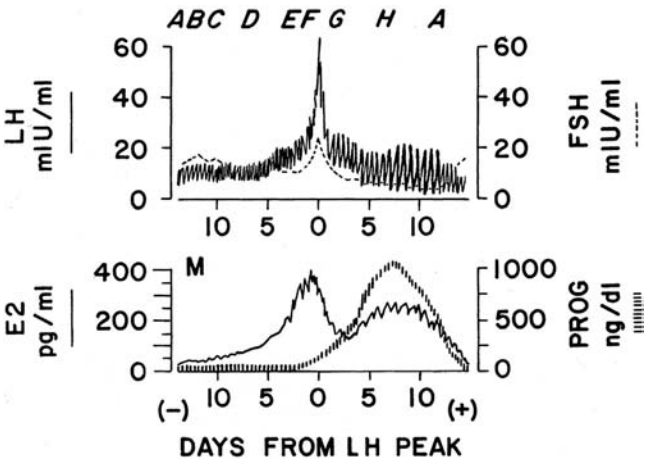

FIGURE 15-14 ■ Diagram of gonadotropin and female hormone levels during the normal menstrual cycle. The levels are centered in reference to the day of the midcycle luteinizing hormone (LH) peak (day 0). Letters A through F above the top panel correspond to stages of follicular development in Figure 15-15. G and H are discussed in the text. M (bottom panel) shows time of menses. E2, estradiol; FSH, follicle-stimulating hormone; PROG, progesterone. (Based on data of Abraham, G. E. (1974). proportion to LH. Shortly after the sex steroids withdraw from the scene, the endometrium sloughs, giving rise to menstrual flow. Meanwhile, the follicular growth induced earlier by FSH begins to gain momentum and the next cycle begins.

Follicular (Proliferative) Phase Ovary. The hormonal functions of the follicle have dual purposes that must be closely coordinated: to change the milieu of the ovum to prepare for ovulation and to signal the pituitary to send the signal to ovulate (i.e., the LH surge). Thus, the ovary is the zeitgeber for the cycle: the normal cyclic pattern of ovarian hormone secretion induces the midcycle surge of pituitary gonadotropins, even in the presence of unchanging circhoral pulses of GnRH.[88] Ovarian hormones also augment the amplitude of the GnRH response,[98-101] which is a fail-safe mechanism that "guarantees" a preovulatory gonadotropin surge.

Ovarian follicular development and steroid secretion in relationship to changing gonadotropin levels are illustrated in Figure 15-15.[31,130-132] FSH and LH play major roles in granulosa and thecal cell differentiation, respectively, whereas a host of local factors modulate gonadotropin action. For example, follicular maturation in response to gonadotropins is enhanced by insulin-like growth factors (IGFs), transforming growth factor (TGF)-β and fibroblast growth factor, whereas it is inhibited by TGF-α, epidermal growth factor, and other factors.

Primordial follicle growth and development is gonadotropin independent. Subsequently, granulosa cells of preantral follicles develop FSH receptors, and theca cells, which encircle granulosa cells, develop LH receptors (Figure 15-15A). Activin causes FSH-independent up-regulation of FSH receptors in preantral follicles,[111] although it opposes FSH stimulation of antral follicle development.[31] Primordial follicle growth is constitutively repressed by nuclear forkhead transcription factor Foxo3; when Foxo3 is released in response to stimulation of the PTEN-PI3K-Akt pathway, follicular growth progresses to the point where follicles become responsive to FSH.[133]

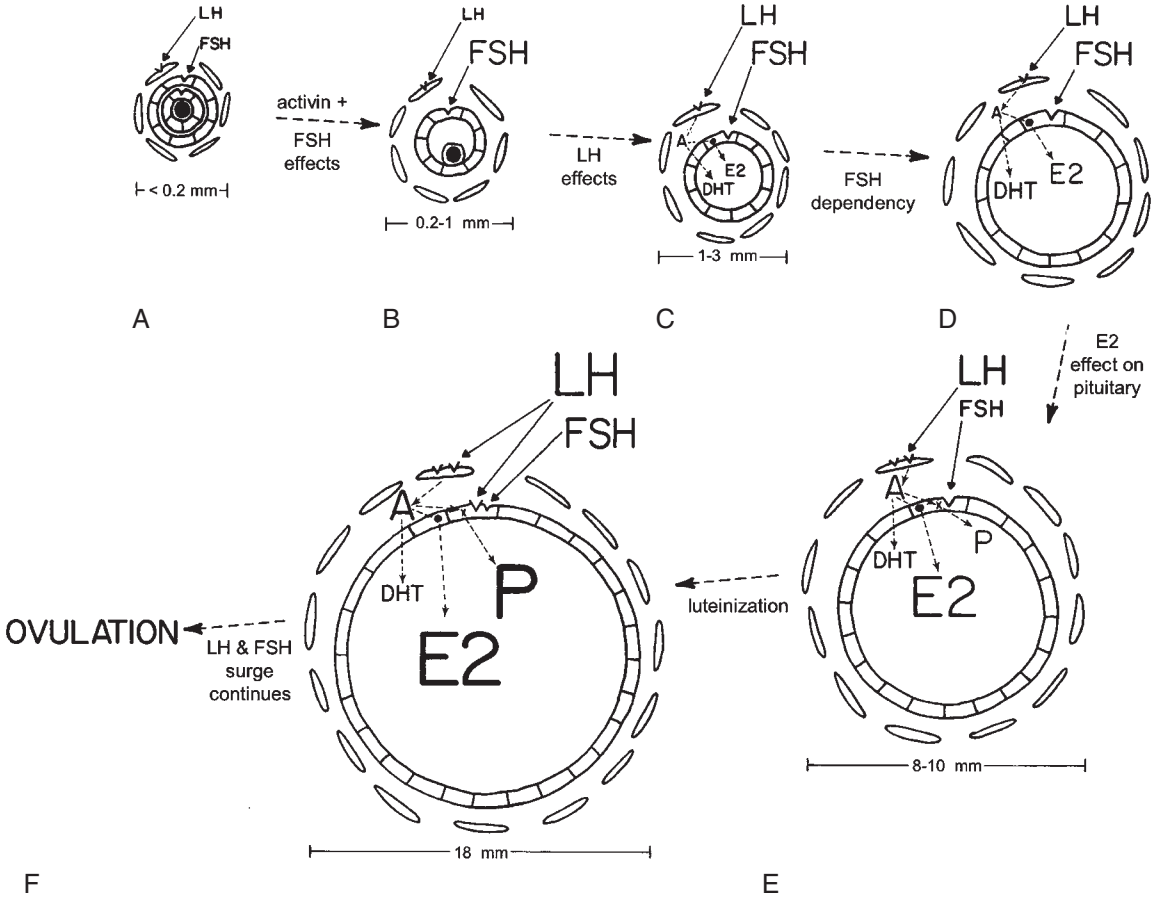

FIGURE 15-15 ■ Relationships among gonadotropins, the ovarian follicle, and ovarian steroids according to the two-cell two-gonadotropin model of ovarian steroidogenesis. **A** through **F,** Stages of ovarian follicular development found during the times of the menstrual cycle designated by the corresponding letters on Figure 15-14. The size of the letters designating hormones relates to the magnitude of their serum and/or follicular concentrations. **A,** Preantral follicle with luteinizing hormone (LH) and follicle-stimulating hormone (FSH) receptors in theca and granulosa cells, respectively. There is no antrum surrounding the ovum (stippled in center). **B,** Small antral follicle. Activin up-regulates FSH receptors, and the FSH receptor activation is required to initiate antrum formation. **C,** Large antral follicle (1 mm or larger). Aromatase activity (.) has been induced in granulosa cells. Interactions between theca and granulosa cells, the former producing androgens (androstenedione: A), result in increasing estradiol (E2) and dihydrotestosterone (DHT) synthesis. **D,** FSH-dependent follicular growth results in more E2 synthesis. **E,** Estradiol enhances pituitary LH secretion in response to GnRH, while at the same time inhibiting pituitary FSH secretion. The increased LH induces more theca LH receptors and stimulates androgen production. Androgens serve as substrate for E2 formation and synergize with FSH to stimulate progesterone (P) secretion, initiating luteinization of granulosa cells. **F,** In the preovulatory follicle, FSH induces LH receptors on the granulosa cell—which completes luteinization of granulosa cells. Steroid secretion is augmented further. Then, increasing progesterone amplifies the positive feedback effect of E2 to initiate the preovulatory gonadotropin surge.

Antrum formation requires a trace (prepubertal) amount of FSH receptor activation (Figure 15-15B).[31,134-137] FSH stimulates androgen receptor expression in primary follicles, and androgens in turn stimulate further expression of FSH receptors and the early stages of follicular growth.[138] Androgen action is also necessary for the development of a full complement of follicles, and androgen excess stimulates excessive follicle number.[139,140] Luteinizing hormone stimulates the appearance in thecal cells of the enzymes necessary for androgen biosynthesis.[141] Evidence that theca cells of small antral follicles form E2 is meager.[142]

As antral follicles grow over 2.5 mm diameter, their granulosa cells begin to form E2 from androgen supplied by theca cells (Figure 15-15C).[143-147] Androgen production at low levels may synergize with FSH to stimulate aromatase activity within the granulosa cells.[107,148,149]

At this stage, follicles are increasingly FSH dependent and are consequently uniformly FSH responsive.[31,134] IGF-1 is required for follicular growth beyond the early antral stage in response to FSH.[150] Antral follicles do not grow over 5 mm in diameter without a pubertal degree of FSH stimulation.[136] By the midfollicular phase, the proliferation of FSH-responsive granulosa cells results in an accelerating rate of E2 production and preferential conversion of androstenedione to E2 rather than DHT by these cells (Figure 15-l5D).[143-145,147,151,152] Estradiol itself clearly stimulates proliferation of granulosa cells and oocyte survival in rodents.[153] In humans, E2 appears to promote antral growth independently of LH[154] and is synergistic with FSH in bringing about the development of the dominant follicle.[155,156]

A dominant follicle is selected at the beginning of the menstrual cycle from a crop of follicles that were recruited 2.5 months prior.[31] Recruitment of a group of follicles is normally promoted by the midcycle FSH surge and regresses with increasing corpus luteum progesterone secretion. Another wave of follicle growth in the late luteal phase is promoted by the rise of FSH as luteal progesterone and E2 secretion wanes. The selected follicle is the one that is the most sensitive to FSH (lowest "FSH threshold"). FSH is critically important during the follicular phase for optimal development of this dominant follicle. By the midfollicular phase of the cycle this follicle becomes virtually the sole source of E2 (Figure 15-15E). Typically, there is only one such follicle. Only this follicle continues to grow so as to reach a diameter of 10 mm or more. All other gonadotropin-dependent follicles undergo atresia.

At this stage the rising E2 level is suppressing FSH secretion and augmenting pituitary LH responsiveness to GnRH. FSH is more bioactive in the dominant follicle because it is more efficiently concentrated[151] and because local factors increase ovarian responsiveness to FSH. The increased LH causes further proliferation of thecal cells and an increase in their LH receptor content.[108] Consequently, androgen production increases. This synergizes with FSH to both augment aromatase activity and bring about increasing progesterone secretion by the well-estrogenized granulosa cells of these follicles. Progesterone then enhances the synthesis of both itself and E2.[108,110] The increased thecal androstenedione production is diverted much more to E2 than to dihydrotestosterone biosynthesis. Antral fluid steroid concentrations reflect these changes (Figure 15-16).[143,144,151] Activin acts so as to prevent premature luteinization of granulosa cells, and activin tone seems to wane as the preovulatory phase approaches.[31,111]

FSH next induces LH receptors in the granulosa cells (Figure 15-15F).[110] These luteinized granulosa cells are capable of augmenting E2 and progestin production in response to LH as well as FSH.

The LH and FSH surge then occurs in response to the positive feedback action of E2 at both the CNS and pituitary levels, an effect amplified by the rising levels of progesterone. The final steps in follicle maturation ensue rapidly: the LH surge induces granulosa cell PR and prostaglandin synthase while inhibiting cyclin gene transcription,[24,157] and the FSH surge up-regulates vascular endothelial growth factor.[158] In the absence of these critical steps, ovulation and follicular rupture do not occur. Then the follicle promptly becomes desensitized to LH and FSH and ceases to grow.[159] This is followed by

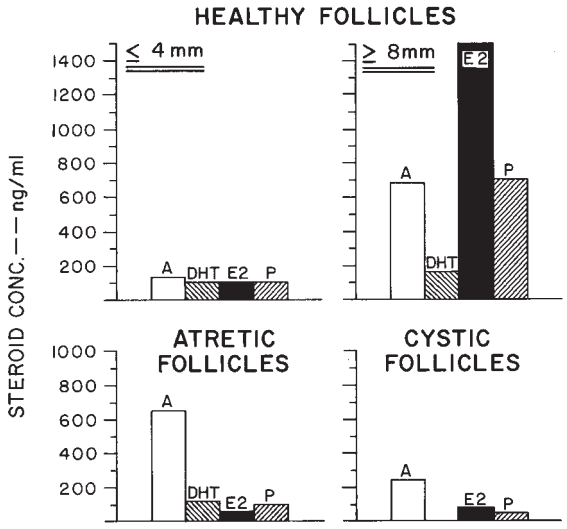

FIGURE 15-16 ■ Normal human antral fluid steroid concentrations. Healthy follicles are well populated by granulosa cells (50% or more of maximal complement). Healthy follicles seem capable of further development because many of them (75%) contain healthy-appearing oocytes (histologically intact germinal vesicles), 96% of which are viable in culture. Moderately large follicles (8 mm or larger in diameter) make their appearance only in the midfollicular phase of the cycle and contain follicle-stimulating hormone. Data are shown only for those large follicles well populated by granulosa cells, only one of which usually arises in the follicular phase of each menstrual cycle. Atretic follicles are small follicles beginning to show degenerative changes in the number of granulosa cells and appearance of the oocyte. Cystic follicles tend to be larger follicles with only a sparse granulosa cell lining. The testosterone content of antral fluid is about a third that of dihydrotestosterone (DHT) owing to the pattern of granulosa cell metabolism of androstenedione (A). E2, estradiol; P, progesterone. (Interpolation based on the data of McNatty, K. P., Makris, A., Reinhold, V. N., et al. (1979). Steroids, 34, 429; McNatty, K. P., Smith, D. M., Makris, A., et al. (1979). The microenvironment of the human antral follicle: interrelationships among the steroid levels in antral fluid, the population of granulosa cells, and the status of the oocyte in vivo and in vitro. *J Clin Endocrinol Metab, 49*, 851.)

an inflammatory-type response. Protease activity, prostaglandin production, and vascular permeability increase, cell junctions loosen, and cumulus cells form a mucopolysaccharide envelope around the oocyte (cumulus expansion).

Oocyte meiotic maturation resumes in response to a specific phosphodiesterase,[160] forming the haploid gamete (secondary oocyte) and the first polar body in response to the LH surge.[161] Ovulation of the cumulus-oocyte complex then occurs. The presence of a favorable follicular steroidal milieu is necessary both for ovulation (a premature LH surge in a subject with an unripe follicle will not result in ovulation) and subsequent developmental competence of the oocyte.[162,163] Meiosis will complete and the second polar body will be extruded only in response to contact with a sperm.

The processes stimulating dominant follicle emergence are delicately balanced by those preventing it. It seems critical that the intraovarian concentration of androgens not become excessive or no follicles will remain viable beyond about the 8-mm stage.[145] Androgen excess seems to prevent the emergence of dominant follicles by antagonizing granulosa cell proliferation and development.[164] The mechanisms involved include inhibition of aromatase in situations of low FSH activity[107,148] and antagonism of LH receptor formation and action.[109,165] Follicles arrested in their growth become atretic, and atretic follicles contain relatively high concentrations of androgens (see Figure 15-16). Progesterone also suppresses further differentiation of nondominant follicles[166] by some of the same mechanisms.[167] High concentrations of estrogen play a critical role in inhibiting selection of the dominant follicles in primates.[168] If there is interference with estrogenization, multiple large cystic follicles develop that are impaired in their ability to ovulate and undergo androgen-dependent atresia.[169-171]

AMH and inhibins have emerged as other follicular factors important in the direct and indirect regulation of follicular development. Granulosa cells of preantral and small antral follicles produce AMH, which regulates growth of follicles by exerting a paracrine negative feedback effect on the recruitment of precursor (primordial) follicles and inhibits aromatase activity.[172,173] AMH levels do not fluctuate during the normal menstrual cycle[174] but are indirectly inhibited by FSH during ovulation induction in response to estradiol produced by large antral follicles.[175] AMH serum levels index the size of the oocyte pool ("ovarian reserve") and gradually fall from young adulthood to become undetectable after menopause.[176] Granulosa cells also produce inhibins, which are regulated by FSH in a negative feedback loop and up-regulate thecal steroidogenesis, as discussed later: inhibin-B is the predominant form of inhibin: inhibin-A is a product of the preovulatory follicle (and corpus luteum) that responds to both LH and FSH.[177,178]

Atresia is the fate of all except the few hundred follicles chosen for ovulation during an individual's life span. Most follicles beyond the primordial stage become atretic. Atresia occurs by the process of programmed cell death.[31] This apoptotic process has diverse determinants, including cell death inducer and repressor genes.[39,132] FSH support becomes increasingly necessary for survival as the follicle matures, and normally only the follicle that has the lowest FSH threshold escapes atresia.

Luteal (Secretory) Phase Ovary. Histologically, luteinization is a process of lipid accumulation and begins as the preovulatory follicle forms. The biochemical hallmark of luteinization is the capacity for progesterone biosynthesis in response to LH; this is accompanied by increased secretion of estrogen and 17-hydroxyprogesterone in man.[179-181] Following ovulatory rupture of the Graafian follicle, capillaries and fibroblasts from the theca proliferate and break down the separating basement membrane. The luteinized granulosa and theca cells then intermingle and complete the luteinization process by forming the corpus luteum.[182]

During its functional life span, the corpus luteum is normally the major source of the sex hormones secreted by the ovary. Corpus luteum function reaches its peak about 4 days after ovulation and begins to wane about 4 days before menstruation (Figure 15-14H). Loss of sensitivity to LH and estradiol heralds luteal senescence. Regression of the corpus luteum—luteolysis—occurs if pregnancy does not provide hCG. Luteolysis is probably mediated by prostaglandin. Transformation of the corpus luteum into an avascular scar, the corpus albicans, then occurs.

Early luteal phase increases in secretion of both E2 and progesterone cause secretory transformation and hyperplasia of the endometrium. A significant rise in basal body temperature, averaging 0.35° C, occurs when serum progesterone reaches an average of 400 ng/dL and continues as long as that level is maintained.[183] Later fall-off in secretion of female hormones to a level insufficient to maintain the endometrium results in menstruation. Withdrawal of progesterone is specifically responsible for constriction of spiral arteries, local prostaglandin accumulation, and subsequent ischemic necrosis of the endometrium. Normal menstrual flow then results from a complete slough of the secretory endometrium.

A major determinant of normal corpus luteum formation and function is optimal development of the corpus luteum predecessor, the dominant follicle. Experimental lowering of FSH levels in the early follicular phase has been shown to impair subsequent corpus luteum function.[184]

Regulation of the Neuroendocrine-Ovarian Axis

Factors Controlling the Onset of Puberty

Pubertal onset is under the control of a complex regulatory network that is able to dynamically respond to numerous endogenous and environmental signals. GnRH neurons play a critical hierarchical role in the direct and indirect integration of these central and peripheral signals. Reproductive development is coupled with metabolic cues that influence the maturational process. The mechanisms by which neuroendocrine and genetic factors control pubertal development remain unknown. Epidemiologic studies indicate that nutrition, ethnicity, and genetic factors are normally important in the pubertal

process.[185] Environmental chemicals and chronic inflammatory disease can disrupt the process.[185-188]

Evidence that there are genetic factors involved at the time of puberty comes from multiple studies.[189-199] It has been estimated that between 50% to 80% of the variation in the timing of puberty is genetically determined. Genes involved in GnRH signaling, pituitary development, hormonal regulation, fatty acid biosynthesis, and energy homeostasis have been implicated.[200-204] Although mutations in these genes have been shown to cause physiologic interruptions in development, their role in the initiation of puberty remains unknown. Specifically, single nucleotide polymorphisms (SNPs) in the GnRH and GnRH receptor genes have not been associated with variations in the timing of puberty in the general population.[205]

The key in the initiation of puberty is the activation of the hypothalamic GnRH pulse generator. The molecular events that control the pulse generator include a complex interplay between both inhibitory and stimulatory factors. The mechanism of central activation of puberty first appears to be a consequence of a removal of a restraint mechanism, with a rise in gonadotropin secretion (initially during sleep).[206] This restraint in the GnRH pulse generator is independent of the presence of gonads[60] and more intense in males.[207] However, the high levels of testosterone to which the male fetus is exposed during the period of sexual differentiation may be responsible for the more prolonged suppression of GnRH release in males than females. A role for decreased estrogen feedback sensitivity by the hypothalamic pulse generator near the time of puberty has also been shown.[208]

Evidence points to an important role for GPR54, a G-protein-coupled receptor, and its ligand, kisspeptin, as a signal for pubertal GnRH release. Expression of both proteins has been found to increase prior to pubertal onset in association with the increase in GnRH pulse generator activity in the hypothalamus.[209] Kisspeptin binding to GPR54 on GnRH neurons stimulates GnRH secretion. Leptin and androgen synergistically up-regulate this system, and estrogen antagonizes it.[210] Mutations in the GPR54 gene result in hypogonadotropic hypogonadism.[201,211,212] However, mutations in GPR54 have not been found in boys with pubertal delay, nor have polymorphic sequences been associated with delay of pubertal development.[213] Elegant studies in primates have demonstrated an increase in kisspeptin during pubertal development with a corresponding increase in GPR54 associated with an increase in LH. The maximum level of expression of kisspeptin and GPR54 in the hypothalamus in both males and females occurs at puberty.[214,215] Chronic administration of kisspeptin to immature female rats induces precocious activation of the central axis.[214] In addition, chronic treatment with kisspeptin restores pubertal development in a rat model of undernutrition.[216] Kisspeptin may thus not only influence the priming of puberty but also the integration of nutritional and energy status.[217] Although it is clear that kisspeptin activation of GnRH neurons occurs at puberty and that GnRH is increasingly sensitive to kisspeptin activation during development,[218,219] other pathways contribute to GnRH activation, as the hypogonadism associated with deficiency of Kiss1 or Gpr54 is not complete.[220]

Neurokinin B signaling seems to be critical for the initiation of puberty.[221] Some kisspeptin neurons coexpress neurokinin B, dynorphin A, and their receptors (TAC3R and KOR), the primary function of which seems to be synchronizing kisspeptin neuron pulsatility.[222] Receptors for neurokinin B are also located on GnRH neurons, where they seem to modulate GnRH release or transport.

Disrupting mutations in makorin ring finger protein 3 (MKRN3), a paternally expressed, imprinted gene located in the Prader-Willi syndrome locus, were discovered to be associated with central precocious puberty.[223] This indicates the presence of a previously unrecognized GnRH release-inhibiting pathway centered in the arcuate nucleus.

Initiation of puberty involves coordinated changes in transsynaptic and glial-neuronal communication.[224] The major inhibitory systems are GABAergic and opioidergic, whereas the major excitatory systems involve glutamate and kisspeptin signaling, with glial cells facilitating GnRH secretion in diverse ways (Figure 15-17).[222,224] It appears that gamma-aminobutyric acid (GABA) receptor signaling develops in advance of glutamate signaling.[225] Increased signaling via glutamate receptors of several types (iontropic and metabotropic) appears to be the major proximate change in neurotransmission involved in puberty onset.[206,207,224] At puberty, however, seemingly as a consequence of glutamate receptor signaling, GABA-A receptor signaling on GnRH neurons increases GnRH secretion.[206,209,226,227] Glial cells facilitate the process through elaboration of transforming growth factors (TGFs), other growth factors, prostaglandin E2, and the elaboration of enzymes that control the concentration of glutamate (glutamic dehydrogenase, which catalyzes the synthesis of glutamate, and glutamine synthase, which converts glutamate to glutamine).

The basis of the change in neurotransmitter balance is becoming clearer. A second tier of control seems to be modulation of these processes by increased hypothalamic expression at puberty of tumor-suppressor genes that integrate glial-neuronal interactions. A yet higher echelon of candidate hypothalamic genes has been identified, made up of transcriptional regulators of the second-tier genes. These genes include Oct-2, a regulator of the POU-domain homeobox genes, EAP1 (enhanced at puberty 1), the knockout of which delays puberty and decreases fertility of mice, thyroid transcription factor I (TTF1), yin yang 1 (YY1), and CUX1.[228] Genes contiguous to elastin appear to be involved in the pace of puberty: deletion of chromosome 7q11.23 in Williams syndrome typically leads to an early normal onset but rapid pace of puberty with an abbreviated pubertal growth spurt.[229] Substantial redundancy of these networks and the signaling neurochemicals exists because the onset of puberty depends on the expression of many genes, likely arranged in a coordinated network. The gene products may function as activators or repressors of targets important for pubertal onset and progression. Sex steroids have been implicated as important modulators in pubertal onset.[225]

Thus, the onset of puberty is controlled by an opposing increase in excitatory and a corresponding decrease

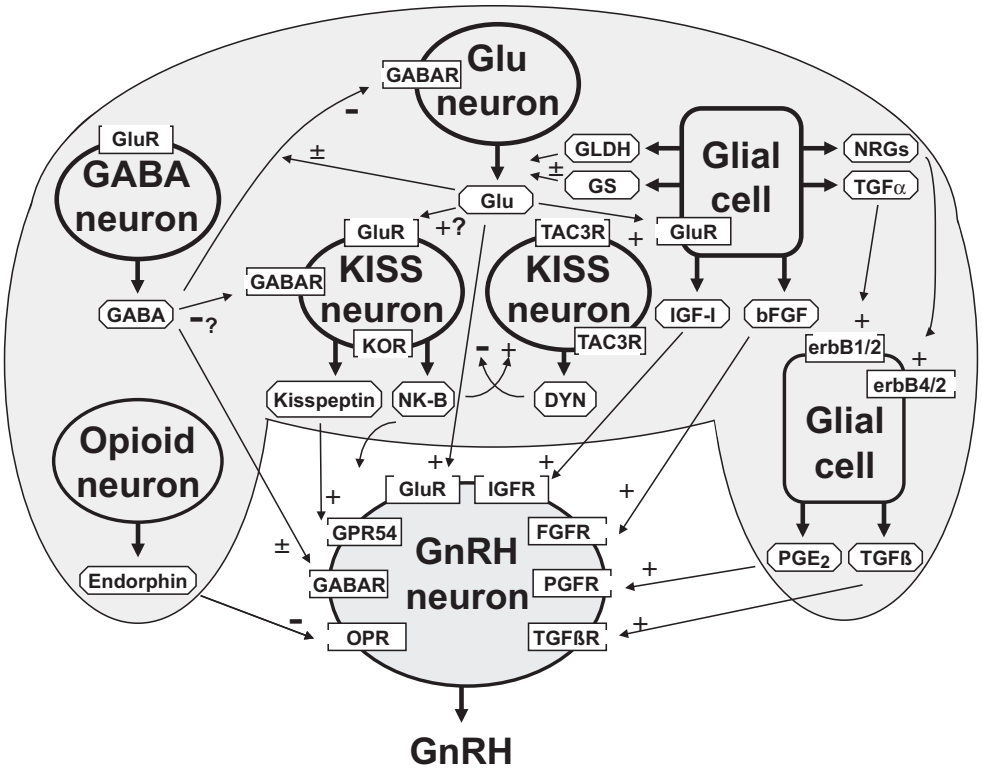

FIGURE 15-17. ■ The molecular biologic basis for the major known proximate hypothalamic pathways regulating GnRH secretion. The left-hand column depicts the major inhibitory pathways, which involve GABA signaling through the GABA receptor and opioidergic signaling through the endorphin receptor (OPR). The central column depicts the major excitatory pathways, which involve glutamate (Glu) signaling through the family of glutamate receptors and kisspeptin (KISS) signaling through GPR54. The right column shows the major glial factors that facilitate GnRH release. These include the elaboration of the enzymes glutamic dehydrogenase (GLDH) and glutamine synthase (GS), which regulate the concentration of glutamate and the elaboration of a variety of growth factors. Most kisspeptin neurons co-express neurokinin B (NKB), dynorphin A (DYN), and their receptors (TAC3R and KOR), the primary function of which seems to be synchronizing kisspeptin neuron pulsatility; receptors for NKB are also located on GnRH neurons. BFGF, basic fibroblast growth factor; erbB 1-4, subunits for the TGFα and NRG receptors; IGF-1, insulin-like growth factor; NRG, neuroregulins; PGE, prostaglandin E; R, receptor; TGFα, tumor growth factor-α; TGFβ, tumor growth factor β; +, positive stimulation; −, inhibition; ± =, either; ?, unknown. (Modified from Ojeda, S. R., Lomniczi, A., Mastronardi, C., et al. (2006). Minireview: the neuroendocrine regulation of puberty: is the time ripe for a systems biology approach? *Endocrinology, 147*, 1166–1174).

in inhibitory signaling from neural networks targeting the GnRH neuron. Lesioning studies indicate that inhibitory tracts mainly seem to be routed through the posterior hypothalamus and stimulatory ones through the anterior hypothalamic preoptic area.[1,230] These studies have been complemented by studies in genetically engineered mouse models. In one such model, the anteroventral periventricular nucleus (AVPV) population of kisspeptin neurons was shown to be the site of estrogen positive feedback in the control of pubertal progression, and kisspeptin cells in the arcuate nucleus of the hypothalamus were shown to be critical for E2 negative feedback.[231] Neonatal androgenization, which ablates the ability to generate a midcycle LH surge, was shown to selectively inhibit development of the AVPV population of kisspeptin neurons.[222]

An overview of the systems involved in regulating the initiation of puberty is shown in Figure 15-18. Pubertal maturation and skeletal maturation seem to have common determinants. Abundant clinical evidence indicates that sex steroid hormones are among these determinants.[232,233] Thus, genes involved in sex steroid hormone metabolism and action are candidate regulators of the onset of puberty. Evidence has begun to appear that early childhood exposures to hormonally active chemicals are among the "environmental disruptors" that may influence the onset of puberty,[185-187] and experience with diethylstilbestrol indicates that fetal exposures can have epigenetic effects.[234] The growth hormone (GH)-IGF system is another determinant. GH facilitates the onset and tempo of puberty.[235] Experimental studies suggest that this occurs through GH or IGF actions at all levels of the neuroendocrine-ovarian axis.[236,237] Girls generally enter puberty when they achieve a pubertal bone age. Pubertal stage normally correlates better with the bone age (r = 0.82) than with the chronologic age (r = 0.72; Rosenfield, unpublished data), particularly as menarche approaches.[238] Skeletal age correlates better with menarche than chronologic age, height, or weight, and its variance at menarche is half that of chronologic age.[239] The bone age at the onset of breast development averages about 10.75 years, and that at menarche averages about 13 years. Disorders that accelerate bone maturation, such as congenital adrenal hyperplasia or hyperthyroidism, tend to advance the age of the onset of true puberty.[240] Disorders that retard skeletal maturation,

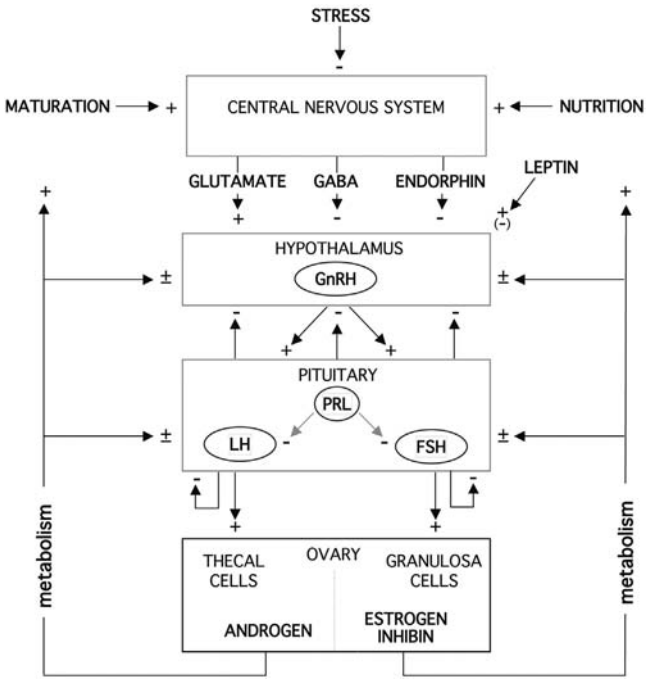

FIGURE 15-18 ■ Diagram of the major mechanisms controlling the development and function of sex hormone secretion by the unripe antral follicle. Regulation may be either stimulatory (+) or inhibitory (−). The central nervous system (CNS) influences gonadotropin-releasing hormone (GnRH) secretion both negatively and positively. For the CNS to relinquish its inhibitory control over GnRH secretion, it must achieve a high level of maturity. Even after this is achieved, psychological or physical stress may negatively influence the system. Nutrition must be optimal. Leptin is a critical mediator of the nutrition effect. Sex steroids have a maturing effect. Whether efferent tracts from the hypothalamus to the cerebrum play a role in reproductive function is unknown. Pineal secretion of melatonin and other substances are known to exert inhibitory influences on GnRH in lower animals (not shown). GnRH stimulates luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Paracrine and autocrine feedback of the gonadotropins on GnRH release and on their own release, respectively, is shown. Prolactin (PRL) has multiple effects on gonadotropin secretion. In unripe antral follicles, LH acts on thecal and interstitial cells and FSH acts on granulosa cells. Androstenedione and testosterone secreted by the theca cells are aromatized by the granulosa cell, under the influence of FSH, to estradiol. The granulosa cell is also the site of production of the FSH inhibitor inhibin B. Estradiol has a biphasic effect on the mature pituitary and on hypothalamic GnRH release as well. Androgens seem normally to be of minor importance in regulating gonadotropin release in females. Intraovarian mechanisms seem to modulate LH action so as to coordinate thecal formation of androgens with granulosa cell formation of estrogens. Paracrine and autocrine factors, including insulin-like growth factors, are involved. GABA, gamma-aminobutyric acid.

such as GH deficiency, hypothyroidism, or anemia, tend to delay the onset of puberty.[241] On the other hand, some data suggest that factors linked to intrauterine growth retardation, although not necessarily the growth retardation itself, predispose to sexual precocity.[185]

Optimal nutrition is clearly necessary for initiation and maintenance of normal menstrual cycles. The hypothesis that body fat is the weight-related trigger for pubertal development originated with the discovery by Frisch and coworkers that weight correlated with initiation of the pubertal growth spurt, peak growth velocity, and menarche better than chronologic age or height.[242] Mid-childhood may be a critical period for weight to influence the onset of puberty.[185] Suboptimal nutrition related to socioeconomic factors is an important factor in the later onset of puberty in underdeveloped when compared to developed countries.[185] Conversely, obesity appears to be an important factor in advancing the onset of puberty in the United States.[243] Some of the obesity effect may be mediated by IGF-1 and adrenal androgen.[244]

Leptin appears to be an important link between nutrition and the attainment and maintenance of reproductive competence.[207,245,246] Leptin deficiency causes obesity and gonadotropin deficiency. Paradoxically, prolonged leptin excess can down-regulate the leptin receptor and GnRH release.[247] Leptin is secreted by fat cells. It acts on the hypothalamus to reduce appetite and stimulate gonadotropin secretion. A critical threshold level appears to signal that nutritional stores are sufficient for mature function of the GnRH pulse-generator and, thus, to be permissive for puberty. Blood leptin levels rise throughout childhood and puberty to reach higher levels in girls than boys.[248] Leptin binding protein, a truncated form of the leptin receptor, falls as puberty begins, which suggests that circulating leptin becomes more bioavailable. Whether leptin has a direct role in the pubertal activation of the GnH pulse generator is unknown. In models of leptin insufficiency, the administration of kisspeptin induced LH secretion.[214] Conversely, leptin's effect on puberty did not require signaling in kisspeptin neurons in other mouse models.[249]

Other factors also link nutrition and gonadotropic function. Part of the leptin effect is mediated by inhibition of hypothalamic neuropeptide Y (NPY) formation.[250] NPY is a potent appetite-stimulating member of the pancreatic polypeptide family that directly inhibits GnRH release during food deprivation.[250] However, in the preovulatory state it stimulates GnRH release,[251] an effect mediated by a different neural network acting on a

different NPY receptor subtype on the GnRH neuron.[252] NPY is also inhibited by the anorexigenic peptide YY (PYY), a gut hormone secreted in response to food and inhibited by growth hormone; the pubertal fall in PYY has been postulated to permit the coordinated pubertal rise in appetite and gonadotropins.[253]

Other cues that provide information on nutritional status to the central reproductive axis may include glucose,[254] ghrelin,[255] and insulin.[256] The effect of these factors on LH pulsatility may be mediated directly at the level of the gonadotroph or indirectly by changes in GnRH secretion. There is little evidence for the role of pineal secretions in human reproduction that is found in lower animals.[257,258]

The essential element for the onset of puberty is an increase in pulsatile hypothalamic GnRH secretion that is regulated by a complex interplay of excitatory and inhibitory signals that have yet to be fully understood or elucidated.[224] During childhood the activity of the GnRH pulse generating system is restrained, an awakening of the pulse generator occurs gradually during late childhood, and the tempo of GnRH neuronal activation increases during puberty. The underlying mechanisms for all these changes are unclear. The pubertal diminution in tone of the CNS centers that inhibit hypothalamic GnRH secretion during childhood has traditionally been considered to result from decreasing sensitivity of a "gonadostat" to negative feedback by sex steroids.[6,259,260] However, this now seems an overly simplistic concept for a mechanism that seems to involve a change in the balance of neural inhibitory and stimulatory signals that impinge on the GnRH neuron.

Many studies have been performed to help explain the initiating developmental events or the "trigger" for pubertal onset. In fact, it is becoming increasingly clear that there is no single trigger for puberty, but instead there is a gradual increase in GnRH pulsatility associated with a complex interplay of factors and hypothalamic developmental programs. Thus, the apparent "sensitivity of the gonadostat" seems increasingly likely to reflect the degree of activity of the GnRH neuron. That is, when GnRH secretory activity is attenuated, the pulse generator is easily inhibited; when the GnRH neuron is active, the pulse generator is relatively insensitive to negative feedback.

The integration of hypothalamic signaling systems along with the developmental changes in the control of GnRH neuronal function seem to converge to trigger the onset of puberty. In the rat, structural remodeling of the GnRH neuron was demonstrated during pubertal progression by an increase in the density of dendritic and somal spines, the percentage of total neurons with spines being lowest at birth and increased gradually postnatally until puberty.[261] The spiny processes of neurons are the location of excitatory synapses important in neuronal plasticity. The greatest percentage of complex neurons is in the peripubertal period, with the percentage decreasing after completion of puberty.[262] These developmental changes are correlated with an increase in excitatory synaptic input to the GnRH neuron triggering the onset of puberty in mice.[262,263] Which excitatory synaptic input (e.g., glutamatergic, kisspeptinergic, or yet unknown neurochemical signals) plays a role in the pubertal increase in GnRH secretion is unknown. Whether primate or human GnRH neurons undergo synaptic excitatory remodeling during development is also unknown.[264]

Regulation of Gonadotropin Secretion

An essential feature of the mature hypothalamic-pituitary-gonadal axis is the long-loop, negative-feedback control of gonadotropin secretion by gonadal secretory products, as depicted in Figure 15-18. The generally tonic nature of gonadotropin secretion is punctuated by two prominent types of periodicity: two- to threefold pulsations of LH above trough levels at 1.5 to 2 hours intervals and, in the sexually mature female, a transient, midcycle, preovulatory gonadotropin surge. The latter is characterized by a greater than 10-fold, rapid rise of LH and a lesser rise of FSH. This surge is brought about by positive feedback when a critical level of E2, facilitated by a modest rise in progesterone, is achieved for a critical period of time, as discussed in relation to Figure 15-14.

E2 in concert with inhibin, reciprocally regulates FSH in a sensitive, log-dose, negative-feedback loop.[265] Progesterone in high (luteal phase) concentrations is a major negative regulator of GnRH-LH pulse frequency.[126] Androgens have a biphasic long-loop feedback relationship with gonadotropins: at modest elevations they stimulate gonadotropin release, and at very high levels they inhibit it.[266]

E2 exerts triphasic, and progesterone biphasic, effects on gonadotropin secretion. As E2 rises after the midpoint of the follicular phase, it selectively reduces the FSH response to GnRH, and when it reaches preovulatory levels, it transiently exerts positive feedback effects on LH and, to a lesser extent, FSH.[267] At sustained high levels, E2 suppresses both gonadotropins. As progesterone reaches a preovulatory level, it enhances the E2 positive feedback effect, but at the higher levels that ensue during the luteal phase, it suppresses LH pulse frequency while enhancing LH pulse amplitude.[126]

The GnRH neurons primarily responsible for maintenance of the reproductive cycle are those of the arcuate (infundibular) nucleus (Figure 15-19).[88] GnRH neurons are inherently pulsatile.[268] Synchrony is promoted by fluxes of ionic calcium into these cells and autocrine GnRH inhibitory feedback. GnRH secretion is modulated by the variety of neurotransmitters and growth factors involved in initiating puberty.[224] Synchrony of the network of GnRH neurons that accounts for pulsatility is conferred when the hypothalamic concentration of GABA periodically falls from levels inhibitory to GABAA receptors in the presence of an excitatory neurotransmitter.[269,270] EAP1, a hypothalamic protein shown to be important for pubertal onset, has also been implicated in the control of menstrual cyclicity in primates.[271]

Sex steroid signals are in part conveyed to GnRH neurons indirectly. Regulation of GnRH secretion by estrogen involves in part induction of PRs in the hypothalamus.[126,272] GnRH neuronal cell lines have been studied in which E2 directly stimulates and inhibits GnRH gene expression under different experimental

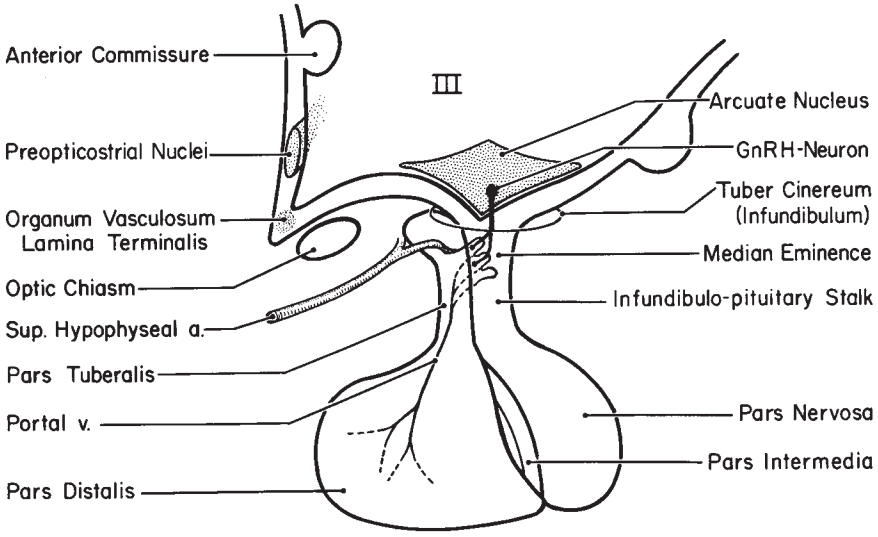

FIGURE 15-19 ■ The location of major gonadotropin-releasing hormone (GnRH)-containing neurons (shaded) in relation to the hypothalamus and pituitary gland. The neurons are of greatest density in the arcuate nuclei and in the periventricular wall of the medial basal hypothalamus. These neurons project to the adjacent median eminence; the second most dense population of GnRH neurons lies in the preopticostrial area. The development of some is altered by early androgenization. Some are connected by the stria terminalis to the amygdalae. Other projections from this area appear to connect indirectly with the median eminence, perhaps via the organum vasculosum lamina terminalis—a midline structure that resembles the median eminence. The pituitary portal veins transport blood rich in releasing factors to sinusoids engulfing anterior pituitary cells.

conditions.[273,274] Although progesterone exerts its main inhibitory effect on GnRH secretion, it has effects at higher CNS levels and at the pituitary level.[275-277] Prolactin suppresses both hypothalamic and gonadotropin GnRH receptor expression.[278,279]

Other clinically relevant factors affecting GnRH release are sleep, endorphins (endogenous opioids), and interleukins. In sexually mature women, sleep inhibits GnRH pulse frequency, and female hormones seem to amplify this effect.[280] Endorphins are important physiologic regulators of GnRH release after puberty has begun. Hypothalamic β-endorphin suppresses oophorectomy-initiated GnRH secretion, and opiate antagonists reverse this effect, as well as the sleep effect. The inhibitory effect of stress on gonadotropin release appears to be mediated by β-endorphin released from proopiomelanocortin in response to corticotropin-releasing hormone.[281] Interleukins also inhibit gonadotropin release.[282] Serotonin seems to modulate LH pulsatility and facilitate the LH surge.[283]

GnRH receptors on the gonadotroph are maintained in an optimally active state only when GnRH is delivered in pulses approximately 1 to 2 hours apart in humans.[88,284] Pulses substantially less frequent result in a hypogonadotropic state. Paradoxically, continuous administration of an initially stimulatory dose of GnRH results in down-regulation of gonadotropin production, after an initial burst of gonadotropin release.[285] This is the physiologic basis for the success of long-acting gonadotropin agonists in suppressing puberty in children with true central precocious puberty. However, whereas gonadotropins are down-regulated, free alpha-subunit production is elevated and responsive to GnRH.

Hypothalamic GnRH receptor function is modulated by autocrine and paracrine factors, including GnRH itself and kisspeptin.[5] Pituitary GnRH receptors appear to be directly and indirectly down-regulated by GnRH, gonadotropins, and inhibins, as well as sex steroids.[286] LH and FSH themselves inhibit GnRH release (short-loop feedback) and inhibit their own release (autocrine feedback).[286,287]

How is differential regulation of gonadotroph LH and FSH release accomplished in response to a single GnRH pulse? The frequency of the GnRH pulse is one determinant. Speeding this signal stimulates LH β-subunit gene expression, whereas slowing this signal stimulates FSH β-subunit and suppresses follistatin gene expression, altering the FSH/LH ratio.[288] Pituitary adenylate cyclase activating polypeptide amplifies LH responses to GnRH while blocking its effect on FSH.[289]

The sex hormone milieu is also clearly a major differential modulator of gonadotroph LH and FSH release.[88,277,290-292] FSH is more sensitive than LH to inhibition by estrogen; this effect of modest levels of E2 is of rapid onset and sustained. LH is the more sensitive to the stimulatory effects of higher E2 levels; this effect is of later onset and short lived. Similar relationships pertain in aromatase null mice. Estrogen receptor (ER) null mice have identified ER-alpha as the predominant receptor isoform that conveys negative feedback regulation to the gonadotroph.[293] Progesterone exerts both negative and positive feedback effects at the pituitary level, and these effects are antagonized by androgen. The progesterone metabolite 3α-hydroxyprogesterone suppresses FSH release.[294]

Inhibins of gonadal origin seem to be the major nonsteroid-specific negative feedback regulator of pituitary FSH synthesis and secretion.[295,296] Inhibins inhibit FSH release at the pituitary level, but they may act at a higher level as well.[297] Serum levels of both inhibins rise upon FSH stimulation.[177,178] Inhibin-B, produced by small antral follicles in response to FSH, is virtually the

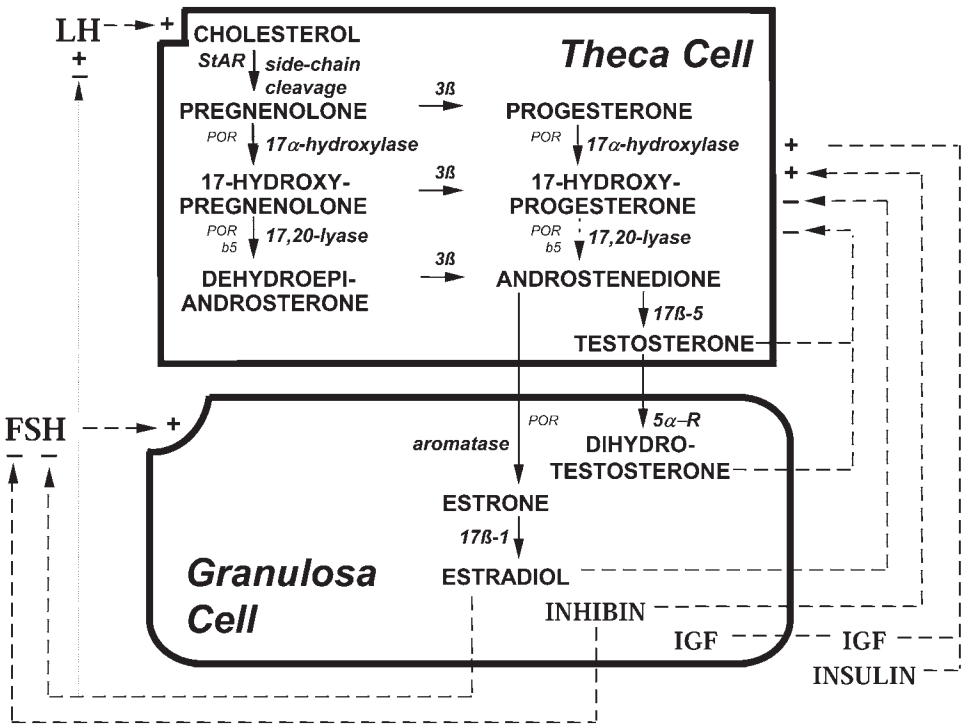

FIGURE 15-20 ■ Major factors regulating ovarian androgen and estrogen biosynthesis during the early follicular phase depicted according to the two-cell two-gonadotropin model. Luteinizing hormone (LH) stimulates androgen formation within theca cells by means of the steroidogenic pathway common to the gonads and adrenal zona reticularis. Follicle-stimulating hormone (FSH) regulates estradiol biosynthesis from androgen by granulosa cells. Estradiol at early to midfollicular phase levels does not exert a long-loop negative feedback effect on LH. Androgen formation in response to LH appears to be modulated by intraovarian and endocrine feedback at multiple levels, prominently including 17-hydroxylase and 17,20-lyase—both of which are activities of cytochrome P450c17. Androgen (via dihydrotestosterone) and estradiol inhibit (–), and inhibin, insulin, and insulin-like growth factors (IGFs) stimulate (+) enzyme activities. The sites of aromatase and IGF gene expression appear to vary with the stage of follicular development. Other peptides probably also modulate the steroidogenic response to LH. 3β-hydroxysteroid dehydrogenase (HSD): 17β-HSD5, type 5 17β-HSD; 5α-R, 5α-reductase. (Modified from Ehrmann, D. A., Barnes, R. B., & Rosenfield, R. L. (1995). Polycystic ovary syndrome as functional ovarian hyperandrogenism due to dysregulation of androgen secretion. *Endocr Rev, 16,* 322.)

only inhibin moiety in blood during puberty. Its blood levels rise during the early follicular phase and then fall thereafter except for a small postovulatory peak, generally paralleling the changes in serum FSH; the latter peak may attenuate the FSH surge. Serum inhibin-A, a marker of the preovulatory follicle and corpus luteum, begins to rise in the late follicular phase and thereafter parallels the levels of progesterone; its fall late in the luteal phase appears to contribute to the early follicular phase rise in the FSH level.

The structurally related activins seem to be important as regulators of both pituitary and ovary function.[298] Activin is formed by gonadotrophs themselves and its primary role is to stimulate FSH release. It also upregulates the activin binding protein follistatin, which arises within folliculostellate cells of the anterior pituitary.[250] Follistatin, by competitively inhibiting binding of activin to its receptor, specifically inhibits activin stimulation of FSH secretion.[265]

Regulation of Ovarian Secretion

Ovarian secretion results from the combined actions of LH and FSH, as discussed previously with regard to Figures 15-14 and 15-15. The early follicular phase follicle functions according to the two-cell, two-gonadotropin model illustrated in Figure 15-20.[141,299,300] In response to LH, androstenedione, the most abundant steroid formed in the ovary, is secreted by the theca-interstitial-stromal (thecal) cell compartment. In response to FSH regulation, aromatase then forms estrogen from precursor androstenedione in granulosa cells. FSH also stimulates granulosa cells to secrete inhibins. As by-products of the secretion of both ovarian E2 and adrenal cortisol, androgens do not normally contribute to negative feedback regulation of gonadotropins. However, they have a biphasic effect on gonadotropin secretion: modest elevations increase GnRH pulse frequency by interfering with progesterone negative feedback, and very high levels directly inhibit gonadotropin secretion.[266]

The regulation of the intraovarian androgen concentration is critical to ovarian function.[141,301] Androgens are obligate substrates for E2 biosynthesis and promote the growth of small follicles. However, in excess they interfere with the process of follicular maturation, preventing the emergence of the dominant follicle, thus committing the follicle to atresia, as well as interfering with LH action on luteinized granulosa cells. Therefore, androgen synthesis must be kept to the minimum necessary to optimize follicular development. This means that the synthesis of ovarian androgens must be coordinated with the needs of the follicle. This is achieved by

intraovarian intracrine, autocrine, and paracrine modulation of LH action.

LH stimulates theca cell development and steroidogenesis and is necessary for the expression of gonadal steroidogenic enzymes and sex hormone secretion. However, once the adult LH levels are achieved, further LH increase normally has little further effect on androgen levels because excess LH causes homologous desensitization of theca cells.[141,301] Desensitization involves down-regulation of LH receptor expression and steroidogenesis. Because steroidogenic down-regulation is primarily exerted on 17,20-lyase activity, which converts 17α-hydroxysteroids to 17-ketosteroids, 17-hydroxyprogesterone levels rise in response to increased LH levels, but there is only a limited rise in androgens.[266]

A model of the intraovarian interaction among the major factors regulating steroidogenesis is shown in Figure 15-20.[141] Stimulation of androgen secretion by LH appears to be augmented by specific intraovarian FSH-dependent factors, such as inhibins and IGFs. These processes seem to normally be counterbalanced by other FSH-dependent processes that down-regulate androgen formation as LH stimulation increases. Androgens and estrogens themselves seem to mediate at least a portion of this desensitization to LH, with estrogens being critical through an ERα-dependent mechanism.[293,302]

Insulin and insulin-like growth factors are important co-regulators of ovarian function. The entire IGF system is represented in the ovary and is essential to full FSH action; indeed, IGF-1 augments FSH receptor expression.[150,303] Insulin is a potent augmentor of both androgen and estrogen biosynthesis in response to gonadotropins, and insulin receptor mRNA is ubiquitous in all ovarian compartments at all phases of the cycle. In addition, insulin may exert its effects indirectly by its interactions with the IGF system in multiple ways. These include binding to the IGF-1 receptor, up-regulating that receptor, and lowering the serum concentration of IGF binding protein-1. GH also promotes granulosa cell steroidogenesis.[304,305]

Many other peptides modulate ovarian cell growth or function in response to gonadotropins.[141,301] Inhibin stimulates ovarian androgen production, whereas androgens reciprocally stimulate ovarian inhibin production. Activin opposes the inhibin effect. A variety of other ovarian peptides are also capable of modulating thecal androgen synthesis.[141] Stimulators include catecholamines, for which an intraovarian system exists,[306] prostaglandin, and angiotensin. Inhibitors include leptin, corticotropin-releasing hormone, epidermal growth factor, tumor necrosis factor, TGF-β, and growth differentiation factor-9.[307] Leptin antagonizes IGF-1 effects.[308] TGF-β is particularly interesting because it suppresses androgen biosynthesis and stimulates aromatase activity; it also stimulates meiotic maturation of the oocyte.[309] Other peptides acting on granulosa cells include cytokines, which have diverse effects,[303] and AMH, which inhibits aromatase.[173] GnRH is also capable of modulating thecal steroidogenesis. A GnRH-like protein has been described in the ovary that may act through ovarian GnRH receptors to suppress steroidogenesis in the human ovary.[310,311] It inhibits FSH induction of progesterone secretion, aromatase activity, and LH receptors in granulosa cells, down-regulates LH receptors, and inhibits the hCG stimulation of progesterone secretion by luteal cells.[110,131]

Prolactin has complex effects on steroidogenesis. In low concentrations, it enhances ovarian E2 and progesterone secretion by increasing LH receptors.[312] On the other hand, high levels of prolactin inhibit ovarian E2 and progesterone biosynthesis.[313] Prolactin also stimulates adrenal androgen production.[314]

Adrenarche and the Regulation of Adrenal Androgen Secretion

Adrenarche denotes the onset of the adrenal androgen production that gradually begins in mid-childhood well before the pubertal maturation of the neuroendocrine-gonadal axis.[15,315] It represents a change in the pattern of adrenal secretory response to ACTH (Figure 15-21). It is characterized by disproportionate rises in the responses to ACTH of the Δ^5-3β-hydroxysteroids 17-hydroxypregnenolone and dehydroepiandrosterone (DHEA), whereas cortisol secretion does not change. Dehydroepiandrosterone sulfate (DHEAS) is the predominant marker for adrenarche. A DHEAS level over 40 μg/dL is usually considered adrenarchal. Other serum androgens and precursors are ordinarily at the upper end of the prepubertal range at the onset of adrenarche (Table 15-1).

Adrenarche reflects the development of the adrenocortical zona reticularis. This zone becomes continuous at about 5 years of age and enlarges steadily over the subsequent decade. Its increasing development correlates

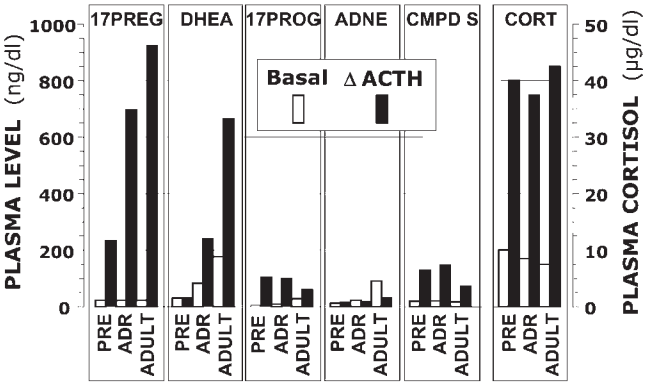

FIGURE 15-21 ■ Changing pattern of adrenal steroidogenic response to adrenocorticotropic hormone with maturation. Shown are plasma steroid levels before (basal, 8:00 a.m. after dexamethasone 1 mg/m²) and the rise (Δ) 30 minutes after cosyntropin (ACTH) administration (10 μg/m²) in healthy prepubertal children, children with premature adrenarche as an isolated phenomenon, and follicular phase adult women. Note that 17-hydroxypregnenolone (17PREG) and dehydroepiandrosterone (DHEA) responses of children with premature adrenarche are intermediate between prepubertal and adult responses. 17PROG, 17-hydroxyprogesterone; ADIONE, androstenedione; CMPD S, 11-deoxycortisol; DHEAS, DHEA sulfate. (Based on data from Rich, B. H., Rosenfield, R. L., Lucky, A. W., et al. (1981). Adrenarche: changing adrenal response to adrenocorticotropin. *J Clin Endocrinol Metab, 52*, 1129.)

with DHEAS levels. This zone's secretion pattern results from a unique enzyme expression profile: it expresses low 3β-hydroxysteroid dehydrogenase type 2 (HSD3B2) but high cytochrome b5 (an enhancer of the 17,20-lyase activity of cytochrome P450c17) and steroid sulfotransferase (SULT2A1) activities.[316]

Although the zona reticularis resembles the fetal zone of the adrenal cortex in its location and function, it appears to originate from stem cells located in the outer definitive zone of the fetal adrenal gland. A pituitary hormone ("adrenarche factor") may well be required to bring about their adrenarchal development.[4] It has been postulated to be an ACTH-related hormone distinct from ACTH, because adrenal androgen production is more sensitive to glucocorticoid suppression than is cortisol production,[317] falls more slowly than cortisol after dexamethasone administration[122], and rises more sluggishly after its withdrawal.[318] Candidates for a dexamethasone-suppressible adrenarchal factor include pro-ACTH related peptides and corticotropin-releasing hormone (CRH), but the data have not been convincing.[319] Prolactin may be involved.[320] Currently the only established adrenal androgen-stimulating hormone in postnatal life is ACTH. Because the adrenarchal secretion pattern represents a change in the pattern of steroidogenic response to ACTH, an adrenarche factor need only control the growth and differentiation of zona reticularis cells or regulate their unique pattern of steroidogenic enzyme expression. A number of factors are known to enhance adrenal androgen output. Insulin and IGF-1 particularly stimulate expression of adrenal P450c17 activities. Leptin has been reported to stimulate P450c17 activity.[321] Intraadrenal cortisol may participate in the regulation of adrenal DHEA secretion through inhibition of 3β-hydroxysteroid dehydrogenase activity.[322] In addition, interleukin-6 is strongly expressed in the zona reticularis and stimulates DHEA secretion.[323] Although gonadal dysgenesis is associated with earlier adrenarche,[324] paradoxically, ovariectomy precipitates an early decline in DHEAS levels that estrogen replacement does not reverse.[325]

Adrenarchal levels of androgens suffice to successively initiate sebaceous gland development, apocrine gland development, and the growth of pubic hair. They may promote stronger cortical bone and mid-childhood growth. Sulfation of DHEA within the adrenal cortex prevents adrenal hyperandrogenism.[326] Whether adrenarche plays a more fundamental role in normal puberty is unknown. DHEAS and its precursor, pregnenolone sulfate, have been found to be stimulatory neuroactive steroids.[327] DHEAS has been suspected of having a number of other functions, but these seem inconsistent; whether they differ from those of low-dose testosterone remains to be established.

Hormonal Secretion, Transport, Metabolism, and Action

Peptide Hormones

Peptide hormones act after binding to specific receptors located in the plasma membranes of target cells. GnRH receptors and gonadotropin receptors are members of the seven-transmembrane receptor family. These receptors are necessary for the actions of their cognate hormones. Receptors expressed in nonclassical sites are not necessarily functionally mature.[328] Mature receptors signal after coupling to a guanine nucleotide (G-protein) subunit (Figure 15-22).[5,284,288,329-331] Gs signaling activates adenylate cyclase and acts via phosphodiesterase-regulated cAMP to activate protein kinase A. Gq signaling activates phospholipase C, which acts via protein kinase C and Ca^{2+}; Ca^{2+} may also be mobilized by other factors that influence ion channels. Phosphorylation of various cytoplasmic and nuclear proteins ultimately mediates the action of the peptide hormones and secondarily involves the RAS and epidermal growth factor (EGF) signaling cascades in the case of gonadotropins.[24] The diversity among target cells in their responses to the action of protein kinases in part relates to diversity and type of kinase, intracellular compartmentalization, substrate availability, and other differences in gene expression that are specific to each type of target cell.

Gonadotropin-releasing hormone is a decapeptide [pyro]Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH2.[284] One gene encodes the single precursor protein for both GnRH and prolactin release-inhibiting factor.[332] Gonadotropin-releasing hormone not only effects prompt release of preformed gonadotropins (the "readily releasable pool"), but it also stimulates

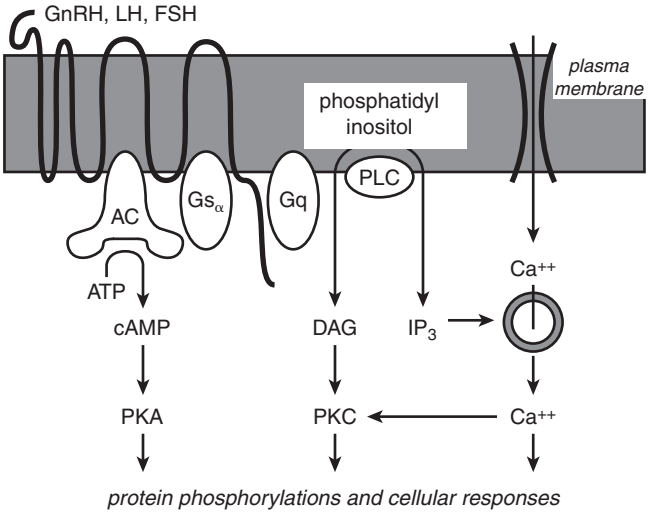

FIGURE 15-22 ■ Overview of the pathways established to mediate gonadotropin-releasing hormone (GnRH) and gonadotropin action. The receptors for these hormones are members of the seven-transmembrane family of receptors. Hormone-receptor binding alters receptor configuration. One consequence is to couple the receptor to adenylate cyclase (AC) via the stimulatory alpha-subunit of G protein (GS_a). This permits the efficient generation of cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). Another consequence is to couple phospholipase C (PLC) to the receptor through Gq. PLC is a phosphodiesterase that hydrolyzes phosphatidylinositol to diacylglycerol (DAG) and inositol-1,4,5-triphosphate (IP3). DAG stimulates the calcium-sensitive protein kinase C (PKC). IP3 mobilizes ionic calcium (Ca^{2+}) from intracellular organelles and stimulates Ca^{2+} influx through calcium ion channels. PKA, PKC, and Ca^{2+} then bring about cellular responses through protein phosphorylations. FSH, follicle-stimulating hormone; and LH, luteinizing hormone.

the synthesis of gonadotropins (the "reserve pool").[333] Repeated administration of GnRH augments the pituitary responsiveness to subsequent GnRH pulses ("self-priming").[102] This has been ascribed partly to up-regulation of GnRH receptors. Gonadotropin-releasing hormone has an important paradoxical effect. As discussed earlier, it acutely stimulates gonadotropin secretion, but upon protracted, continuous administration, it down-regulates pituitary gonadotropin secretion. The significance of the expression of GnRH and its receptor in nonhypothalamic reproductive tissues[334] is unclear.

An evolutionarily conserved form of GnRH (GnRH-II) acts primarily through the type 2 GnRH receptor[335]; GnRH-II and the type 2 GnRH receptor are products of unique genes, rather than being modified products of the GnRH or type 1 GnRH receptor genes.[336] The cell bodies of the GnRH-II neurons lie predominantly in the midbrain and only a minority project to the hypothalamic-pituitary area. GnRH-II function in humans is unknown; there is speculation that it is a neurotransmitter involved in sexual behavior.

Luteinizing hormone and FSH are synthesized in a single type of cell, and both are sometimes identified within the same cell.[337] A vestigial population of hCG-secreting pituitary cells has been described.[338] Luteinizing hormone, FSH, and hCG are glycoprotein hormones that consist of two chains.[339] After synthesis of these hormones on the ribosomes, the carbohydrate moieties, which constitute about 16% of the weight, are added in the rough endoplasmic reticulum and Golgi apparatus. The α chains of LH, FSH, hCG, and thyroid-stimulating hormone (TSH) are identical in amino acid sequence (92 amino acids). Although the β chain of each hormone is different in both primary amino acid sequence and length, these β chains nevertheless share 30% to 80% amino acid homology. Biologic activity is conferred when an α and β chain are glycosylated and assemble within the cell. The α/β dimer is stabilized by a β subunit derived "seat belt" that wraps around the α subunit. Neither the isolated α nor the β glycosylated protein subunit exhibits biologic activity unless noncovalently bound to one another.

The gonadotropins exhibit considerable molecular heterogeneity.[95,340-342] The major basis for this is variation in the relative degree of glycosyl sialylation or sulfonation, steps which occur reciprocally in the pituitary gland.[343] These differences affect in vitro and in vivo bioactivity. Polymorphisms in the amino acid sequence of the LH-β and hCG-β gene also may affect the expression or bioactivity of LH or hCG.[344] Reproductive status affects isoform distribution, with sialylation predominating in the hypogonadal state.[345] Androgens increase and estrogens decrease in vitro LH biopotency by altering LH sialylation.[346,347] Thus, the pituitary gland contains multiple isoforms of LH and FSH that vary in bioactivity. Consequently, different pituitary LH and FSH standards as well as serum contain variable proportions of immunoreactive material of varying bioactivity.

One corollary of the molecular heterogeneity is that the antibodies generated from these gonadotropin moieties detect heterogeneous epitopes that are not necessarily bioactive; indeed some may even act as gonadotropin antagonists.[348] These factors combine to cause the ratio of bioactive to immunoreactive (B/I) gonadotropin to vary in a wide variety of circumstances.[95,340] The purest of standards, even recombinant ones, interact very differently in the diverse immunoassay systems. Likewise, the putative level of LH or FSH in a serum sample differs substantially among immunoassays. Furthermore, bioactivity assessments vary with the bioassay model system.[95,349] Monoclonal antibody-based immunometric assays yield results that correlate with, but are not necessarily equivalent to, those by bioassay.[95,350] The "third generation" immunometric assays have the advantage of being more sensitive and specific for low levels of gonadotropins in serum than polyclonal antiserum-based RIA, but B/I discrepancies remain.

The major determinant of in vivo gonadotropin bioactivity is the serum half-life. Terminal sialic acid residues retard clearance by the liver, the primary site of metabolism, whereas sulfonated ones facilitate clearance.[343] About 10% to 15% of gonadotropins are excreted in urine according to radioimmunoassay[351]; only about one third of this is in a biologically active form.[352]

Luteinizing hormone is cleared more rapidly from the blood than FSH or hCG.[353,354] Luteinizing hormone disappears from blood in an exponential pattern: radioimmunoassay indicates that the half-life of the first component is about 20 minutes and that of the second component is about 4 hours. The bioactive LH half-life is about 25% to 50% shorter.[355] The respective components for immunoreactive FSH are 4 and 70 hours; those for hCG are 11 and 23 hours. Hormone production rates in follicular phase women, which approximate midpubertal values, are given in Table 15-2.[356-362]

Prolactin has structural and functional similarities to GH and placental lactogen. Prolactin has a considerable degree of structural heterogeneity, which results from genetic and posttranslational events within pituitary cells as well as modifications such as glycosylation in the periphery.[363] Lactotrope growth and prolactin secretion are stimulated by estrogens. Prolactin release from the anterior pituitary is primarily under the control of hypothalamic inhibition, probably mediated by dopamine[364] and prolactin release-inhibiting factor.[332] The latter is contained within the same precursor protein as GnRH, thus providing a potential mechanism for reciprocal control of these two peptides. Prolactin secretion also is inhibited by thyroxine and is directly responsive to thyrotropin releasing hormone (TRH). Estrogen and suckling are stimulatory. These signals may be positively mediated by α-melanocyte stimulating hormone.

Inhibins and activins are members of the TGF-β superfamily and signal accordingly.[298,365] Inhibin was discovered as the result of the search for the nonsteroidal gonadal hormone capable of specifically suppressing FSH. Activin was serendipitously discovered as the FSH-stimulating activity in the side fractions in these studies. These hormones are formed by the differential disulfide-linked dimerization of two of three subunits (α– β_A, and β_B), each encoded by a distinct gene. The combination of an α– and β-subunit yields the inhibins, inhibin-A ($\alpha\beta_A$) and inhibin-B ($\alpha\beta_B$). Activins are dimers of β-subunits,

TABLE 15-2 **Average Hormone Blood Production Rates in Midfollicular-Phase Women***

Hormone	Production Rate	Pertinent References
Luteinizing hormone	615 IU/day†	356
Follicle-stimulating hormone	215 IU/day†	357
Androstenedione	3.4 mg/day	358
Dehydroepiandrosterone	7 mg/day	358
Dehydroepiandrosterone sulfate	7 mg/day‡	359, 360
Dihydrotestosterone	0.06 mg/day	358
Estradiol	0.1 mg/day	361
Estrone	0.1 mg/day	361
Progesterone	1.1 mg/day	362
17-Hydroxyprogesterone	1.2 mg/day	362
Testosterone	0.2 mg/day	358

*These production rates are roughly equivalent to those in midpuberty. The average daily production of those hormones that fluctuate cyclically is substantially greater. For example, E_2 production transiently peaks to about 0.5 mg/day, and thus the average production over the monthly cycle is about 0.2 mg/day or 6 mg/month.
†In terms of second International Reference Preparation, human menopausal gonadotropin.

$\beta_A\beta_A$, $\beta_B\beta_B$, and $\beta_A\beta_B$ (activin-A, B, and AB). Inhibin antagonizes all known actions of activin. The genes for all three subunits are differentially expressed in a wide variety of tissues. Furthermore, these factors, particularly activin, have proven to exert effects not only on gonadotrophs but within other pituitary cells, the gonads, and in nonsexual target tissues.

Steroid Hormones

The ovary and adrenocortical zona reticularis share the core of the steroid biosynthesis pathway (Figure 15-23).[301,366,367] Gonadal cholesterol seems to be derived more from low-density than high-density lipoprotein in humans, and cholesterol can also be formed de novo. Most steroidogenic steps are mediated by cytochrome P450 family members. These are the terminal enzymes in electron transfer chains, which include P450 oxidoreductase (POR) as the clinically relevant electron donor for all in the endoplasmic reticulum. The initial step in the biosynthesis of all steroid hormones is the conversion of cholesterol to pregnenolone. This is a two-stage process. The rapidity of the process depends on the transport of cholesterol from the outer to the inner mitochondrial membrane by the steroidogenic acute regulatory protein (StAR). The conversion itself is carried out by the cholesterol side chain cleavage activity (scc) of cytochrome P450scc. The next steps are either the 3β-hydroxysteroid dehydrogenase/Δ^5-isomerase (3β-HSD) step or 17α-hydroxylation. 3β-HSD converts Δ^5-3β-hydroxysteroids to steroids with the Δ^4-3-keto configuration—that is, pregnenolone to progesterone, 17-hydroxypregnenolone to 17-hydroxyprogesterone, and DHEA to androstenedione. This step is obligatory for the synthesis of all potent steroid hormones. The type 2 3β-HSD isozyme accounts for the majority of the 3β activity in the human ovary and adrenal; the type 1 isozyme accounts for 3β-HSD activity in liver and skin. Pregnenolone alternatively undergoes a two-step conversion to the 17-ketosteroid DHEA along the Δ^5-steroid pathway: this conversion is accomplished via cytochrome P450c17. P450c17 is a single enzyme with both 17α-hydroxylase and 17, 20-lyase activities, the latter being less efficient and critically dependent on electron transfer from cytochrome *b*. Progesterone undergoes a parallel transformation to androstenedione in the Δ^4-steroid path: 17α-hydroxylation of progesterone by P450c17 forms 17-hydroxyprogesterone, but in humans P450c17 does not efficiently utilize 17-hydroxyprogesterone as a substrate for 17,20-lyase activity, so P450c17 seems to form little if any androstenedione. There is some evidence for the existence of a P450c17-independent Δ^4-pathway to androstenedione, but most seems to be formed from DHEA by the action of 3β-HSD.[368] Sulfotransferase 2A1 is uniquely expressed in the adrenal zona reticularis and requires the co-factor 3′-phosphoadenosine-5′-phosphosulfate synthase type 2.[326] Other sulfotransferases (e.g., for formation of estrone sulfate) and steroid sulfatase (for the reverse reaction) are widely expressed.[369]

17β-Hydroxysteroid dehydrogenase (17β-HSD) and aromatase activities are required for the formation of potent sex steroids. In the ovary, androstenedione is the major precursor for sex steroids. The conversion of 17-ketosteroids to 17β-hydroxysteroids by 17β-HSDs is essential for the formation of both androgen and estrogen: testosterone is formed in the ovary by 17β-HSD type 5 (also termed aldo-keto reductase, AKR,1C3), whereas E2 formation requires 17β-HSD type 1.[370] Aromatase activity, effected by P450arom, is essential for E2 formation. Alternate promoters are utilized by the P450arom gene in the gonads, placenta, and adipose tissue, which yields alternatively spliced forms of aromatase. The organization and regulation of steroidogenesis in the developing follicle is depicted in Figure 15-20.

The ovary normally accounts for about 25% of testosterone secretion in the mature female (0.06 mg daily),

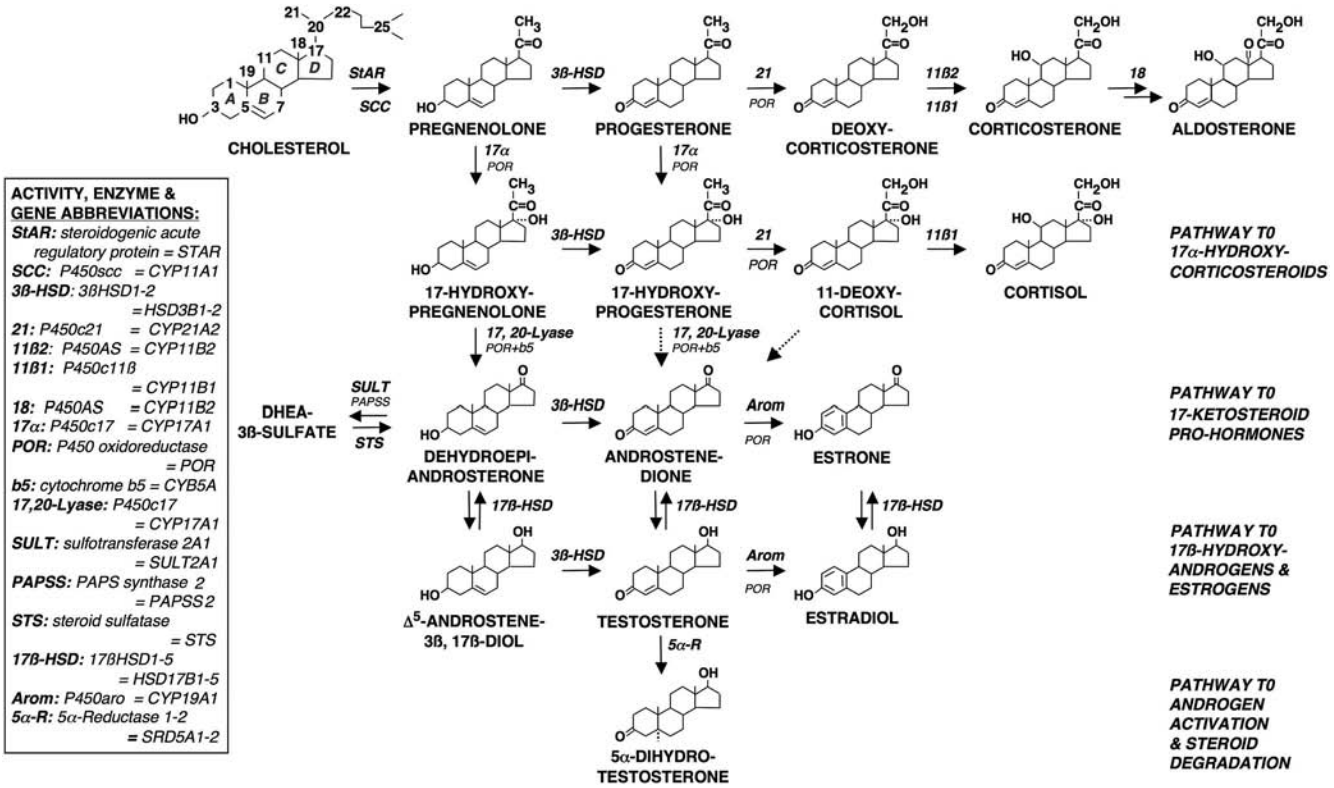

FIGURE 15-23 ■ Major pathways of steroid hormone biosynthesis from cholesterol. Carbon atoms of cholesterol are designated by conventional numbers and rings by conventional letters. The flow of hormonogenesis is generally downward and to the right. The top row shows the pathway to progesterone and mineralocorticoids, the second row the pathway to glucocorticoids, the third row the 17-ketosteroid pro-hormones, the fourth row the potent 17β-hydroxysteroids, and the bottom row the activation of androgen. The steroidogenic enzymes are italicized. Abbreviations for enzymes include the following cytochrome P450 enzyme activities: cholesterol side-chain cleavage (scc), 17α-hydroxylase (17α), 21-hydroxylase (21), 11β-hydroxylase (11β1), aldosterone synthase (11β2, 18-hydroxylase/oxidase), and aromatase (Arom). Non-P450 enzyme activity abbreviations include Δ^5-isomerase-3β-hydroxysteroid dehydrogenase (3β) and 17β-hydroxysteroid dehydrogenase (17β-HSD). Clinically relevant electron transfer enzymes include P450 oxidoreductase (POR), cytochrome b5 (b5), and 3′-phosphoadenosine-5′-phosphosulfate synthase type 2 (PAPSS). (Modified from Rosenfield, R. L., Lucky, A. W., & Allen, T. D. (1980). The diagnosis and management of intersex. *Curr Prob in Pediatr, 10,* 1.)

but it secretes about 30 times as much androstenedione (1.6 mg daily).[358] These amounts are similar to those secreted by the adrenal. However, the ovary secretes less than one tenth as much DHEA as the adrenal.

The "production rate" of a hormone equals its secretion rate plus the rate of formation of the hormone by peripheral conversion of secreted precursors outside of endocrine glands. The "blood production rate" is calculated as metabolic clearance rate x serum concentration; in the steady state, the amount of hormone irreversibly leaving the plasma compartment equals the amount entering it. Because of extensive steroid interconversions, the quantity of these hormones excreted in urine is not necessarily indicative of the amount reaching target tissues.[358] For example, so large a fraction of urinary testosterone glucuronide is formed directly from androstenedione by compartmentalized metabolism within the liver that the range of urinary excretion of testosterone in women overlaps that in men (Figure 15-24).[371] Estrone sulfate, like DHEAS in the androgen pathway, forms a circulating reservoir of inactive estrogen that can be returned to the active pool by hepatic sulfatase activity.[372] The blood production rates of representative steroid hormones are given in Table 15-2 and are shown for estrogens in Figure 15-25. During the luteal phase of the menstrual cycle, E2 production doubles[361] and progesterone production rises 15-fold or more.[373]

Sex hormones also have environmental origins. Structurally distinct biologic estrogens include equine estrogens and plant-derived phytoestrogens.[372] Synthetic estrogens include pharmacologic compounds such as ethinyl E2, diethylstilbestrol, selective estrogen receptor modulators (SERMs), and some industrial chemicals such as organochlorines and plasticizers. Environmental estrogens act as "endocrine disrupters," environmental chemicals that interfere with normal endocrine signaling systems by mimicking or blocking hormone signaling through its receptor, or by modulating the synthesis, release, transport, metabolism, binding, or elimination of natural hormones.[187]

Peripheral conversion of secreted prehormones by nonendocrine organs accounts for a major portion of sex hormone production. The ovary and the adrenal cortex are sources of prehormones as well as secreted hormones. About 50% of serum testosterone (0.1 mg daily) normally is formed indirectly by peripheral conversion. Although 85% of normal estrogen production in women

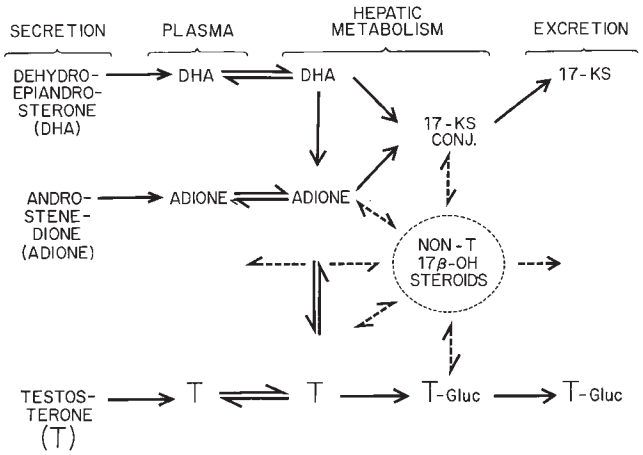

FIGURE 15-24 ■ Diagram illustrating the relationship among secreted, plasma, and urinary steroids. 17-ketosteroid (17-KS) excretion does not reflect accurately the excretion of the most important plasma androgens. Only 25% or less of testosterone is excreted as 17-KS metabolites. Therefore, important changes in testosterone production may not appreciably affect urinary 7-KS excretion. Furthermore, even the major 17-KS (DHA-sulfate) is excreted poorly until its production rate becomes quite high. On the other hand, about half 17-KS will not be identified by the standard colorimetric test and 2 mg daily of 17-KS in adults results from hydrocortisone metabolism. In addition, testosterone glucuronide excretion does not accurately reflect the plasma testosterone level: less than 2% of testosterone appears in the urine as such. Furthermore, the plasma 17-KS androstenedione may be converted to testosterone glucuronide without ever circulating as unconjugated testosterone. (From Rosenfield, R. L. (1973). Relationship of androgens to female hirsutism and infertility. *J Reprod Med, 11*, 87.)

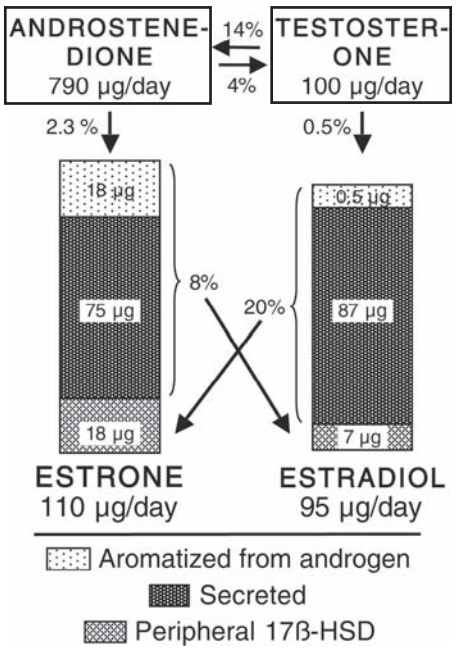

FIGURE 15-25 ■ Sources of estrone and estradiol in blood of follicular phase premenopausal women. Estrogen is derived from direct secretion by the gonad, aromatization of androgen, or conversion of an estrogen precursor by 17β-HSD activities. The percentage of substrate converted per day and total approximate production in micrograms per day are noted for each source. (Modified from Alonso, L. C., & Rosenfield, R. L. (2002). Oestrogens and puberty. *Best Pract Res Clin Endocrinol Metab, 16*, 13.)

arises by secretion in midcycle, 50% of estrogen production can arise from extraglandular sources during the low-estrogen phases of the menstrual cycle.[374] Peripheral formation of active steroids occurs in a wide number of sites, including liver, fat, and target organs.[301,375] For example, hepatic 17β-hydroxysteroid dehydrogenase and 5α-reductase activities are involved in steroid degradation (Figure 15-23).

Peripheral steroid metabolism is not tightly regulated. It seems determined to some extent by the perinatal androgenic milieu,[376] the effect of which is possibly mediated by GH.[377] Postnatally, it is influenced by the sex hormone binding globulin level (SHBG) and the state of nutrition. Adipose tissue becomes a major site of conversion of androstenedione to both estrone and testosterone in the obese.[266,378] Cytochrome P450 mixed function oxidases, the most important of which is CYP3A4, affect steroid efficacy by forming hydroxylated steroid metabolites of varying potency.[379,380] They are subject to induction or inhibition by numerous drugs. Phytoestrogens increase E2 bioavailability by inhibiting hepatic sulfotransferase.[381]

Plasma steroids appear to reach their sites of action and metabolism by simple diffusion from the vascular compartment.[382] The bioactive portion of serum testosterone seems to be the free testosterone and a portion of the albumin-bound testosterone that differs among tissues according to the diffusion characteristics of the vascular bed.[383] About 98% of serum testosterone and E2 are bound to albumin and SHBG. The SHBG concentration determines the fraction of serum testosterone and other ligands (e.g., E2, dihydrotestosterone) that are free or bound to albumin. It is also a major determinant of ligand egress from plasma (Figure 15-26).[384] Some sex steroid effects may be mediated by SHBG binding to membrane receptors and activation of adenylate cyclase.[385,386] A number of physiologic and pathologic states affect the SHBG level: it is increased by estrogen and thyroid hormone excess; it is decreased by androgen, insulin-resistant obesity, glucocorticoid, GH, and inflammatory cytokines.[387-389]

Target cell metabolism influences the cell's response to the steroid hormones that reach it (Figure 15-27).[390] The intracellular conversion of testosterone to dihydrotestosterone by one of the two isozymes of 5α–reductase is important for many but not all effects of testosterone,[391] dependent on the tissue-specific pattern of steroid metabolism. An important mode of testosterone action is via E2, notably within the brain. Although transformation is not fundamental to the mode of action of E2, its effectiveness is influenced by target cell metabolism: the induction of 17β-hydroxysteroid oxidation in target tissues by progesterone, resulting in conversion of E2 to the less potent estrogen estrone, counterbalances estrogenization.[392] There is also evidence that novel steroid metabolites exert tissue-specific effects.[393,394]

Within target cells, all steroid hormones regulate the genome similarly, starting with binding to high-affinity intracellular receptors (Figure 15-28).[395-397] The steroid hormone receptors belong to the superfamily of nuclear hormone receptors. The estrogen, progesterone, and androgen receptors are, thus, homologous. Classic sex

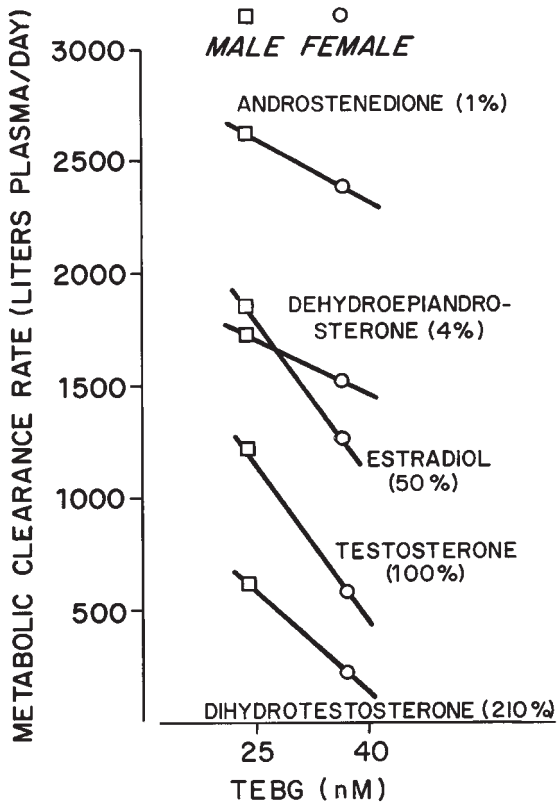

FIGURE 15-26 ■ The relationship between the metabolic clearance rate (MCR) and binding of sex hormones to sex hormone binding globulin (SHBG = testosterone-estradiol binding globulin, TEBG). The MCR of each steroid has been related to the mean SHBG levels of men and women. The approximate affinity of each steroid for SHBG relative to testosterone is indicated in parentheses. (From Rosenfield, R. L. (1975). Studies of the relation of plasma androgen levels to androgen action in women. *J Steroid Biochem, 6,* 695.)

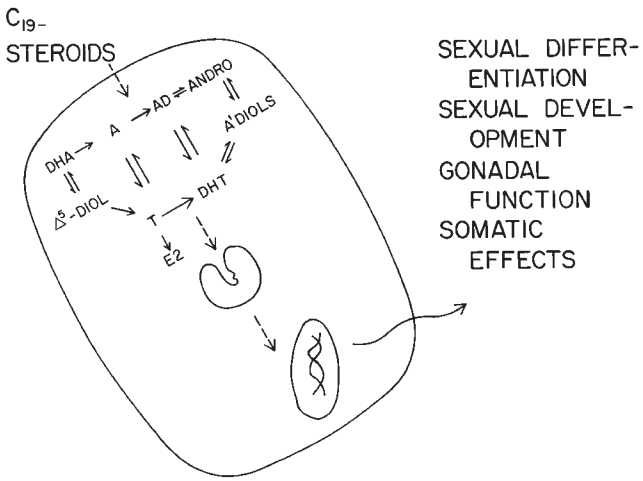

FIGURE 15-27 ■ Model of the mechanism of androgen action emphasizing the effect of steroid metabolism within a target cell on the mode of action. Solid arrows indicate pathways of steroid metabolism from 17-ketosteroid precursors as laid out in Figure 15-23. Broken arrow indicates transport. The cell-specific intracellular pattern of C19-steroid metabolism determines the relative availability of testosterone or dihydrotestosterone (DHT) to the cytosol receptor for translocation to the nucleus. In cells such as the rat granulosa cell in which Δ^5,3β-hydroxysteroid dehydrogenase activity is high, androstenediol (Δ^5-diol) is as potent as testosterone. The human sebaceous gland has a similar pattern of steroid metabolism. A, androstenedione; AD, androstanedione; DHA, dehydroepiandrosterone. (From Nimrod, A., Rosenfield, R. L., & Otto, P. (1980). Relationship of androgen action to androgen metabolism in isolated rat granulosa cells. *J Steroid Biochem, 13,* 1015, with permission from Elsevier Science.)

hormone effects are exerted by the interaction of steroid with receptor, not by either alone. Steroid binding triggers the dissociation of inhibitory chaperone heat shock proteins from the receptor.[398] The active receptor-ligand complex then undergoes noncovalent dimerization and binding to its specific hormone response element on the gene. The DNA-bound steroid-receptor complex acts as a transcriptional regulator of the target gene promoter. Sensitivity to steroids is also modulated by molecular chaperone proteins that influence receptor configuration, intracellular trafficking, and receptor turnover, all of which are determinants of steroid action.[399,400]

The binding properties of steroids to their cognate receptors are the initial determinants of classical steroid action.[395,396] Ligand-based selectivity is one element of this interaction. E2 is a more potent estrogen than estrone and estriol, partly because it binds best to the steroid binding domain of the estrogen receptor.[401] Dihydrotestosterone is an inherently more potent androgen than testosterone mainly because of its higher association rate constant and its lower dissociation rate constant.[402] The antiestrogens tamoxifen and clomiphene and the antiandrogens cyproterone acetate and spironolactone competitively inhibit the active ligands from binding to their specific receptor sites by weakly and transiently occupying receptor sites. These differences result from potent agonists snugly fitting into the binding pocket, which induces a receptor conformation different than that of antagonist-bound receptor. One such change is the C-terminal tail of the receptor flipping over to close the "door" when a potent agonist enters; this simultaneously provides a different outer surface for interaction with co-regulator proteins.

Thus, ligand-based selectivity arises not only because of tighter ligand binding but because alternative ligands produce both intermediate and unique conformational changes in the receptor, which in turn induce altered receptor interactions with co-regulator proteins that result in a spectrum of activities.[403] Thus, steroids do not simply switch receptors on; they induce selective functions that depend on the nature of the co-regulators that are recruited to the complex.[404-407] In part, this selectivity arises because different domains of these receptors mediate these different functions. For example, the AF-1 domain of the ER mediates interactions with mitogen-activated protein (MAP) kinase and TGF-β3, whereas the AF-2 domain mediates interactions with co-regulator proteins.[408] Coactivators, in turn, regulate alternative splicing, gene activation and repression (in some cases via their dual enzymatic functions), ubiquitin-proteosome-mediated turnover of the receptor–co-regulator complex,[409] and also determine cell-specific, site-based actions,[396] as discussed later.

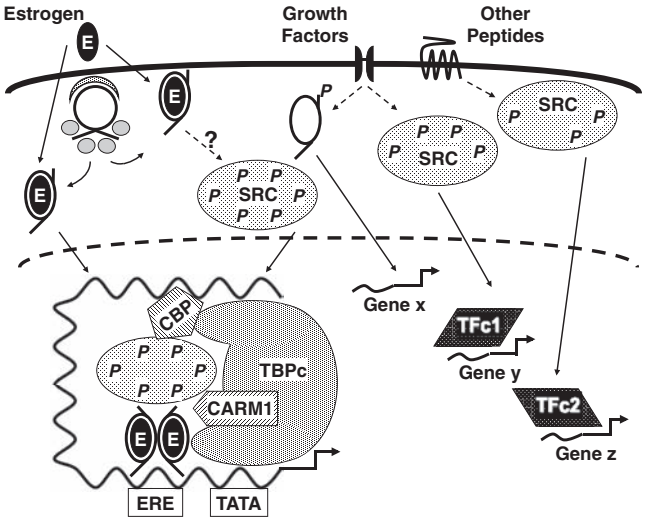

FIGURE 15-28 ■ A model for the mechanism of estrogen (E) action that emphasizes the role of interactions of the estrogen receptor with steroid receptor co-regulator (SRC) and phosphorylation signaling. Estrogen causes the 4S subunit and heat-shock proteins to dissociate from the unliganded estrogen receptor. Then estrogen entry into the binding pocket causes a conformational change in the receptor. Estrogen also stimulates phosphorylation of SRC in a specific pattern (*P*s), possibly via liganded membrane-bound ER as it does some transcription factors, and recruits it to the nuclear DNA steroid-receptor complex with the estrogen response element (ERE). SRC in turn recruits other co-activators, such as the cAMP response element binding protein-binding protein (CBP) and coactivator-associated methyltransferase (CARM1) to the hormone binding complex. This aggregate then interacts with the TATA binding protein initiation complex (TBPc) to initiate estrogen-specific gene transcription. The genomic E2 effect is modulated by the effects of environmental signals on other cell-specific transcription factors (TF), some of which involve differentially phosphylated SRC complexes (TFc) in gene activation, others of which involve ligand-independent ER. Dotted lines indicate diverse kinase pathways. ER recycling is not shown. (Based on Katzenellenbogen, B. S., Montano, M. M., Ediger, T. R., et al. (2000). Estrogen receptors: selective ligands, partners, and distinctive pharmacology. *Recent Prog Horm Res*, *55*, 163–193; O'Malley, B. W. (2005). New insights into the classical and non-classical actions of estrogen: evidence from estrogen receptor knock-out and knock-in mice. *Mol Cell Endocrinol*, *290*, 24–30.)

Receptor-based selectivity is a second element in steroid action. There are now known to be two isoforms of each of the sex steroid receptors. The α and β forms of the estrogen receptor, though homologous, are coded by separate genes.[170] A and B forms of the progesterone and androgen receptors exist.[410,411] These forms of the PR arise by transcription from alternate promoters within the same gene, whereas those of the androgen receptor arise from posttranslational modification of a single mRNA. These isoforms have variously been shown to manifest a differential tissue expression pattern and respond differentially to antagonists. Interactions of a steroid with different forms of receptor can regulate some target genes differentially. One role of ERβ is apparently to modulate ERα activity: ERα and ERβ can have opposite actions at AP-1 and SP-1 sites, and studies of transcriptional activity in bone and breast tissue of mice indicate a restraining effect of ERβ on responses to E2.[170,412] Thus, different target tissues exposed to the same hormone may respond selectively because of a distinct repertoire of receptor isoform expression. Some examples are notable. Although both forms of estrogen receptor are expressed in most target tissues, the classic form of the estrogen receptor, ERα, plays the key role in regulation of LH and estrogen actions on the uterus, breasts, sex-specific behavior, and bone.[170,413,414] In the mouse ovary, knockout experiments show that ERα is expressed in thecal cells where it prevents androgen excess in response to LH. In contrast, ERβ is expressed only in granulosa cells, where its inhibition of androgen receptor expression is critical to prevent premature follicular atresia.[171] Both are necessary for oocyte survival and the ability of preovulatory follicles to rupture. Furthermore, loss of both causes transdifferentiation of granulosa cells to Sertoli-like cells and massive oocyte death.[153] Liganded progesterone receptor$_A$ is essential for ovulation[415] and is the more effective antagonist of estrogen receptor action.[395] In addition, sequence variation in hormone response elements contributes to differential gene regulation.[416]

Effector site-based selectivity is a third variable in classical sex hormone action. In other words, the potency and character of a response to a ligand-receptor complex are not simply inherent properties of the complex. Rather, they depend on the array of effector molecules present in the site of action. Thus, the array of genes expressed locally and the relative expression level of co-regulators (coactivators and corepressors) are extremely important in the determination of appropriate and graded responses to a ligand by a target cell.[395,417] Heterodimerization of the estrogen receptor with other nuclear receptors can modulate its action.[418] Androgens appear to exert some of their genomic effects by directly complexing with transcription factors other than the androgen receptor.[419] Both estrogen and androgen appear to exert antiapoptotic effects in osteoblasts and osteocytes by activating a ligand-dependent, but nongenomic, kinase-mediated signaling pathway.[420]

Nuclear receptor coactivators are critical for sensing cell-specific environmental signals and coordinating signals emanating from membrane receptors with nuclear receptor action.[396] Surface receptors send signals through kinase pathways that result in specific serine/threonine phosphorylation patterns of coactivators. These phosphorylation patterns serve as a code for the coactivator to preferentially bind and activate distinct sets of downstream transcription factors (see Figure 15-28). Overexpression of steroid receptor coactivator-3 (SRC-3) is as important in the pathogenesis of some breast cancer as is estrogen receptor positivity.

The effects of an alternative ligand-ER complex often differ from those of the E2-ER complex among cell types. This is the basis for the development of selective estrogen receptor modulators (SERMs): these compounds exert effects in a tissue-specific manner depending on the cell context.[395,403] The chemical structure of a SERM—or any ER ligand, for that matter—determines the configuration of the ER, resulting in a spectrum of activities from agonist to antagonist, depending on which co-regulators are

available for recruitment in the target cell. Raloxifene is an E2 agonist in bone and epiphyseal cartilage but is antiestrogenic in uterus and breast; tamoxifen is estrogenic in uterus but antiestrogenic in breast and bone. Both appear to retain neural and endothelial estrogenic activity.[421,422]

Nonclassical mechanisms play a role in sex steroid action.[397] The nonclassical mechanisms are mainly of two general types: (1) genotropic estrogen response element (ERE)-independent signaling, in which liganded ER acts as a co-regulator of other transcription factors that act through their specific DNA response elements; and (2) nongenotropic signaling, in which E2 binding to membrane-associated receptors, including ERα, rapidly stimulates phosphorylation pathways.[423,424]

The nongenomic effects via membrane signaling occur rapidly (within minutes) and can mediate cell proliferation, apoptosis, and migration in cell-specific ways.[420,425]Nongenomic E2 actions account for most of the LH-inhibitory and energy balance effects of E2.[424,426] These effects can be mediated by binding to nuclear ER in plasma membrane domains provided by scaffolding proteins such as caveolin. On such platforms, the E2-ER complex acts like a membrane receptor, coupling with G proteins and activating cytoplasmic pathways involving SRC and MAP kinase. Androgens appear to act similarly. Nongenomic actions of nuclear PR have also been reported. Some nongenomic effects seem to involve the activation of novel G-protein coupled transmembrane receptors for E2 and progesterone that interact with either steroids or their metabolites.

Genomic ER signaling may also be ligand independent. For example, cell membrane signaling by growth factors or other peptides stimulates ER phosphorylation. Epidermal growth factor activates phosphorylation of the ER and simulates diverse estrogen effects.[427] Activation of unliganded ERα seems to be involved in repressing expression of the androgenic 17β-HSD testicular isoform in the ovary.[293]

Steroids that act by binding to membrane-bound receptors in the brain are termed *neuroactive*.[327] Neuroactive steroids synthesized in the brain are termed *neurosteroids*.[428-430] The best documented of these effects are on neurotransmitters that control ion channels. Allopregnanolone (3α-hydroxy-5α-tetrahydroprogesterone) and 3α-androstanediol are GABAA receptor agonists and so have sedative and antiepileptic properties.[431] Pregnenolone sulfate and DHEAS have the opposite effect, the former also stimulating the glutamate receptors. Receptors for 5-hydroxytryptamine have been implicated in mediating some of effects of sex steroids and certain of their metabolites.[432,433] Some estrogen effects in brain are membrane mediated.[434]

The tissue-specific posttranscriptional events involved in sex steroid signaling are poorly understood. E2 and progesterone modulate the actions of each other through effects on their specific receptors: increased estrogens in the preovulatory phase of the cycle up-regulate target organ receptors for both E2 and progesterone; luteal phase levels of progesterone then suppress the production of both receptors.[435,436] Estrogen prevents bone loss by blocking the production of proinflammatory cytokines.[437] Androgen action seems to involve the arachidonic acid cascade in genitalia[438] and peroxisome proliferator-activated receptors in sebaceous cells,[439] whereas in epiphyseal cartilage testosterone stimulates the IGF-1 system.[440]

Maturation of Sex Hormone Target Organs

Genital Tract

The Müllerian system of the embryo gives rise to the uterus, cervix, upper vagina, and fallopian tubes in the absence of AMH secretion by fetal testes during the first trimester of gestation.[366] Genital swelling develops to engulf the base of the penis-like clitoris between 11 and 20 weeks' gestation in parallel with the development of the ovarian follicular system.[441] Estrogen receptors are expressed in the labia minora, prepuce, and glans in females, but not in the homologous structures of males.[442] An association between antiestrogen and genital ambiguity has been reported.[443] Diethylstilbestrol induces dysplasia of the genital tracts.[444] These data suggest that estrogen may play a direct role in female genital tract differentiation. However, knockout of estrogen receptors has no obvious effect on genital tract differentiation.[153]

The infantile uterus and cervix enlarge under the influence of estrogen during puberty. The endometrium and cervical glands then undergo cyclical changes in concert with cyclic ovarian function. In response to rising estrogen during the follicular phase of the cycle, the endometrial epithelium and stroma proliferate. The uterine glands increase in number and lengthen. Endometrial hyperplasia is prevented by progestin[445] and androgen excess.[446] In response to progesterone secretion after ovulation, the endometrium increases in thickness: stromal edema occurs, and the uterine glands enlarge, become sacculated, and secrete a glycogen-rich mucoid fluid. The coiled arteries lengthen further during this time and become increasingly spiral. These changes are critical to permit implantation. High-dose progestin is an effective postcoital contraceptive because it prevents implantation when taken within 3 days of unprotected intercourse.[447]

Endocervical gland secretions lubricate the vaginal vault. The endocervical mucus is scanty and relatively thin during the low-estrogen phase of the cycle. The increase in mucus flow with advancing follicular development seems to require tissue-specific stimulation of the cystic fibrosis transmembrane regulator by estrogen.[448] Cervical mucus becomes more viscous and elastic as estrogens rise in the later follicular phase of the cycle—the extent to which it can be stretched into a long spindle, *spinnbarkeit*, is a function of the estrogen level.

The mucosa of the vagina and the urogenital tract is comprised of hormone-responsive stratified squamous epithelium (Figure 15-29).[2] The basal layer is the regenerative area. In the absence of estrogen, there is only a parabasal layer of cells over this, and the vagina is thin, with a tendency to alkalinity, which predisposes it to local infection (nonspecific vaginitis).[449] In response to

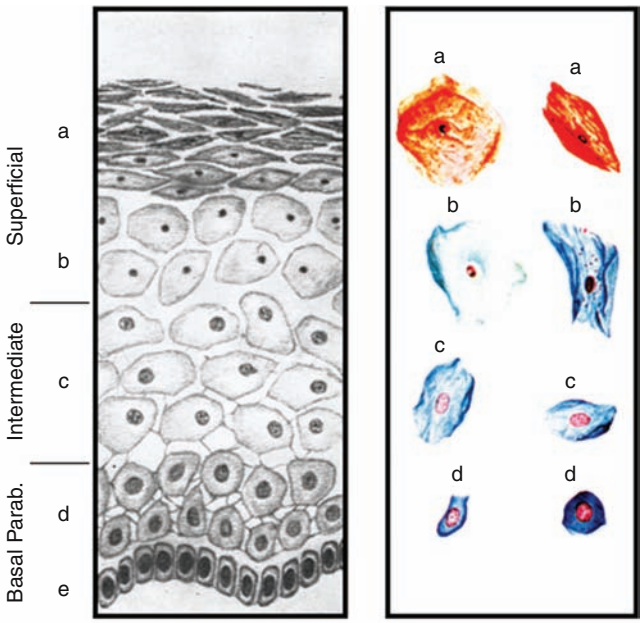

FIGURE 15-29 ■ The layers of vaginal epithelium of the well-estrogenized adult. The superficial layer contains surface cells that are cornified (squamous) with eosinophilic cytoplasm and pyknotic nuclei (a) as well as large intraepithelial cells that are also karyopyknotic but basophilic (b). The intermediate zone contains basophilic cells that have less cytoplasm and intermediate-size nuclei (c). Parabasal and basal cells have successively smaller amounts of basophilic cytoplasm and more vesicular nuclei (d, e). *This image can be viewed in full color online at ExpertConsult.* (Modified from Wilkins, L. (1968). *The diagnosis and treatment of endocrine disorders in childhood and adolescence.* Springfield, IL: Charles C Thomas.)

estrogen, epithelial proliferation occurs, with formation of successive intermediate and superficial layers. With this maturation the cytoplasm of each cell first expands, leading to formation of small intermediate cells. With further estrogenization, the nuclei become pyknotic and large intermediate cells form. Greater estrogenization brings about their transformation to cornified squamous superficial cells: the cytoplasm changes from basophilic to acidophilic with the accumulation of glycogen. Resistance to infection of the fully developed vaginal mucosa results from its thickness and from its acid pH, which occurs from the fermentation of the glycogen of the superficial cells. In response to luteal phase progesterone, degenerative changes appear in vaginal mucosal cells: superficial cells decrease, the cytoplasm assumes a "crinkled" appearance, cells degenerate, and bacterial proliferation increases.

Vaginal smears show the characteristic cyclic changes in the cell types comprising the vaginal epithelium (see Figure 15-29).[450] In the prepubertal years parabasal cells predominate, and characteristically 10% or less are small intermediate cells. A pattern consisting entirely of intermediate cells is typical of early puberty. The early follicular phase of the menstrual cycle is characterized by the predominance of large intermediate cells with few, if any, superficial cells. Peak maturation is reached at midcycle, at which time 35% to 85% of the cells seen on vaginal smear are superficial; the remainder are large intermediate cells. This cornification develops over a 1-week period in response to E2 levels of about 70 pg/mL and persists 1 to 2 weeks after estrogen withdrawal (see Figure 15-11).[451]

Progesterone antagonizes estrogen effects on the vaginal epithelium and cervix. Inhibition of cervical ripening by progestins is used to prevent recurrent spontaneous preterm delivery.[452,453]

Many normal variations have been recognized in the appearance of the hymen. The transverse diameter increases with age.[454,455]

Mammary Glands

Multiple rudimentary branching mammary ducts are found beneath the nipple in infancy; they grow and branch very slowly during the prepubertal years.[456] Estrogen stimulates the nipples to grow, mammary terminal duct branching to progress to the stage at which ductules are formed, and fatty stromal growth to increase until it constitutes about 85% of the mass of the breast. GH (via IGF-1) and glucocorticoids play a permissive role.[457,458] These hormones interact with breast stroma and local growth factors to stimulate the development of breast epithelium. Lobulation appears around menarche, when multiple blind saccular buds form by branching of the terminal ducts. These effects are due to the presence of progesterone. The breast stroma swells cyclically during each luteal phase. Full alveolar development normally only occurs during pregnancy under the influence of additional progesterone and prolactin. Prolactin does not play a role in breast growth without priming by female hormones.[459]

Estrogen and progesterone also play a role in breast cancer susceptibility.[460] Earlier than average age at menarche is a modest risk factor for breast cancer, regardless of BRCA status[461,462]; notably, however, breast cancer risk has not been shown to be increased in precocious puberty, the *BRCA1* gene normally restrains mammary growth, at least in part, by inhibiting expression of ERα and PRs, and cancer-related mutations reverse these processes.[463]

Pilosebaceous Unit

The pilosebaceous unit (PSU), with but few exceptions, consists of both a piliary and a sebaceous component.[464] Androgens are a prerequisite for the growth and development of PSUs in their characteristic pattern. Androgens exert their effects both on the dermal papilla, which regulates the hair growth cycle, and on PSU epithelium. Before puberty, the androgen-dependent PSU consists of a prepubertal vellus follicle in which the hair and sebaceous gland components are virtually invisible to the naked eye (Figure 15-30). Under the influence of androgens, in the *sexual hair areas* the PSU switches to producing a medullated terminal hair follicle that expresses a unique type of keratin that is androgen responsive.[465] The difference in the apparent density of sexual hair between men and women is due to differences in the density of terminal hairs that develop in response to androgen. In the *balding-prone area* of scalp in individuals genetically predisposed to pattern alopecia, androgens weakly attenuate the hair

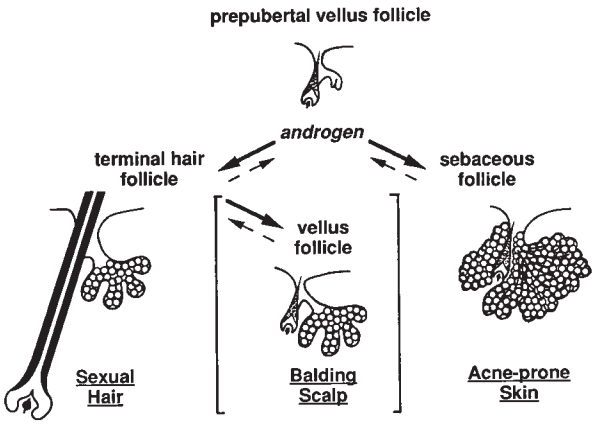

FIGURE 15-30 ■ Role of androgen in the development of the pilosebaceous unit. Androgens (solid lines) are responsible for the patterned differentiation of the pilosebaceous unit at puberty. Dotted lines indicate effects of antiandrogens. Hairs are depicted only in the anagen (growing) phase of the growth cycle. In balding scalp (bracketed area), terminal hairs not previously dependent on androgen regress to vellus hairs under the influence of androgen. (From Rosenfield, R. L., & Deplewski, D. (1994). Role of androgens in the developmental biology of the pilosebaceous unit. *Am J Med, 97*, 80.)

growth cycle, so that the PSU gradually generates only vellus follicles.[466] In *acne-prone areas*, androgen causes the prepubertal vellus follicle to develop into a sebaceous follicle, in which the sebaceous epithelium develops and the hair remains vellus. Adrenarchal levels of androgens suffice to successively initiate sebaceous gland development and the growth of pubic hair. Progressively greater amounts of androgen are in general required to stimulate terminal hair development along a pubic to cranial gradient. All these effects of androgen are to some extent reversible by antiandrogens.

Estrogens modestly stimulate hair growth, probably by inhibiting the catagen (resting) phase of the hair cycle[467]; this may well be due to induction of androgen receptors by estrogen. Estrogens also directly inhibit sebum secretion. GH synergizes with androgen action on the PSU, in part by acting through IGF-1. Retinoic acid receptor agonists antagonize the effects of androgen on the sebaceous gland by inhibiting sebocyte proliferation and differentiation. Insulin, prolactin, glucocorticoids, thyroxine, and catecholamines also play roles in PSU growth, development, and function.

Bone

Increased secretion of sex hormones clearly initiates the pubertal growth spurt. About half of this effect of sex hormones is due to their stimulation of the GH-IGF axis.[468] The remaining effects of sex steroids on skeletal growth are direct.[469,470]

Differences between the actions of sex hormones contribute to women's bones being shorter and narrower than men's.[471,472] The basis for these differences are diverse and involve interactions with IGF-1 and effects on cortical, cancellous, and periosteal bone formation.

Estrogen and androgen both stimulate epiphyseal growth. E2 is the critical hormone that brings about epiphyseal closure.[473] Estrogen also is particularly effective in reducing bone turnover. To some extent these effects may be prenatally programmed.[474]

Bone accrual during puberty is a major determinant of adult fracture risk. Menarche after 15 years carries a 1.5-fold increase in fracture risk, and the risk rises with age of menarche.[475]

Adipose Tissue

Women have a greater percentage of body fat than men.[476] During puberty they develop both more and larger fat cells than men in the lower body. Serum levels of leptin rise throughout puberty to reach higher levels in females than males,[248] whereas levels of the antilipolytic adipocytokine adiponectin remain stable in females but fall in males.[477]

The reasons for this sexual dimorphism are complex. Androgens inhibit adipogenic differentiation of human mesenchymal stem cells and pluripotent cells reciprocally to their stimulation of the myogenic lineage, in a dose-dependent fashion.[478,479] The role of estrogen itself in body fat accrual is unclear. In young women estrogen promotes lipogenesis and a lower-body (gluteofemoral) fat distribution; this contrasts with androgen, which generally promotes lipolysis and upper-body (visceral) fat accumulation. However, hypogonadal adults become obese. Studies in rodents suggest that estrogen deficiency causes obesity and that estrogen reverses this effect; the data are compatible with estrogen stimulating energy expenditure and weight loss by a hypothalamic effect.[426] In rats, progesterone counters the estrogen effect. In humans, use of the progesterone analogue megestrol acetate is approved to stimulate appetite and weight gain; use of progestins is associated with insulin resistance.[480]

Central Nervous System

Genetic, epigenetic, biologic, social, and psychological factors are all important determinants of gender-related aspects of human development and behavior. Sex chromosomes directly affect sexually dimorphic neuronal differentiation.[481] The maternally inherited X chromosome is preferentially expressed in glutamatergic neurons of the cerebral cortex, and sex-specific imprinting of autosomal genes of the hypothalamus is common in females.[482] These findings suggest sex-specific parent-of-origin influences over neurologic and hypothalamic function of offspring.

Considerable evidence supports the concept that sex hormone exposure prenatally or during the period of transient activation of the hypothalamic-pituitary-gonadal axis of the neonate organizes gene expression and neural substrates in a sexually dimorphic manner. This predisposes to sex-typical behavior or function that is activated when the child is exposed to the sex-specific pubertal hormonal milieu.[483,484]

Several human brain structures are sexually dimorphic, some becoming so at puberty.[485-487] In lower species, sexually dimorphic nuclei develop only if the brain is exposed to androgen during a critical time in the newborn period, but not if the androgen exposure is too late or too little.

For example, in rats the preoptic nucleus of the hypothalamus is larger in males, and treatment of newborn females with testosterone or E2 permanently increases neuronal development and causes subsequent masculinized sexual behavior and anovulation.[13,488]

This and many other such effects appear to be mediated by the intraneuronal aromatization of testosterone to E2 in a manner that is regulated in a site-specific fashion by androgen and estrogen.[489,490] Thus, it has been postulated that low levels of E2 promote the development of the brain and greater amounts masculinize it. These higher levels of estradiol are generated in the male brain by neuronal aromatization of circulating testosterone. Estrogen receptor-α knockout in female mice reduces sexual behavior and parenting behavior while increasing aggressiveness.[491] On the other hand, some masculinizing effects of testosterone on behavior are androgen specific.[492]

Androgen has been shown to up-regulate brain 5α-reductase and aromatase only in the perinatal period.[493,494] There is also sexual dimorphism in cerebral progestin receptors, and progesterone attenuates the testosterone effect on the brain and reduces the number of estrogen receptors in the cerebral cortex.[495,496]

Sex hormones also have diverse effects on areas of the adult brain that variously exhibit apoptosis-mediated morphologic plasticity in synaptic patterns or are involved in reproductive behavior and function and nonreproductive functions such as memory and learning. Estrogen, for example, alters the pattern of synaptic connections in spatially specific and precise patterns that appear to fine-tune the sensitivity of certain regions of the brain to excitatory and inhibitory amino acids.[497,498] Hypothalamic changes in synaptic remodeling have been correlated with the preovulatory surge of GnRH. Androgen up-regulation of androgen receptor levels and the nuclear size of sexually dimorphic hypothalamic areas of the brain has been shown to occur in adult animals.[499,500] Progestins seem to protect against brain injury in adults, but studies indicate that they act oppositely in immature animals, possibly in relation to maturational changes in GABA action.[501,502]

On average, women tend to perform better than men on tasks that involve verbal skills, processing speed and accuracy, and fine-motor skills, whereas men tend to excel in visual-spatial memory; the sexes do not differ in vocabulary or math skills.[484,503-505] These differences are quantitatively modest, of the order of 0.4 to 1 SD, leading, therefore, to large overlaps in these skills between the sexes. The male advantage in visual-spatial skills is established by 4.5 years of age. Because both boys and girls who are congenitally sex hormone deficient are relatively poor in visual-spatial abilities, and sex hormone treatment at puberty does not ameliorate these deficits, this difference seems to be the result of estrogen-mediated patterning in both sexes. The extent to which these differences are innate or due to sociocultural factors is a subject of considerable debate.

A wide variety of sexual behaviors can be found in young children, but normally they have a different character than in adults.[506] Gender identity is established by 3 years of age.[486] Sexual orientation is established by 10 years of age; it has been postulated that this is dependent on adrenarche rather than true puberty.[507] Early pubertal amounts of androgen or estrogen have little effect on sexual behaviors but increase some aspects of aggressive behavior.[508,509] Only later in puberty is there activation of the sex drive, which has been programmed in early development.

A male level of androgen acting through the androgen receptor pre- or perinatally seems to be an important determinant of male gender role behavior and mildly disruptive to female gender identity.[486,510] Differences in the size of specific brain structures in men with gender identity disorders has raised the possibility that these disorders similarly have a biologic basis. In homosexuals, the human homologue of the rat preoptic nucleus is smaller than that of heterosexual men, as is the case in females,[511] and the anterior commissure is larger than that of heterosexual men or women.[512] In male-to-female transsexuals, a nucleus within the stria terminalis is small, female sized.[513] Male homosexuals have a pattern of nuclear activation in response to pheromone-like chemosignals like heterosexual women rather than like heterosexual men, and homosexual women have an intermediate type of activation.[514]

Androgen and estrogen metabolites in sweat and urine, which contain unusual steroids such as androst-4,14-diene-3-one,[515] have been found to exert sexually dimorphic activation of the anterior hypothalamus that is independent of their odor.[514] Therefore, they appear to act as pheromone-equivalent chemosignals. Human pheromones appear to modulate the timing of ovulation[516] and mood.[517] It is likely that a dedicated population of olfactory receptors that project to GnRH neurons act as pheromone receptors.[518]

Other Targets of Sex Hormone Action

Sex steroid hormones affect a wide variety of tissues in ways that are often unrecognized. An estrogen effect on stabilizing muscle integrity has been noted in muscular dystrophy.[519] Female and male sex steroids exert both complementary and antagonistic effects on immune function, but the extent to which differences in sex steroid levels underlie sex differences in immune function is unclear. Estrogen down-regulates blood levels of the inflammatory cytokine interleukin-6.[520]

The cardiovascular effects of estrogen include up-regulation of estrogen and progesterone receptors in vascular tissue and nongenomic effects on endothelial nitric oxide synthase.[521] Estrogens and progestins also exert hemostatic effects that are associated with increased resistance to the anticoagulant action of activated protein C.[522] Although estrogen improves the disturbed endothelial dysfunction of young hypogonadal women and is necessary for the cardioprotective effect of exercise,[523] oral conjugated estrogen use with and without medroxyprogesterone have been found to increase cardiovascular risk in postmenopausal women. However, such cardiovascular risks were not found in users of transdermal E2 doses $\leq$ 50 μg daily, whether or not combined with progestin.[524,525] Whether these results apply to premenopausal females or to other forms of estrogen is an area of

active research. Current evidence suggests that estrogen protects against the development of atherosclerosis but may be harmful after atherosclerosis is established.[526,527]

Oral contraceptives containing estrogen carry about a four-fold increased risk of venous thromboembolism in first-time users.[528,529] The risk falls with decreasing dose of estrogen and duration of use and may double in those containing the third-generation progestins drospirenone and desogestrel. Nevertheless, the risk is less than that of pregnancy. Progestin-only contraceptives are not associated with any increased risk of venous or arterial thrombosis.[528,530]

The differences between the sexes in lipid levels are not explained by physiologic differences in estrogen levels.[531] Although oral estrogens raise triglycerides, this is due to a first-pass hepatic effect. Differences in androgen (lowers high-density lipoprotein [HDL] cholesterol) and progesterone (lowers triglycerides and HDL-cholesterol) levels only explain part of the difference.

NORMAL SEXUAL MATURATION: HORMONAL AND PHYSICAL STAGES

The Fetus and Neonate

Steroid hormone levels from birth through puberty are shown in Table 15-1.[15,83,532-534] The fetus grows in a richer steroidal milieu than the pubertal female owing to the function of the fetoplacental unit. Concentrations of estrogens in fetal serum are extremely high. The umbilical cord plasma free testosterone level is modestly greater than that in normal adult females.[358] Dehydroepiandrosterone sulfate is at an adrenarchal level in the neonate. Pubertal hormone levels fall to a nadir within the first week of withdrawal from the intrauterine environment and then rise to maximal values in the early pubertal range at 3 to 4 months of age, as discussed in reference to Figures 15-5 and 15-8.

In premature infants, the "neonatal minipuberty" evolves according to a developmental program based on gestational age. Gonadotropin and sex steroid levels become normal for term infants when term gestational age is achieved. Adrenal contributions to steroid levels are higher in premature infants due to the persistence of the fetal adrenocortical zone and immaturity of the definitive adrenocortical zones.[535-537] Meanwhile, ovarian development and function lag, whereas compensatory gonadotropin levels are higher in premies.[18,538]

The newborn shows some signs of the pubertal degree of hormonal stimulation from the intrauterine environment. Hypertrophic labia minora and superficial cell transformation of the urogenital epithelium are consistently observed estrogen effects, and a palpable breast bud is present at term in one third of babies.[532] Menstrual bleeding and colostrum production sometimes occur as the newborn is withdrawn from the estrogenic environment. Sebaceous gland hypertrophy results from the androgenic state,[539] and the clitoral shaft sometimes is prominent, particularly in small premature babies.[441]

The activation of the hypothalamic-pituitary-gonadal axis of the newborn seems to be sufficient to sustain breast development through the first several months of life.[79] These phenomena then regress gradually over the first 2 years of life as the inhibitory tone of the neuroendocrine-gonadal axis undergoes juvenile maturation. Whether the transient activity of the neuroendocrine-gonadal axis in the newborn ("minipuberty of the newborn") has a programming influence on subsequent behaviors remains unclear.[486]

Childhood

As the neuroendocrine-gonadal axis becomes quiescent and the fetal zone of the adrenal cortex regresses, steroid hormone levels fall through infancy to reach a nadir in mid-childhood (see Table 15-1). Although gonadotropin levels are low, there is considerable evidence that secretion of bioactive gonadotropins is occurring. Though there is seldom obvious sexual development as a consequence of prepubertal gonadotropin production, there is a low level of bioactive gonadotropin production (see Figure 15-13) and ovarian follicular development[28,76,77] and occasional evidence of transient estrogen secretion.[540]

Adolescence

Hormonal

The earliest hormonal change during the preadolescent years is the adrenarchal rise in DHEAS (see Table 15-1). The earliest hormonal changes of true puberty occur gradually during late preadolescence—clinically prepubertal 10-year-olds develop greater average gonadotropin and sex hormone levels than do prepubertal 7-year-olds.[69]

In the average girl, serum gonadotropins achieve pubertal levels after 8 years of age. However, the chronologic age at which puberty begins varies considerably among children. Therefore, the pubertal rise in gonadotropins is best appreciated by relating gonadotropin levels to pubertal stage. Daytime serum LH rises 25-fold from prepuberty to late puberty according to bioassay, but this rise is underestimated by polyclonal radioimmunoassay (see Figure 15-13).[94] "Third-generation" immunometric assays, using monoclonal antibodies and a more purified standard than earlier radioimmunoassays, show a rise similar to that found by bioassay.[67,69]

The hallmark of early puberty is an increase in the sleep-related rise in LH (see Figure 15-12).[69,93] Daytime sampling underestimates the rise in gonadotropins in early puberty because it does not detect most of this sleep-related increase. In early puberty, third-generation assays show that LH rises during sleep to reach peaks in the lower adult range, generally above 1 U/L, and then typically falls during the day to 0.6 U/L or less.[69,83,541,542] A single daytime sample does not necessarily truly represent a child's pubertal status because it does not account for episodic and cyclic changes in gonadotropin secretion (see Figure 15-12).[91,543] The serum LH response to GnRH is slightly more indicative of the pubertal status than a morning basal sample (see Figure 15-9) (see Table 15-1).[85,541,542] An LH level 1-hour post-GnRH agonist of $\geq$ 3.2 U/L is 90% sensitive and $\geq$5.5 U/L is 95% specific for the onset of puberty in girls.[83]

The response of LH to GnRH or GnRH agonist administration increases more than that of FSH during puberty, with a resultant increase in the LH:FSH ratio.[67,544] GnRH agonists add a dimension to GnRH testing: they provide a sufficiently potent and prolonged stimulus to LH and FSH release to bring about an increase in ovarian E2 secretion in pubertal girls.[545] These responses likewise increase characteristically with sexual maturation (see Figure 15-6).[58]

Sex hormone levels rise further as the consequence of ovarian and adrenal maturation. Pubertal levels are intermediate between those of prepubertal and sexually mature individuals. Table 15-1 shows typical normal ranges for serum levels of the major steroid hormones. Once pubertal levels of estrogens and androgens are achieved, their effects ordinarily become obvious within 6 months.

Serum prolactin rises moderately in females at about 14 years of age.[546] This may be a response to estrogen secretion, because it does not occur in boys.

Clinical

The first physical sign of puberty is breast development (thelarche). In a minority of girls, pubic hair development (pubarche) occurs before thelarche. Thelarche represents a response to estrogen, and pubarche a response to androgen. When pubarche precedes thelarche, it is a reflection of adrenal androgen production (adrenarche) rather than a sign of puberty. The stages of breast and pubic hair development are shown in Figure 15-31.[547,548] Tanner stage 1 is prepubertal. The initial stage of breast development (stage 2, B2) is appreciated as a palpable subareolar bud before it can be seen as an elevation. Stage B3 is obvious enlargement and elevation of the whole breast. Stage B4, the phase of areolar mounding, is very transient and may not necessarily appear. Stage B5 is the stage of attainment of mature breast contour. Pubic hair first starts as presexual pubic hair development (PH2)—hairs which are shorter, lighter, and straighter than sexual pubic hairs but longer than vellus body hair. Hypertrichosis is sometimes mistaken for stage 2 pubic hair; these can be differentiated by comparing genital hair to hair on the forearm. Sexual pubic hair development (PH3)—curly terminal (long, dark) hair—usually commences on the labia majora before spreading to the pubis. Pubic hair then gradually progresses to the mature female escutcheon (inverted triangle pattern, stage 5). Axillary hair usually appears about a year later than pubic hair and passes through similar stages.

The age at which pubertal milestones are normally attained is not known with certainty. There has been considerable debate about the normalcy of pubertal changes between 6 and 8 years of age.[185,198,549] The debate stems from office practice observations that breast and pubic hair development were found more frequently than expected in black girls in this age range, whereas the age of menarche was unremarkable. The increasing prevalence of obesity interacting with ethnic factors now appears to be a major factor in this early onset of puberty.[243] The prevalence of pubertal milestones has been estimated for the general U.S. population by modeling data collected on children 8 years of age and older by the National Health and Nutrition Examination Survey III (NHANES III).[193,194,243] Although NHANES data has the advantage of nationally representative sampling, the quality of the data for early breast and pubic hair development is questionable, and modeling assumptions that permit extrapolation to younger ages may not be valid.[243,550,551] The ages at which the major pubertal milestones are currently attained in normal-weight U.S. girls according to this database are given in Table 15-3.[243] It appears that puberty begins before 8 years in $< 5\%$ of the normal general female population, although breasts may normally appear during the 7th year in blacks and Mexican Americans.

An important normal variable is the span of time between the onset of breast development (B2) and menarche. The concept that this is constant at 2.3 ± 1 year regardless of the age at which B2 occurs[547] has been challenged. In several normal populations of girls observed longitudinally, the onset of puberty was only weakly correlated with the age at menarche, and the earlier puberty began, the longer its duration and the greater the incremental growth so that height potential was preserved.[552-554] These studies suggest that the factors governing the onset

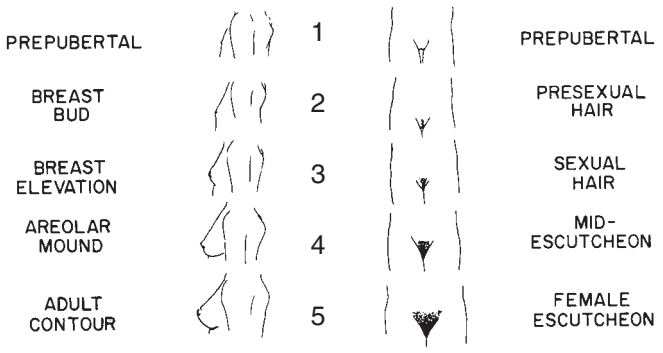

FIGURE 15-31 ■ The stages of breast and pubic hair development. (Redrawn from Ross, G. T., Vande Wiele, R. (1974). The ovary. In R. H. Williams (Ed.), *Textbook of endocrinology* (5th ed.) Philadelphia, WB Saunders.)

TABLE 15-3 **Pubertal Milestone Attainment in Normal BMI Girls in the General U.S. Population (Estimated Age in Years)***

Stage	5%	50%	95%
Breast stage 2	8.25	10.2	12.1
Pubic hair stage 3	9.25	11.6	13.9
Menarche	11.0	12.6	14.1

*Breasts appear before age 8 years in 12% to 19% and sexual pubic hair (stage 3) in ≤ 3% of normal-BMI non-Hispanic black and Mexican-American girls. Menarcheal milestones are attained at similar ages in these ethnic groups except for the 5th percentile being significantly earlier in blacks (10.5 years) than non-Hispanic whites (11.3 years).

Adapted from Rosenfield, R. L., Lipton, R. B., & Drum, M. L. (2009). Thelarche, pubarche, and menarche attainment in children with normal and elevated body mass index. Pediatrics, 123, *84–88.*

of puberty and its tempo differ. Longitudinal and hormonal data are compatible, with excess adiposity slowing the tempo of puberty, although less so than prepubertal adiposity advances puberty onset.[552,554-556] A subgroup of early maturers with a history of intrauterine growth retardation seem to have an unusually rapid tempo of puberty and lose height potential.[557]

The onset of puberty is more closely related to an individual's bone age than to chronologic age. This is particularly important in the case of subjects who are later than average in entering puberty, as discussed previously. The great majority of girls can be expected to begin puberty by the time their skeletal age reaches 12.5 years and to experience menarche by the time skeletal age reaches 14 years.

The pubertal growth spurt in girls occurs during early adolescence. The peak of linear growth velocity corresponds most closely with stage B2,[558] and the increase in serum alkaline phosphatase levels corresponds with B3.[559] Fat accumulation increases, and fat distribution changes as well.[552] As a consequence of these pubertal changes occurring out of phase with chronologic age, girls begin to differ considerably in size and habitus during the ninth year of life.

Adult Menstrual Cycle

The menstrual cycle of young adults averages 28 days in length (90% population limits, 22 to 42 days after the fifth gynecologic year).[560] The variation in cycle length is almost entirely due to differences in the duration of the follicular phase. The luteal phase, the time between ovulation and the onset of menses, invariably lasts 14 ± 1 (SD) days.[123]

The cyclic changes of LH, FSH, E2, and progesterone serum levels during the menstrual cycle are shown in Figure 15-14. Diurnal and episodic fluctuations are superimposed upon these diurnal changes. Because testosterone and androstenedione have both adrenal and ovarian origins, their levels fluctuate to some extent in cyclic, diurnal, and episodic patterns. For example, testosterone levels tend to be 20% greater in the morning than in the evening and tend to rise 50% to 100% in midcycle.[122,561] The normal range for most of the important ovarian sex hormone levels of women during the early follicular phase of the menstrual cycle is given in Table 15-1. Progesterone levels are below 100 ng/dL until the periovulatory phase of the cycle and then peak to over 500 ng/dL in the midluteal phase. Hormonal production rates for the midfollicular phase in women are given in Table 15-2. Serum prolactin increases transiently in midcycle with maximum ovarian E2 secretion.[562] Prolactin levels also transiently rise in response to mammary stimulation and psychological factors.[563]

Normal Variations in Pubertal Development

Although the onset of breast development (stage B2) characteristically precedes the appearance of sexual pubic hair (PH3) and the onset of menses substantially (see Table 15-3), there is normally considerable variation in the sequence of these events. Pubic hair may appear before breasts begin to develop, a situation arising from lack of direct linkage between adrenarche and gonadarche. Menarche may occur within months after the appearance of breasts; however, this is so unusual that its occurrence demands exclusion of an abnormal hyperestrogenic state.

A common normal variant is the unilateral onset of breast development. Unilateral breast development may exist up to 2 years before the other breast becomes palpable. This phenomenon seems related to an asymmetry that normally persists into adulthood. Excisional biopsy of a normal unilateral breast papilla in search of a nonexistent tumor should be avoided, because such a procedure excises the entire breast anlage.

Two extreme variations of normal are the most common causes of premature sexual development.[564] These are the isolated appearance of breast development *(premature thelarche)* and the isolated appearance of sexual hair *(premature pubarche)*.

Premature Thelarche

Breast development before 8 years usually seems to be due to idiopathic subtle overfunction of the pituitary-ovarian axis, occurring in girls whose FSH levels tend to be sustained about the upper end of the prepubertal normal range.[540] Average serum levels of FSH at baseline and in response to GnRH are significantly increased, whereas those of LH are not. E2 levels are generally below the level of detection in most standard assays, but they are significantly elevated according to ultrasensitive assay,[565] and intermittent low-grade estrogenization of the urogenital mucosa is sometimes found (see Figure 15-11). Ovarian ultrasound examination shows an increased prevalence of antral follicles ("microcysts"). Nevertheless, a growth spurt does not occur, the bone age does not advance abnormally, and menses does not appear until the usual age.

In infants the syndrome seems to be due to a lag in inhibition of the transient activation of the hypothalamic-pituitary-gonadal axis of the newborn and is usually unsustained. In older children the breast development is more likely to persist. A subgroup with "exaggerated thelarche" has an increased growth rate with relatively proportionate bone age advancement. The unsustained or intermittent neuroendocrine activation seems to lie on a spectrum between ordinary premature thelarche and true sexual precocity (Figure 15-32).[566] However, the McCune-Albright syndrome mutation is found in the peripheral blood of about 25% of such patients.[567] Premature thelarche may be the first sign of feminizing disorders (see "Precocious Puberty"). Therefore, follow-up of these patients is indicated.

Premature Pubarche

Pubarche before 8 years of age usually is due to "premature adrenarche," which is indicated by adrenarchal androgen levels—that is, DHEAS 40 to 130 μg/dL with other androgen levels in the marginally early pubertal range (see Table 15-1).[15,568] However, it may occur at androgen levels that are less ("idiopathic premature pubarche") or more ("exaggerated adrenarche"). The androgen excess is ordinarily so subtle that the only other

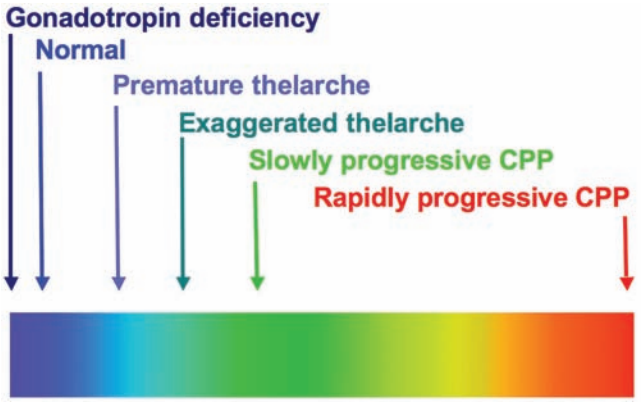

FIGURE 15-32 ■ The spectrum of gonadotropin secretion in girls. Normal girls are conceptualized as having a small amount of pituitary-ovarian axis activation, which is more than that of congenitally hypogonadotropic girls. Premature thelarche, exaggerated thelarche, slowly progressive precocity, and rapidly progressive precocity fall along a spectrum of increasing activation of the axis—with deterioration of height potential occurring only in those near the most activated end. *This image can be viewed in full color online at ExpertConsult.* (Modified from Kreiter, M. L., Cara, J. F., & Rosenfield, R. L. (1993). Modifying the outcome of complete precocious puberty: to treat or not to treat. In G. D. Grave, & G. B. Cutler (Eds.), *Sexual precocity: etiology, diagnosis, and management* (pp. 109–120). New York: Raven Press.)

sign of increased androgen production may be microcomedonal acne and apocrine body odor. There is no obvious growth spurt, the bone age typically does not advance abnormally, and there are no other signs of sexual maturation.

Exaggerated adrenarche is an extreme type of premature adrenarche. These girls have clinical features that suggest subtle androgen excess (e.g., significant bone age advancement, but not clitoromegaly) or insulin resistance (e.g., central adiposity or acanthosis nigricans). Such children generally have a slightly advanced onset of true puberty, but height potential is not compromised. Adrenal steroid levels are in the mid- or late pubertal range (e.g., DHEAS > 130 to 185 μg/dL, androstenedione > 75 to 99 ng/dL, or post-ACTH 17-hydroxypregnenolone > 750 ng/dL). Testosterone does not exceed the lower end of the adult female range.

It is unclear whether premature adrenarche is simply an extreme normal variant due to advanced onset of normal zona reticularis development or an early manifestation of the steroidogenic dysregulation of polycystic ovary syndrome. Carriers for congenital adrenal hyperplasia may be overrepresented in this group.[569,570] Premature adrenarche appears to carry about a 10% to 20% risk of developing polycystic ovary syndrome; it is unclear whether those with exaggerated adrenarche are primarily at risk. The differential diagnosis includes virilizing disorders, of which nonclassic congenital adrenal hyperplasia is the most common. Girls with premature adrenarche should be followed through puberty.

Constitutional Delay of Pubertal Development

By statistical definition, delayed puberty occurs in 3% of girls. Most of these girls are otherwise normal, in which case this is termed *constitutional delay of growth and pubertal development*. It is familial[195,196]; 80% in a large series had a parent with objectively delayed puberty.[571] Although its inheritance likely is complex, some predisposing genetic factors seem to have a dominant effect. Delayed puberty seems overrepresented in families with idiopathic hypogonadotropic hypogonadism or hypothalamic amenorrhea cases, and rare variants in genes underlying these conditions appear to contribute to the etiology.[572,573] Girls with constitutional delay are generally more slight in habitus and have lower bone mineral density upon entering puberty than earlier maturing girls.[574] Girls do not usually become concerned about delayed puberty until they enter high school at 14 years of age and realize that not only has pubertal development not begun but most of their friends are menstruating. When puberty does ensue in such girls, it is perfectly normal in tempo. Endocrinologic status is normal for the stage of puberty. The differential diagnosis includes chronic endocrine, metabolic, and systemic disease of almost any kind, as well as gonadotropin deficiency, which it closely resembles and from which it is distinguished with difficulty (see "Gonadotropin Deficiency" and the discussion of functional hypothalamic amenorrhea presented in "Hypothalamic Anovulation").

Physiologic Adolescent Anovulation

Because of immaturity of the hypothalamic-pituitary-ovarian axis, about half of menstrual cycles during the first 2 years after menarche are anovulatory or have attenuated ovulation that results in luteal insufficiency.[575-577] This accounts for the greater menstrual irregularity and longer average intermenstrual length in the early postmenarcheal years than in adults (Figure 15-33).[560,578] Although about half of these seemingly "anovulatory" cycles are irregular, half are of normal length by adult standards, so menstrual regularity is greater than ovulatory frequency would

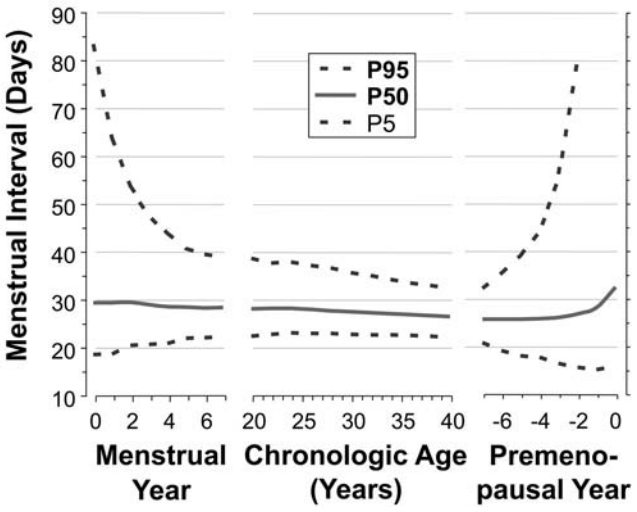

FIGURE 15-33 ■ Normal range for interval between menstrual cycles. Note that cycle intervals averaging more than 90 days or fewer than 22 days are abnormal at any age. P5 and P95 = 5th and 95th percentiles, respectively. (Modified from Treloar, A., Boynton, R., Benn, B., & Brown, B. (1967). Variation of human menstrual cycle through reproductive life. *Int J Fertil, 12,* 77–84.)

suggest. Although there is considerable variation in the time it takes for menstrual cycles to mature, menstrual regularity approximates adult standards in most girls within a year of menarche: three quarters have a cycle length between 21 and 45 days, and 5% more fall within these bounds by each of the next 3 years.[575,576] By the fifth gynecologic year onward, 90% of menstrual cycles last 21 to 40 days, and about 75% of cycles are ovulatory, though ovulatory adequacy continues to mature for several years thereafter.

Menstrual abnormalities in adolescence can be defined similarly to those in adults.[578,579] *Primary amenorrhea* is failure to begin menses at a normal age (by 15 years of age or within 3 years of thelarche). *Secondary amenorrhea* is the absence of menstrual periods for 90 days or more after initially menstruating. *Oligomenorrhea* is defined during the first postmenarcheal year as having fewer than four periods a year; during the second year as fewer than six periods a year; and from three until five years postmenarche it is defined as fewer than eight periods per year (i.e., missing more than four periods per year, which amounts to > 45 days between menstrual periods). Thereafter it is defined according to the adult criterion of having less than 9 periods a year. Anovulatory bleeding may also be excessive, as discussed in the later section on *Dysfunctional uterine bleeding*.

Menstrual abnormalities in adolescents are more appropriately considered "symptomatic" rather than being considered "physiologic" adolescent anovulation. By 1 year postmenarche, failure to establish and sustain a normal adult menstrual pattern carries approximately a 50% risk of persistent oligo-ovulation, and failure to do so by 2 years after menarche carries approximately a two-thirds risk (Figure 15-34).[574] Thus, persistence of menstrual irregularity for 1 year or more is a strong indication for investigation (see "Abnormal Puberty").

Serum LH, testosterone, and androstenedione levels are significantly higher in adolescents with anovulatory than those with ovulatory cycles.[580,581] It is unclear whether this is the cause or the result of the anovulation; however, if hyperandrogenemia is found, it seldom regresses.[116] A polycystic ovary is common in adolescents and is usually a variant of normal, unless associated with menstrual abnormality or hyperandrogenism.[73,116-118,121,534]

Other Normal Adolescent Variations

There is considerable variation in the amount of *acne*, *hirsutism*, and *adiposity* among normal adolescent girls, most of which is related to familial factors. Three quarters of adolescent girls experience some degree of acne, with one quarter experiencing mild inflammatory acne.[582,583] The initiation of acne is more closely related to blood levels of DHEAS than of other androgens.

Profound *psychological* changes occur during adolescence. Sexually immature girls tend to be socially immature, and the onset of puberty is associated with increased

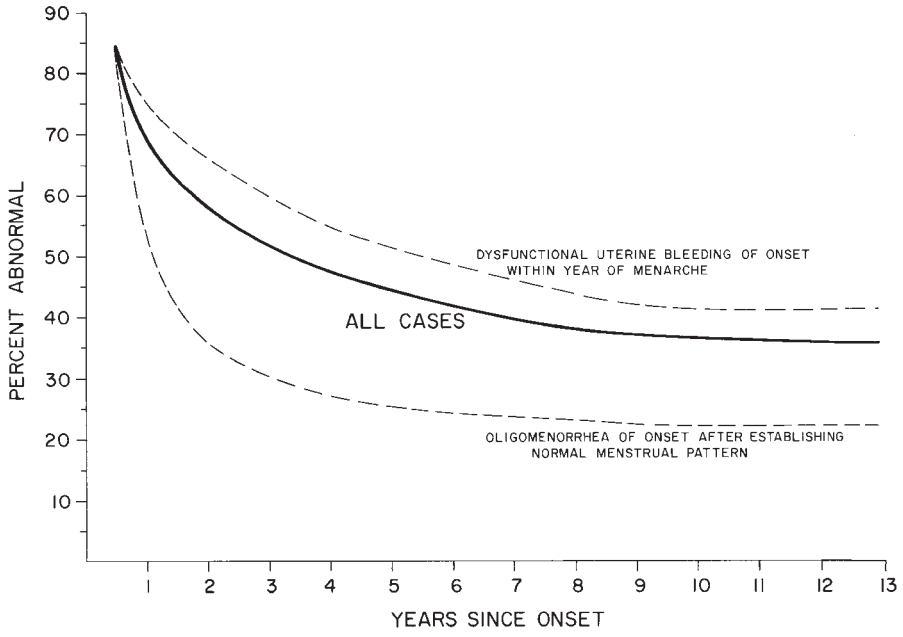

FIGURE 15-34 ■ Probability that an adolescent with a menstrual abnormality severe enough to require gynecologic consultation will have continued menstrual abnormality. The lines show the cumulative rates at which subjects with menstrual abnormalities converted to normal patterns. The heavy curve shows the overall incidence of continued menstrual abnormality in adolescents when considering both types of anovulatory manifestation (dysfunctional uterine bleeding and oligomenorrhea) regardless of time of onset. The dotted lines show those subgroups that differ most from the overall pattern. Other subgroups fall within approximately 5% of the mean for the entire group. Note that dysfunctional uterine bleeding of onset within 1 year of menarche carries the worst prognosis for continuing menstrual abnormality (upper dotted line). Note also that oligomenorrhea of relatively short duration occurring after a normal menstrual pattern has been established carries the best overall prognosis. Nevertheless, it can be seen that if the menstrual abnormality persists for 1 year there is about a 50% probability, and if for 2 years there is nearly a 67% probability, that the patient will not spontaneously evolve to normal cycles. Similarly, if the problem persists for 5 years, there is an 80% likelihood of persistence of the abnormality. (Redrawn from Southam, A. L., & Richart, E. M. (1966). The prognosis for adolescents with menstrual abnormalities. *Am J Obstet Gynecol*, *94*, 637.)

independence and profound changes in outlook on life and intellectual capacities. The extent to which these developments occur in reaction to the physical changes of puberty and the extent to which they are direct effects of sex hormones are unknown. Masculine tomboyish traits usually have no clear hormonal basis, although there is some evidence that they may have prenatal hormonal determinants. Social interactions have effects on these aspects of development. They affect even the synchrony of the menstrual cycle.[584]

Despite the popular notion that adolescence is inherently a period of turmoil, the majority of teenagers do not develop significant social, emotional, or behavioral difficulties.[585] Occasional experimentation and risk-taking are normal, as are withdrawal from and conflict with parents. Adolescent behavior must be understood in the context of individual susceptibility, family upbringing and interactions, peer group interactions, changes in brain maturation, and adolescents' reaction to their perception of the bodily changes and to the sexual urges that are the direct consequences of puberty. Simply because a problem is displayed during adolescence does not mean that it is a direct consequence of puberty.

Many behavioral problems that emerge during adolescence have earlier roots. Although the prevalence of depression increases during puberty, many children who develop depression during adolescence have had preexisting symptoms of psychological distress. Likewise, most delinquent teenagers have had antecedent problems at home and school.

Early-maturing girls in Western cultures are more popular, but they have more emotional problems, lower self-image, and higher rates of depression, anxiety, and disordered eating than their peers. Early maturation appears particularly to be a risk factor for problem behavior among girls who have had a history of difficulties prior to adolescence, when they have more opposite-sex friendships and relationships, and when they attend coeducational schools.

Short-term administration of testosterone or estrogen has minimal effects on behavior or mood in adolescents.[508,586] Thus, variation in hormone levels accounts for only a small fraction of adolescents' affective issues, and social influences account for considerably more. Although there is little evidence that psychological difficulties stem directly from hormonal changes during normal puberty, it is likely that the bodily changes of adolescence play a role in the development of a negative body image when they occur out of synchrony with sociocultural norms.

Problems with initiating and maintaining sleep are common in adolescents and contribute a small amount to poor school performance.[587] Although insufficient sleep might be due to environmental factors (e.g., social and academic pressures), intrinsic factors clearly play an important role. A 50% decline in the intensity of deep (slow wave, delta) sleep occurs during adolescence, and half of this change occurs between 12 and 14 years of age.[588] Evidence indicates that this change is related to age and sex, beginning earlier in girls, but not to pubertal stage. It has been proposed that this shift is a manifestation of the widespread synaptic pruning that is related to the emergence of adult cognitive capacity.

The causal direction of the link between pubertal development and the quality of family relationships has come into question. Several studies have indicated that family dynamics may affect the timing and course of puberty, with earlier and faster maturation observed among adolescents raised in homes characterized by more conflict and among girls from homes in which the biologic father is not present.[585]

ABNORMAL PUBERTY

Abnormal Development

Disorders of Sex Development

Patients with disorders of sexual development (DSD) (formerly termed *intersex*)—those whose genitalia are ambiguous or inappropriate for their gonadal sex as a result of endocrinopathy—may come to a physician's attention for the first time at puberty. These syndromes have been categorized as 46, XX DSD, which encompasses cases formerly termed *female pseudohermaphroditism* and including 46, XX testicular DSD (formerly termed *XX sex reversal*); 46, XY DSD, which encompasses cases formerly termed *male pseudohermaphroditism* and including 46, XY complete gonadal dysgenesis (XY sex reversal, Swyer syndrome); and sex chromosome DSD, which includes Turner syndrome, Klinefelter syndrome, mixed gonadal dysgenesis, and chimeric ovotesticular DSD.[486] In the absence of chromosomal mosaicism, ovotesticular DSD, formerly termed *true hermaphroditism*, is categorized as either 46, XX DSD or 46, XY DSD. Patients with any of these disorders may undergo inappropriate puberty. They may present with clitoromegaly and be found upon examination to have a degree of genital ambiguity that was previously overlooked. Virilization beginning at puberty is sometimes the presenting complaint. Ovotesticular DSD and 46, XX DSD due to congenital adrenal hyperplasia are compatible with fertility.[366] Androgen insensitivity syndrome in a genetic male may present as primary amenorrhea in an otherwise phenotypically normal adolescent girl. The disorders of sexual differentiation are reviewed in detail in Chapter 5.

Congenital virilization of the female developmentally programs the emergence of polycystic ovary syndrome at puberty. These observations are consistent with studies of fetal androgenization of the female in several species, including primates.[15,16,589] There is a persistent increase in LH pulse frequency and impairment of the negative feedback effect of progesterone on LH release that appear to be related to suppression of hypothalamic PR in response to E2. Experimental animals exposed to androgen excess early in gestation develop classic polycystic ovary syndrome features: these animals have elevated LH levels, ovarian and adrenal hyperandrogenism, oligomenorrhea, and polyfollicular ovaries. They also have abdominal obesity, insulin resistance, impaired glucose tolerance, and dyslipidemia, which likewise appear to result from developmental programming.

Genetic males with androgen insensitivity have low LH levels and poor LH responsiveness to GnRH in the neonatal period.[54] Gonadotropin levels are normal to high at puberty, yet these individuals lack the capacity for positive feedback, which therefore appears to be mediated by estrogen metabolites of testosterone.[590]

Other Dysgenetic Disorders

Failure of the onset of menses can result from structural abnormalities of the genital tract that do not have an endocrinologic basis. The hymen may be imperforate, which results in hydrocolpos if the vagina is intact. The vagina may be aplastic, which will result in hydrometrocolpos if the uterus is intact. The uterus may be congenitally aplastic. Uterine synechiae develop as the consequence of endometritis, which may result from infection or irradiation (Asherman syndrome). Congenital absence of the vagina may be associated with varying degrees of uterine aplasia; this is the Rokitansky-Kustner-Hauser syndrome.[591] This syndrome seems to occur as a single gene defect or as an acquired teratogenic event involving mesodermal development and the mesonephric kidney, the latter resulting in abnormalities of the genital tract and sometimes the urinary tract. A subtype due to *Wnt4* gene defects is associated with hyperandrogenism.[592]

Precocious Puberty

Causes

When breast or sexual pubic hair development begins before the age of 8 years or when menses begins before the age of 9.5, puberty is traditionally considered precocious, or premature. It should be kept in mind that breast development during the 7th year is within normal limits in ethnic minority girls. In addition, presexual pubic hair (stage 2) may be normal in 6- and 7-year-old ethnic minority girls.

Puberty can occur prematurely as an extreme variation of normal, because of a disturbance in the hypothalamic-pituitary-gonadal (HPG) axis normally involved in sexual maturation, or because of a disturbance outside the HPG axis. Depending on which part of this hormonal axis is involved, different forms of precocious puberty are distinguished. A classification of the causes of premature puberty, together with typical findings, is given in Table 15-4.

It is important to distinguish between *true* precocious puberty and pseudoprecocious puberty. True precocious puberty is gonadotropin dependent; thus, *central* is another term applied to this type of precocity. Maturation is *complete*: both breasts and pubic hair develop as the result of CNS activating pituitary secretion of the respective gonadotropins FSH and LH (although breast development may be the sole manifestation of early complete precocity for as long as 6 to 12 months). Patients with true precocious puberty have "isosexual" precocity because the secondary sexual characteristics are appropriate for the sex of the child. Pseudoprecocious puberty is gonadotropin independent; it is not mediated by pubertal pituitary gonadotropin secretion and is sometimes termed *peripheral*. Maturation is *incomplete*, with only one type of secondary sexual characteristic developing early. Peripheral precocity has diverse causes. In some patients with pseudoprecocity, pubertal development is isosexual; in others it is *contrasexual*, meaning that characteristics of the opposite sex are manifested.

Complete Precocious Puberty. True isosexual precocity results from pubertal function of the hypothalamic-pituitary-gonadal axis. About 95% of true precocity in girls is idiopathic. *Idiopathic* true sexual precocity appears to be due to premature triggering of the normal pubertal mechanism. Pubertal development usually is qualitatively and quantitatively normal except for its early occurrence. The predominance of the idiopathic cases in females and its benign nature are compatible with the likelihood that this disorder is an extreme exaggeration of the normal tendency of girls to have relatively high gonadotropin levels. Most cases are sporadic, a few familial. The majority of these patients seem to go on to have normal menstrual cycles and fertility.[593] Indeed, pregnancy has been documented to occur as early as 4 years of age.

Rapidly progressive puberty with a growth spurt ensues when activation of the pituitary-ovarian axis is sustained. However, precocious puberty is not necessarily sufficiently intense or sustained to cause inexorable progression or bring about deterioration of height potential.[594] Precocity in the 6- to 8-year age range usually is not rapidly progressive and most commonly seems to be due to excessive adiposity.[243]

Any type of intracranial disturbance can cause true isosexual precocity. These *neurogenic* disturbances are presumed to cause true sexual precocity by increasing the prevalence of excitatory inputs or by interfering with CNS inhibition of hypothalamic GnRH secretion.[595] These include congenital brain dysfunction, such as cerebral palsy or hydrocephalus, or acquired disorders, such as irradiation,[596] trauma, chronic inflammatory disorders, or masses in the region of the hypothalamus. The activation of GnRH release by hypothalamic injury may be mediated by TGF-α elaborated by reactive astrocytes. An empty sella is occasionally found.[597] The precocity of neurofibromatosis type 1 (von Recklinghausen disease) usually results from an optic glioma, which is often of low-grade malignancy, or from a hamartoma,[598] though occasionally with neither.[599] Hamartoma of the hypothalamus may cause central sexual precocity; this effect is most likely caused by an anatomic effect on hypothalamic structures rather than by acting as an "accessory hypothalamus" that releases pulses of GnRH into the pituitary portal circulation.[600,601] Figure 15-35 shows a hypothalamic hamartoma.

A small proportion of pineal tumors cause true sexual precocity.[602,603] The incidence of sexual precocity is about 3.5 times as great in nonparenchymatous neoplasms (such as gliomas and teratomas) as in parenchymatous pineal tumors. This suggests that these tumors cause sexual precocity via the absence of a normal pineal inhibitory factor rather than by destructive effects on inhibitory tracts. Although pineal masses may cause paralysis of upward gaze by pressure on the corpora quadrigemina, this sign is present in only a minority of cases.

TABLE 15-4 **Typical Findings in Female Sexual Precocity**

Locus	Type	HA*	BA*	Estrogens†	Androgens†	LH/FSH†	Pathology	Characteristics
Complete Precocity (Central, Gonadotropin-Dependent)								
Hypothalamic	Isosexual	+	++	+	+	+	Idiopathic Neurogenic Advanced somatic maturation	95% of female cases
Incomplete Precocity (Peripheral, Gonadotropin-Independent)								
Normal variant	Isosexual	−	−	±	−	±	None	Thelarche
	Isosexual	−	−	−	±	−	None	Pubarche/adrenarche
Neuroendocrine	Contrasexual	+	++	−	+	+/+++	LH/hCG excess	Familial or tumor
	Isosexual	Low	Low	−	−	+	Hypothyroid	Growth arrest
Ovary	Isosexual	+	++	+/+++	−	±	McCune-Albright	Bone lesions ± nevi ± ovarian cysts
	Isosexual/contrasexual	+	++	+/+++	+/+++	−	Tumor	
Adrenal	Contrasexual	+	++	±	+++	−	Congenital adrenal hyperplasia	Dexamethasone suppressible
	Contrasexual/isosexual	+	++	+/+++	+/+++	−	Tumor	
Ectopic	Isosexual	+	++	−/+++	−	−	Aromatase excess	
Exogenous	Contrasexual/isosexual	±	±	−	−	−	Sex steroid exposure	
End organ	Isosexual/contrasexual	−	−	−	−	−	Vaginal foreign body, abuse, tumor	

*HA (height for age) and BA (bone age); − normal; + advanced; ++ markedly advanced.
†Hormone levels; − normal prepubertal; + pubertal level; ++ adult level; +++ abnormally high.
FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone.

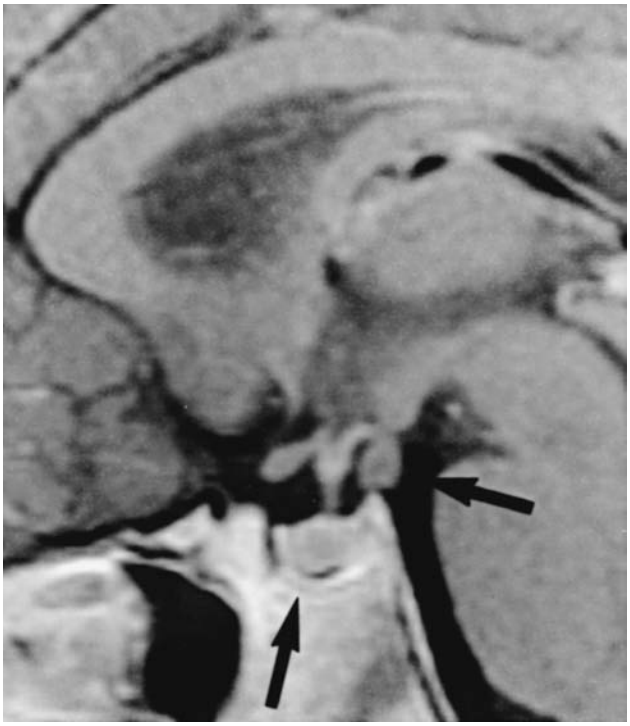

FIGURE 15-35 ■ Magnetic resonance image showing a hypothalamic hamartoma (right-hand arrow) as the cause of true sexual precocity in a 2.5-year-old girl. The hamartoma is hanging from the floor of the hypothalamus just posterior to the pituitary infundibulum. The sella turcica (bottom arrow) contains a normal pituitary gland with pituitary stalk hanging from the infundibulum.

Pineal or hypothalamic hCG-secreting germ cell tumors occasionally cause true sexual precocity.[604,605] Because hCG is a LH receptor agonist, possible explanations for this unusual situation are disinhibition of hypothalamic GnRH release due to a mass effect of the neoplasm, the weak FSH effect of massive elevation of hCG, or the capacity of some dysgerminomas to secrete E2 as well as hCG.[606]

Advancement of somatic maturation due to peripheral endocrine disorders that advance the bone age to a pubertal level sometimes causes true sexual precocity. Thus, true puberty may begin after correction of virilizing or feminizing disorders that have advanced the bone age to 10 to 12 years.[232,233]

The hypergonadotropism of premature ovarian insufficiency has been reported to cause sexual precocity or rapid progression of puberty prior to premature menopause.[607,608] Although polycystic ovary syndrome has occasionally been reported to follow true sexual precocity,[609] there is currently no evidence of a significant association.[593]

Rare causes of true sex precocity include mutations that enhance kisspeptin signaling,[610,611] inactivating mutation in a GnRH release-inhibiting signaling molecule MKRN3,[223] maternal uniparental disomy of chromosome 14, which causes the combination of intrauterine growth retardation and sex precocity,[612] and hyperglycinemia.[613] A genetic variant of a hepatic mixed function oxidase has been associated with female sexual precocity.[379]

Incomplete Precocity. The most common causes of incomplete sexual precocity in girls are the extreme variants of normal mentioned previously, premature thelarche and premature pubarche. These are incomplete forms of sexual precocity in which *either* breast development (thelarche) *or* sexual hair development (pubarche) is of a degree appropriate for an early stage of puberty and isosexual. Isolated prepubertal menses is a rare disorder that has been attributed to transient ovarian activity.[614]

LH- or hCG-producing tumors have not been reported to virilize girls, perhaps because of their limited capacity for thecal androgen production over short periods of time. However, familial isolated elevation of LH has been reported to cause mild virilization of siblings[615]: one was a girl who developed premature pubarche and clitoral hypertrophy at 4 years of age, with slight to moderate advances in height and bone age in association with an adrenarchal level of DHEAS and a moderately elevated testosterone level (91 ng/dL).

The *Van Wyk-Grumbach syndrome* is one of the most puzzling pediatric complexes.[616] This is an unusual syndrome of sexual precocity associated with juvenile hypothyroidism. A case is illustrated in Figure 15-36. This syndrome is often characterized by galactorrhea, which is often not spontaneous; a few drops of milky fluid may become apparent only upon "milking" the subareolar ductal tissue. Multicystic ovaries are often demonstrable by ultrasonography.[617] Modern assays show that levels of LH at baseline and post-GnRH are suppressed and those of FSH are early pubertal.[618] There is little, if any, sexual hair development. There is another clinically unique feature about the sexual precocity of hypothyroidism: it is the only form of sexual precocity in which growth is arrested rather than stimulated and is an exception to the general rule, indeed followed by most chronically hypothyroid children, that a delayed growth pattern is associated with delayed puberty.

Van Wyk and Grumbach postulated that this syndrome resulted from hormonal "overlap" in the negative feedback regulation of pituitary hormone secretion, with overproduction of gonadotropins as well as TSH in response to the thyroid deficiency. The specific nature of hormonal overlap has been considerably clarified, but the pathogenesis remains unclear. The increases in serum TSH and prolactin that characterize the syndrome could well be accounted for by common neurohumoral control systems, TRH stimulating and dopamine inhibiting both hormones. It has been suggested instead that the ovarian FSH receptor is activated by the weak intrinsic FSH activity of extreme TSH elevation,[619] analogous to the rare ovarian hyperstimulation syndrome in which pregnancy levels of hCG activate the FSH receptor.[620]

Prolactin excess has been postulated to underlie the FSH-predominant gonadotropin pattern by slowing GnRH pulsations, and it is this FSH stimulation of the TSH-sensitized ovary that seems to be the proximate cause of the sexual precocity.[621] Hyperprolactinemia alone does not correspond with pubertal development in normal

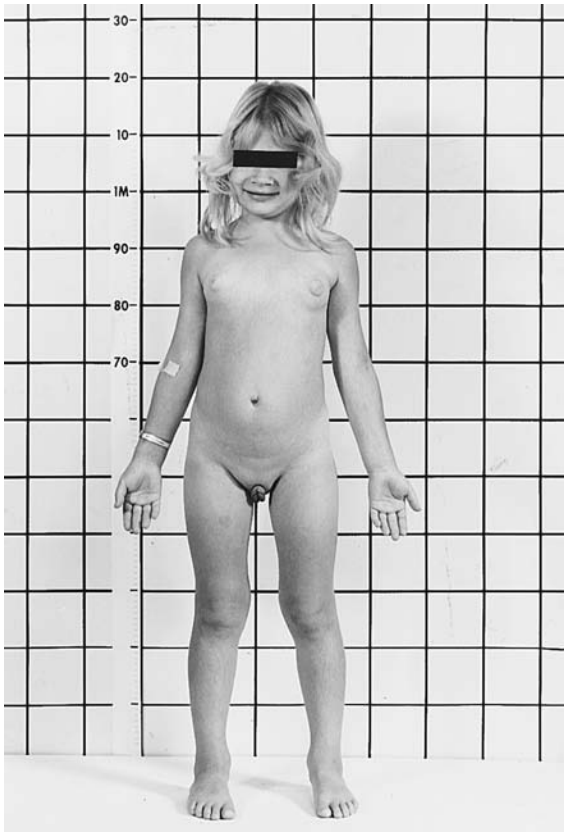

FIGURE 15-36 ■ Sexual precocity caused by hypothyroidism in a 9.1-year-old with breast development since age 7 years and menarche at 9 years. Growth failure had occurred, and her height age was 6 years. In addition to breast enlargement and galactorrhea, the labia minora were noted to be enlarged and pigmented. There was no sexual hair or clitoromegaly. Rectal examination revealed an enlarged and palpable cervix without adnexal masses. There were typical physical findings of hypothyroidism. Bone age was 6.2 years. Thyroxine was less than 1 μg/dL. Thyrotropin-stimulating hormone was 438 μU/mL. Prolactin was 66 ng/mL. Serum estrogens were 72 to 182 pg/mL. Vaginal smear showed 45% superficial cells and 55% large intermediate cells. Immunoreactive luteinizing hormone (LH) and follicle-stimulating hormone were 300 and 174 ng LER-907/mL, respectively (see Figure 15-5 for reference ranges). However, bioactive LH was undetectable. Immunoreactive gonadotropins failed to suppress upon estrogen administration. Their response to a 100-μg gonadotropin-stimulating hormone bolus was minimal, and they seemed responsive to thyrotropin-releasing hormone. All of these hormonal findings were not obviously different from those of hypothyroid girls without sexual precocity except for the higher estrogens. She had withdrawal bleeding and evidence of regression of breast development within the first 3 months of thyroid hormone replacement treatment. After 6 months of treatment, normal puberty began. Menarche occurred at 12.5 years of age.

or hypothyroid children. However, hyperprolactinemia may itself also sensitize the ovaries to gonadotropins. Induced hyperprolactinemia causes sexual precocity in female rats.[312] Ovarian estrogen and progesterone responsiveness to hCG is increased by prolactin, possibly by its induction of ovarian LH receptors. Conversely, suppression of hyperprolactinemia in experimental hypothyroidism blocks the ovarian cyst formation characteristic of hypothyroidism.[622]

McCune-Albright syndrome is another intriguing disorder causing incomplete isosexual feminization.[623,624] This is a syndrome of precocious puberty, cafe-au-lait pigmentation occurring in nevi that have an irregular ("coast of Maine") border, and polyostotic fibrous dysplasia. The disorder is caused by a somatic activating mutation of the G_s-alpha subunit protein that couples transmembrane receptors to adenylate cyclase. The syndrome has been recognized predominantly in females and occurs in incomplete as well as expanded forms. Precocious puberty or mono-ostotic bone lesions may occur in the absence of cutaneous pigmentation; not all patients have sexual precocity. The sexual precocity is of the gonadotropin-independent type. Luteinized follicular cysts within the ovaries function autonomously. Pituitary adenomas capable of secreting excess LH, FSH, GH, or prolactin have been reported. Patients may have Cushing syndrome and hyperthyroidism due to autonomous multinodular hyperplasia. These girls may be at increased risk of breast carcinoma.[625] Nonendocrine abnormalities include cardiopulmonary disease, hypertension, and hepatobiliary disease. Molecular studies have shown an R201H mutation in over 90% of cases where an affected tissue could be studied, but in only 50% of blood samples.[626] Because of the variation in the number and degree of tissue involvement in individual patients, due in large part to the extent of mosaicism present, precocious puberty may be the only feature present in an individual who is mosaic for the activating mutation of G_s-alpha. Thus, these mutations have been found in blood samples from 25% to 33% of subjects with isolated gonadotropin-independent precocity or exaggerated thelarche.[567,626]

Congenital adrenal hyperplasia (CAH) is a well-known cause of premature pubarche. Either nonclassic CAH, a form of the disorder that is so mild that there is no genital defect in girls, or poor control of classic CAH may be responsible. Each form on occasion has been reported to mimic true sex precocity.[627,628]

Tumor may cause isosexual or contrasexual development. The most common tumor is the feminizing benign ovarian follicular cyst.[629,630] Most are isolated and large (> 1 cm diameter). The cells lining these cysts are often luteinized. Estrogen levels may be markedly elevated. Testosterone levels tend to be in the adult female range (about 40 ng/dL). Many function intermittently. They may be gonadotropin dependent and respond to GnRH agonist or progestin therapy. A case is illustrated in Figure 15-37. The second most common hormonally active ovarian neoplasm in girls is the juvenile granulosa cell tumor.[631,632] These have variable degrees of ovarian sex cord–stromal elements and are usually localized and benign in spite of having a malignant histologic appearance. They are more commonly feminizing than masculinizing in young children. They may produce hCG, AMH, and inhibin. Elevation of hCG is found in many ovarian dysgerminomas (a primitive germ cell tumor) and hypercalcemia in some, though less frequently than in small cell carcinoma.[631,633] A granulosa-theca cell tumor is occasionally associated with mesodermal dysplasia syndromes. It has been reported in the adrenal gland, presumably arising in an ovarian rest.[634] FOXL2 mutations are typical of adult-type

FIGURE 15-37 ■ The appearance of a 5.2-year-old child with complete isosexual precocity caused by a luteinized follicular cyst. Her breast development is no different from that of girls with idiopathic premature thelarche. She presented at 4.7 years with a 2-week history of breast development. Height and bone ages were 5 years. Over a 5-month follow-up period, breast development progressed, she developed sexual pubic hair and presexual axillary hair, and menstrual flow commenced at 3- to 5-week intervals. Four weekly determinations of plasma unconjugated estrogens (estradiol and estrone) showed them to consistently range between 158 and 215 pg/mL. Luteinizing hormone was pubertal and follicle-stimulating hormone was suppressed (averaging 50 and 13 ng LER-907/mL, respectively; see Figure 15-5 for reference ranges). Testosterone was 37 ng/dL, and dehydroepiandrosterone sulfate (DHEAS) was 82 μg/dL. Exploratory laparotomy was performed when she was 5.2 years old. Her height age was 5.8 years, and her bone age was 7.5. The laparotomy revealed a right ovarian cyst about 5 cm in diameter, which was removed. Subsequently, there was a rapid fall in plasma estrogens and testosterone to prepubertal levels. However, DHEAS was unchanged. Menses ceased, but intermittent vaginal cornification (maturation index 90/10/0 to 0/90/10) was found repeatedly. Breast enlargement and sexual hair development resumed at 8.5 years, with normal pubertal sex hormone levels. Menarche occurred at 9.5 years.

granulosa cell tumors but are found in only 10% of the juvenile type. A related feminizing ovarian sex cord–stromal tumor may be caused by loss of a tumor-suppressor gene, as in Peutz-Jeghers syndrome.[635] Adult-type ovarian carcinoma of epithelial cell origin is rare. Ovarian masculinizing tumors are discussed in the section "Hyperandrogenism in Adolescence."

Adrenocortical tumors, as discussed in Chapter 6, typically cause rapid virilization characterized by very high DHEAS production; however, androstenedione is the predominant androgen in many cases. A case discussion is given with Figure 15-38. Many are accompanied by Cushingoid changes. On occasion they cause feminization. When adrenocortical tumors secrete both androgen and estrogen, the clinical picture may resemble complete isosexual precocity.[636] Structural abnormalities of chromosome 11p15 and mutations of the tumor suppressor p53 are fairly common in pediatric adrenocortical tumors.[637]

Aromatase excess syndrome is a rare cause of ectopic feminization.[638] This is an autosomal dominant disorder with variable penetrance that results from constitutive aromatase gene overexpression.

Exogenous steroids can cause sexual precocity. Estrogen-containing contraceptive pills and creams are widely available. Some cases of precocious thelarche may be caused by ingesting food contaminated with artificial estrogens.[639] Soy formulas are potential sources of phytoestrogens, as are many commonly consumed foods, herbs, and topicals.[640-642] It has been proposed that childhood exposure to estrogenic chemical contaminants in underdeveloped countries predisposes to sexual precocity when children emigrate to developed countries.[185] Premature pubarche or acne can result from anabolic steroid use. Topical nonprescription androgen use by a parent, such as for sexual dysfunction or anabolic effects, can cause premature pubarche without necessarily being detectable by standard tests.[643]

Vaginal bleeding in the absence of breast development suggests foreign body, sexual abuse, or tumors of the

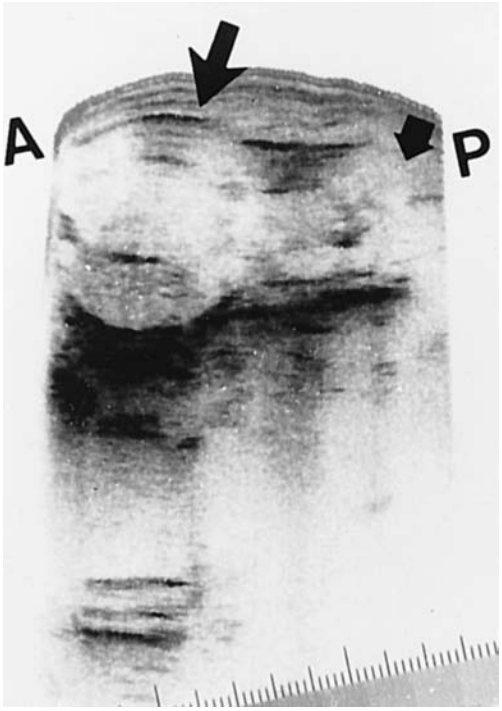

FIGURE 15-38 ■ Abdominal ultrasound (decubitus view) showing a pedunculated encapsulated 5-cm adrenal adenoma (large arrow) near upper pole of kidney (small arrow). This 1.3-year-old girl was virilized. Pubic hair had appeared 2 months previously, height had changed from the 10th to the 30th percentile, and clitoromegaly had occurred. Bone age was 2.3 years. Dehydroepiandrosterone sulfate was 3000 to 4271 μg/dL. Testosterone was 121 ng/dL. A, anterior; P, posterior.

genital tract. A rare cause is "premature menarche," which may result from an extreme variation in the normal intermittent ovarian activation of young girls.[83] Malodorous discharge is highly suggestive of foreign body. A hymenal opening of greater than 5 mm or posterior notches is compatible with sexual abuse.[454,455] Neurofibromas have been reported to simulate breast development and clitoral hypertrophy.

Differential Diagnosis

A physician need not be experienced in endocrinology to diagnose and manage most girls presenting with early breast or pubic hair development. For the most part, the isolated appearance of one of these signs is due to the benign processes of either premature thelarche or premature pubarche, respectively. An otherwise normal history and physical examination, together with a normal bone age constitutes sufficient workup.

In the history, the physician should inquire about the possibility of exposure or access to exogenous steroids in the form of unusual creams, pills, or diet. The possibility of sexual abuse, vaginal infection, or foreign body must be kept in mind when evaluating the child with isolated vaginal bleeding. During the examination the physician should search for nevi, acanthosis nigricans, and signs that might suggest intracranial or abdominal-pelvic disease, and should inspect the external genitalia. The child's height and weight should be carefully recorded, the growth curve examined, and the body mass index (BMI) percentile plotted.

If the history and examination are unremarkable, only a bone age determination is indicated to screen for whether the symptom is indeed an isolated phenomenon or whether appreciable hormone excess exists. If the skeletal age is not abnormally advanced relative to height age, it is likely that the presenting symptom is an isolated and benign extreme variant of normal, which requires no treatment.[540,644] To confirm the diagnosis of premature thelarche or premature pubarche, the child must be similarly reevaluated after 3 to 6 months. If the results are still negative, the family can be reassured with a high degree of confidence that true puberty including menses will not occur until the usual age.

If more than one sign of precocious puberty is present or develops or if the growth is accelerated, a more extensive workup is indicated. For example, if a young girl with early breast development begins to grow pubic hair, or vice versa, then something more than premature thelarche or premature adrenarche is involved. The same is true if she develops a growth spurt or if she begins menstruating. These additional signs indicate the need for more extensive studies. Isolated vaginal bleeding (i.e., bleeding in the absence of secondary sex characteristics) suggests sexual abuse, foreign body, or genital tract tumor, rarely isolated menarche. Cytology, anaerobic culture, pelvic ultrasound, and serum E2 examinations are indicated.

Bone age advancement that is or becomes disproportionate to height (as indicated by compromised height potential or bone age ≥ 20% greater than height age) suggests a sustained excess of sex hormone and is an indication for a more extensive investigation to determine the cause of the precocity. The importance of the recheck is illustrated by the case presented in Figure 15-37.

One must be particularly aware that girls with neurogenic precocity, especially those who have had cranial irradiation, are at risk of paradoxically having concomitant GH deficiency.[566] Coexistent GH deficiency masks the seriousness of the precocity: the growth rate is normal (not accelerated) and breast development is attenuated. However, the disparity between bone age and height age is extreme.

The laboratory investigation of premature pubertal development requires determinations of sex steroids, LH, and FSH by assays of high sensitivity: at least 10 pg/mL for E2, 10 ng/dL for testosterone, 5 μg/dL for DHEAS, and 0.2 U/L for LH and FSH.[593] The modern multichannel platform assays that are widely available generally meet these specifications for the assays of DHEAS, LH, and FSH, but they are totally inadequate for testosterone and E2. These require assays of high sensitivity and specificity, such as are provided by postchromatographic radioimmunoassay or tandem mass spectrometry, in laboratories with well-established normal ranges for children.[645] Prepubertal E2 levels are normally less than 10 pg/mL, and prepubertal testosterone is normally less than 20 ng/dL. Measurement of serum thyroxine and prolactin is indicated if the sexual precocity is accompanied by growth arrest or galactorrhea.

In central precocity, daytime serum E2 concentration is usually pubertal, 10 pg/mL (37 pmol/l) or more.[646] An E2 level in the upper premenarcheal normal range (≥ 75 pg/mL) is atypical and necessitates a prompt workup to distinguish ovarian or adrenal tumor from true isosexual precocity.[647] If the estradiol level is atypically high, weekly determinations of E2 may help to determine whether the level is fluctuating in the normal cyclic fashion of true precocious puberty. Because of the episodic and cyclic nature of sex hormone secretion, examination of the vaginal mucosa (see Figure 15-11) for estrogen effect is a more sensitive indicator of the presence of early puberty than is an E2 blood level because it represents the integrated effect of estrogen over the preceding 2 to 3 weeks. Uterine size (e.g., uterine length > 3.8 cm and endometrial thickness of ≥ 2 mm) has been used as an objective indicator of overall estrogenization.[75,76] Androgen levels are appropriate for the stage of pubarche in true precocity.

Third generation, monoclonal-antibody-based, "pediatric" immunoassays for gonadotropins are necessary for early detection and monitoring of therapy.[593] Early morning basal LH > 0.6 has been reported to be 62% to 95% sensitive and 92% to 100% specific for the diagnosis of central precocious puberty in girls.[541,648] A post-GnRH peak LH > 6.9 U/L has been reported to be 92% sensitive and 100% specific,[541] whereas a post-GnRH agonist peak LH > 4 to 5 U/L has been reported to be ≥ 90% accurate for the diagnosis of central precocious puberty.[544,649,650] The GnRH agonist test also permits assessment of the ovarian gonadotropin-responsiveness: an E2 peak ≥ 34 pg/mL is approximately 90% sensitive and

≥ 60 pg/mL 95% specific for puberty (see Table 15-1).[83] FSH levels are not as helpful diagnostically because prepubertal values overlap considerably with pubertal ones and they may be elevated in premature thelarche. In response to GnRH or GnRH agonist testing, children with unsustained pseudopuberty as variants of normal will have a minimal gonadotropin response, whereas children with gonadotropin-independent precocity will have suppressed responses.[651,652] Demonstration of a sleep-related rise of serum LH is an alternate diagnostic procedure. Box 15-2 summarizes laboratory criteria for the diagnosis of complete sexual precocity.[653]

Premature pubarche must be distinguished from hypertrichosis, the generalized excessive growth of vellus body hair that is prominent in nonsexual areas. The most common cause, by far, of premature pubarche is premature adrenarche. Premature adrenarche must be distinguished from virilizing disorders, the most common of which is virilizing nonclassic congenital adrenal hyperplasia and the most serious of which, though rare, is virilizing tumor.

Determination of the early morning baseline serum androgen pattern is useful for discriminating among the causes of premature pubarche and virilization. Premature adrenarche is characterized by a pubertal level of DHEAS, whereas serum testosterone and androstenedione are, at most, marginally elevated above the prepubertal range. A greatly elevated level of DHEAS suggests either adrenal tumor or the 3β-hydroxysteroid dehydrogenase deficiency form of congenital adrenal hyperplasia. Androstenedione and 17-hydroxyprogesterone levels are disproportionately elevated compared to testosterone or DHEAS levels in other forms of virilizing congenital adrenal hyperplasia and many ovarian tumors.

An ACTH stimulation test is the definitive test to exclude congenital adrenal hyperplasia. We advise performing an ACTH test in children with premature pubarche who have an early morning serum 17-hydroxyprogesterone concentration above 200 ng/dL,[654] though levels above 1500 ng/dL do not require a confirmatory ACTH stimulation test. The diagnosis of congenital adrenal hyperplasia is discussed in detail in Chapter 5 The differential diagnosis of hyperandrogenic disorders is discussed further in the "Hyperandrogenism in Adolescence" section.

Ultrasonography is indicated to screen for abdominal or pelvic masses when feminizing or virilizing disorders are suspected.[655,656] The ovaries of girls with true sexual precocity resemble those of normal pubertal girls.[72,74,657] A "cyst" of 10 mm or more in diameter usually is due to a transient preovulatory follicle. However, the differential diagnosis of a persistent cyst or multicystic ovaries includes McCune-Albright syndrome,[624] tumor,[658] and premature ovarian failure.[659]

The ability of ultrasonography to detect small adrenal neoplasms is highly dependent on the expertise of the ultrasonographer. On rare occasions, ultrasonography has been insensitive in detecting an ovarian tumor in adults.[660] Computed tomography and magnetic resonance imaging (MRI) permit better visualization and a more detailed assessment of tumors.

MRI of the hypothalamic-pituitary area is indicated in progressive true sexual precocity, especially those less than 6 years old or those at risk of organic causes by virtue of their underling condition or neurologic symptoms and signs.[646,661]

Management

The goals in management are to rule out an organic disorder that requires treatment in and of itself and to ascertain whether sexual precocity is either compromising height potential or resulting in important secondary emotional disturbances in the child.

The situation of a girl between 6 and 8 years of age presenting with the onset of breast development or pubic hair warrants special consideration. Breast development between 7 and 8 years of age is normal in blacks and Hispanics. Although presexual pubic hair (stage 2) may be seen in 6- to 8-year-old black and Hispanic girls, sexual pubic hair (stage 3) is abnormal if present before 8 years of age (see Table 15-3). However, pubertal development in girls in the 6- to 8-year age range may be associated with pathology, with excessive adiposity being the major consideration in most [243]

Many 6- to 8-year-old girls with central precocious puberty, including whites, have slowly progressive precocity, with a normal timing of menarche, and are at low risk of short adult stature. Most such girls do not require GnRH agonist therapy to preserve adult stature.[593,594,662,663] Thus, a less comprehensive investigation may be warranted in selected girls between 6 and 8 years of age who present with thelarche or stage 2 pubic hair. For most such girls, a complete history and physical exam, including an obesity evaluation and a bone age determination, may be all that is needed, along with careful longitudinal follow up to rule-out a disorder that requires therapy.[594,663] However, 6- to 8-year-old girls with a suggestion of rapidly progressive or excessive androgenization or feminization, neurologic symptoms, linear growth acceleration, or significant bone age

BOX 15-2 Laboratory Criteria for Diagnosis of Complete Precocious Puberty in Girls

Bone Age Advancement

- Bone age > height age > chronologic age
- Compromised predicted adult height

LH Level Pubertal*

- Sleep-associated LH peak > 1 U/L
- LH (early morning) ≥ 0.6 U/L†
- Post-GnRH (1 hour) agonist LH ≥ 3.2-5.5 U/L†
- Suppressible by chronic GnRH agonist administration

Sex Hormone Level Pubertal (Diurnal Early)

- Estradiol (early morning, cyclically): > 9 pg/mL†
- DHEAS normal for age or early puberty

*Essential criterion
†Typical values for sensitive assays. Exact values vary among laboratories.

advancement should be more completely evaluated, as outlined earlier.

Intracranial lesions must be treated by appropriate measures, such as neurosurgery or irradiation. Shunting for hydrocephalus may stop the precocity. Granulosa cell tumors confined to the ovary have a good prognosis for cure by unilateral oophorectomy. Recurrence of tumor may occur up to 20 years after the initial operation, however. Biopsy of the opposite ovary is indicated in unilateral ovarian neoplasms. Compensatory ovarian hypertrophy can be expected at any age after removal of a single ovary.[664]

The only permanent physical complication of true isosexual precocity, all else being normal, is short adult height. Excessive sex hormone production in the first decade of life causes early maturation of the epiphyses, resulting in their premature closure. About half the girls with this disorder reach an adult height of 53 to 59 inches and the remainder are over 60 inches tall.[594,663] The mismatch between physical, hormonal, and psychological development may cause behavior changes ranging from social withdrawal to aggression or sexuality. However, frank behavioral problems are unusual in girls and so are by themselves seldom indications for treatment.

When central precocity is accompanied by documented progression of pubertal development that accelerates growth and compromises normal height potential, GnRH agonist treatment is indicated.[593] Documentation typically requires 3 to 6 months, but it may be unnecessary if puberty is substantially advanced clinically and hormonally on presentation. The down-regulating effect of GnRH agonists on pituitary gonadotropin release inhibits gonadotropin secretion within 1 month. Suggested criteria for the use of these drugs are presented in Box 15-3.[593,653] The commonly used agents in the United States are leuprolide acetate (ordinarily given as Lupron Depot-Ped 7.5 to 15 mg/mo or 22.5 mg/3month IM),[665,666] nafarelin acetate (Synarel 800 μg bid IN), and a histrelin implant (Supprelin LA 50 mg implant yearly).[667] These starting doses are larger than the usual adult dosage in order to avoid worsening the status by an agonist effect; dosage can be adjusted later as necessary.

Treatment is adequate if the E2 and baseline LH levels become prepubertal[668] or LH is below 4 (1 hour) to 6.6 U/L (2 hours) after GnRH agonist[666,669] one month after institution of therapy. Withdrawal menses may occur at that time, but none should be expected thereafter. Arrest of breast development and the pubertal growth spurt become apparent by 3 to 6 months. Concomitantly, epiphyseal closure is delayed and adult height potential improves, because a type of catch-up growth occurs, in which height age catches up to bone age. Adult height is greatest when treatment is started soon after onset at an early age, yielding an average height gain above pretreatment height prediction of about 1.4 cm for each year of therapy.[593] Adult height prediction at the end of treatment tends to be overestimated from bone age. Therefore, prolonging treatment beyond a chronologic or bone age of 12 to 12.5 years of age generally leads to little further increase in adult height potential, regardless of the prediction of residual height potential.

Coincident GH-deficiency must be treated for optimal growth.[670] GH-sufficient patients with central precocity who are started on treatment relatively late and whose height velocity falls below 4 cm/year after 2 to 3 years appear to gain an average of 2 cm/year when GH therapy is added.[671,672]

Use of the depot form of GnRH agonist is complicated by sterile abscesses at injection sites in about 5% of cases. Anaphylaxis is a rare complication.[673] No other serious side effects have come to light. Long-term safety data remain incomplete, but current studies following subjects into young adulthood are reassuring, including no difference in menstrual cycle characteristics of treated compared to untreated subjects.[674] GnRH agonist treatment does not seem to cause or aggravate obesity, as judged from BMI.[593] Bone mineral density dips with the onset of treatment, but it normalizes after discontinuation of GnRH agonist therapy of precocious puberty.[593]

Girls with idiopathic slowly progressive puberty of onset between 6 and 8 years of age or with early fast puberty between 8 and 9 years of age tend to be tall at the onset of puberty, follow an advanced growth pattern, and reach their target height without GnRH agonist therapy.[594,663,675-677] Therefore, this treatment is only indicated if height potential is compromised or there are other compelling reasons to slow the pace of puberty.

Medroxyprogesterone acetate (Depo-Provera) is useful for stopping menses and as a contraceptive in mentally retarded girls in whom preservation of height potential is not important. It is begun in a dosage commencing at 50 mg/month intramuscularly. Doses as high as 400 mg/month have been used, although cushingoid side effects may be observed at this level.[678] Although this treatment reverses some of the physical changes of premature puberty, it does not reverse the inordinately rapid maturation of the skeleton, possibly because of its inherently weak androgenicity. In addition, use of medroxyprogesterone acetate is associated with a loss of bone mineral density, which must be considered if long-term use is being considered.[679]

A variety of drugs have been used off-label to treat gonadotropin-independent precocity. Both antiestrogen and aromatase inhibitor treatments have demonstrated partial efficacy for McCune-Albright syndrome.[666,680,681] Ketoconazole, an antifungal agent that inhibits 17,20-lyase activity and other steroidogenic enzymes, may be useful.[682] GnRH agonist treatment may be necessary for

BOX 15-3 Indications for Gonadotropin-Releasing Hormone Agonist Therapy of Precocious Puberty

1. Documentation of central precocious puberty
2. Documentation of pubertal progression
3. Plus presence of one of the following:
   - Progressive compromise of predicted adult height *or*
   - Emotional or behavioral disturbance *or*
   - Menses in the emotionally immature or disabled

Modified from Rosenfield, R. L. (1994). Selection of children with precocious puberty for treatment with gonadotropin releasing hormone analogs. J Pediatr, 124, 989.

those in whom true puberty becomes superimposed because the bone age has reached a pubertal level.[232,233,683] Bisphosphonates are often effective at relieving the bone pain of fibrous dysplasia in McCune-Albright syndrome, although they do not appear to have an effect on the course of the lesions and are not a suitable long-term treatment.[684]

Patients with premature thelarche or pubarche as variations of normal are counseled as follows. The child's early development seems to be a matter of a normal stage of puberty occurring early. It is due either to an incomplete, slow kind of puberty or to increased sensitivity to the trace levels of hormones that are normally present in childhood. Feminization with breast development and eventual menstruation can be expected to occur at an appropriate age. No treatment is indicated. To exclude subtle sex hormone excess or eventual anovulatory syndromes, long-term follow-up is advisable.

Besides dealing with the physical consequences of true isosexual precocity, the physician must be ready to help the family and child cope with the psychological problems that come with early physical maturation. The doctor can help the family by explaining that even though their child looks older and more mature than other children of the same age, the child will not behave more maturely. The libido of young children with precocity is not increased. The family should be advised to take some precautions to downplay their child's development—for example, in the choice of clothing and swimsuits. Friendships with children a bit older will help shorten the time affected children spend in social limbo. This may be more easily said than done, however, because the intellectual and social maturity of these patients is not advanced. Early on, any children with these disorders tend to be withdrawn because they feel that they are different from their peers. Later on, they tend to enter into romantic relationships early. It is important to remind the family and child that in a few years the child will not be unique from the standpoint of sexual development.[566] The following books may be helpful in explaining precocious puberty: for children, *What's Happening to Me?* by Peter Mayle (Lyle Stuart, Secaucus, New Jersey, 1973); for parents, Sex *Errors of the Body*, by John Money (Paul H Brookes Publishing, Baltimore, Maryland, ed. 2, 1994).

Hypogonadism

Causes

If hypogonadism is complete and present prepubertally, it causes sexual infantilism. In genetic males, congenital primary hypogonadism may also cause a completely female or ambiguous phenotype (see Chapter 17). If hypogonadism in girls is partial or of onset in the early teenage years, feminization will be of too limited a degree to permit the onset of menses at a normal age (primary amenorrhea). Milder, partial, or incomplete forms of hypogonadism may cause secondary amenorrhea or oligomenorrhea. At its mildest, hypogonadism may present in adolescence with the anovulatory symptoms of dysfunctional uterine bleeding or with excessively frequent periods due to short luteal phase. Consequently, disorders causing hypogonadism appear in the differential diagnosis of disorders of sexual differentiation, sexual infantilism, failure of pubertal progression, and menstrual irregularity. The causes of hypogonadism are listed in the differential diagnosis of amenorrhea in Box 15-4.

Primary Ovarian Failure. Primary ovarian failure is characterized by high levels of gonadotropins, particularly FSH. Two exceptions exist to this rule. First, the gonadotropins may not be elevated until CNS maturation has reached a pubertal stage, as indicated by a bone age of approximately 10 to 11 years (Table 15-5).[685] Second, patients with *partial* ovarian failure (primary ovarian insufficiency), as occurs during the menopausal transition, do not have high baseline gonadotropin levels.[686-688] FSH may hyperrespond to GnRH and estrogen hyporespond to GnRH agonist challenge. It seems as if relatively few ovarian follicles—too few to permit the cyclic emergence of preovulatory follicles—suffice to prevent the characteristic rise in basal FSH levels. Serum AMH levels are a less sensitive indicator of ovarian failure than FSH, but may be useful in prognosticating the potential for fertility.[689,690]

Primary ovarian failure may occur before or during puberty, causing primary amenorrhea, or after puberty has occurred, causing secondary amenorrhea. The latter is termed *premature* ovarian failure and clinically resembles premature menopause, except that about 25% of the cases sometimes resume ovarian function.[691] Because of this fluctuating ovarian function in some women, *premature ovarian insufficiency* may be a better descriptor.

Gonadal dysgenesis due to deficiency of genes on the X chromosome is the most common cause of primary ovarian failure. It is usually due to a relatively large-scale deletion of X-chromosomal material, which is associated with a characteristic, but variable, phenotype and is termed Turner syndrome (see Chapter 16). Fetuses with a 45,X karyotype have a normal number of oocytes in the ovary at midgestation, but a drastic reduction in the number of follicles,[32] which appears to cause gonadal streaks via an accelerated rate of apoptosis. However, the gonadal dysgenesis, like other features of the syndrome, is often incompletely expressed.[692,693] Thus, Turner syndrome should be considered in all girls with primary hypogonadism or secondary amenorrhea whether or not they have the typical stigmata of Turner syndrome.

Specific loci on the X chromosome are associated with primary ovarian failure. Xp11.2 harbors BMP15, a specific ovarian differentiation factor, heterozygous mutation of which is a rare cause of gonadal dysgenesis. Xq harbors two independent loci, in addition to the fragile X premutation, that are associated with about 5% of sporadic and 14% of familial primary ovarian failure.[694] The premutation is an expansion of CGG repeats that is insufficiently long to cause fragile X syndrome. Women with the premutation allele have a substantially increased risk of primary ovarian insufficiency, possibly because raised intracellular mRNA concentrations might sequester CGG binding proteins that are important for RNA processing.

BOX 15-4 Differential Diagnosis of Amenorrhea

Abnormal Genital Structure

- Ambiguous genitalia
  - Disorders of sex development
  - Pseudointersex
- Aplasia*
  - Hymenal
  - Vaginal
  - Müllerian
  - Disorders of sex development
- Endometrial adhesions

Anovulatory Disorders

Hypoestrogenism, FSH Elevated

Primary Ovarian Failure

- Congenital
  - Gonadal dysgenesis
    - —Chromosomal
    - —Genetic
    - Other genetic disorders
- Acquired
  - Oophorectomy
  - Radiotherapy or chemotherapy
  - Oophoritis
  - Idiopathic

Hypoestrogenism, FSH Not Elevated

- Primary ovarian insufficiency
  - Complete if bone age < 11 years*
  - Incomplete if bone age > 11 years
- Delayed puberty
  - Constitutional delay*
  - Growth-retarding disease
- Gonadotropin deficiency
  - Congenital
  - Acquired
  - —Organic
  - —Functional
  - Virilization

Estrogenized

- Hypothalamic anovulation
  - Hypothalamic amenorrhea
  - Athletic amenorrhea
  - Psychogenic amenorrhea
  - Epilepsy
- Nonhypothalamic nonovarian disorders
  - Pregnancy
  - Obesity or undernutrition
  - Chronic disease
  - Cushing syndrome
  - Hypothyroidism
  - Drug abuse
  - Hyperprolactinemia
  - Post-pill amenorrhea
  - Gonadotropin-producing tumor
- Hyperestrogenism
- Hyperandrogenism

*Cause only primary amenorrhea.
FSH, follicle-stimulating hormone.

TABLE-15-5 Bone Age in Workup of Sexually Infantile Girls with a Normal Follicle-Stimulating Hormone Level

	Bone Age (Years)		
	< 11	11-13	> 13
Primary hypogonadism	Yes		
Delayed puberty	Yes	Yes	
Gonadotropin deficiency	Yes	Yes	Yes

Based on Rosenfield, R. L., & Barnes, R. B. (1993). Menstrual disorders in adolescence. Endocrinol Metab Clin North Am, *22, 491.*

Gonadal dysgenesis also results from 46,XY complete gonadal dysgenesis and certain forms of autosomal aneuploidy.[486,694,695] A variable degree of ovarian dysgenesis occurs in trisomy 21; delayed menarche, anovulatory cycles, and primary gonadal failure are occasionally seen.[696] However, pregnancy has been reported; trisomic offspring are common.[697] Oocytes are virtually absent in trisomies 13 and 18. Ovarian dysgenesis also occasionally occurs as part of the Denys-Drash syndrome due to a *WT-1* mutation.[698] Gonadal dysgenesis also occurs in ataxia telangiectasia and related DNA-repair disorders.[699] Other autosomal genetic disorders causing premature ovarian failure include inactivating mutations of FOXL2, which are found in sporadic cases as well in the autosomal dominant type 1 blepharophimosis syndrome.[700] Premature ovarian failure also occurs in galactosemia,[701] leukodystrophies, and myotonia dystrophica.[702,703] Mutation of the inhibin alpha subunit predisposes to premature ovarian failure, an effect that appears to vary depending on ethnicity; this is postulated to be due to deficient paracrine interactions with TGFβ family receptors.[704] Mutations incriminated in the ovarian failure of mouse models[705] or in genes involved in follicle development[24] can be anticipated to be incriminated as causes of human primary ovarian failure.

Injury to the ovary is a common cause of primary ovarian failure. *Mumps* oophoritis is a classic but rare cause of ovarian failure. Very high-dose estrogen treatment in adolescence increases the risk of hypergonadotropic subfertility.[690]

Irradiation and chemotherapy for childhood neoplasia are frequent causes of primary ovarian failure now that life is effectively prolonged.[694,706-709] Ionizing radiation and alkylating agents damage DNA whether or not a cell is replicating.[710] The damage is dose-related and additive. A radiation dose of ≥ 20 Gy causes acute ovarian failure in > 70% of girls. A cumulative cyclophosphamide dose of about 100 mg/kg causes equivalent damage. Prepubertal girls may be about half as sensitive to these therapies as postpubertal females: among girls who receive 1 to 10 Gy, acute ovarian failure develops in about 10% of girls under 13 years but in 25% of those ≥ 13. Some with

early hypergonadotropism will experience ovarian recovery with normal pituitary-ovarian function after several years.[711] After prepubertal cancer treatment, 94% of girls can be anticipated to enter puberty and menstruate regularly, but 8% of these will develop nonsurgical premature menopause because of the reduced number of oocytes.[708] The risk for premature menopause is 30% in those who have received both radiation and chemotherapy and 5% to 13% for those receiving either alone. Fertility is reduced by about 50% in those receiving 5 to 10 Gy abdominal-pelvic radiation and 75% in those receiving more.[712] Fertility is reduced by about 25% in those receiving high cumulative doses of chemotherapy (e.g., cyclophosphamide > 10 gm/m^2).[712] Several nonalkylating chemotherapies are also gonadotoxic.[713,714] However, data are scarce, and interactions among the various classes of chemotherapeutic agents are poorly understood. Methotrexate and vinca alkaloids pose low risk for ovarian failure.[694] As a consequence of gonadotropin elevation when gonadal failure begins, puberty may progress rapidly.[608]

Sterilization by irradiation can be obviated by transposing the ovaries out of the irradiation field if possible. Administration of a GnRH agonist prior to cyclophosphamide administration does not clearly decrease ovarian injury.[710] Imatinib (Gleevec) is a potential oocyte-protective treatment, as it blocks an apoptotic pathway activated by radiation and cisplatin in mouse oocytes.[715]

Gonadotropin resistance (Savage syndrome) can arise from an autosomal recessive loss of function mutation of the LH or FSH receptor.[716-718] The reported cases have had some degree of pubertal development followed by primary or secondary amenorrhea or oligomenorrhea. The ovaries of LH receptor mutants contain follicles in all stages of development, whereas those of FSH receptor mutants vary from hypoplastic to normal size, with antral follicle development varying from nil to 5 mm. Partial gonadotropin resistance is common in the Albright osteodystrophy form of pseudohypoparathyroidism, as part of the generalized defect in G-protein signal transduction.[719]

Autoimmune oophoritis is the basis of approximately half of the cases of spontaneous premature ovarian failure, though estimates vary from 5% to 85% in various series.[720] It is diagnosed by its association with any of a variety of autoimmune endocrine or nonendocrine disorders, manifest or subclinical, that have in common defects in T-cell suppressor function. Autoimmunity may be directed against the granulosa cell, oocyte, or theca cell. The clinical picture may resemble relatively selective resistance to FSH or, less frequently, to LH. The latter results from lymphocytic destruction of theca cells with sparing of granulosa cells from small antral follicles, which lack substrate to form E2 and can only respond to the compensatory increase of FSH by producing inhibin-B.[721] These patients have autoantibodies to steroidogenic cells and are at risk for adrenal failure. Usually these antibodies are directed against 21-hydroxylase, less frequently to side chain cleavage enzyme or 17-hydroxylase, seldom to 3β-hydroxysteroid dehydrogenase. Replacement glucocorticoid therapy may temporarily ameliorate the immune oophoritis in such cases.[722] A case with autoantibodies to testosterone has been reported.[723] Autoimmune gene regulator (AIRE) gene mutations have been identified as causative of type 1 polyendocrine failure. Ultrasonographic and histologic findings are variable in premature ovarian failure and include large or small ovaries, inactive or polyfollicular ovaries, loss or preservation of primordial follicles, and infiltration by lymphocytes or plasma cells[659]

Functional ovarian failure can also result from specific autosomal recessive defects in the biosynthesis of sex steroids. Both androgen and estrogen deficiency occur in lipoid congenital adrenal hyperplasia (StAR and side chain cleavage mutations; see Figure 15-23), 17α-hydroxylase deficiency, P450 oxidoreductase deficiency, 17,20-lyase deficiency, and 17β-HSD3 deficiency.[724,725] Thus, affected genetic males may present with a female phenotype. Hypoestrogenism is associated with virilization in aromatase and 3β-HSD deficiency. Aromatase and 17β-HSD3 deficiency are unique in not being associated with congenital adrenal hyperplasia. Congenital lipoid adrenal hyperplasia is unique in that underlying StAR deficiency has too little direct impact on ovarian function to interfere with the early phases of puberty, but the gradual buildup of intraovarian lipid deposits resulting from enzyme deficiency—a "second hit"—causes ovarian damage with anovulation and late ovarian failure. SF-1 deficiency can cause primary ovarian failure in the absence of adrenal insufficiency.[726]

Estrogen resistance due to inactivating mutation of ER-alpha was recently reported in an 18-year old girl.[726a] Hypoestrogenism and hyperestrogenemia were profound, the ovaries were enlarged and multicystic, and gonadotropin and testosterone levels were marginally elevated.

Gonadotropin Deficiency (Hypogonadotropic Hypogonadism). *Congenital* gonadotropin deficiency can occur in association with cerebral, hypothalamic, or pituitary dysfunction or as an isolated defect.[727] Congenital defects in hypothalamic-hypophyseal formation may be associated with midline facial defects. Congenital hypothalamic dysfunction may be associated with other neurologic or endocrine dysfunction, such as in the Prader-Willi syndrome (congenital hypotonia and neonatal failure to thrive followed by hypothalamic obesity, sometimes with hypopituitarism)[728] or the Laurence-Moon-Biedl syndrome (retinitis pigmentosa, obesity, mental deficiency).

Congenital hypogonadotropic hypogonadism often results from mutations (Table 15-6).[200-202,208,211,213,221,572,729-739] The autosomal recessive forms of congenital combined pituitary hormone deficiency due to PROP1, HESX1, LHX3, and OTX-2 mutations are associated with gonadotropin deficiency. Leptin and leptin receptor inactivating mutations cause gonadotropin deficiency in combination with moderate or extreme obesity.[738,740] The report of a natural pregnancy in a woman with a homozygous mutation in the leptin receptor lends controversy to the current concept that leptin function is essential for reproduction.[741]

Gonadotropin deficiency may be associated with anosmia (olfactory-genital dysplasia or Kallmann syndrome).[202] This syndrome is one tenth as frequent in females as in males. Mutations in the KAL-1 gene on the pseudoautosomal region of the X chromosome,

TABLE 15-6 **Mutations Associated with Congenital Hypogonadotropic Hypogonadism**

Gene	Function	Phenotype	Inheritance	Reference
FGF8	GnRH neuronal migration	Kallmann syndrome or normosmic IHH	Autosomal dominant	202, 571, 730, 731
GnRHR	GnRH signaling	Normosmic IHH	Autosomal recessive	732-734
Hesx1	Somatotroph, thyrotroph, gonadotroph, development, and gene expression	ACTH, GH, gonadotropin, and TSH deficiency	Autosomal dominant, autosomal recessive	735-737
KAL1	GnRH neuronal migration	Kallmann syndrome	X-linked	200, 202
KISSR	GnRH secretion	Normosmic IHH	Autosomal recessive	201, 211, 213, 221
LEPR	GnRH regulation	Obesity and normosmic IHH	Autosomal recessive	738
Lhx3	Somatotroph, thyrotroph, gonadotroph, development, and gene expression	Rigid cervical spine causing limited neck rotation, GH, gonadotropin, and TSH deficiency	Autosomal recessive	735-737, 739
NELF	GnRH neuronal migration	Kallmann syndrome	Autosomal dominant?	202, 571, 730, 731
PROK2, PROKR2	GnRH neuronal migration	Kallmann syndrome or normosmic IHH	Autosomal recessive	730
Prop1	Somatotroph, thyrotroph, gonadotroph, development, and gene expression	GH, gonadotropin, PRL, and TSH deficiency	Autosomal recessive	735-737
Otx2	Somatotroph, thyrotroph, gonadotroph, development, and gene expression	ACTH, GH, gonadotropin, PRL, and TSH deficiency	Autosomal dominant Autosomal recessive	736, 737, 739
TAC3, TACR3	Synchronizing kisspeptin neuron pulsatility?	Normosmic IHH	Autosomal recessive	221

which encodes anosmin, a key protein for GnRH neuronal migration, cause the highly penetrant X-linked form and rarely affect females. Inactivating mutations of other genes in the anosmin signaling pathway (FGF8/FGFR1, PROK2/R2, NELF, and CHD7) account for the majority of female cases; these are inherited as autosomal dominant or recessive (heterozygous, compound heterozygous, or digenic) traits with variable penetrance.[202,572,730,731,742] Neurologic and somatic abnormalities, such as synkinesia, cerebellar ataxia, sensorineural deafness, mental retardation, unilateral renal agenesis, and cleft palate, are variably associated genetic features of Kallmann syndrome. Rare affected individuals have only delayed puberty. These same mutations sometimes are responsible for normosmic idiopathic GnRH deficiency; CHD7 mutations typically have features of CHARGE syndrome. Research is increasingly revealing new elements in the GnRH developmental and signaling pathway. A single-nucleotide polymorphism in the EAP1 gene was associated with amenorrhea/oligomenorrhea in primates.[743]

GnRH receptor mutations account for about half of autosomal recessively inherited cases of isolated, normosmic gonadotropin deficiency.[732] The degree of hypogonadism is variable, even within a family, with delayed puberty and delayed menarche as presentations.[733,734,744]

Loss-of-function mutations of GnRH[745] and in signaling systems that modulate GnRH release (kisspeptin/GPR54, neurokinin B/TAC3R) are rare causes.[211,221] The hypogonadism of most subjects with neurokinin B/TAC3R mutations is reversed by sex steroid therapy, which suggests that this signaling system is important for the startup of puberty, but not its maintenance. Isolated hypogonadotropic hypogonadism also has been reported in a woman homozygous for a nonsense mutation of the X-linked *DAX1* gene, which was associated with adrenal insufficiency in her brothers.[746]

Isolated FSH deficiency due to mutation in the β-subunit has been reported to cause primary amenorrhea in association with a unique test panel—low FSH, elevated LH, and low testosterone levels.[136,718] Carbohydrate-deficient glycoprotein syndrome (phosphomannomutase deficiency) is characterized by high levels of immunoreactive, but bioinactive gonadotropins, mimicking primary ovarian insufficiency.[747] Isolated LH deficiency due to LHβ gene inactivating point mutations has been reported to lead to secondary amenorrhea following normal pubertal development, but undetectable LH, high FSH, low E2, and macrocystic ovaries.[748] However, some inactivating LH mutations in men have high immunoreactive LH levels.[718]

Acquired gonadotropin deficiency can be a consequence of tumors, trauma, autoimmune hypophysitis,[749,750] degenerative disorders involving the hypothalamus and pituitary,[751] irradiation,[752] chemotherapy,[753] or chronic illness.[754] Hypogonadotropic hypogonadism will develop in about one third of those receiving 20 to 30 Gy cranial irradiation, whereas it is typical in those receiving > 50 Gy.[596,755] Pituitary adenoma, craniopharyngioma, and dysgerminoma are the most common neuroendocrine neoplasms responsible for hypopituitarism in children. Most "nonfunctioning" pituitary adenomas are gonadotroph adenomas, which secrete gonadotropin subunits in response to thyrotropin-releasing hormone.[756] A case of

hypothalamic tumor is presented with Figure 15-39. Pinealomas most commonly cause sexual infantilism. They may act by secreting an inhibitory substance, rather than by compressing key areas of the hypothalamus.[603]

Anorexia nervosa is the prototypic form of eating disorder, a common cause of hypogonadotropism in teenagers. It is a syndrome of undernutrition due to voluntary starvation with a particular psychological dysfunction that results in amenorrhea.[757-759] These patients uniformly consider themselves too fat in the face of objective evidence that they are underweight. The psychiatric criteria that distinguish this disorder from food faddism and fear of obesity consist of refusal to gain or maintain body weight to a minimally normal level for height and age (< 85th percentile of expected body weight based on average BMI for age)[760] with all the following being present: (1) intense fear of gaining weight or becoming fat, even though underweight, (2) an inaccurate perception of body weight, such that they have a disturbance in the way that body weight, size, or shape is experienced; undue influence of body shape and weight on self-evaluation; or denial of the seriousness of current low body weight, and (3) amenorrhea for 3 or more months in postmenarcheal females. Bulimia nervosa, the binge-eating/purging variant eating disorder, is similar in the overevaluation of body shape and weight and the use of extreme weight control behaviors. Physical activity tends to be high. These disorders may be manifest at an early stage as atypical eating disorders, before weight or amenorrhea criteria are met or when the binge is subjective. The cognitive defect that weight can serve as the predominant value in judging self-worth is central to anorexia nervosa. In contrast to other depressive individuals, these patients are generally content with themselves in the areas of intellectual and vocational achievement.

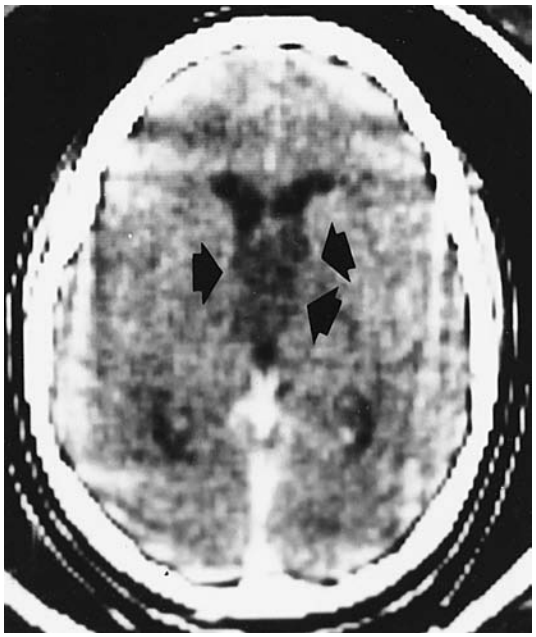

FIGURE 15-39 ■ Computed tomography of the brain of a 16-year-old girl with hypothalamic astrocytoma. The low-density tumor mass (arrows) extends superiorly from the hypothalamus, obliterates the third ventricle, and partially compresses the frontal horns of the lateral ventricles (particularly the right). This patient presented with secondary amenorrhea. Menarche had occurred at age 13, and menses was normal until 15.3 years. The patient then became amenorrheic in association with lethargy, episodic headaches, polyuria, and weight gain—despite little change in appetite. Physical examination was negative. The skull radiograph, electroencephalogram, visual fields, and serum prolactin and thyroxine levels were normal—and urine-specific gravity was 1.016. After biopsy of the cyst wall, studies revealed her to have gonadotropin, growth hormone, and partial antidiuretic hormone deficiencies.

The cause is multifactorial. It involves a genetic predisposition. Concordance rates for the anorexic type are about 50% for monozygous twins, compared with about 5% for dizygotic twins. Many other risk factors have been implicated. Familial factors also include eating disorders of any type, depression, substance abuse, and adverse family interactions. Premorbid experiences, such as sexual abuse or social pressures, or premorbid characteristics, such as low self-esteem, compulsiveness, and perfectionism, are also important. Dieting meets a need for approval in our culture with its emphasis on dietary restriction and thinness as goals for women. Anorexia is often precipitated in vulnerable children by a new experience, such as puberty, leaving home or beginning college, or by adverse life events. The disorder is perpetuated by the complications of starvation, such as depression and reduced gastric emptying.

The onset tends to be at 12 years of age or later. Earlier onset is associated with growth arrest, delay of puberty, and primary amenorrhea.[761] GH deficiency is common.[762,763]

The medical complications of anorexia nervosa are serious. The risk of death is increased approximately 10-fold: electrolyte imbalance, hypoglycemia, cardiovascular instability, bone marrow hypocellularity predisposing to silent infection, and renal failure account for about half of the mortality, and suicide accounts for the rest.

The weight changes leading to cessation or restoration of menstrual cycles are in the range of 10% to 15% of body weight. Recovery is associated with achieving a critical level of body fat stores above the 10th percentile (over approximately 20% body fat) (Figure 15-40), at a BMI of approximately 20 (i.e., midnormal).[764,765] There is an inverse relationship between body weight and the maturity of gonadotropin release in these patients. The 24-hour pattern of gonadotropin release tends to be immature (prepubertal or pubertal), and the diurnal LH pattern becomes mature upon recovery from undernutrition.[766] Luteinizing hormone pulsatility is low and may be restored by opiate antagonists.[89] The gonadotropin response to GnRH and ovulatory response to clomiphene citrate are blunted in the malnourished state and become normal with weight gain to about 80% of ideal.[767,768] Leptin levels are significantly decreased and are a major contributor to both the gonadotropin deficiency and to changes in the thyroid and GH axes.[769]

Mild hypercortisolism is frequent and may contribute to the anovulation by mechanisms discussed further under "Hypothalamic Anovulation."[770] Afternoon ACTH and cortisol levels are significantly higher and the response to CRH is significantly lower than normal.

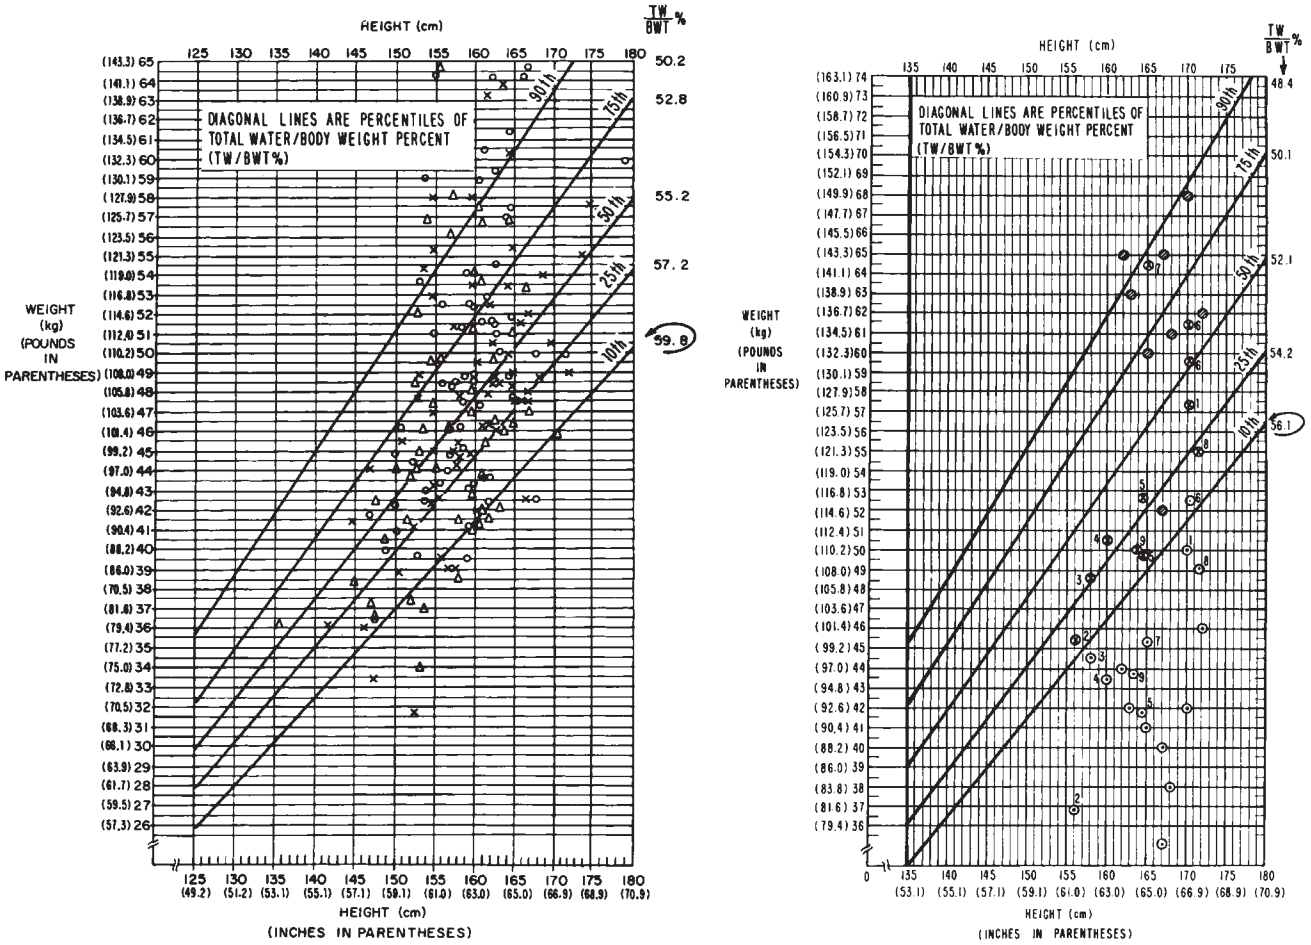

FIGURE 15-40 ■ Percentiles of fatness (diagonal lines) for white girls at menarche (left) and after menarche (right) equated with computed percentiles of total water as a percentage of total body weight. The minimal weight necessary at a particular height for the onset or maintenance of menses is very close to the 10th percentile of fatness on these respective charts. Data for anorexia nervosa cases are shown on the right-hand chart: • at presentation; x at resumption of menses. (From Frisch RE, McArthur JW [1974]. Menstrual cycles: fatness as a determinant of minimum weight for height necessary for their maintenance or onset. Science 185:949. Copyright © by the American Association for the Advancement of Science.)

In contrast to Cushing syndrome, DHEAS levels tend to be blunted as a consequence of undernutrition.[771]

A fundamental neuropsychological flaw or hypothalamic disturbance[772] seems necessary to explain the high incidence of GH deficiency, why some patients become amenorrheic before losing weight, and why about half of the cases remain amenorrheic after treatment. The serotonergic systems implicated in the regulation of feeding and mood seem to remain altered even after weight restoration. The authors favor the concept that these psychological problems lead to amenorrhea only in women who are predisposed to it by a unique preexisting hypothalamic dysfunction. Evidence has been obtained for marked individual differences in reactivity of the neuroendocrine system to stress.[773]

A number of features attributed to hypothalamic dysfunction, such as cold intolerance, may be due to the subtle hypothyroid state that is secondary to the malnutrition.[770] Serum triiodothyronine levels are consistently low, serum thyroxine levels tend to be lower than average (although usually within normal limits), the pattern of TSH release indicates TRH deficiency, and the state of deep tendon reflexes and metabolism is consistent with hypothyroidism. Hypothyroidism may in part complicate malnutrition as a consequence of the interference with IGF-1 generation: low IGF-1 initiates GH excess, compensatory somatostatin release, and subsequent inhibition of the thyrotropin response to thyrotropin-releasing hormone. Undernutrition also diverts the generation of thyroxine metabolites away from triiodothyronine and toward reverse triiodothyronine.

Hyperprolactinemia is a potentially reversible cause of gonadotropin deficiency.[774] Galactorrhea is present in about half of the patients, particularly those with residual estrogen production. The causes of hyperprolactinemia are diverse, including hypothalamic or pituitary disorders, drugs, hypothyroidism, renal or liver failure, peripheral neuropathy, stress, autoimmune disorders, macroprolactinemia, genetic, and idiopathic origins.[775-777a] Elevated serum prolactin levels occur with a variety of tumors that cause functional or anatomic pituitary stalk section, thereby preventing inhibitory pituitary control. About one third of hyperprolactinemic women have an identifiable pituitary adenoma. Prolactinomas smaller than 1 cm

in diameter (microadenomas) cause no problems due to local extension. Prolactinoma may be associated with multiple endocrine neoplasia type 1.[778] In about a quarter of adult hyperprolactinemia cases, the malfunction is due to the ingestion of drugs such as phenothiazines, estrogen, or cocaine.[779] Considerable hyperprolactinemia is idiopathic: decreased sensitivity to dopaminergic inhibition may underlie such cases.[780]

Macroprolactinemia is due to a variant molecule or autoantibody formation. In this situation, direct immunoassay indicates elevated levels of prolactin. However, the biologically available or active prolactin level is normal; thus there is no physiologic consequence to the macroprolactinemia.

Hyperprolactinemia results in LH pulses that tend to be infrequent and LH secretion that is variable in response to GnRH.[781] Selective prolactin excess causes variable degrees of gonadotropin deficiency, ranging from severe to partial (hypothalamic amenorrhea). Adrenal hyperandrogenism, hirsutism, and seborrhea are common.[314]

Frank virilization as a result of very high androgen levels suppresses gonadotropin levels and so causes defeminization. However, the moderately hyperandrogenic disorders discussed later, which are more common, are associated with normal estrogenization.

Differential Diagnosis

The differential diagnosis of hypogonadism is included in Box 15-4. Investigation should begin for hypogonadism when puberty is delayed or does not progress normally. Delayed puberty is indicated by a lack of thelarche by the chronologic or bone age of 13 years. Abnormal progression of puberty is suggested by failure of menses to occur within 4.5 years of the onset of puberty or if secondary amenorrhea or oligomenorrhea has persisted for 1 year. A family history of delayed puberty is compatible with the delay being constitutional rather than having an organic basis. The history should include a thorough past medical history and systems review, including intracranial, visual, olfactory, emotional, abdominal, or pelvic symptoms and systemic symptoms that might indicate chronic endocrine, metabolic, or systemic disorders that delay puberty. Upon examining the patient, the height and weight should be carefully measured and growth rate and appropriateness of weight for height determined (see Figure 15-40). Careful categorization of the stage of breast and sexual hair development are essential. Inspection of the external genitalia is indicated, but an internal pelvic examination seldom is necessary for diagnosis.[782] Examination of the mature breast should include an attempt to express milk from the ducts to the nipple. The finding of a structural genital abnormality may indicate that amenorrhea is due to abnormal genital tract development, whereas clitoromegaly[783] is a clue to a virilizing disorder. Neurologic examination should include evaluation of eye movements, visual fields, and optic fundi, as well as a search for anosmia and midline defects.

An algorithmic approach to the workup of patients with menstrual disorders is shown in Figures 15-41 through 15-43.[784] The laboratory workup depends on the degree of estrogenization, as initially assessed from the stage of breast development: it includes a bone age radiograph in adolescents who are not sexually mature and generally begins with a chronic disease panel, and determination of gonadotropins, E2 and testosterone level. A pregnancy test is indicated in a sexually mature adolescent. The diagnostic considerations differ in the anovulatory girl without FSH elevation depending on whether she is hypoestrogenic or estrogenized (see Box 15-4; also see Figures 15-41 and 15-42).

FSH elevation indicates primary ovarian failure (see Figures 15-41 and 15-42). Chromosome abnormalities are ordinarily the first consideration, as the most common cause is Turner syndrome and its variants. Individuals with primary ovarian failure that is not due to Turner syndrome and its variants should be investigated for the fragile X premutation.

Lack of FSH elevation in a prepubertal patient does not rule out primary ovarian failure if bone age is below 11 years, because neuroendocrine puberty may not have occurred; in this situation primary ovarian failure is not hypergonadotropic (see Table 15-5).[685] If FSH is not elevated and bone age has reached 11 years, in a prepubertal girl without a growth-attenuating or retarding disorder, one is dealing either with constitutional delay of puberty or isolated gonadotropin deficiency (see Figure 15-41). "Constitutional" delay of puberty is the most likely diagnosis until the bone age reaches 11 to 13 years (see Table 15-5).[685] Its distinction from isolated gonadotropin deficiency may be difficult. The features that help to distinguish it from isolated gonadotropin deficiency are listed in Box 15-5 and discussed in the footnotes to Figure 15-41. The single most useful test is the LH level in response to GnRH testing because random LH levels in hypogonadotropic patients often overlap those of pre- and midpubertal normal children.[95] GnRH agonist testing may discriminate between these disorders better because the LH response at 3 to 4 hours is the best indicator of gonadotropin secretory reserve and because this test permits assessing the gonadal secretory response to the secreted gonadotropins at 24 hours.[651]

The assessment of an adolescent's degree of estrogenization is often difficult. Breast development indicates that there has been estrogen exposure, but it does not mean that the exposure is current. Determination of serum E2 is the simplest test, but diurnal and cyclic variations must be taken into account. Determination of the hormonal effects on vaginal cytology is the most indicative of overall estrogen exposure (see Figure 15-29), but patients do not accept it as well. A progestin withdrawal test is often helpful. A female who does not experience progestin withdrawal bleeding (see Figure 15-42) probably has an ambient E2 level of less than about 40 pg/mL.[785] If bleeding does not occur in response to this maneuver, the integrity of the uterus can be demonstrated by eliciting withdrawal bleeding after a 3-week course of estrogen-progestin, most conveniently administered in the form of birth control pills.

A prolactin level is indicated in the initial workup of normogonadotropic patients, regardless of their

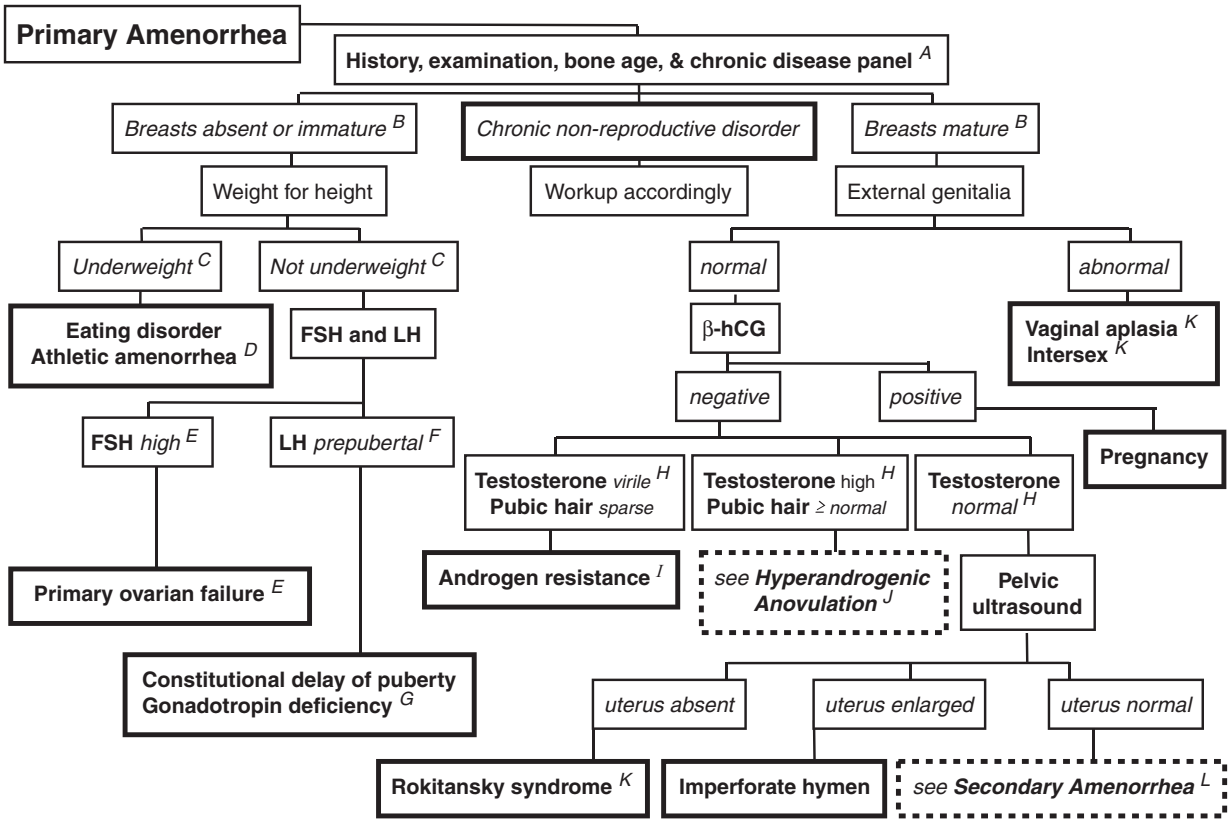

FIGURE 15-41 ■ Differential diagnosis of primary amenorrhea. (Modified with permission from Rosenfield, R. L. (2003). Menstrual disorders and hyperandrogenism in adolescence. In S. Radovick, & M. H. MacGillivray (Eds.), *Pediatric endocrinology: a practical clinical guide* (pp. 451–478). Totowa, NJ: Humana Press.)

A. Prime among the causes of primary amenorrhea are growth-retarding or attenuating disorders. In the absence of specific symptoms or signs to direct the workup, laboratory assessment for chronic disease typically includes a bone age radiograph if the adolescent is not sexually mature and a chronic disease panel (complete blood count and differential, sedimentation rate, comprehensive metabolic panel, celiac panel, thyroid panel, cortisol and insulin-like growth factor-I levels, and urinalysis).

B. Breast development ordinarily signifies the onset of pubertal feminization. However, mature breast development does not ensure ongoing pubertal estrogen secretion (see Figures 15-5 and 15-6).

C. BMI < 10th percentile generally corresponds to a body composition that is < 20% body fat, which is the critical factor.

D. BMI may not accurately reflect body fat in serious athletes (who have a disproportionately greater muscle mass) or bulimia nervosa.

E. FSH is preferentially elevated over LH in primary ovarian failure. The most common cause of primary amenorrhea due to primary ovarian failure is gonadal dysgenesis due to Turner syndrome, but acquired causes must be considered (such as cytotoxic therapy). The workup of primary ovarian failure is considered in detail in the next algorithm (Figure 15-5, secondary amenorrhea and oligomenorrhea). Lack of FSH elevation virtually rules out primary ovarian failure only when the bone age is appropriate for puberty (11 years or more).

F. "Pediatric" gonadotropin assays sensitive to ≤ 0.15 U/L are critical to the accurate diagnosis of gonadotropin deficiency and delayed puberty. A low LH level is more characteristic of these disorders than a low FSH level. Congenital gonadotropin deficiency is closely mimicked by the more common extreme variation of normal, constitutional delay of puberty.

G. History and examination may yield clues to the cause of hypogonadotropic hypogonadism, such as evidence of hypopituitarism (midline facial defect, extreme short stature, visual field defect), anosmia (Kallmann syndrome), or functional hypothalamic disturbance (bulimia, excessive exercise). Random LH levels in hypogonadotropic patients are usually below 0.15 IU/L, but they often overlap those of normal pre- and midpubertal children. The GnRH test, measuring the gonadotropin response to a 50- to 100-mg bolus, in the premenarcheal teenager strongly suggests gonadotropin deficiency if the LH peak is less than 4.2 IU/L by monoclonal assay. However, the GnRH test has limitations because of overlap between hypogonadotropic and normal teenager responses. GnRH agonist testing (e.g., leuprolide acetate injection 10 mg/kg SC) may discriminate better. It may not be possible to definitively establish the diagnosis of gonadotropin deficiency until puberty fails to begin by 16 years of age or progress at a normal tempo.

H. Plasma total testosterone is normally 20 to 60 ng/dL (0.7 to 2.1 nM) in women, 300 to 1200 ng/dL in men, but varies somewhat among laboratories. Plasma free (or bioavailable) testosterone is about 50% more sensitive than total testosterone in detecting hyperandrogenemia. However, there are many pitfalls in testosterone assays at the low levels common among women, reliable testosterone assays are not available to many physicians, and assaying the free testosterone introduces other potential sources of error. Therefore, it is reasonable to begin the evaluation with a total testosterone determination if a free testosterone test in a reliable specialty laboratory is not available to the practitioner.

I. Androgen resistance is characterized by a frankly male plasma testosterone level when sexual maturation is complete, male karyotype (46,XY), and absent uterus. External genitalia may be ambiguous (partial form) or normal female (complete form).

J. The differential diagnosis of hyperandrogenism is shown in a later algorithm (see Figure 15-7).

K. Vaginal aplasia in a girl with normal ovaries may be associated with uterine aplasia (Rokitansky-Kustner-Hauser syndrome). When the vagina is blind and the uterus aplastic, this disorder must be distinguished from androgen resistance. If the external genitalia are ambiguous, it must be distinguished from other disorders of sex development (intersex).

L. Secondary amenorrhea differential diagnosis is presented in Figure 15-42.

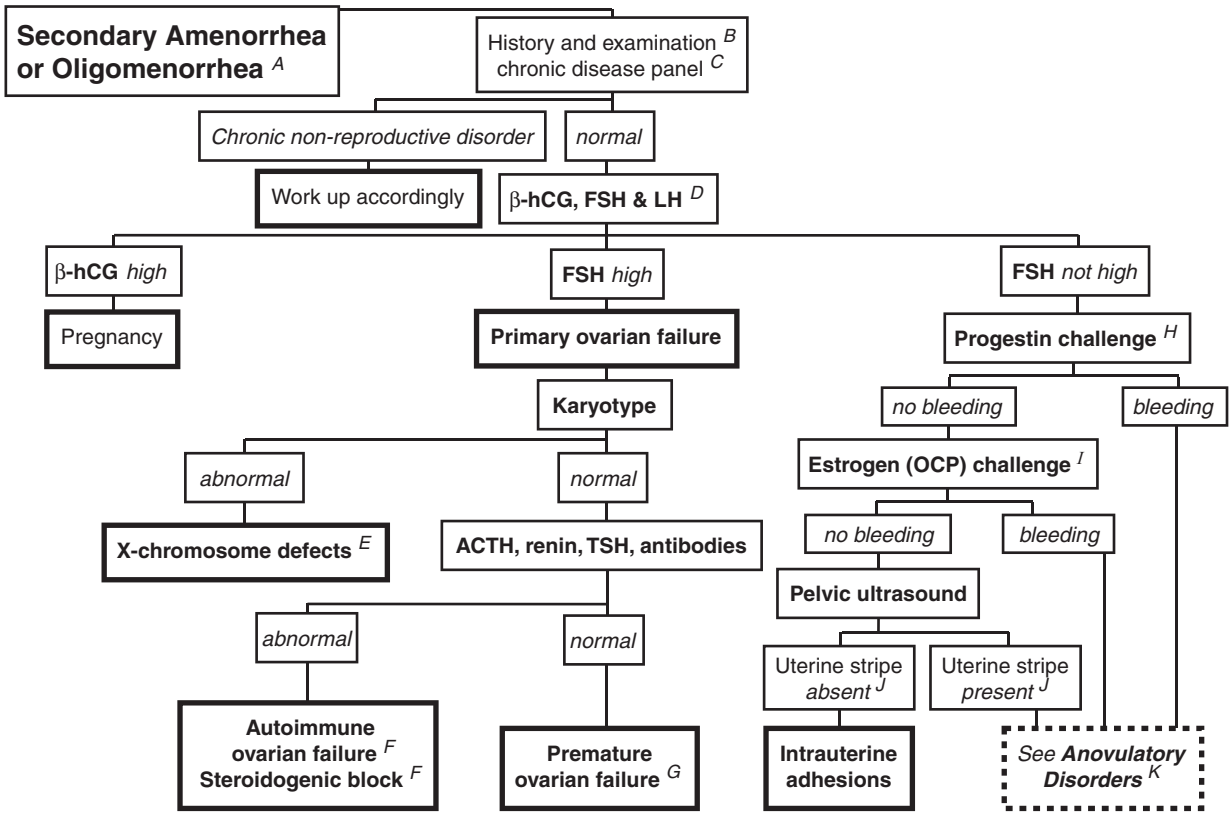

FIGURE 15-42 ■ Differential diagnosis of secondary amenorrhea or oligomenorrhea. (Modified with permission from Rosenfield, R. L. (2003). Menstrual disorders and hyperandrogenism in adolescence. In S. Radovick, & M. H. MacGillivray (Eds.), *Pediatric endocrinology: a practical clinical guide* (pp. 451–478). Totowa, NJ: Humana Press.)

A. Mature secondary sex characteristics are characteristic because the occurrence of menarche indicates a substantial degree of development of the reproductive system.

B. Diverse disorders of many systems cause anovulation. The history may reveal excessive exercise, symptoms of depression, gastrointestinal symptoms, radiotherapy to the brain or pelvis, or rapid virilization. Physical findings may include hypertension (forms of congenital adrenal hyperplasia, chronic renal failure), short stature (hypopituitarism, Turner syndrome, pseudohypoparathyroidism), abnormal weight for height (anorexia nervosa, obesity), decreased sense of smell (Kallmann syndrome), optic disk or visual field abnormality (pituitary tumor), cutaneous abnormalities (neurofibromatosis, lupus), goiter, galactorrhea, hirsutism, or abdominal mass.

C. In the absence of specific symptoms or signs to direct the workup, evaluation for chronic disease in a sexually mature adolescent typically includes complete blood count and differential, sedimentation rate, comprehensive metabolic panel, celiac panel, thyroid panel, cortisol and insulin-like growth factor 1 levels, and urinalysis.

D. "Pediatric" gonadotropin assays sensitive to ≤ 0.2 U/L are critical to the early diagnosis of many anovulatory disorders.

E. Patients missing only a small portion of an X chromosome may not have the Turner syndrome phenotype. Indeed, among 45,X patients, the classic Turner syndrome phenotype is found in less than one third (with the exception of short stature in 99%). Ovarian function is sufficient for about 10% to undergo some spontaneous pubertal development and for 5% to experience menarche. If chromosomal studies are normal and there is no obvious explanation for the hypogonadism, special studies for fragile X premutation and autoimmune oophoritis should be considered.

F. Autoimmune ovarian failure may be associated with tissue-specific antibodies and autoimmune endocrinopathies such as chronic autoimmune thyroiditis, diabetes, adrenal insufficiency, and hypoparathyroidism. Nonendocrine autoimmune disorders may occur, such as mucocutaneous candidiasis, celiac disease, and chronic hepatitis. Rare gene mutations causing ovarian insufficiency include steroidogenic defects that affect mineralocorticoid status (17-hydroxylase deficiency is associated with mineralocorticoid excess and lipoid adrenal hyperplasia with mineralocorticoid deficiency) and mutations of the gonadotropins or their receptors. Ovarian biopsy is of no prognostic or therapeutic significance. LH is disproportionately high in steroidogenic defects or autoimmune disease specifically affecting theca cells.

G. The history may provide a diagnosis (e.g., cancer chemotherapy or radiotherapy). Other acquired causes include surgery and autoimmunity. Chromosomal causes of premature ovarian failure include X-chromosome fragile site and point mutations. Other genetic causes include gonadotropin-resistance syndromes such as LH or FSH receptor mutation and pseudohypoparathyroidism. A pelvic ultrasound that shows the preservation of ovarian follicles carries some hope for fertility.

H. Withdrawal bleeding in response to a 5- to 10-day course of progestin (e.g., medroxyprogesterone acetate 10 mg HS) suggests an overall estradiol level greater than 40 pg/mL. However, this is not entirely reliable, thus in the interest of making a timely diagnosis it is often worthwhile to proceed to further studies.

I. A single cycle of an OCP containing 30 to 35 mg ethinyl estradiol generally suffices to induce withdrawal bleeding if the endometrial lining is intact.

J. A thin uterine stripe suggests hypoestrogenism. A thick one suggests endometrial hyperplasia, as may occur in polycystic ovary syndrome.

K. The differential diagnosis of other anovulatory disorders continues in Figure 15-43.

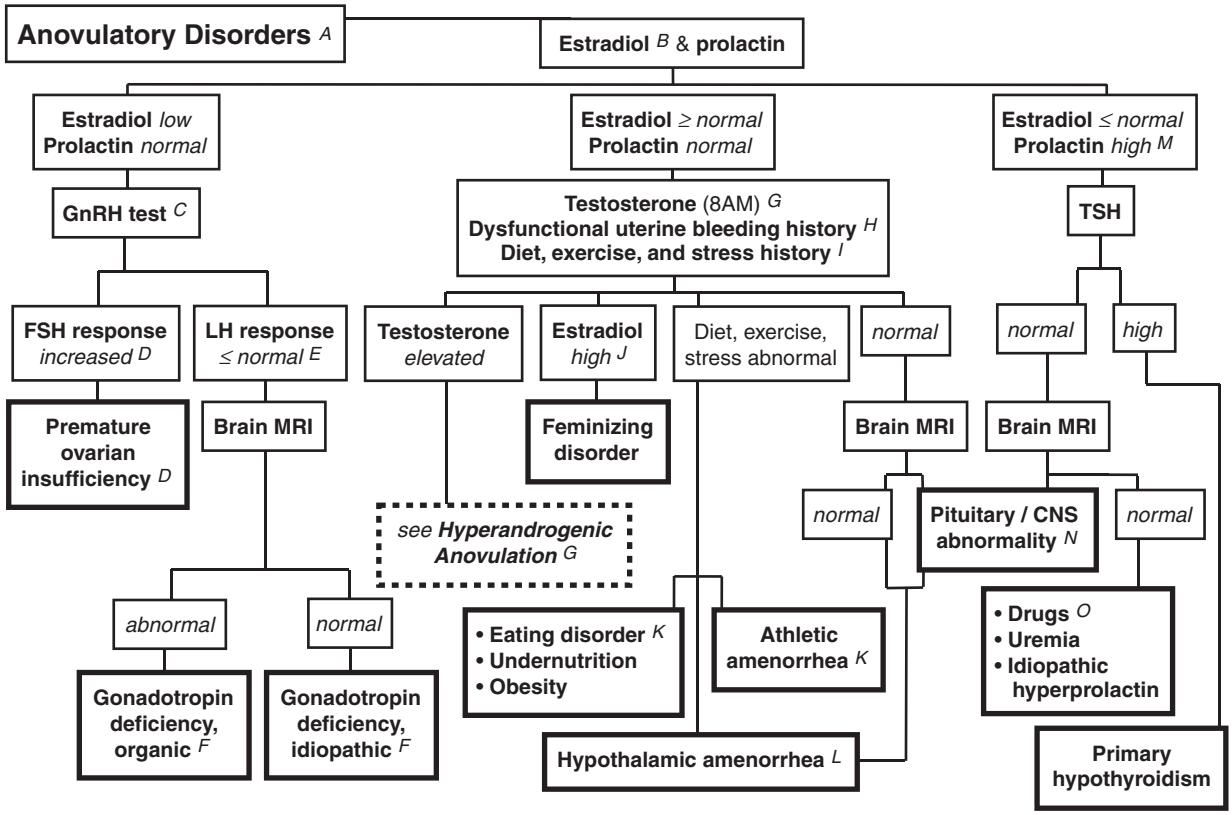

FIGURE 15-43 ■ **Differential diagnosis of anovulatory disorders.** (Modified with permission from Rosenfield, R. L. (2003). Menstrual disorders and hyperandrogenism in adolescence. In S. Radovick, & M. H. MacGillivray (Eds.), *Pediatric endocrinology: a practical clinical guide* (pp. 451–478). Totowa, NJ: Humana Press.)

A. Anovulatory disorders should be considered in any girl with unexplained amenorrhea or oligomenorrhea, irregular menstrual bleeding, short cycles, or excessive menstrual bleeding. The workup in this algorithm progresses from negative studies in the Figure 15-5 algorithm.

B. Once breast development has matured, the breast contour does not substantially regress when hypoestrogenism develops. Hypoestrogenism is suggested if plasma estradiol is persistently < 40 pg/mL in a "pediatric" assay sensitive to < 10 pg/mL. However, a single estradiol level may be misleading because of cyclic or episodic variations.

C. Gonadotropin-releasing hormone (GnRH) testing is usually performed by assaying LH and FSH before and 0.5 hour after the administration of 1 μg/kg GnRH intravenously. GnRH agonist testing may alternatively be performed by administering 10 μg/kg leuprolide acetate subcutaneously and assaying LH and FSH at 3 to 4 hours to assess gonadotropin reserve and at 18 to 24 hours to assess the ovarian steroid response to endogenous gonadotropin release.

D. Baseline gonadotropin levels may be normal as the ovary begins to fail, as in early menopause, but an exaggerated FSH response to GnRH and subnormal E2 response to the gonadotropin elevation induced by acute GnRH agonist challenge are characteristic. The further workup is shown in Figure 15-5.

E. LH responses to GnRH may vary from nil to normal in gonadotropin deficiency: normal LH and FSH responses in the presence of hypoestrogenism indicate inadequate compensatory hypothalamic GnRH secretion.

F. Gonadotropin deficiency may be congenital or acquired, organic or functional. Congenital causes include midline brain malformations or specific genetic disorders such as Prader-Willi syndrome, Laurence-Moon-Biedl syndrome, or Kallmann syndrome. Kallmann syndrome, the association of anosmia with gonadotropin deficiency, occurs in both the X-linked and autosomal-recessive forms. Special MRI views often demonstrate the absence of the olfactory tracts. Acquired gonadotropin deficiency may be secondary to a variety of organic CNS disorders, varying from hypothalamic-pituitary tumor to radiation damage to empty sella syndrome. Autoimmune hypophysitis is a rare disorder, sometimes accompanying a polyendocrine deficiency syndrome. The prototypic form of functional gonadotropin deficiency is anorexia nervosa. Idiopathic hypogonadotropic deficiency may sometimes occur in families with anosmia, suggesting a relationship to Kallmann syndrome.

G. Plasma free (or bioavailable) testosterone is about 50% more sensitive than total testosterone in detecting hyperandrogenemia. However, there are many pitfalls in testosterone assays at the low levels observed in women, reliable testosterone assays are not available to many physicians, and assaying the free testosterone introduces other potential sources of error. Therefore, it is reasonable to begin the evaluation with a total testosterone determination if a free testosterone test in a reliable specialty laboratory is not available to the practitioner. Simultaneous assay of 17-hydroxyprogesterone is indicated in subjects at high-risk for congenital adrenal hyperplasia, such as Ashkenazi Jews. A differential diagnosis of hyperandrogenic evaluation is outlined in Figure 15-46.

H. Dysfunctional uterine bleeding or menorrhagia not controlled by progestin or OCP therapy additionally requires a pelvic ultrasound examination (for genital tract tumor or feminizing tumor), coagulation workup (which includes platelet count, prothrombin time, thromboplastin generation test, bleeding time, and von Willebrand factor), and consideration of the possibility of sexual abuse.

I. The equivalent of 4 miles per day or more is generally required before body fat stores fall to the point where amenorrhea occurs. Physical or psychosocial stress may cause amenorrhea.

J. The normal range for estradiol over the menstrual cycle is wide: values > 95 pg/mL usually indicate the preovulatory or luteal phase but are compatible with a feminizing disorder.

K. Mild forms of stress disorders associated with low body fat (anorexia nervosa, bulimia nervosa, and athletic amenorrhea) may cause acquired hypothalamic amenorrhea rather than frank gonadotropin deficiency. The low body fat content of athletic amenorrhea may not be reflected by weight for height because of high muscularity. A dual-photon absorptiometry scan may be useful for documenting body fat below 20%.

Patients with anorexia nervosa may become amenorrheic before or when weight loss begins, indicating an important psychological component to the etiology. Obesity is also associated with anovulatory cycles and raises the possibility of Cushing syndrome.

L. Hypothalamic amenorrhea is a diagnosis of exclusion. It is a form of partial gonadotropin deficiency in which baseline estrogen secretion is normal but a preovulatory LH surge cannot be generated. It may result from organic CNS disorders or be functional, due to stress, undernutrition or obesity, diverse types of endocrine dysfunction, chronic disease, or idiopathic causes. It may be difficult to distinguish from hyperandrogenemia.

M. Hyperprolactinemia is heterogeneous in its presentation. Some have normoestrogenic anovulation, which may be manifest as hypothalamic anovulation, hyperandrogenism, dysfunctional uterine bleeding, or short luteal phase. On the other hand, some are hypoestrogenic; these do not have galactorrhea.

N. Large hypothalamic-pituitary tumors or other types of CNS injury cause variable pituitary dysfunction, which may include complete or partial gonadotropin deficiency and various manifestations of hypopituitarism (including secondary hypothyroidism). If they interrupt the pituitary stalk, hyperprolactinemia ensues. Hyperprolactinemia may also be caused by prolactinomas.

O. Drugs, particularly neuroleptics of the phenothiazine or tricyclic type, may induce hyperprolactinemia.

BOX 15-5 Features That Distinguish Gonadotropin Deficiency from Constitutional Delay of Puberty

In a healthy delayed prepubertal girl with BA >11 years and prepubertal FSH, gonadotropin deficiency is:

- Possible if:
  - Weight loss greater than 5% to 8% (BMI < 10th to 15th percentile for height age)
  - Midline facial defect
  - CNS dysfunction
  - CT or MRI brain scan abnormal
- Probable if:
  - BA > 13 years and LH < 0.15 U/L in early daytime
  - Anosmia or panhypopituitarism
- Diagnostic if:
  - Sleep-associated increase in LH lacking
  - GnRH agonist test subnormal response
  - Chronologic age >16 years

Modified with permission from Rosenfield, R. L., Barnes, R. B. (1993). Menstrual disorders in adolescence. Endocrinol Metab Clin N Am, 22, 491–505.

estrogen status. The prolactin level correlates with the size of prolactinomas, and a level over 200 ng/mL is typical of a macroprolactinoma. A prolactin level that does not correlate with the size of a large pituitary tumor suggests that either the tumor is not a prolactinoma and is causing a functional pituitary stalk section or it is a macroprolactinoma elaborating such high levels of prolactin as to artifactually lower the immunoassayable prolactin level by a "hook effect."[786] Very high blood or cerebrospinal fluid prolactin levels suggest invasiveness. The workup for this should include formal testing of visual fields (Goldman perimetry or evoked response). Pituitary microadenomas may be "incidentalomas" of no clinical significance, judging from an approximate 10% incidence in autopsy material.[787] However, they require careful assessment of pituitary function and follow-up.[788] Macroprolactinemia should be considered in the absence of clearly related symptoms and when the MRI is negative or in the setting of autoimmune disease.[776,777] Macroprolactinemia is confirmed when the prolactin level measured after precipitation of serum using polyethylene glycol is normal (or substantially reduced compared to the level measured in untreated serum.)

Imaging studies are important ancillary measures. Pelvic ultrasound may demonstrate hypoplastic ovaries, endometrial hypoplasia or disorders, or polycystic ovaries. Magnetic resonance imaging of the hypothalamic-pituitary area is important in the workup of gonadotropin deficiency, hyperprolactinemia, and hypothalamic anovulation.

Anorexic patients require psychiatric evaluation and consideration of brain tumor and partial bowel obstruction. Diet faddism and athletic addiction may be difficult to distinguish from anorexia nervosa. Constitutionally thinness is a variant of normal with normal menses and a distinctive hormonal profile.[789] It is unclear whether the superior mesenteric artery syndrome is a primary disorder that mimics anorexia nervosa or is a complication of it.[790]

Management

Underlying disorders must be treated appropriately. For example, tumors require surgery or radiotherapy. For prolactinoma, dopaminergic treatment is the initial treatment of choice unless the patient's condition or eyesight is critical.[778,791] Hyperprolactinemia will be maximally suppressed within 1 month and the menstrual cycle normalized within 3 months by an effective dopaminergic agonist regimen. Cabergoline 0.5 to 1 mg once or twice weekly will usually control galactorrhea and shrink prolactinomas.[775,792] To minimize nausea it is best to start with a low dose at bedtime. Data implicate cabergoline as increasing the risk of cardiac valve regurgitation about 5-fold in the elderly, albeit at generally 10-fold or higher doses than used to treat hyperprolactinemia. Bromocriptine does not activate the serotonin 5-HT(2B) receptor, the proposed mechanism through which cabergoline is thought to stimulate valve hypertrophy, and so bromocriptine does not seem to be associated with an increased risk of cardiac valve regurgitation and may be considered as an alternative to cabergoline treatment, albeit a less-effective one. The usual bromocriptine maintenance dose is 0.25 to 0.5 mg twice daily. After 2 years of treatment, if the prolactin level is normal and there is no tumor evident on MRI,

dopamine agonist may be tapered and possibly discontinued. Prolactin levels are then measured to monitor for recurrance.[793]

Anorexia nervosa is best managed by an experienced multidisciplinary team. Refeeding is the first priority, and once steady weight gain is evident, the psychodynamic issues can be addressed.[794] Family therapy of medically uncomplicated cases of anorexia nervosa on an outpatient basis generally yields the best results, with good improvement in over half of patients. Inpatient intervention for rehydration and metabolic stabilization or failure of weight gain with ongoing cachexia may be required at any time. Menses resumes when psychotherapy is effective and body fat is restored to normal (see Figure 15-40). The induction of menses by estrogen-progestin replacement is usually injudicious because it provides a false sense of recovery and does not yield the recovery of bone loss that occurs with weight gain.[795] Although the acute episode can usually be successfully treated, there is a high rate of ongoing psychiatric disability and medical complications. Anorexia nervosa "by proxy" has been described in the offspring of former patients.[796]

There are two aspects of therapy that are uniformly involved in managing hypogonadism: psychological support and hormone administration. Patients with delayed development that is a variation of normal should be reassured that there is nothing wrong, only a delay in timing of the onset of puberty. The wide normal variation in the pattern and time of the pubertal growth spurt should be explained in detail and the girl should be informed of her predicted eventual height. Most children with delayed puberty do not have overt psychological symptoms. Complex compensations and sublimations obviously occur. However, peer group pressures may make adjustment to sexual infantilism especially difficult when the child approaches age 13,[797] and a poor self-image may lead to social withdrawal and feelings of hopelessness. Physical immaturity may prolong psychological immaturity. A 6- to 12-month course of physiologic sex hormone therapy at this time may help alleviate these anxieties. The physician should discuss the fact, when the evidence favors it, that the odds are overwhelmingly in favor of the "timer in the subconscious area of the brain" eventually turning on. When this will happen can be approximated from the skeletal age. One should not hesitate to advise more intensive psychological counseling if it becomes apparent that the concern about puberty is but one aspect of a more general maladjustment. Ultimately the decision as to whether to undertake treatment for delayed puberty is up to the patient and her family.

It is important to assure the teenager with an organic basis for hypoestrogenism that feminization will occur, although in response to appropriate hormone treatment. Some genetic forms of gonadotropin deficiency are actually reversed by sex steroid therapy.[221] However, most will benefit from lifelong hormone replacement therapy. It should be kept in mind that attainment of normal breast development in the girl with panhypopituitarism requires replacement of GH and cortisol deficits. It is difficult, however, to induce secondary sex characteristics in some patients with systemic chronic inflammatory disease such as lupus erythematosus.

In patients in whom short stature is an important concern, as in Turner syndrome, growth potential must be considered before undertaking estrogen replacement. GH therapy improves the adult height potential of patients with Turner syndrome, especially when started as soon as growth failure becomes apparent.[798] GH therapy in the United States is generally initiated at a dose of 0.375 mg/kg per week as approved by the U.S. Food and Drug Administration (FDA). In older girls, or those with extremely short stature, therapy with oxandrolone (2-oxo-17α-methyldihydrotestosterone [Anavar]) 0.05 mg/kg/day, which augments GH action, can be considered.[799] Clitoromegaly is ordinarily negligible on this dosage; liver function should be monitored.

Two controlled studies have shown that pubertal estrogen replacement therapy is safe and efficacious when started as young as 11 to 12 years of age using very low estrogen doses in conjunction with growth hormone therapy in Turner syndrome.[800,801] Both therapeutic regimens, one utilizing monthly depot E2 and the other using daily oral ethinyl E2, maximized growth potential and age-appropriate feminization. However, the doses used were far below those available by prescription. The estrogen content of oral contraceptive pills is supraphysiologic for the induction of breast development or for linear growth.

We favor the use of one of the following hormone replacement regimens. Whichever form of estrogen is used, pubertal development and growth should be monitored every 6 months, with bone age determinations at 6- to 12-month intervals to avoid unanticipated loss of growth potential.

Intramuscular depot E2 in a starting dose of 0.2 mg/month will usually induce breast budding; the dose should be increased by 0.2 mg every 6 months.[800] A midpubertal dose of 1 to 1.5 mg monthly, which is half the adult replacement dose, typically induces menarche within 1 year. An alternative oral regimen begins with 5 μg/kg micronized E2 (Estrace, 0.25 mg for a 50 kg girl) daily; the adult replacement dose is 1 to 2 mg/day.[802]

Transdermal E2 is a convenient, physiologic form of therapy[803] that appears to have long-term health advantages over commonly used oral estrogens,[524,525] but there are little data on its use for inducing puberty. We recommend starting transdermal feminization with 25 μg daily for 1 week per month, a marginally feminizing dose that is in accord with current guidelines,[798] and escalating at 6-month intervals to an adult dose at 3 years. A suggested protocol for female pubertal induction for hypogonadal patients is provided in Table 15-7.[802]

For girls with hypogonadism and an intact uterus, cyclic progestin should be added after 2 years of estrogen therapy or when bleeding begins to occur at unpredictable times. A simple regimen is to use 100 mg of micronized progesterone (Prometrium) at bedtime for 7 to 14 days during the second to third week of estrogen therapy or equivalent doses of medroxyprogesterone acetate (5 to 10 mg/day) or norethindrone acetate (5 mg/day). This will bring about normal menstruation during the week

TABLE 15-7 **Suggested Pubertal Transdermal Estradiol Replacement Regimen Beginning at 11 years of Age***

Age	Estradiol Dose
0-6 months	25 μg, day 1-7 each month
6-12 months	25 μg, day 1-14 each month
12-18 months	25 μg, day 1-21 each month
18-24 months	37.5 μg, day 1-21 each month
2-2.5 years	28-day cycle: 50 μg day 1-21 and Prometrium 100 mg† day 12-21 every 28 days
	OR
	Continuous: 50 μg day 1-14, then CombiPatch (50 μg estradiol/0.14 mg norethindrone) day 15-28 every 28 days
2.5-3 years	28-day cycle: 75 μg day 1-21 and Prometrium 100 mg day 12-21 every 28 days
	OR
	Continuous: 75 μg day 1-14 then CombiPatch (50 μg estradiol/norethindrone) day 15-28 every 28 days
3-3.5 years	28-day cycle: 100 μg day 1-21 and Prometrium 100 mg day 12-21 every 28 days
	OR
	100 μg day 1-14 then CombiPatch (50 μg estradiol/norethindrone) day 15-28 every 28 days
> 3.5 years	Continue regimen or offer oral contraceptive pill

*In children ≥ 13 years old, consider starting with 25 μg for 2 to 3 weeks monthly and increasing the dose at shorter intervals (e.g., 3 months). †If inadequate bleeding, increase Prometrium to 200 mg day 12-21 or change to CombiPatch 50 μg E2/0.25 mg norethindrone.

Modified from Rosenfield, R., Kiess, W., & Keizer-Schrama, S. (2006). Physiologic induction of puberty in Turner syndrome with very low-dose estradiol. In C. Gravholt, & C. Bondy (Eds.), Wellness for girls and women with Turner syndrome *(pp. 71–79). Amsterdam: Elsevier Science.*

preceding the resumption of estrogen therapy. The addition of progestin will decrease the risk of endometrial hyperplasia and endometrial carcinoma, but premenstrual symptoms should be anticipated.

Once optimal height is achieved, most patients prefer to switch to birth control pills as a convenient form of estrogen-progestin therapy. The pills containing the lowest dose of estrogen that will result in normal menstrual cycles are advisable. The potential risks of oral contraceptives must be kept in mind when counseling adolescents.[804] The lowest estrogen dosages currently available in combination contraceptive pills in the United States contain 20 μg (Mircette) to 30 μg (Yasmin) ethinyl E2. Low-dose androgen replacement has been controversial but may confer benefits to body composition, cognition, bone mineralization, and libido.[805]

Hypogonadotropic patients can achieve ovulation with gonadotropin therapy. Hypothalamic GnRH deficiency can be successfully treated by pulsatile GnRH.[89,806] Because several genes in the GnRH signaling system are expressed in the gonads, some hypogonadotropic patients have primary defects in gonadal function.[728,807] Induction of ovulation is best carried out by a gynecologist specializing in reproductive endocrinology.

Patients with primary ovarian failure usually require oocyte donation and in vitro fertilization to successfully achieve pregnancy.[691,694,808] Activation of residual follicle growth in autografts has recently been accomplished, with successful pregnancy after embryo transfer.[808a] Turner syndrome patients are, however, at high risk for obstetrical complications in the areas of uterine anomalies, carbohydrate intolerance, and cardiovascular complications. Oocyte cryopreservation and ovarian tissue cryopreservation and transplantation have been explored to preserve fertility in patients with gonadal dysgenesis and disorders requiring cytotoxic chemotherapy or gonadectomy.[809-811] There has been some success with these experimental procedures, but outcomes data are sparse. Feasibility is a limitation in children because of time constraints and the need for ovarian stimulation.[709] Female germline stem cell research holds promise as a future fertility treatment.[38] Up-to-date information for physicians and patients can be found through the Oncofertility Consortium (myoncofertility.org).

Nonhypoestrogenic Menstrual Disturbances

Hypothalamic Anovulation

Hypothalamic anovulation causes menstrual disturbances in sexually mature women through a deficiency in GnRH secretion that is too subtle to cause frank hypoestrogenism. The neuroendocrine system stimulates ovarian estrogen secretion to a level normal for an early- or midfollicular phase female, but follicular development is inadequate for a normal dominant follicle to emerge. Amenorrhea or oligomenorrhea may result. However, in some patients sufficient estrogenization occurs to cause dysfunctional uterine bleeding, which is discussed in the next section.

Reduced LH pulsatility[812] and failure to generate a midcycle LH surge[813,814] are characteristic. The pathophysiology seems to be mediated primarily by undernutrition or CRH excess. Negative energy balance may be present even in patients of normal, but less than average, weight and fat stores.[418,769] Leptin deficiency is an important determinant of the decreased LH pulsatility. Ghrelin may play a role in LH inhibition.[815] The anovulation of psychic or physical stress seems to involve CRH excess.[770] In the brain, CRH releases β-endorphin from proopiomelanocortin, and the endorphin in turn inhibits GnRH release. Naloxone blockade of opioid action normalizes gonadotropin secretion.[89] In the pituitary, CRH increases the set point for ACTH release. This brings about a new steady state of increased cortisol secretion. Further ACTH response to CRH is blunted by the negative feedback of this cortisol excess. The result is a mildly Cushingoid cortisol rhythm. Cortisol excess itself can contribute to the amenorrhea by inhibiting the response to GnRH,[816] as well as antagonizing some sex hormone actions. Adrenal androgens are elevated in competitive athletes who maintain body fat stores.[817]

Causes. *Functional hypothalamic amenorrhea* is the term commonly used to describe hypothalamic anovulation that is unexplained by organic CNS disorders or chronic disease. The endocrine features of these patients resemble those of patients with the athletic or psychogenic types of hypothalamic anovulation. Twenty-four percent of women in one series had a history of delayed menarche.[573] A primate model indicates that hypothalamic anovulation develops in stress-sensitive individuals from an innocuous combination of mild stress and mild caloric restriction.[818] Heterozygosity for genes associated with Kallmann syndrome has been identified as a predisposing factor in 13% of cases; more than half of those in this subgroup had a family history of hypothalamic amenorrhea or delayed puberty.[573]

Athletic amenorrhea is the term given to hypothalamic anovulation associated with excessive exercise related to low body fat stores. The female athletic triad consists of menstrual disturbance, eating disorder, and osteoporosis.[819] Primary or secondary amenorrhea, oligomenorrhea, or short luteal phase are common in athletes.[820] Ovarian function decreases approximately in proportion to the amount of physical activity and dietary restriction. Weight-bearing exercise only partially protects against the effects of hypoestrogenism on weight-bearing bone. There is concern that amenorrheic athletes may be left with a permanent deficit in bone mass.[821] Weight loss to 10% below ideal body weight and body fat less than 12% are risk factors for amenorrhea. Body mass index does not accurately reflect body fat stores in athletes.[822] Energy balance seems to be more critical than low body fat stores in mediating the anovulation.[820,823] Menarche may occur or menses may resume when the athlete's activity level suddenly decreases and before weight gain occurs. Other factors also contribute to amenorrhea. Nutritional deficiencies may coexist. Chronic undernutrition may suppress thyroid function as in anorexia nervosa.[770] Athletic amenorrhea resembles anorexia nervosa in patients' obsession with weight control.[820,824]

Psychogenic amenorrhea from severe psychic stress has long been known (e.g., "boarding-school amenorrhea").[825] The onset of psychogenic amenorrhea may be identified as being associated with a discrete event, but the ovarian dysfunction tends to be long lasting. Subtle nutritional deficits contribute.[418]

Epilepsy causes menstrual disturbances that seem to result from abnormal neuroendocrine regulation independently of drug treatment.[826]

Pseudocyesis is an extremely rare form of psychogenic amenorrhea that is due to the persistence of the corpus luteum. This syndrome tends to occur in infertile women with an overwhelming desire for pregnancy and conversion hysteria. Prolactin and LH excess appear to mediate this rare syndrome.[827]

Differential Diagnosis. *Disorders outside the neuroendocrine-gonadal axis* may cause or mimic hypothalamic anovulation. These include pregnancy, nutritional disturbance, glucocorticoid excess, disturbed thyroid function, drug abuse, chronic illness, hyperprolactinemia, and ectopic gonadotropin secretion.

Pregnancy must be excluded in all sexually mature adolescents with amenorrhea. An elevation of the serum β-hCG level is the earliest laboratory sign.[828] Placental hCG initially drives constant overproduction of estrogens and progestins by the maternal corpus luteum, then production of estrogen and other sex steroids shifts to the fetoplacental unit and suppresses maternal pituitary gonadotropin release.

Optimal fat mass is necessary for normal gonadotropin levels in sexually mature women, and both *obesity* and *undernutrition* suppress gonadotropins: thus, the gonadotropin response to relative adipose mass seems biphasic.[266] Obesity is associated with blunted LH pulse amplitude that is partially attributable to the increased LH clearance rate. Overproduction of estrogen from plasma precursors in adipose tissue[378] may play a role in suppressing LH pulsatility.[829] The extent to which sleep disruption may contribute to LH suppression is unclear.[830] The effect of undernutrition seems to be mediated by factors related to energy balance, as discussed under "Hypothalamic Anovulation."

Cushing syndrome (glucocorticoid excess) of any etiology causes anovulation by inhibiting the gonadotropin response to GnRH.[816] *Thyroid hormone deficiency* interferes with gonadotropin action on the ovary[831] and may interfere with endometrial function by influences on steroid metabolism[832] and action.[833] *Drug abuse* with tetrahydrocannabinol, ethanol, or opiates causes hypothalamic anovulation.[834,835] Cocaine causes menstrual irregularity by suppressing gonadotropin secretion through mechanisms that include depletion of dopaminergic stores, resulting in hyperprolactinemia, and stimulation of CRH release.[779,836] *Inflammatory illness* acutely disrupts the E2-induced LH surge,[837] and chronic illness causes gonadotropin deficiency, which may be mediated partly by undernutrition and partly by cytokines.[188,754] Disorders as diverse as *diabetes mellitus* and *iron overload* all affect GnRH secretion.[838,839] *Chronic renal failure* causes complex dysfunction of the reproductive system, including poor clearance of

gonadotropins and prolactin in the presence of an inhibition of gonadotropins by a nondialyzable factor.[840]

Hyperprolactinemia occasionally causes secondary amenorrhea without frank hypoestrogenism.[841] This situation probably results from a mild diminution in FSH secretion that only inhibits the emergence of a dominant follicle and, therefore, ovulation.

Post-pill amenorrhea has been a term applied to the amenorrhea that sometimes follows the long-term use of hormonal contraceptives. In the past this was attributed to oversuppression, but oversuppression should not be expected to be the case with the current generation of oral contraceptives.[292] About one third of patients with secondary amenorrhea after discontinuation of estrogen and progestin-containing pills have a history of previous menstrual disturbance and ongoing menstrual problems.[842] Another third can expect spontaneous remission of the amenorrhea. In about half of the remaining cases, the patient's menstrual disturbance will resolve after induced pregnancy. The most common cause of post-pill amenorrhea is probably hyperprolactinemia, because in over 20% of such cases the patients have galactorrhea. How often this antedates ingestion of the contraceptive pill is unknown. Menses may be restored in normoprolactinemic cases by dopaminergic treatment, which suggests that in such cases there is excessive pituitary prolactin secretion that is too subtle to be detected by measurement of serum levels.[843] The anovulation resulting from depot-medroxyprogesterone acetate contraception is related to the extremely slow rate of absorption and metabolism of this steroid; menses returns when the blood levels of this progestin fall below the threshold for suppression of the LH surge,[844] and only rarely has it been associated with disturbed prolactin secretion.[845]

Gonadotropin or hCG secretion by a *tumor* can cause normoestrogenic or hyperestrogenic anovulation.[846,847] In one LH-producing tumor, sex steroid levels were normal; the lack of virilization was attributed to ovarian desensitization to LH,[846] whereas in another case, virilization occurred, which was attributed to preexisting polycystic ovary syndrome-hyperthecosis and extreme LH elevation.[848] Other hyperestrogenic disorders that cause anovulatory bleeding are discussed under "Precocious Puberty."

Hypothalamic anovulation is ordinarily a diagnosis of exclusion. The medical evaluation should be performed as discussed in the preceding section, with particular attention paid to the possibilities of emotional stressors, excessive exercise, the use of birth control pills or other drugs, and state of health. The physical examination should be particularly directed to the state of nutrition, the possibilities of intracranial or systemic disease, galactorrhea, thyroid dysfunction, glucocorticoid excess, hirsutism, and obesity. If this workup is negative, an MRI of the hypothalamic-pituitary area is indicated. Hypothalamic anovulation may be documented by demonstrating subnormal LH pulse frequency, but this is not generally practical. Leptin levels tend to be low but nondiagnostic.[769] The response to a GnRH agonist test is normal but seems to lack the normal priming response to repeat testing.[849] Dysfunctional uterine bleeding from hypothalamic anovulation must be distinguished from that due to other causes (see next section).

Management. Many patients with hypothalamic anovulation will benefit from nutritional counseling. Diet faddists and athletes should be advised about the necessity of optimal body energy reserves for the maintenance of normal menstrual cycles (see Figure 15-40). The teleologic significance of this factor may be pointed out, namely, that inherent in the evolutionary process is the inhibition of pregnancy in times of inadequate food supplies. Ongoing psychological counseling is advisable for patients who cannot change their dietary or exercise patterns because of an abnormal body image. Estrogen replacement only partially corrects osteoporosis unless nutrition is optimized.[795] Obese girls should be advised that there is a substantial possibility that reduction to a normal weight will restore menses and improve the probability of fertility.

Mature teenagers whose amenorrhea is unexplained should be assured that they have a high likelihood of fertility with appropriate endocrinologic treatment. However, such treatment is unlikely to be of any benefit to them until such time as they desire to become pregnant. In the meanwhile, the main objective of therapy is to normalize the endometrial cycle by periodic progestin administration. For this purpose, progestin (micronized progesterone 100 to 200 mg orally at bedtime for 14 consecutive days) usually is effective in inducing withdrawal periods. During the first few years after menarche, it is reasonable to administer this treatment on alternate months to allow detection of late maturation of a regular menstrual cycle.

Induction of an ovulatory cycle has been reported to occasionally result in the resumption of spontaneous normal menses.[842] An ovulatory cycle can normally be induced by the administration of clomiphene citrate once nightly for five doses. If treatment is successful, bleeding generally occurs about 1 month from commencement of the treatment. One should start with the 50-mg dose, because larger doses may cause hyperstimulation of the ovaries with the development of ovarian cysts. For this reason, an ultrasound examination should be performed to rule out cystic ovaries before the patient progresses successively to a 100 to 150 mg dosage. This treatment is not generally recommended in the teenage years, however. Dopaminergic therapy has been reported to be successful in causing the resumption of ovulation in post-pill amenorrhea, modest undernutrition, and other unexplained cases of secondary amenorrhea. Otherwise, induction of ovulation is best left to the endocrinologic gynecologist to supervise at such time as the woman wishes to conceive. The majority of patients with no obvious cause for their secondary amenorrhea will become pregnant after appropriate treatment with estrogen, clomiphene, dopaminergic agonist, human menopausal gonadotropins, or pulsatile GnRH therapy.

Dysfunctional Uterine Bleeding

Causes. Heavy uterine bleeding is usually due to ovulatory dysfunction. It may be abnormally frequent or

intermenstrual ("polymenorrhea"), as indicated by intervals less than 21 days, or excessively prolonged or profuse ("menometrorrhagia"), as indicated by a menstrual flow that lasts more than 7 days or soaks more than one pad or tampon every 1 to 2 hours.[578] Dysfunctional bleeding occurs from an uncycled, hyperplastic endometrium.[685] It is most often a manifestation of physiologic adolescent anovulation. Hyperandrogenism, particularly polycystic ovary syndrome and its variants, is a common cause of dysfunctional bleeding. In some cases it arises from hypothalamic anovulation. Less common are estrogen-producing cysts or tumors, hypothyroidism, hyperprolactinemia, and incipient premature ovarian failure. The workup should, therefore, include measurement of serum androgen, prolactin, thyroid, and gonadotropin levels.

Corpus luteum insufficiency may present as short (less than 21 days) or infertile *ovulatory* cycles. The immediate cause of an inadequate luteal phase is insufficient progesterone production to sustain sufficient endometrial development to support implantation.[850,851] This in turn may arise from subtle deficiency of LH or FSH during the early follicular phase or an inadequate preovulatory LH surge, resultant incomplete emergence of a dominant follicle, and the subsequent formation of an inadequate corpus luteum. Alternatively, the corpus luteum may not be responsive to LH.[852] Luteal insufficiency is common during early post menarcheal cycles[579] and may otherwise be the result of hyperprolactinemia,[853] obesity,[829] hypothalamic amenorrhea, or hyperandrogenism.

Differential Diagnosis. Dysfunctional uterine bleeding must be distinguished from the other causes of abnormal genital bleeding listed in Box 15-6.[685,854] The possibility that it is pregnancy related must be considered and a pregnancy test performed. Sexual abuse is a prime consideration in recurrent vaginal bleeding. Genital tract or feminizing tumors characteristically cause bleeding that cannot be controlled with cyclic progestin or estrogen-progestin therapy. Menstrual bleeding can be considered to be excessive if it is associated with iron deficiency anemia. Often, abnormally heavy menstrual flow in adolescents is idiopathic ("essential menorrhagia"); it is theorized to result from an imbalance of vasodilating and vasoconstricting prostanoid action on the endometrium.[855] However pathologic causes must be considered because bleeding disorders are present in about 20% of adolescents with menorrhagia requiring hospitalization and in 50% of those presenting at menarche. Patients requiring hospitalization for abnormal bleeding should have a platelet count, prothrombin time, partial thromboplastin time, von Willebrand panel, and bleeding time performed. Transvaginal ultrasound, which is not often feasible in the virginal adolescent, is as reliable as hysteroscopy in determining whether or not the endometrial cavity is normal.

Failure of serum progesterone to rise over 500 ng/dL during the luteal phase is diagnostic of corpus luteum insufficiency with 71% accuracy.[851] However, a higher progesterone level than this must be sustained to transform the endometrium sufficiently to support implantation.

BOX 15-6 Differential Diagnosis of Abnormal Genital Bleeding

- Ovulatory dysfunction ("dysfunctional") uterine bleeding
  - Physiologic anovulation (perimenarcheal)
  - Hyperandrogenism
    —Polycystic ovary syndrome
  - Hyperestrogenism
  - Hypothyroidism
  - Hypothalamic anovulation
    —Hyperprolactinemia
  - Chronic disease
  - Incipient premature ovarian failure
  - Luteal phase defects
- Pregnancy-related uterine bleeding
  - Threatened, missed, or incomplete abortion
  - Molar pregnancy
  - Ectopic pregnancy
- Uterine tumor, polyp, adenomyosis
- Coagulopathy
- Endometrial
  - Idiopathic ("essential menorrhagia")
- Iatrogenic
  - Breakthrough bleeding (intrauterine device or contraceptive pills)
- Vaginal bleeding
  - Trauma
  - Tumor
  - Foreign body
  - Infection

Based on Rosenfield, R. L., & Barnes, R. B. (1993). Menstrual disorders in adolescence. Endocrinol Metab Clin North Am, 22, 491.

Management. Nonsteroidal anti-inflammatory agents may lessen the flow. An estrogen-progestin oral contraceptive with 35 μg ethinyl E2 is first-line treatment to stop dysfunctional bleeding that is acute or associated with anemia. For active bleeding, the dosage is advanced rapidly until bleeding stops, up to four times daily, and then sustained for 7 days. Treatment is then stopped for 5 days and the patient warned that heavy withdrawal bleeding with cramps may occur. Therapy with a low-dose pill, given as for contraception, is then initiated to prevent the recurrence of dysfunctional bleeding and is continued for about three cycles. Hemoglobin should be monitored and supplemental iron prescribed.

Cyclic progestin can be used as an alternative to the oral contraceptive pill to prevent recurrent dysfunctional bleeding in a patient who is not sexually active. Micronized progesterone 100 to 200 mg/day for 1 week is given at 3- to 4-week intervals. After the third month, therapy is stopped and the patient is observed for 1 to 2 months for spontaneous bleeding. If none occurs, the progestin can be given every other month in a dosage of 5 to 10 mg for 7 to 14 days to prevent recurrent dysfunctional bleeding. If in the progestin-free month a normal spontaneous menstrual period occurs, progestins are withheld in the subsequent month to determine if the patient has developed regular ovulatory cycles.

Hemodynamic instability is an indication for hospitalization and treatment with intravenous fluids and blood products as necessary. Premarin can be administered in a

dose of 25 mg intravenously every 3 to 4 hours for three to four doses.

When medical management fails, a bleeding diathesis or uterine structural abnormality should be considered. If heavy bleeding persists, a gynecologist should perform uterine curettage.

Unexplained ("essential") menorrhagia is treated much the same way as dysmenorrhea. The oral contraceptive pill will decrease menstrual blood loss by about 50% in these women. Antiprostaglandins, such as naproxen 500 mg twice a day, decrease blood loss nearly as effectively.

Perimenstrual Symptoms

Dysmenorrhea. Uterine cramping is characteristic of normal ovulatory cycles, apparently as the result of prostaglandin release within the endometrium upon the withdrawal of progesterone. Pain with menses becomes a source of morbidity in 14% of adolescents.[856] When pain is acute and qualitatively different from the usual menstrual pain, *ectopic pregnancy* must be considered.[828,857] An ectopic pregnancy often causes vaginal bleeding that occurs 2½ weeks later than the time of the expected next menstrual period and is typically light. However, the bleeding may be heavy and so resemble an episode of dysfunctional uterine bleeding. Ectopic pregnancy is usually diagnosable by a combination of ultrasonography, a serum β-hCG level over 1000 IU/L, and a progesterone level of < 2500 ng/dL.

In patients with chronic pelvic pain unresponsive to antiprostaglandins or the oral contraceptive pill, *psychological overlay* is possible, but attention should be directed to the possibility of *endometriosis*, *uterine outlet obstruction*, *gynecologic tract masses*, or the poorly defined entity of *vulvodynia*.[858] Ultrasonography and laparoscopy may be indicated to further evaluate these patients. Endometriosis is an estrogen-dependent disorder that accounts for approximately half of the cases of chronic pelvic pain in teenagers.[859] Genetic factors and congenital obstruction of the genital tract predispose to endometriosis, and aberrant E2 formation in endometrial stroma has been incriminated in the pathogenesis.[860] GnRH agonist therapy is approved to provide symptomatic relief, but adolescents are at particular risk for bone loss, and progestin therapy may be an effective alternative.

Dysmenorrhea may be ameliorated by antiprostaglandin therapy. Naproxen (275 mg qid after a 550 mg loading dose) has been shown to be superior to aspirin (650 mg qid) or placebo when begun 2 days before the anticipated onset of menses.[861] The oral contraceptive pill is an alternative that will relieve dysmenorrhea in about 90% of cases by reducing endometrial mass.[685] Because smoking, alcohol intake, and excessive weight are risk factors, lifestyle counseling is advisable.

Premenstrual Syndrome. This is the term applied when cyclic mood changes confined to the second half of the menstrual cycle become debilitating.[862] It is often disruptive to women's personal, social, and occupational function. If symptoms of marked mood swings, depressed mood, anxiety, and irritability occur, it is classified as premenstrual dysphoric disorder.[863] Neuropsychiatric symptoms may include epilepsy[864] and bizarre behavior.[865] These seem to represent aberrant responses to normal cyclic hormonal changes.[866] Subnormal activation of the hypothalamic-pituitary-adrenal axis in response to progesterone has been found.[867] Some evidence indicates that variation in the degree of progesterone metabolism to neuroactive steroids affects the severity of symptomatology.[868] Oral contraceptive therapy with the antimineralocorticoid progestin drospirenone is indicated if psychotropic therapy is unsuccessful. Down-regulation of pituitary gonadotropin secretion by GnRH agonist therapy is efficacious, but its usefulness is limited by the side effects of estrogen deficiency.

The relationship of premenstrual syndrome to rare other luteal phase symptomatology, such as recurrent fever and autoimmune symptoms, may be related to the hyperresponsiveness of cytokines to progesterone.[869,870]

Hyperandrogenism in Adolescence

Hyperandrogenism of a mild to moderate degree is the most common cause of normoestrogenic menstrual disturbances. It is usually due to polycystic ovary syndrome, but the differential diagnosis includes other ovarian or adrenal disorders, abnormal peripheral formation of androgen, and drugs (Box 15-7).[871,872]

BOX 15-7 Causes of Adolescent Hyperandrogenism

Functional Gonadal Hyperandrogenism

- Primary functional ovarian hyperandrogenism (common form of polycystic ovary syndrome)
- Secondary polycystic ovary syndrome
  - Virilizing congenital adrenal hyperplasia
  - Ovarian steroidogenic blocks
  - Syndromes of severe insulin resistance
  - Acromegaly
  - Portohepatic shunting
  - Epilepsy ± valproic acid therapy
  - Disorders of sex development
  - Chorionic gonadotropin excess

Functional Adrenal Hyperandrogenism

- Primary functional adrenal hyperandrogenism (uncommon form of polycystic ovary syndrome)
- Congenital adrenal hyperplasia and related adrenal steroid metabolism disorders
- Prolactin excess
- Dexamethasone-resistant functional adrenal hyperandrogenism
  - Cushing syndrome
  - Glucocorticoid resistance

Peripheral Androgen Overproduction

- Idiopathic hyperandrogenism
- Obesity

Tumoral Hyperandrogenism

Androgenic Drugs

Modified with permission from Buggs, C., & Rosenfield, R. L. (2005). Polycystic ovary syndrome in adolescence. Endocrinol Metab Clin North Am, 34, 677–705.

Causes

Polycystic Ovary Syndrome. Polycystic ovary syndrome (PCOS) is the most common cause of hyperandrogenism presenting at or after the onset of puberty. Ever since its description by Stein and Leventhal as a syndrome of amenorrhea and polycystic ovaries, with hirsutism (57%) or acne (14%) and/or obesity (57%),[873] the definition of PCOS has evolved.[874,875] Most recently, three international conferences developed somewhat different, but overlapping, diagnostic criteria for adult women: National Institutes of Health conference criteria (1992),[876] Rotterdam consensus criteria (2004),[877] and Androgen Excess-PCOS Society consensus criteria (AES, 2006).[878]

Rotterdam criteria are the broadest and include features of all the others, namely all combinations of otherwise unexplained hyperandrogenism, anovulation, and a polycystic ovary. This generates four phenotypes, which are here listed in order of decreasing specificity (Box 15-8).[879] Insulin resistance, obesity, and LH excess, though not diagnostic features of the syndrome, are common and contribute to its pathogenesis; like hyperandrogenism, their severity has generally proven to correlate with specificity.[880,881] Phenotypes 1 to 3 have hyperandrogenic ovarian dysfunction of successively lesser degree. Phenotype 3, which allows diagnosis in the presence of cutaneous or metabolic symptoms in the absence of anovulatory symptoms ("ovulatory PCOS"), is controversial because it permits a PCOS diagnosis in apparently normal females with a polycystic ovary and subclinical hyperandrogenemia.[534] Phenotype 4, which lacks hyperandrogenemia, is the most controversial[878]; the extent to which it is due to undetected ovarian hyperandrogenism is unclear.[880,881] Furthermore, it is too nonspecific for application to adolescents.

Criteria for PCOS diagnosis have been additionally controversial in adolescents because menstrual cycles, hyperandrogenic features, polycystic ovary morphology, and insulin resistance have special characteristics during this developmental stage that have led to the following questions.[579] How can one be certain that adolescent hyperandrogenemia is not a normal phase of pubertal development (i.e., the consequence of prolonged anovulatory cycles) rather than PCOS? Is the correlation between adolescent and adult androgen levels and menstrual patterns sufficiently high that adolescent hyperandrogenic anovulation accurately predicts adult PCOS? Is the polycystic ovary, as currently defined in adults, normal during adolescence?

Endocrine Society guidelines recently suggested that the diagnosis in adolescents be confined to those who have persistent hyperandrogenic oligomenorrhea (Box 15-8).[882] Persistence of symptoms for two years has been suggested by reproductive endocrinology consensus to avoid overdiagnosis.[883]

However, the actuarial risk of 1 year of persistent menstrual abnormality persisting is substantial, and the combination of PCOS risk factors and an abnormal menstrual pattern may facilitate the documentation of hyperandrogenemia and permit PCOS diagnosis by NIH criteria within 1 year of the last menstrual period. Waiting ≥ 2 years to diagnose and treat PCOS may unnecessarily delay treatment and recognition of comorbidities and increase the possibility of lost follow-up.[579] The syndrome in adolescents resembles that in adults, with similar clinical and endocrinologic heterogeneity. The cardinal symptoms typically begin in the perimenarcheal stage, and PCOS has been documented in children as young as 10 years of age.

Clinical Manifestations (Figure 15-44). Cutaneous signs of hyperandrogenism are variably expressed. They are present in about two thirds of cases. Hirsutism is the most common manifestation, but the hirsutism equivalents, seborrhea, acne vulgaris, or androgenetic alopecia, sometimes occur instead. On the other hand, hyperandrogenemia may be entirely cryptic, manifesting neither cutaneous signs nor anovulatory symptoms.

Menstrual irregularity indicative of anovulation is present in approximately two-thirds of cases with the PCOS type of ovarian dysfunction.[141] The distinction between PCOS and physiologic anovulation is often delayed in adolescents because patients, families, and physicians alike often are unsure about the normal range of menstrual cycle variation. Abnormal degrees of adolescent menstrual irregularity are discussed in the "Physiologic Adolescent Anovulation" section. PCOS is a state of relative, not absolute, infertility in which oligo-amenorrheic patients typically ovulate unpredictable. Menstrual regularity does not exclude the presence of ovulatory dysfunction. On the other hand, many eumenorrheic cases have virtually normal ovulatory cycles ("ovulatory PCOS") or have a subtle

Hyperandrogenic Rotterdam Criteria Phenotypes** (2004)

1. Phenotype 1 (Classic)
   - Clinical or biochemical evidence of hyperandrogenism
   - Evidence of oligo-anovulation
   - Ultrasonographic evidence of a polycystic ovary
2. Phenotype 2 (National Institutes of Health Criteria, 1992)
   - Clinical and/or biochemical evidence of hyperandrogenism
   - Evidence of oligo-anovulation
3. Phenotype 3 ("Ovulatory PCOS")
   - Clinical and/or biochemical evidence of hyperandrogenism
   - Ultrasonographic evidence of a polycystic ovary

Nonhyperandrogenic "Rotterdam criteria" Phenotype (2004)

4. Phenotype 4 (Nonhyperandrogenic PCOS)
   - Evidence of oligo-anovulation
   - Ultrasonographic evidence of a polycystic ovary

Adolescent Criteria

The Endocrine Society Clinical Practice Guideline (2013)

- Clinical or biochemical evidence of hyperandrogenism
- Persistent oligomenorrhea

*All criteria involve exclusion of other causes of hyperandrogenism and anovulation.
**AES-endorsed criteria

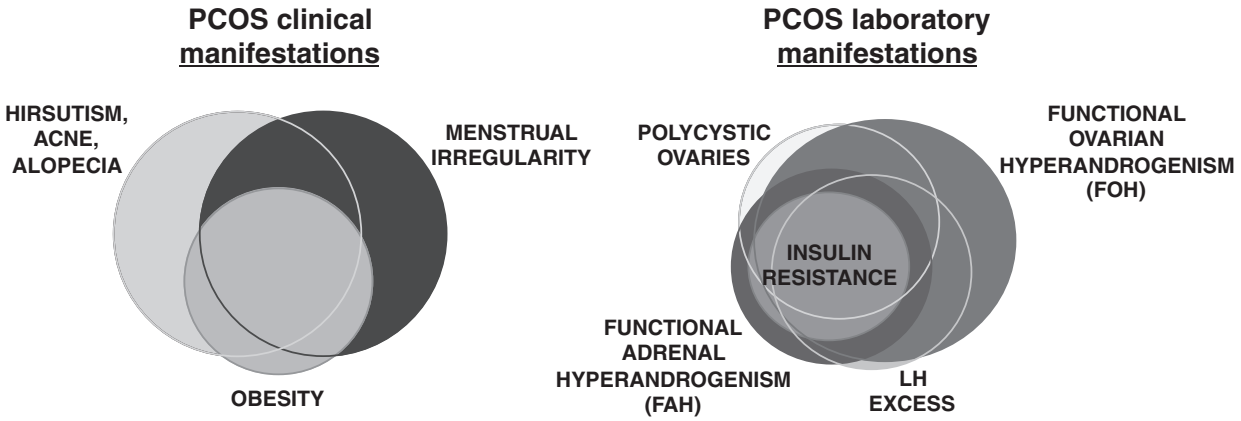

FIGURE 15-44 ■ The major clinical and laboratory manifestations of polycystic ovary syndrome (PCOS) are shown in approximate proportion to their relative incidence and coincidence. (Modified with permission from Buggs, C., & Rosenfield, R. L. (2005). Polycystic ovary syndrome in adolescence. *Endocrinol Metab Clin North Am, 34,* 677–705.)

ovulatory abnormality that escapes notice until presentation in adulthood with unexplained infertility[884] or recurrent miscarriages.[885]

Obesity, present in approximately half of patients with PCOS, often is the initial complaint. PCOS is the single most common endocrine obesity syndrome in females. The obesity occasionally begins in mid-childhood. Even normal-weight young women with PCOS are reported to have a body fat content that is 50% greater than normal.[886] The concept that central obesity or visceral fat is more fundamentally related than global adiposity to the insulin resistance of PCOS has been challenged.[887] Acanthosis nigricans, a manifestation of insulin resistance, may be the presenting complaint of patients with PCOS.

Laboratory Manifestations (see Figure 15-44). Hyperandrogenism may be defined on the basis of cutaneous signs (see Box 15-8) but is best established biochemically if a reliable testosterone assay is available because hirsutism, particularly mild hirsutism, is an unreliable surrogate for hyperandrogenemia. The problematic nature of many androgen assays is discussed in the "Differential Diagnosis" section.

Functional ovarian hyperandrogenism (FOH) can be documented in 85% of PCOS cases by specific tests of ovarian androgenic function.[141,888] The GnRH agonist test and hCG tests evaluate the gonadal response to, respectively, endogenous gonadotropin release or exogenous administration of the LH analog hCG. In two thirds of PCOS patients these tests show a distinctive pattern of ovarian steroidogenic hyperresponsiveness in which 17-hydroxyprogesterone (17OHP) responses are increased compared to normal women without PCOS; there is no evidence of a steroidogenic block, and, indeed, E2 is significantly hyperresponsive. The dexamethasone androgen-suppression test (DAST) is predicated on the principle that residual concentrations of androgens after suppression of adrenal function by glucocorticoid administration ordinarily arise from the ovary. It shows elevated testosterone postdexamethasone in 80% of PCOS patients. Both ovarian function tests are normal in 15% of PCOS patients: the androgen excess of this "nonovarian" PCOS appears to be secondary to isolated functional adrenal hyperandrogenism (FAH) in about one third of cases or to obesity in about two thirds of cases.

A polycystic ovary is found in about two thirds of adolescents with PCOS, which is slightly less frequently than in adult PCOS.[534] An adult polycystic ovary is defined as one with ≥12 small antral follicles (2-9 mm) or >10 cc in volume (in the absence of a follicle >10mm);[877] these follicle number criteria are likely to change with improved ultrasound technology since recent studies indicate that these parameters fall during the adult reproductive years and about half of normal young adults have a polycystic ovary by follicle count criteria.[579] The normal adolescent ovary often exceeds these adult criteria [73,116-119] (see the section of this chapter Maturation of the Neuroendocrine-Ovarian Axis, Adolescent).

A polycystic ovary occurs in 10% of regularly menstruating schoolgirls,[73,117] and up to half of adolescent research volunteers.[116,119,534] Polycystic ovary morphology is not highly stable during adolescence: it develops transiently in about one third of adolescents, yet it may not develop until 2 or more years after menarche.[116,121]

Polycystic ovaries are functionally heterogeneous.[534] Most asymptomatic young women with a polycystic ovary have normal serum androgen concentrations. Such women typically ovulate normally and seldom develop PCOS. Serum levels of anti-Müllerian hormone (AMH) are mildly, but significantly, increased in such females.[889] This seems to indicate an enlarged follicle pool ("increased ovarian reserve") and prognosticate a lengthened reproductive life span.[889]

On the other hand, many asymptomatic volunteers with a polycystic ovary have subclinical abnormalities of ovarian androgenic function. This group is itself heterogeneous. Some of them have baseline hyperandrogenemia and thus meet Rotterdam/AES criteria for PCOS. Those without baseline hyperandrogenemia have been postulated to be carriers for PCOS.[534,890] These considerations call into question the clinical significance of making a diagnosis of PCOS by polycystic ovary criteria in the absence of hyperandrogenic symptoms.

AMH levels are independently associated with polycystic ovaries and hyperandrogenism.[889] Thus, although a mildly increased AMH level is common in asymptomatic females with a polycystic ovary, AMH elevation of twofold or more suggests PCOS with high specificity. AMH elevation occurs in PCOS because of an increased number of small growing follicles. The underlying altered granulosa cell function of PCOS seems likely to result from excessive androgen production by intrinsically defective theca cells,[891] although it may in part be intrinsic.[889]

The increased LH of PCOS was initially considered the cause of the androgen excess and was long considered diagnostic.[892] However, accumulating evidence suggests that LH levels in PCOS are determined by the severity of hyperandrogenemia, moderate degrees of which stimulate LH production, and the extent of obesity, which suppresses LH levels.[266]

Insulin resistance has been estimated from homeostatic model assessment data to occur in 50% to 75% of adults with PCOS.[893] It is excessive for the degree of adiposity. About half of obese adolescents with PCOS have greater insulin resistance than do age-, stage- and BMI-matched adolescents according to the euglycemic clamp method.[894] Adolescents with PCOS are also at increased risk for glucose intolerance,[895,896] consistent with an independent relationship of PCOS to pancreatic beta-cell dysfunction.

Metabolic syndrome results from the interaction of insulin resistance with obesity and age. It is a cluster of critical levels of abdominal obesity, blood pressure, serum triglycerides, HDL cholesterol, and glucose. It is found in approximately 25% of adolescents with PCOS, which is two- threefold the prevalence expected for BMI of matched populations.[897] It poses a twofold increased risk for sleep-disordered breathing in adolescence, as well as long-tem risks for diabetes and cardiovascular disease.[898]

Pathogenesis. Excessive LH secretion, found in 50% to 75% of cases, was once thought to be central to the pathogenesis of PCOS. Although PCOS is gonadotropin dependent, gonadotropins being necessary for the expression of gonadal steroidogenic enzymes, LH excess does not seem to ordinarily be the fundamental cause of the hyperandrogenism. The variable LH excess seems to depend on obesity-androgen balance.[266] When LH is elevated, homologous desensitization normally limits the androgenic response to it: thus, LH excess alone seems unlikely to cause the hyperandrogenism of PCOS, although it may aggravate it in PCOS, where intrinsic ovarian dysfunction causes "escape" from desensitization. Evidence is accumulating that LH excess results from hyperandrogenemia interfering with the progesterone negative feedback effect on LH secretion. Nevertheless, the possibility of a primary role for LH excess remains, particularly in the PCOS that is secondary to congenital virilizing disorders.

PCOS ordinarily seems to be due to intraovarian androgen excess (Figure 15-45). The disproportionately high intraovarian androgen concentration arising from FOH seems to cause polycystic ovaries by recruiting excessive growth of small follicles while hindering the emergence of a dominant follicle, as well as causing thecal and stromal hyperplasia. The hyperandrogenemia results in the pilosebaceous manifestations.

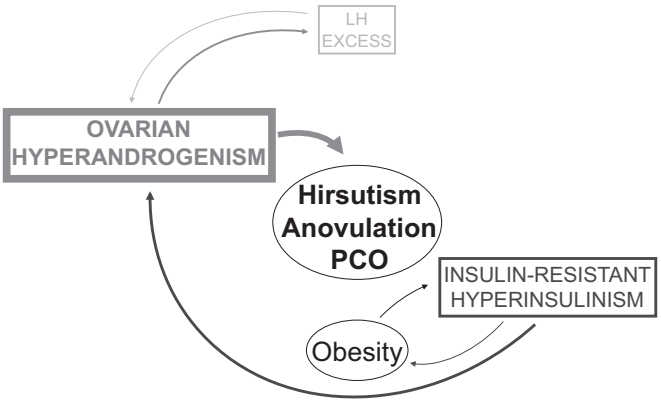

FIGURE 15-45 ■ A model for the pathogenesis of PCOS. Ovarian hyperandrogenism is nearly universal and causes the cardinal clinical features of the syndrome, including the polycystic ovary (PCO). About half of patients have insulin-resistant hyperinsulinism, which aggravates ovarian hyperandrogenism and contributes to adiposity. Androgen excess may also cause LH excess, which aggravates ovarian hyperandrogenism in the presence of hyperinsulinism. Obesity increases insulin-resistance, and the resultant increased hyperinsulinism further aggravates hyperandrogenism. The cause of the ovarian hyperandrogenism and insulin resistance is usually intrinsic and may have common genetic or environmental determinants. This model does not exclude the possibility that the unknown intrinsic ovarian defects that underpin the ovarian steroidogenic dysfunction involve granulosa cell folliculogenesis as well, and it does not depict other associated defects, such as the adrenal hyperandrogenism that parallels the ovarian hyperandrogenism. Excess adipose tissue can produce excess androgen as well as estrogen. However, as with most other extrinsic causes of androgen excess, the hyperandrogenemia of simple obesity is mild and polycystic ovaries unusual. In contrast to PCOS, the anovulation of simple obesity is the consequence of suppression, rather than augmentation, of LH pulse amplitude.

The FOH of PCOS, in turn, seems to arise from a unique ("primary") dysregulation of steroidogenesis that is ordinarily due to intrinsic theca cell dysfunction.[141,299,300] The dysregulation is thought to result from imbalance among the various intrinsic and extrinsic factors involved in the modulation of trophic hormone action. Within the ovary, there appear to be flaws in the processes that normally coordinate androgen and estrogen secretion (see Figure 15-20). The intrinsic theca cell defect causes constitutive overexpression of most steroidogenic enzymes, most prominently at the level of 17-hydroxylase and 17,20-lyase activites, both properties of P450c17, which are the rate-limiting steps in the biosynthesis of testosterone precursors. As in the ovary, dysregulation of local steroidogenic regulatory processes within the adrenal cortex appears to cause a characteristic type of primary FAH in which excessive dehydroepiandrosterone is formed as a by-product of cortisol secretion.

As a consequence of dysregulated steroidogenesis, PCOS theca cells do not undergo the normal down-regulation of steroidogenesis in response to excess LH stimulation, and so are hypersensitive to LH stimulation. "Escape" from desensitization to LH excess appears to be

the basis for the distinctive pattern of steroidogenic hyperresponse to GnRH agonist or hCG testing, which is characterized by disproportionate hyperresponsiveness of 17-hydroxyprogesterone relative to other ovarian steroids without evidence of a steroidogenic block.

Granulosa cell functions are also defective in PCOS. Folliculogenesis of small follicles is excessive, which contributes to the tendency of PCOS women to develop the dangerous ovarian hyperstimulation syndrome during fertility treatment. Inhibin-B hyperresponsiveness to FSH also appears to aggravate thecal androgen secretion via a paracrine action.[899]

Insulin-resistant hyperinsulinism appears to be an important extrinsic factor in dysregulation. Insulin resistance results in compensatory hyperinsulinemia. Insulin, like IGFs, synergizes with trophic hormones to cause ovarian or adrenal androgen excess. The ovaries and adrenal glands function as if responding to the hyperinsulinemic state in spite of the resistance to the effects of insulin on skeletal glucose metabolism. This paradox seems to result from differential insulin sensitivity of insulin target tissues, some of which appear to be result from intrinsic signaling defects and others from the endocrine environment.[900,901] Notably, a common transcription factor, KLF15, mediates insulin stimulation of both adipogenesis and testosterone formation.[902] This has led to the proposal that increased KLF15 expression in response to the compensatory hyperinsulinemia of insulin resistance may mediate the obesity of PCOS, while aggravating hyperandrogenism. These observations suggest that PCOS commonly results from intrinsic ovarian dysfunction that seems to be but one manifestation of a generalized disorder in which there is dysregulation of transcription factors common to the function of a wide variety of tissues.

Etiology. Increasing evidence suggests that PCOS arises as a complex trait with contributions from both heritable and nonheritable factors.[15] Twin studies indicate that genetic factors explain about 70% of the variance in pathogenesis. Hyperandrogenemia and polycystic ovaries each appear to be inherited as an independent autosomal dominant trait. Nearly half of sisters of women with PCOS have an elevated serum testosterone level, although only half of them are symptomatic. Seventy percent of sisters of PCOS probands, diagnosed by either NIH (80%) or Rotterdam criteria, had a polycystic ovary; 25% of these met NIH criteria and 42% met other Rotterdam criteria for PCOS.[903] Central obesity and insulin resistance not only seem to play important roles in PCOS by accentuating steroidogenic dysregulation, but polycystic ovaries in PCOS probands that were unrelated to a maternal polycystic ovary were reported to be associated with paternal metabolic syndrome. Gestational factors have also been incriminated: the syndrome has been associated with both high and low birthweight, and it can develop secondary to fetal virilization. Thus, the syndrome seems to become manifest when an intrinsic genetic trait interacts at puberty with other congenital or environmental factors, excessive adiposity being a common precipitant.

Other Causes of Functional Ovarian Hyperandrogenism. Secondary PCOS can result from several disorders (see Box 15-7).[904] Virilizing congenital adrenal hyperplasia frequently causes ovarian hyperandrogenism. Three mechanisms are involved.[905] For one, poor control of adrenal hyperandrogenism causes polycystic ovaries and amenorrhea by direct effects on the ovary. Adrenal rests of the ovaries may cause polycystic ovaries and hyperandrogenism. Finally, patients with CAH, particularly those with classic CAH, are at high risk for the emergence of PCOS at puberty due to developmental programming (see "Disorders of Sex Development," presented earlier).

Steroidogenic blocks in ovarian steroid synthetic pathways, such as caused by 3β-HSD[906] or aromatase deficiency,[907] can cause hyperandrogenism in association with grossly polycystic ovaries and elevated LH levels. Ovarian 17-ketosteroid reductase deficiency has been reported to be responsible for a PCOS-like picture in two families, but there has been no molecular confirmation of an underlying mutation.[908]

All known forms of extreme insulin resistance, including hereditary cases of insulin receptor mutations and acquired lipodystrophy, are accompanied by PCOS, possibly by acting through the IGF-1 signal transduction pathway to cause escape from desensitization to LH. Acromegaly itself is associated with PCOS. PCOS has also been reported as a complication of portasystemic shunting; impaired steroid metabolism has been postulated as the mechanism. The antiepileptic drug valproic acid causes hyperandrogenism and polycystic ovaries, and an association of epilepsy itself with PCOS is possible.[383,826] Functional ovarian hyperandrogenism may also result from an ovotesticular disorder of sex development.

Excessive hCG stimulation mediates the hyperandrogenism of hyperreactio luteinalis and luteoma of pregnancy,[909] and excessive LH appeared to mediate hilus cell hyperplasia in a case of FSH-resistant ovarian follicles.[910] An extremely high level of hCG due to tumor has been reported to virilize a nonpregnant woman with preexisting PCOS.[848]

Other Causes of Functional Adrenal Hyperandrogenism. The PCOS type of primary FAH that appears to arise from dysregulation of adrenal steroidogenesis occurs as an isolated entity, not associated with FOH, in 15% to 25% of hyperandrogenic women.[888] This may sometimes be an outcome of premature adrenarche. This type of adrenal dysfunction was previously mistaken for nonclassical 3β-hydroxysteroid dehydrogenase deficiency, which is now known to be a rare disorder.[911] Less than 10% of adrenal hyperandrogenism can be attributed to the more well-understood disorders listed in Box 15-7. The most common of these are nonclassic congenital adrenal hyperplasia, which accounts for under 5% of hyperandrogenism in the general U.S. population, and the more rare various hyperandrogenic forms of Cushing syndrome. Prolactin excess causes adrenal hyperandrogenism, sometimes in association with polycystic ovaries. Adrenal hyperandrogenism can on rare occasions arise from other rare congenital disorders of adrenal steroid action or metabolism, such as glucocorticoid resistance, apparent cortisone reductase deficiency, and apparent sulfotransferase deficiency.[326,912,913]

Peripheral Androgen Overproduction. In about 10% of hyperandrogenemic patients, an ovarian or adrenal source cannot be ascertained by thorough testing. This is discovered in two settings. When hirsutism is not accompanied by evidence of ovarian dysfunction, it is termed *idiopathic hyperandrogenism* (as distinct from *idiopathic hirsutism*, discussed later).[383] Quirks in steroid peripheral metabolism have been suspected to be the cause. When the source of androgen cannot be located in subjects with hyperandrogenic anovulation, it has been termed functionally atypical PCOS.[888] Obesity may explain such cases, because adipose tissue has the capacity to both cause anovulation and to form testosterone from androstenedione.

Tumoral Hyperandrogenism. Virilizing tumors are rare, accounting for about 0.2% of hyperandrogenism; about half are malignant.[383] About half are ovarian, half adrenal. Masculinizing sex cord-stromal tumors of the ovary are unusual before the teenage years. Leydig-Sertoli cell tumor (androblastoma, arrhenoblastoma) is the most common type. Virilizing granulosa-theca cell tumor (thecoma) is unusual before menopause.[848,914] Dysgerminomas virilize only if they have interstitial cell elements. Lipid cell tumors tend to respond to ACTH as well as LH and produce 17-hydroxyprogesterone; thus, they must be considered in the differential diagnosis of late-onset congenital adrenal hyperplasia.[915] The abnormal differentiation that underlies tumor formation typically leads to an abnormal pattern of steroid secretion with androstenedione predominating over testosterone secretion.[916] However, some thecomas have been reported to predominantly secrete testosterone.[917,918] Gonadoblastomas are virilizing tumors virtually confined to individuals with dysgenetic gonads with Y-chromosomal material in their genome. Some masculinizing ovarian sex cord-stromal tumors may be caused by activating mutations of stimulatory G proteins.[919] Leydig cell and adrenal rest tumors of the ovary are extremely rare causes of masculinization in childhood.[20,358,920] Adrenal virilizing tumors are rare in adolescence; their peak incidence is in early childhood and adulthood[637] (see the "Incomplete Precocity" section).

Androgenic Drugs. Drug-induced masculinization in adolescence is encountered most often in athletes. The medical history is important in detection, as standard clinical laboratory tests for androgens are not helpful in the detection of either natural or artificial androgens.[921] This is also the case for masculinization that results from unintended contact with topical androgens used by a parent or by a sexual partner.[643] Valproic acid use in epileptics raises testosterone levels and may mimic PCOS.[383]

Differential Diagnosis.

Hyperandrogenism should be considered in any girl who presents with hirsutism or cutaneous hirsutism equivalents, menstrual disturbance, or central obesity during puberty.

Hirsutism and hirsutism equivalents are variably expressed manifestations of excess androgens that are present in approximately two thirds of hyperandrogenic females. Hirsutism may be absent in young adolescents whose hyperandrogenism has not evolved fully.

Hirsutism is defined clinically as excessive sexual hair that appears in a male pattern.[383] It is commonly graded according to the hormonal Ferriman-Gallwey system, which quantitates the extent of hair growth in the most androgen-sensitive areas (Figure 15-46). Focal hirsutism (score < 8) is a common normal variant, whereas generalized hirsutism (score of 8 or more) is abnormal in the general U.S. population. The normal score is lower in Asian populations and higher in Mediterranean populations.[922]

Hirsutism must be distinguished from hypertrichosis, the generalized excess growth of vellus hair that sometimes occurs on a hereditary basis or in patients taking glucocorticoids, phenytoins, diazoxide, or cyclosporine. Hypertrichosis is distributed in a nonsexual pattern (e.g., generalized distribution or more prominent distribution on the forehead or shoulders) and is not caused by excess androgen, although it may be aggravated by excess androgen.

The absence of hirsutism in approximately one third of hyperandrogenic adults appears to be because of relatively low sensitivity of their pilosebaceous unit to androgens. Conversely, hirsutism without elevated circulating levels of androgen—"idiopathic hirsutism"—accounts for approximately half of mild hirsutism and one sixth of moderate-severe hirsutism.

Acne vulgaris, androgenetic (pattern) alopecia, seborrhea, hyperhidrosis, and hidradenitis suppurativa are cutaneous hirsutism equivalents. Hyperandrogenism should be considered in adolescent females who have inflammatory acne that is unusual in severity (≥ moderate) or poorly responsive to topical dermatologic therapy.[583] Balding may be either male pattern (affecting the fronto-temporo-occipital scalp) or pattern (affecting the crown, typically manifest early as a midline part widened in a "Christmas tree" pattern).

Symptomatic menstrual abnormality (primary or secondary amenorrhea, oligo-amenorrhea, or dysfunctional uterine bleeding) in a normally feminized girl is reason to consider hyperandrogenism. Failure to establish normal adult menstrual cyclicity by 2 years after menarche is a strong indication for investigation even in the absence of hirsutism or obesity (see the "Physiologic Adolescent Anovulation" section, presented earlier).

Intractable obesity, high waist circumference (> 88 cm), or acanthosis nigricans should raise concern for PCOS. The possibility of PCOS is heightened if the preceding symptoms are associated with a history of prepubertal risk factors for PCOS: congenital virilizing disorders; premature adrenarche; intractable prepubertal obesity, particularly if associated with pseudo-Cushing syndrome or pseudo-acromegaly; or a family history of PCOS or metabolic syndrome.

Diagnostic Approach

The goals of the laboratory evaluation for hyperandrogenism are to attempt to obtain evidence of hyperandrogenism and anovulation, to determine the specific etiology, and to provide a baseline in case it becomes necessary to reassess because of progression of the disorder. The diagnosis of hyperandrogenism is on the firmest

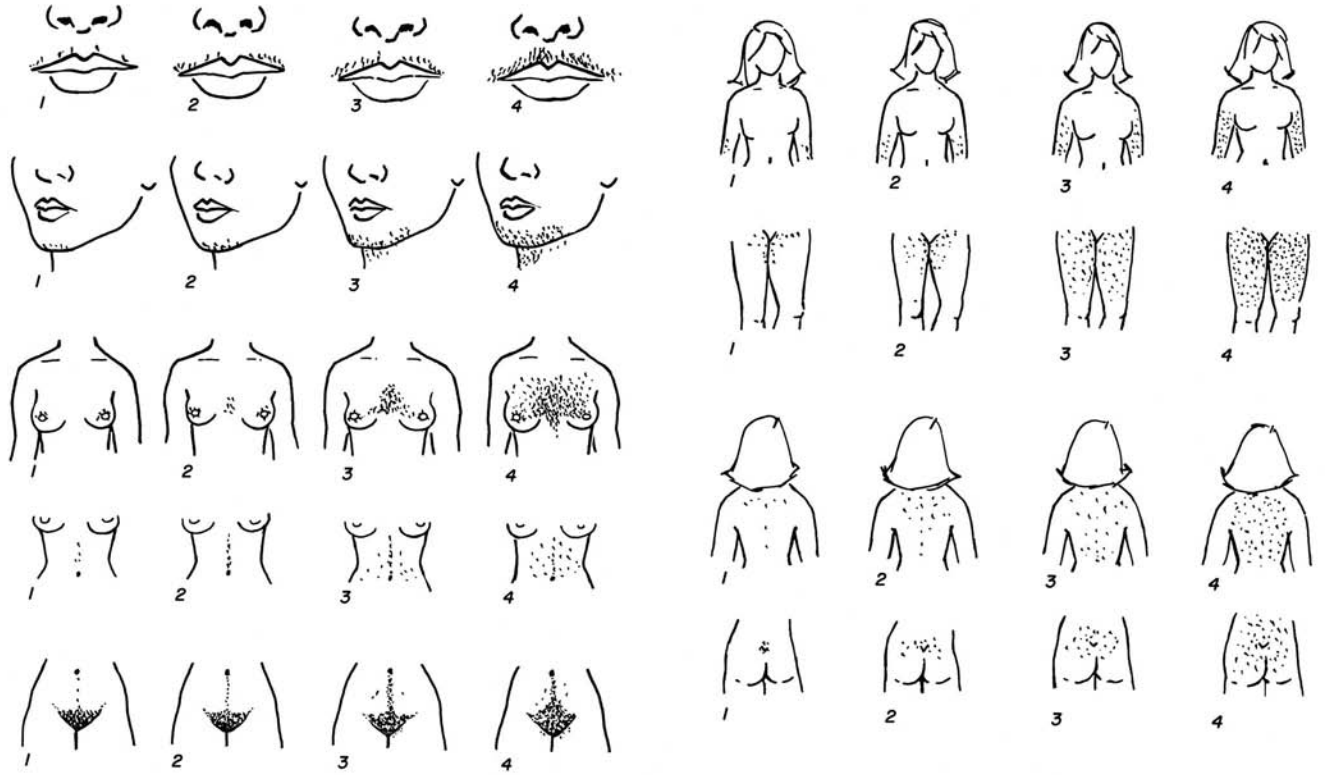

FIGURE 15-46 ■ Ferriman-Gallwey hirsutism scoring system. Each of the nine body areas most sensitive to androgen is assigned a score from 0 (no hair) to 4 (frankly virile), and these are summed to provide a hormonal hirsutism score. (Copyright © 2008, The Endocrine Society. Reproduced with permission from Martin, K. A., Chang, R. J., Ehrmann, D. A., et al. (2008). Evaluation and treatment of hirsutism in premenopausal women: an Endocrine Society Clinical Practice Guideline. *J Clin Endocrin Metab, 93*, 1105–1120.)

grounds if hyperandrogenemia is demonstrated biochemically, rather than relying on hirsutism as a clinical surrogate for it, although documentation of hyperandrogenemia can be problematic. Menstrual abnormality of most sorts provides evidence of anovulation.

Most hyperandrogenic girls present when fully feminized. In girls with menstrual irregularity who lack cutaneous manifestations of hyperandrogenism, the evaluation should address the possibility of hypoestrogenism by including bone age, E2, and gonadotropin levels, as outlined earlier (see Figure 15-43).

An approach to the workup that depends on assessing the degree of hirsutism, identifying anovulatory symptoms, and elucidating risk factors for virilizing disorders, androgenic medications, and other endocrinopathies (see Box 15-7) is suggested (Figure 15-47).[383] A rapid pace of development or progression of hirsutism, evidence of virilization (such as clitoromegaly, genital ambiguity, or increasing muscularity), or an abdominal mass raise concern for an androgen-secreting neoplasm. However, tumors producing moderately excessive androgen can have indolent presentations. Inspection of the external genitalia is indicated, but an internal pelvic examination seldom is necessary.[782] If hirsutism is sufficiently mild or focal that it can be managed by dermatologic means and menses is regular with no evidence of risk factors that would suggest an underlying cause, it is reasonable *not* to pursue laboratory evaluation, given the high likelihood of idiopathic hirsutism (a cutaneous rather than an endocrine disorder), unless the patient is of Asian ethnicity. If hirsutism is sufficiently symptomatic that hormonal therapy is contemplated[922] or there are features to suggest an underlying disorder, excess androgen production should be ruled out. Risk factor assessment includes follow-up to evaluate response to therapy.

Serum testosterone is the single most important androgen to evaluate (see Figure 15-47). Serum free testosterone is about 50% more sensitive in detecting excessive androgen production because hyperandrogenic women have a relatively low level of SHBG. There are many pitfalls in testosterone assays at the low levels found in women and children, and reliable testosterone assays are not available to many physicians. Assays of high sensitivity and specificity, such as those provided by postchromatographic radioimmunoassay or tandem mass spectrometry, are required; furthermore, they are best performed by a specialty laboratory that has extensively validated them. Assaying the free testosterone level introduces other potential sources of error. Direct assays of the free testosterone concentration are inaccurate and should be avoided. The best methods calculate free testosterone as the product of the total testosterone and a function of SHBG: free testosterone = total testosterone × percentage of free testosterone, where the percentage of free testosterone is most commonly determined by dialysis or calculated from the SHBG concentration. The combination of a

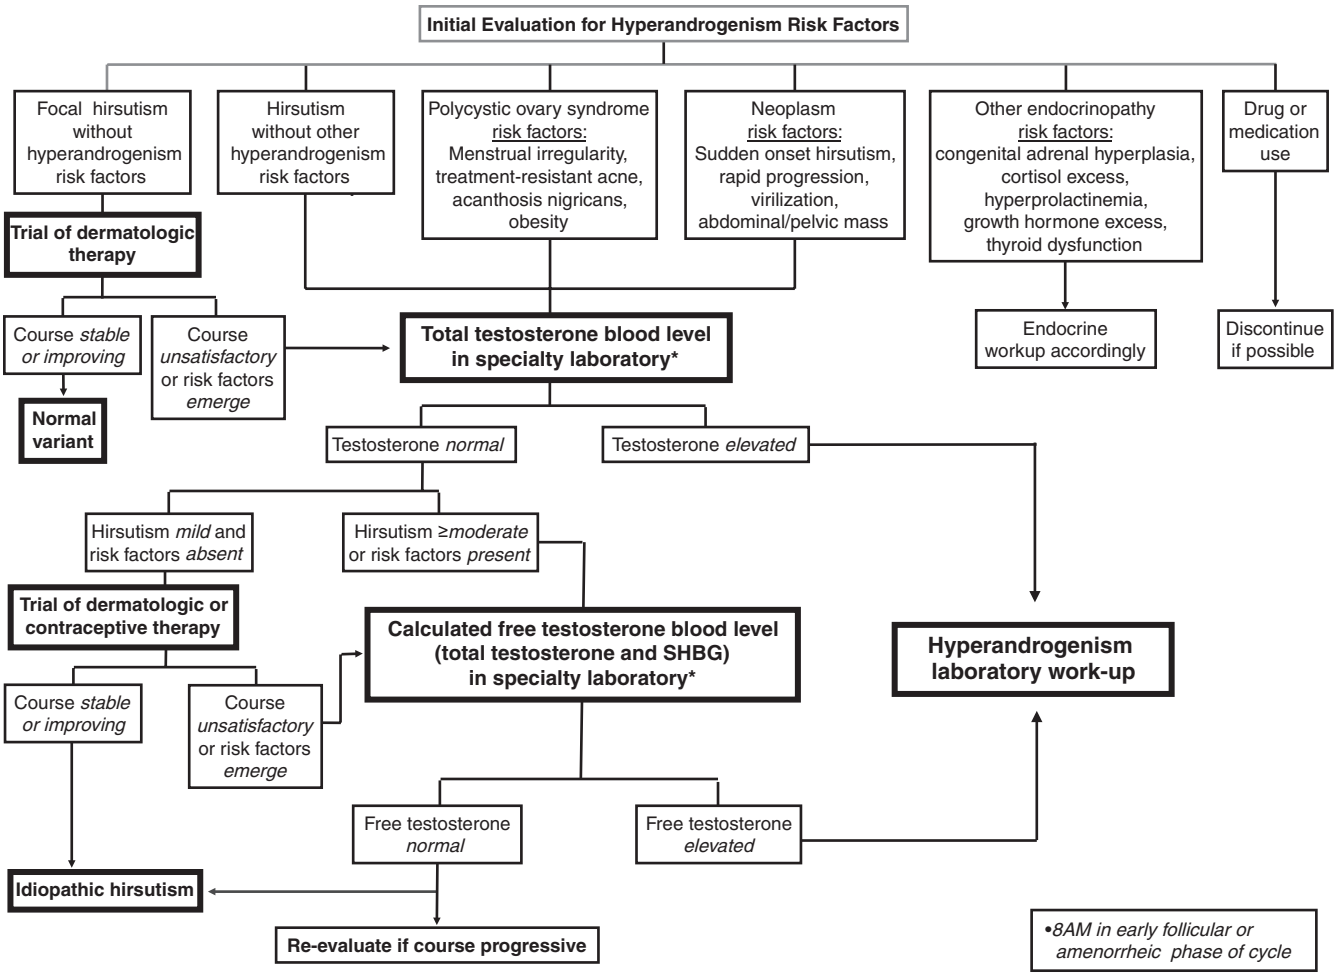

FIGURE 15-47 ■ Initial evaluation of women for hyperandrogenism. Risk assessment includes more than the degree of hirsutism. Drugs that cause hirsutism include anabolic or androgenic steroids (which should be considered in athletes and patients with sexual dysfunction) and valproic acid (which should be considered for neurologic disorders). Localized areas of hair growth that do not meet the criteria for hirsutism ("focal hirsutism") and are not accompanied by other risk factors for hyperandrogenism do not require an endocrine workup if hormonal treatment is not contemplated. In women with symptomatic hirsutism who will have hormonal treatment, androgen levels should be assessed. PCOS is the most common cause to be considered, but androgen-secreting tumors, congenital adrenal hyperplasia, and diverse androgenic disorders, as shown, should be excluded. Serum testosterone is best assessed in the early morning, on days 4 to 10 of the menstrual cycle in eumenorrheic women and on random days in amenorrheic women. Females with mild hirsutism (a score of 8 to 15), normal total testosterone level, and no risk factors probably have idiopathic hirsutism, which may be responsive to oral contraceptive therapy. Serum free testosterone should be measured (which involves measuring total testosterone and either SHBG or the percentage of free testosterone by dialysis) in a specialty reference laboratory if the serum total testosterone is normal in the presence of risk factors or progression of hirsutism on therapy. A simultaneous assay of 17-hydroxyprogesterone may be indicated in subjects at high risk for congenital adrenal hyperplasia. Some women diagnosed with idiopathic hirsutism by this algorithm will have polycystic ovaries on ultrasound, but the significance is unclear in the absence of ovulatory dysfunction. Progression of hyperandrogenism in the presence of a normal serum free testosterone is very unusual; such patients should be thoroughly reevaluated. (Modified with permission from Martin, K. A., Chang, R. J., Ehrmann, D. A., et al. (2008). Evaluation and treatment of hirsutism in premenopausal women: an endocrine society clinical practice guideline. *J Clin Endocrin Metab, 93,* 1105–1120. © The Endocrine Society).

high-normal total testosterone and a low-normal SHBG yields a high free testosterone concentration.

Although other androgens are present in blood, their assessment ordinarily makes little difference in diagnosis and management if serum free testosterone is normal. However, the variation in androgen levels may miss an occasional case of nonclassic congenital adrenal hyperplasia, so further studies are indicated in patients at high risk by virtue of family history or ethnicity.

If otherwise unexplained hyperandrogenism is confirmed, the next step in the workup is ordinarily to obtain an ultrasound examination of the pelvis (Figure 15-48). These findings are not completely specific for PCOS, and require excluding disorders that may secondarily cause PCOS. On the other hand, a normal ultrasound examination does not exclude PCOS. However, it is useful for ruling out tumor and disorders of sexual differentiation as a cause of the androgen excess. Simultaneous ultrasound imaging of the abdomen can be a cost-effective screening test for adrenal neoplasm in the hands of an experienced ultrasonographer.

Endocrine screening is indicated to rule out the most common mimes of PCOS. These include exclusion of pregnancy and hyperprolactinemia. It may also include measurement of DHEAS and early morning 17-hydroxyprogesterone to screen for nonclassic congenital adrenal

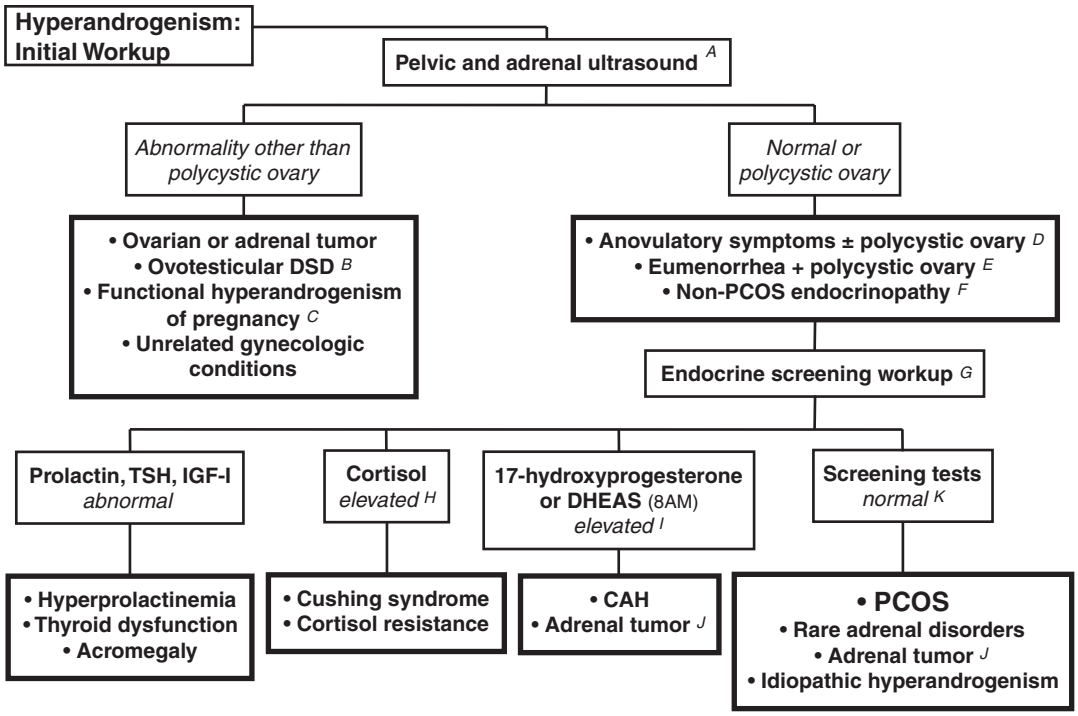

FIGURE 15-48 ■ Initial workup for causes of hyperandrogenism. This algorithm identifies the common causes of hyperandrogenism, which is most often due to PCOS. (Modified with permission from Rosenfield, R. L. (2012). Polycystic ovary syndrome in adolescence: clinical features and diagnosis of polycystic ovary syndrome in adolescents. UpToDate. Retrieved from http://www.uptodate.com)

A. Ultrasonography is the initial study that detects polycystic ovaries and excludes ovarian pathology other than polycystic ovaries. The abdominal ultrasound that is indicated for pelvic ultrasonographic imaging in virginal adolescents can be used to screen for adrenal enlargement/mass. A polycystic ovary has been defined by international consensus in adults as an ovary with a volume > 10 cc or containing ≥ 12 follicles 2 to 9 mm in diameter in the absence of a dominant follicle (≥ 10 mm diameter) or corpus luteum. In adolescents ovaries are normally are up to 10-8-11.8 cc in volume with 10-17 follicles in the maximum plane. Unless the ultrasound reveals an abnormality other than a polycystic ovary, further workup for hyperandrogenism is indicated.
B. Ovotesticular disorder of sex development (DSD) was formerly termed *true hermaphroditism*.
C. Virilization during pregnancy may be due to androgen hypersecretion by a luteoma or hyperreactio luteinalis.
D. The presence of a polycystic ovary supports the diagnosis of PCOS in hyperandrogenic patients. The presence of a polycystic ovary is not necessary—nor does it suffice—for the diagnosis of PCOS in a patient with hyperandrogenic anovulation.
E. In a eumenorrheic symptomatically hyperandrogenic adolescent with normal menses, the presence of a polycystic ovary (which meets Rotterdam-AES diagnostic criteria in adults) is provisional evidence for the diagnosis of PCOS.
F. A polycystic ovary is not specific for PCOS; it has been reported in several specific endocrinopathies (e.g., hypothyroidism and Cushing disease) and is also common in asymptomatic individuals.
G. Further evaluation should include levels of serum prolactin, thyroid-stimulating hormone (TSH), insulin-like growth factor 1 (IGF-1), cortisol, 17-hydroxyprogesterone, and dehydroepiandrosterone sulfate (DHEAS). An abnormality of any of these endocrine tests is suggestive of one of the hyperandrogenic disorders that most commonly mimics PCOS.
H. Plasma cortisol < 10 μg/dL essentially rules out endogenous Cushing syndrome unless the clinical index of suspicion is high.
I. 8AM 17-hydroxyprogesterone > 170 to 200 ng/dL is approximately 95% sensitive and 90% specific for detecting common type (21-hydroxylase deficient) nonclassic congenital adrenal hyperplasia (CAH) in anovulatory or follicular phase women; it is often found in virilizing neoplasms. DHEAS > 700 μg/dL suggests an adrenal virilizing tumor or a rare type of CAH (3β-hydroxysteroid dehydrogenase deficiency).
J. Computed tomographic scanning of the adrenal gland is a more definitive study for identifying adrenal tumor than is ultrasound.
K. Exclusion of the preceding disorders in a hyperandrogenic patient with menstrual dysfunction meets standard diagnostic criteria for PCOS with approximately 95% reliability. However, this workup does not identify rare adrenal disorders (e.g., some types of CAH and related types of congenital adrenal steroid metabolic disorders), the rare testosterone-secreting adrenal tumor, or, most commonly, idiopathic hyperandrogenism (hyperandrogenism of unknown origin, which can arise from obesity or possibly metabolic abnormalities).

hyperplasia, and assessment for Cushing syndrome, thyroid dysfunction, or acromegaly, if clinically indicated. If this evaluation for the most common disorders that mimic polycystic ovary syndrome is negative, the combination of testosterone elevation with anovulatory symptoms fulfills the most widely accepted diagnostic criteria (criteria established by the National Institutes of Health [NIH]) for PCOS. The combination of testosterone elevation with a polycystic ovary in the absence of menstrual irregularity permits a provisional diagnosis of PCOS by Rotterdam/AES criteria (see Box 15-8). However, this evaluation does not exclude some fairly rare hyperandrogenic disorders that mimic PCOS. The approach to further studies to determine the source of hyperandrogenemia varies among subspecialists and with the needs of the individual patient.

Our preference is to use a dexamethasone androgen-suppression test (DAST) to attempt to make a positive diagnosis of the ovarian dysfunction of PCOS versus determining whether further workup is necessary for rare forms of CAH or other rare adrenal disorders (Figure 15-49).[888] Suppression of serum androgens and cortisol in response to a low-dose dexamethasone suppression test segregates patients diagnostically. Subnormal testosterone suppression

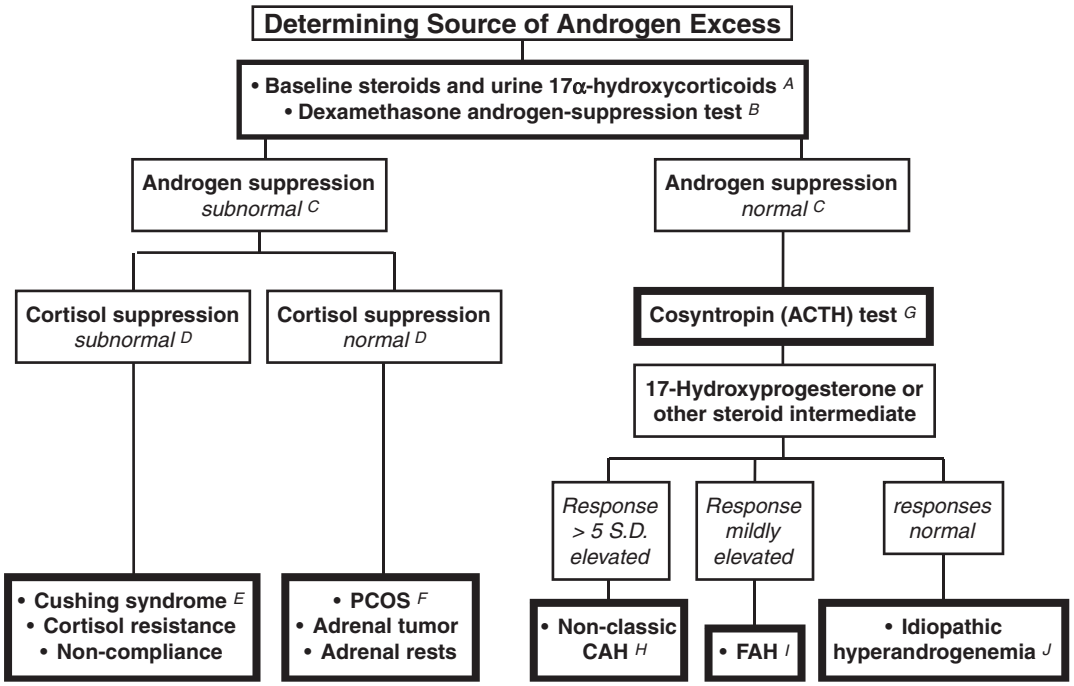

FIGURE 15-49 ■ An approach to determining the source of androgen excess. The association of testosterone elevation with otherwise unexplained anovulatory symptoms (see Figures 15-42 and 15-43) or a polycystic ovary fulfills standard diagnostic criteria for PCOS, which accounts for over 80% of adolescent hyperandrogenism. Determination of the source of excess androgen often permits a positive diagnosis of the characteristic ovarian and adrenal dysfunction of PCOS and will elucidate rare disorders that mimic PCOS. (Modified with permission from Rosenfield, R. L. (2012). Polycystic ovary syndrome in adolescence: clinical features and diagnosis of polycystic ovary syndrome in adolescents. UpToDate. Retrieved from http://www.uptodate.com)

A. After obtaining an early morning blood sample for baseline steroid intermediates (e.g., 17-hydroxypregnenolone, 17-hydroxyprogesterone, 11-deoxycortisol, dehydroepiandrosterone, androstenedione) and a 24-hour urine for corticoids (i.e., free cortisol and 17α-hydroxycorticoids, as well as creatinine to control for completeness of collection), a dexamethasone androgen-suppression test (DAST) is performed.
B. A short DAST (sampling blood 4 hours after a single noontime 0.5 mg dexamethasone dose) maximally suppresses total and free testosterone and 17-hydroxyprogesterone, but DHEAS and cortisol are not maximally suppressed in comparison to the 4-day DAST. A long (4-day) DAST is a definitive test: this consists of a 4-day course of dexamethasone 0.5 mg four times daily prior to an early morning posttest blood sample on day 5.
C. Normal androgen suppression in response to the 4-day DAST is indicated by total testosterone < 28 ng/dL (1 nmol/L), free testosterone < 8 pg/mL (28 pmol/L), DHEAS < 40 mg/dL (1 micromol/L) (> 75% fall), and 17-hydroxyprogesterone < 26 ng/dL (0.8 nmol/L).
D. Normal corticoid suppression is indicated by serum cortisol < 1.5 mg/dL (40 nmol/L) and urinary cortisol < 10 mg (27 nmol) per 24 hours by the second day of dexamethasone administration.
E. If androgen and cortisol are both not normally suppressed, Cushing syndrome and cortisol resistance should be considered. Poor suppression can also result from noncompliance with the dexamethasone regimen.
F. Subnormal suppression of testosterone (as well as androstenedione and 17-hydroxyprogesterone) and a normal suppression of cortisol and DHEAS are characteristic of PCOS, but the rare virilizing adrenal tumor or adrenal rests should be considered on the basis of clinical factors.
G. A cosyntropin (ACTH) stimulation test is appropriate if androgen suppression by dexamethasone is normal.
H. The diagnosis of congenital adrenal hyperplasia (CAH) is suggested if the response to ACTH is > 5 SD above the average: for 17-hydroxyprogesterone this is > 1000 ng/dL (30 nmol/L) and for 17-hydroxypregnenolone it is > 5000 ng/dL (158 nmol/L).
I. Primary functional adrenal hyperandrogenism (FAH) (suggested by a modest rise in 17-hydroxypregnenolone or 17-hydroxyprogesterone that does not meet the criteria for the diagnosis of CAH) is sometimes the only demonstrable source of androgen excess in PCOS. A rare mime of FAH and idiopathic hyperandrogenemia is (apparent) cortisone reductase deficiency: baseline urinary corticoids consist primarily of cortisone metabolites rather than cortisol metabolites, so 17α-hydroxycorticoid excretion is elevated, but cortisol excretion is normal.
J. Idiopathic hyperandrogenism (distinct from idiopathic hirsutism) is the diagnosis when the source of hyperandrogenemia remains unexplained after intensive investigation (occurs in approximately 10% of cases). It often appears to be due to obesity.

with normal adrenocortical suppression indicates a source of androgen other than an ACTH-dependent adrenal one and is found in 80% of PCOS. However, tumor or other ovarian pathology must be excluded by ultrasound examination. If both cortisol and androgen suppression are subnormal, then the androgen excess may be secondary to noncompliance with taking dexamethasone, Cushing syndrome, or glucocorticoid resistance. If testosterone suppression is normal, then ACTH (cosyntropin) stimulation testing to rule out nonclassic congenital adrenal hyperplasia is recommended. If both dexamethasone and ACTH testing are normal, the most likely diagnosis is idiopathic hyperandrogenism, of which obesity seems to be the most likely cause.

A short (4-hour) DAST, as described in the legend for Figure 15-49, suffices in the absence of high suspicion for virilizing disorder. It is helpful in distinguishing the potentially reversible pseudo-PCOS of simple obesity, in which case testosterone suppresses normally, from the persistent ovarian dysfunction of ordinary PCOS.[888] However, a more prolonged course of low-dose dexamethasone (long DAST, 4-days) is required to

suppress the hyperandrogenism of congenital adrenal hyperplasia.

Further extensive diagnostic studies are seldom indicated unless there is reason to suspect a virilizing tumor or a disorder of sexual differentiation. On rare occasions, ultrasonography has been insensitive in detecting a virilizing ovarian tumor in adults.[660] Computed tomography and magnetic resonance imaging permit the best visualization and more detailed assessment of tumors. Further or alternative workup may include acute gonadotropin releasing hormone agonist testing or assessment of the response to ovarian suppression treatment to determine the source of androgen.

Management

Management is individualized according to symptoms and patient goals—hirsutism, acne, and alopecia; menstrual irregularity; obesity and insulin resistance—and the source of androgen excess.[871,872,923] Because PCOS is associated with the early development of type 2 diabetes mellitus and metabolic syndrome, a fasting lipid panel and oral glucose tolerance test are recommended in patients with obesity or risk factors for these metabolic dysfunctions.[897] Obesity and insulin-resistant patients should be screened for sleep-disordered breathing. Because PCOS is closely related to parental metabolic syndrome, we recommend a similar evaluation of primary relatives. Women with PCOS are at increased risk of mood and anxiety disorders and depression and should be screened for these disorders.[924]

Cosmetic measures are the cornerstone of care for hirsutism.[383] Bleaching and shaving suffice for many. Depilating agents and waxing treatments are useful but prone to cause skin irritation. Eflornithine hydrochloride cream brings about marked improvement of hirsutism in 32%, with the maximal effect by 2 to 6 months. The FDA has permitted marketing of many laser devices, and equivalents such as diode and flashlamp, as effective for permanent hair reduction, for which the criterion is persistent reduction in hair density by 30% or more after three to four treatments of a site. Wavelengths between 694 and 1064 nm damage hair follicles by combining relatively selective absorption of heat by dark hairs with penetration into the dermis. Light-skinned individuals are the best candidates, requiring the lower energy pulses. Those with heavily tanned or darker skin require the use of cooling procedures and adjustment of energy levels to minimize the risk of skin side effects. Laser treatment is preferred to electrolysis, but both types of treatment require trained personnel; are repetitious, expensive, and painful; are practical only for treating limited areas; and may result in local reactions, including burns, dyspigmentation, and scarring. Endocrine therapy is directed at interrupting androgen production or action. This causes the pilosebaceous unit to revert toward the prepubertal vellus type.

Endocrinologic treatment of cutaneous symptoms is indicated before undertaking treatment with laser treatment, Accutane, or Rogaine if standard cosmetic or topical dermatologic measures are inadequate. The maximal effect on the sebaceous gland occurs within 3 months, but that on sexual hairs requires 9 to 12 months of treatment, because of the long duration of the hair growth cycle. All are effective only as long as the patient wishes to maintain her improvement in hirsutism.

Combination oral contraceptive pills (OCPs) are the first-line endocrine treatment for women with the dermatologic or menstrual abnormalities of PCOS. They act by suppressing serum androgens, particularly free testosterone, mainly by inhibiting ovarian function. They also raise SHBG and modestly lower DHEA sulfate levels. They normalize androgen levels by 3 weeks of therapy.

All estrogen-progestin combinations generally suffice for women with acne or mild hirsutism, in combination with cosmetic measures. Those with nonandrogenic progestins, such as norgestimate or ethynodiol diacetate combined with 35-μg ethinyl E2, have generally favorable risk-benefit ratios and optimize lipid profiles. Those with antiandrogenic progestins in low doses may confer an additional benefit: drospirenone is available in the United States with 30-μg ethinyl E2 and cyproterone acetate 2 mg with 35-μg ethinyl E2 in Canada, Mexico, and elsewhere. The larger estrogen doses may be necessary in larger girls to provide menstrual regularity. Overall, combination pills carry about a 4-fold increased risk of venous thromboembolism in first-time users; this risk decreases with duration of use and decreasing estrogen dose but is less than that of pregnancy.[528,529,579]

OCPs are also effective in the management of menstrual irregularity, which requires treatment because chronic anovulation is associated with increased risk of developing endometrial hyperplasia and carcinoma. There are, however, several potential disadvantages to the use of OCPs in the management of PCOS in adolescents. They will bring growth to end in perimenarcheal girls. OCPs may be contraindicated in patients who are at risk for venous thrombosis, and they should be used with caution and in the lowest estrogen dose possible in patients with migraine headaches. Patients may use OCPs as an excuse for not losing weight. The patient may believe that the treatment is curative and defer a definitive diagnostic workup. OCPs do not permit conception if and when it is desired. The long-term consequences of these agents on fertility are unknown; although there is the theoretic possibility of post-pill amenorrhea, very high-dose estrogen initiated in early adolescence increases the risk of primary ovarian insufficiency rather than hypogonadotropinism.[690]

It is advisable to recheck patients after 3 months of therapy to assess the efficacy of treatment and normalization of androgen levels. As a general rule, OCP treatment should be continued until the patient is gynecologically mature (5 years postmenarcheal) or has lost a substantial amount of excess weight. At that point, withholding treatment for a few months to allow recovery of suppression of pituitary-gonadal function and to ascertain whether the menstrual abnormality persists is usually advisable. In doing so, however, one must keep in mind that the anovulatory cycles of PCOS lead to relative infertility, not absolute infertility. The need for continued use of OCP for contraceptive purposes must be considered.

Progestin monotherapy is an alternative to OCPs for the control of menstrual irregularities. Micronized progesterone (Prometrium) 100 to 200 mg daily at bedtime

for 7 to 10 days induces withdrawal bleeding in the majority of patients, but some do not respond, apparently because of an antiestrogenic effect of androgen excess on the endometrium, and breakthrough bleeding is more likely than with OCPs. Progestin therapy has the appeal of permitting the detection of the emergence of normal menstrual cyclicity. However, it does not normalize androgen levels and is not an adequate treatment if hirsutism or hirsutism equivalents are a problem. The perimenarcheal girl who responds well to progestin therapy can be maintained at approximately 6-week cycles to permit the detection of spontaneous menses. Side effects of progestin include mood symptoms (depression), bloating, and breast soreness. Patients must be informed that oral progestin dosed in this way is not a means of contraception.

Antiandrogens generally yield improvement in hirsutism beyond that attainable with OCPs. They can be expected to reduce the Ferriman-Gallwey score by 15% to 40%, although there is considerable variation among individuals. Antiandrogen use for this purpose is off-label because all carry the risk of causing pseudohermaphroditism of the male fetus. Therefore, all antiandrogens should be prescribed with a contraceptive, preferably an OCP. They may have a modest effect on the metabolic abnormalities associated with PCOS.[925]

Spironolactone in high dosage is the safest potent antiandrogen in the United States. We recommend starting with 100 mg twice a day until the maximal effect has been achieved and then attempting to reduce the dose to 50 mg twice a day for maintenance therapy. Spironolactone usually is well tolerated, but it is contraindicated in patients with adrenal, hepatic, or renal insufficiency. Women are at risk of hyperkalemia if on potassium-sparing diuretics, potassium supplements, daily nonsteroidal anti-inflammatory drugs, angiotensin converting enzyme inhibitors, heparin, or such drugs. Therefore, electrolytes should be monitored. Alone, it tends to cause irregular bleeding.

Other antiandrogens used to treat hirsutism and hirsutism equivalents include cyproterone acetate, flutamide, and finasteride. Cyproterone acetate is a potent progestational antiandrogen that is used with estrogen in a reverse sequential regimen: 50 to 100 mg is given during days 1 to 10 of cycles in which estrogen is given from days 1 to 21. Flutamide is a more specific antiandrogen with efficacy similar to that of cyproterone and spironolactone, but it is more expensive and carries a seemingly idiosyncratic risk of fatal hepatocellular toxicity. Finasteride, a type 1 5-alpha-reductase inhibitor, may be as effective as other antiandrogens in the treatment of hirsutism, but it is less effective in pattern hair loss in females than in males. Although topical minoxidil is the only medication approved for alopecia treatment, antiandrogen-OCP therapy may be superior in those with PCOS.

Insulin-lowering treatments, from weight loss to drug treatment, uniformly improve hyperandrogenism. They have about a 50% probability of improving menstrual cyclicity and ovulatory status, which seems greater than explicable by the modest reduction in androgen levels that they bring about. The effect on hirsutism is negligible. Although weight reduction is indicated in obese PCOS patients, it is typically difficult to achieve. Bariatric surgery has led to improvement in androgen levels and menses in the majority, but improvements in hirsutism and ovulation have been inconsistent in adults. [926,927] This option is currently limited in adolescents to select patients with extremely high BMI and access to highly specialized centers.[926]

Metformin appears to have more utility than thiazolidines in management because it suppresses appetite and enhances weight loss. However, well-controlled studies in adults indicate that metformin therapy offers no advantage over lifestyle modification in regard to weight, menstrual frequency, or ovulation,[883,928,929] though it may have additive biochemical effects.[930] Abnormal glucose tolerance is the only clear indication for metformin. Thus, metformin is most effective in combination with a behavioral weight-reduction program.[925,926] Therapy should start with 500 mg daily of the extended release form before the evening meal, with an increase in the dose by 500 mg per week to a maximal dose of 2000 mg daily as tolerated. The larger doses often are better tolerated when divided into two daily doses. It is advisable to obtain a comprehensive metabolic panel at baseline to confirm normal hepatic and renal function. Although extremely rare, lactic acidosis is a potential complication of metformin use; patients should be made aware of this risk.

Other hormonal manipulations may be useful in specific unusual situations. Prednisone therapy has little utility in the management of the hirsutism or menstrual irregularity of PCOS. Gonadotropin releasing hormone agonists are an alternative when OCPs are contraindicated; they should be used with E2 replacement therapy.

FUTURE DIRECTIONS

Tremendous advances continue to occur in our understanding of puberty. The identification of genes involved in ovarian differentiation, the discovery of new hormones and hormone receptors, new insights into the regulation of gene transcription and signal transduction, further identification of the role of genetic factors and prenatal imprinting on pubertal disorders, and advances in the application of mass spectrometry to steroid assays can also be anticipated to occur in the coming years. We are in the midst of an explosion of information in the biologic sciences. It is becoming clear that the body puts a wide but finite repertoire of hormones and growth factors to myriad and unexpected uses. Many concepts that we hold dear at this moment are, at best, likely to be shown to be oversimplifications or, at worst, likely to be wrong. New information comes to light faster than we can assimilate it. The understanding of the interactions of the human genome with environmental factors can be expected to yield new insights into our understanding of puberty and its disorders.

QUESTIONS

1. Which statement is true about the control of GnRH secretion in the hypothalamus:
   a. Secreted factors from the gonads are necessary for the prepubertal restraint of the GnRH pulse generator.
   b. Prior to the onset of puberty, there is a decrease in the expression of GPR54.
   c. Leptin serves as a signal of sufficient nutritional stores with a threshold level necessary for activation of the GnRH pulse generator at the onset of puberty.
   d. Prepubertal secretion of kisspeptin suppresses GnRH production through activation of its receptor, GPR54.

Answer: c

2. Which statement is false:
   a. Multiple isoforms of LH are produced in the pituitary gland; these isoforms differ in bioactivity, with androgens and estrogens affecting the relative expression of these isoforms.
   b. Prolactin secretion is stimulated by estrogen and TRH, and is inhibited by thyroxine, dopamine and prolactin release-inhibiting factor.
   c. Activins and inhibins are different splice variants of a single gene
   d. Gonadotropin-releasing hormone and prolactin release-inhibiting hormone are unique cleavage products of a common precursor protein.

Answer: c

3. Which statement about sex steroid receptor signaling is false:
   a. There are two estrogen receptors (α and β) that are encoded by separate genes
   b. Estrogen can rapidly stimulate intracellular phosphorylation pathways through binding to membrane-associated estrogen receptors.
   c. The A and B forms of the androgen receptor are produced through differing post-translational modifications
   d. Selective estrogen receptor modulators (SERMs; e.g. tamoxifen and raloxifene) are estradiol agonists in some tissues, but are anti-estrogenic in other tissues, effects predominantly related to their relative affinity for the α versus β isoforms of the estrogen receptor.
   e. The genomic response to estrogen varies depending on the relative expression of co-activators and co-repressors within target cells

Answer: d

4. A 5-year-old girl presents to you after an episode of vaginal bleeding. Her height is at the 75th percentile for age, her weight is at the 90th percentile for age; Her mid-parental height is at the 50th percentile. Her examination was unremarkable except for Tanner II breast development without pubic hair development. Laboratory studies show an LH < 0.2 U/L, FSH < 0.2 U/L, estradiol 115 pg/ml. The best next step in evaluating this child would be:
   a. Brain MRI
   b. Pelvic ultrasound
   c. Exploratory laparotomy
   d. GnRH agonist stimulation test

Answer: b

5. Which statement is true about LH secretion:
   a. In the normal child, there is no LH secretion after infancy until the onset of puberty
   b. In early puberty, LH secretion is pulsatile, which becomes continuous once menstrual cycles are established.
   c. In early puberty, the majority of LH is secreted during the night
   d. An LH level less than 0.5 U/L is sufficient to exclude a diagnosis of central precocious puberty

Answer: c

CHAPTER 16

Turner Syndrome

Paul Saenger, MD • Carolyn A. Bondy, MD

CHAPTER OUTLINE

HISTORICAL BACKGROUND

Turner syndrome is a chromosomal disorder due to complete or partial monosomy for the X chromosome, associated with short stature and primary ovarian failure in phenotypic females. The eponym derives from a study published in 1938 by Henry Turner describing seven women with short stature, sexual immaturity, neck webbing, low posterior hairline, and cubitus valgus[1](Figure 16-1). Several years earlier, Otto Ullrich had described an 8-year-old girl with short stature, lymphedema of the hands and feet, neck webbing, high arched palate, low-set auricles, and several other features now associated with Turner syndrome.[2] Ullrich later recognized that his patient and those of Turner appeared to have the same condition[3] and called attention to the work of Bonnevie, who described cervical distention and malformations of the ears, face, and limb buds in mice secondary to dissection of subcutaneous fetal tissues by fluid. Ullrich suggested that fetal lymphatic obstruction may cause neck webbing and other superficial features of Turner syndrome and proposed the eponym *Bonnevie-Ullrich* to describe this constellation of anomalies. Ullrich's contributions gave rise to the eponym *Ullrich-Turner* syndrome sometimes used in Europe.

Endocrine and pathology studies of the 1940s revealed primary ovarian failure in women with Turner syndrome, associated with elevated gonadotropins, reduced estrogen and "streak" ovaries consisting of connective tissue depleted of germ cells. These early studies also discovered an extraordinary incidence of hypertension and aortic disease in young women with Turner syndrome.[4] The first link between Turner syndrome and sex chromosome anomaly was provided in 1954 by Polani and colleagues, who reported three patients with Turner syndrome and coarctation of the aorta who were sex chromatin negative.[5] Soon thereafter advances in cytogenetic identification of specific chromosomes revealed that Turner syndrome was associated with the presence of a single X chromosome (X monosomy).[6] These observations were paradigm shifting in our understanding of the role of the human sex chromosomes in sex determination, as reviewed by Opitz and Pallister.[7] They also described the significant heterogeneity of patients grouped under the concept of gonadal dysgenesis and pointed out that the terms *dysgenesis* and *agenesis* are inaccurate, as fetal ovarian development seems to be normal in Turner syndrome, with degeneration occurring in most cases around the time of birth. Although eponyms have their disadvantages, the designation *Turner* or *Ullrich-Turner syndrome* is more specific than *gonadal dysgenesis.*

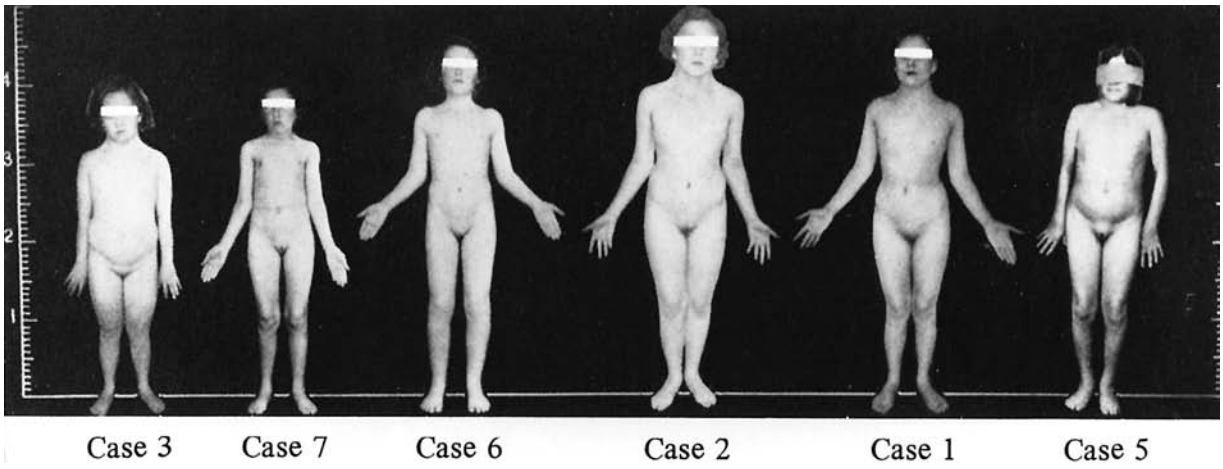

FIGURE 16-1 ■ Patients described by Dr. Henry Turner. Note the height marker at the left indicating the short stature, although with large variation in absolute height among these women. Note also lack of obesity among these women evaluated in the 1930s. (From Turner, H. H. (1938). A syndrome of infantilism, congenital webbed neck and cubitus valgus. *Endocrinology, 23,* 566.)

GENETICS

Chromosomal Origins

Refinements in cytogenetic methodology over the last half of the 20th century promoted the elucidation of the chromosomal basis for Turner syndrome and other aneuploidies. The standard cytogenetic karyotype describes the number and morphologic features of condensed metaphase chromosomes under light microscopy (Figure 16-2A). Karyotype studies of the products of conception and newborns have shown that X monosomy is the only chromosomal monosomy compatible with life, as monosomy for the Y chromosome or autosomes have never been reported.[8] This distinction among chromosomes is explained by the fact that the Y chromosome has relatively few essential genes aside from those involved in male sex determination and spermatogenesis, and the second X chromosome in females is largely inactivated, or silenced early in development. There are, however, a number of genes that escape X inactivation and that have homologs represented on the Y chromosome.[9] Haploinsufficiency for these genes results in short stature and other aspects of the Turner phenotype (discussed later).

The loss or fragmentation of a sex chromosome is most commonly traced to error(s) of recombination and segregation occurring during meiotic divisions.[8] The molecular triggers for such errors are poorly understood but appear to differ for autosomes and sex chromosomes.[10] Thus, in contrast to trisomy 21, Turner syndrome is not preferentially linked to maternal meiotic errors or age and may be more commonly associated with paternal meiotic errors.[11] A less common cause of Turner syndrome is the loss of a sex chromosome due nondisjunction in early embryonic mitotic cell divisions, resulting in a 45,X cell line together with cell lines with normal or supernumerary sex chromosome complement (e.g., 45,X/47,XXX; 45,X/46,XX; 45,X/46,XY).

Epidemiology

Cytogenetic studies found that X chromosome monosomy (45,X) was present in approximately 1/300 spontaneous abortions versus 1/5000 live births,[2-13] indicating that most 45,X gestations do not survive to birth. The ratio of 46,X,i(X)q and 46,X,r(X) to 45,X cases increases from early gestation to birth, leading to the view that X monosomy is incompatible with survival and that surviving 45,X girls started out as 46,X, fragmentary X or Y gestations.[13] It was hypothesized that fragmentary sex chromosomes are lost due to mitotic instability during the course of fetal development, so the girls appear to be 45,X after birth.[13,14] Early in the study of aneuploidy it was thought that monosomy per se would interfere with normal cell proliferation and differentiation.[15] However, it has since been learned that mice with pure X monosomy have normal survival, development, and fertility[16] and that human 45,X cells are able to proliferate and differentiate into various cell types in vitro.[17,18] Thus, it seems that X monosomy need not always be lethal, and the survival and relatively healthy development of some 45,X girls may be related to variations in autosomal genes that compensate for the X chromosome haploinsufficiency. Newborn cytogenetic screening during the 1970s and 1980s found that approximately 1:2500 liveborn females had complete or partial X monosomy consistent with Turner syndrome.[12,13,19] Danish health registry data indicate, however, that only about half the number of cases predicted by the birth incidence receive a clinical diagnosis.[20] This discrepancy may be due to a relatively mild phenotype in some cases. The birth rate for Turner syndrome is going down in some countries,[21] associated with the increasing use of fetal ultrasound screening.[22]

Turner syndrome is reported in all races and countries with similar prevalence. X monosomy does not run in families and is not associated with any known environmental or behavioral factors.[23] There is one known case of an apparently pure 45,X woman with spontaneous puberty and pregnancy giving birth to a 45,X daughter.[24] Epidemiologic observations including more than 1000 girls with Turner and their families suggest that increased parental age modestly increases the risk of having a child with Turner syndrome.[23,25] The single normal X chromosome is identified as maternal in approximately 70%

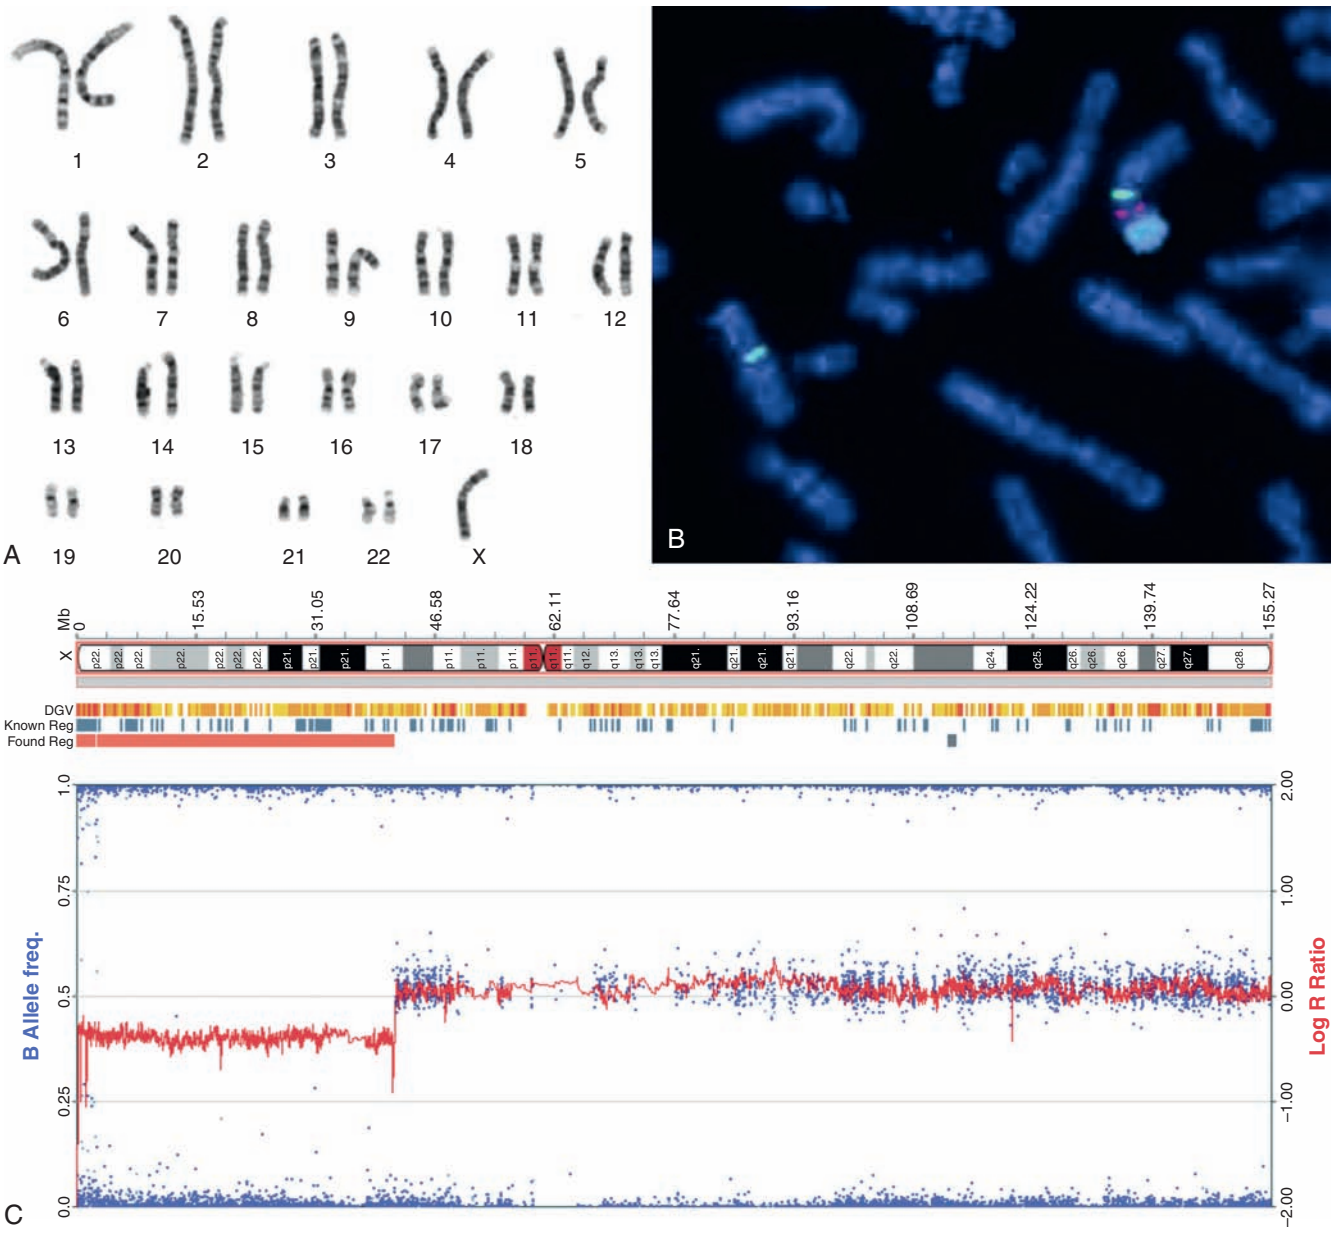

FIGURE 16-2 ■ Sex chromosome analyses. **A,** Standard G-banded metaphase karyotype in which the 22 pairs of autosomes are grouped according to size and the sex chromosomes placed at the end; in this case, there is only one X chromosome. **B,** Fluorescent in situ hybridization (FISH) of metaphase chromosomes showing a normal X chromosome on the left side of the micrograph identified by an X centromere-specific probe (DXZ1; green). The abnormal chromosome seen on the right has an X long arm and centromere joined to a Y chromosome centromere (DYZ3; red bifurcated signal) and long arm (DYZ; large blue signal). This is described in cytogenetic terms as der(X)t(X;Y)(p.11.4;p11.2). **C,** SNP genotyping array of DNA isolated from a Turner patient blood sample. The beta-allele frequency is a measure of the allelic intensity ratio, plotted as (blue) dots with reference to the left y-axis. When there is equal representation of two alternative SNP alleles, the beta allele frequency is 0.5; when only one allele is present, the frequency is 1.0 or 0. The log R ratio is a measure of total signal intensity for the test subject compared to control and is plotted as (red) graph against the y-axis on the right. When test subject signal intensity is equal to that for the control, the ratio is 1:1 and the log is 0. The array results are plotted alongside the X chromosomal ideogram at the top of the panel and show a loss of heterozygosity and reduced signal intensity from chrX: 0-41,500,000, consistent with the deletion of more than half the X chromosome short arm with breakpoint at cytologic band Xp11.4. (**B,** The FISH micrograph was kindly provided by Dr. Marie-France Portnoi of Service de génétique et embryologie médicales, Hôpital Armand-Trousseau, Paris, France. *This image can be viewed in full color online at ExpertConsult*)

and paternal in origin in ~30% of cases with cytogenetically confirmed Turner syndrome.[26-29] The expected ratio, if each parent has an equal probability of contributing a normal X to offspring, is 2:1. The consistent finding of a slightly greater than expected prevalence of X-maternal cases suggests that there may a greater propensity for meiotic errors involving the sex chromosomes during spermatogenesis. Women with Turner syndrome due to partial Xp deletion or translocation who are fertile may pass on the abnormal X chromosome to offspring.[30-32] The possibility of passing on a fragmented sex chromosome underscores the importance of obtaining a full

karyotype in the diagnosis of Turner syndrome, because if such a chromosome is found in the child, the parents need genetic testing and counseling about potential recurrence, or transmission if the daughter is fertile. There does not seem to be an increase in monosomy X or any aneuploidy in assisted pregnancies compared to natural conceptions.[33] Historical case reports have described an association of trisomy 21 and mosaic X monosomy,[34] but this association has not been observed in a large population-based investigation.[23]

Turner Karyotypes

Cytogenetic nomenclature reports the total number of chromosomes followed by the sex chromosomes listed individually, thus the normal female karyotype is "46,XX" and Turner syndrome patients with a single X chromosome are "45,X." The most common karyotype found in Turner syndrome is 45,X.[11,35,36] *Mosaicism* is defined as the presence of two or more cell lines showing different chromosome constitutions. If more than one cell line is detected, the karyotypes are separated by a slash, with the relative cell counts in brackets. For example, 45,X [10]/46,XX[10] describes an individual with 50:50 mosaicism for X monosomic and normal 46,XX cells based on scoring 20 metaphases. This type of cell line mosaicism occurs due to sex chromosome nondisjunction during postzygotic cell divisions. Depending on the developmental timing and cell populations affected, the clinical phenotype may be attenuated by mosaicism for a normal cell line.

The isoXq chromosome is the most common structural abnormality causing Turner syndrome.[11,35,37] It is a mirror image chromosome composed of two copies of the long arm fused head to head with a variable amount of centromeric and proximal Xp sequences in between, most commonly reported as 46,X,i(X)q. Variants that have subtotal Xp deletion are termed *isodicentric* and *pseudo-isodicentric* X chromosomes.[38,39] Individuals with isoXq chromosome are monosomic for the X short arm and trisomic for the X long arm. The presence of an isoXq chromosome is commonly associated with a 45,X cell line, as the abnormal isoXq chromosome is frequently lost during postzygotic cell divisions. This mosaic chromosomal constitution is reported as 45,X/46,X,i(X)q. Because all cells are monosomic for Xp, there is no tendency for moderation of the monosomic phenotype in this type of cell line mosaicism. The isoXq chromosome is not associated with mosaicism for a normal 46,XX cell line.

A ring X chromosome (rX) is fairly common in the etiology of Turner syndrome; the ring results from fusion of broken ends of short and long arms. Most often the ring has lost a major portion of Xp but retains the large part of Xq, and it is functionally equivalent to Xp deletion. The ring X is commonly lost during cell divisions in the course of development, resulting in mosaicism denoted as 45,X/46X,r(X). A ring X missing the X inactivation site (XIST) at Xq13.2 has been associated with severe mental retardation and somatic features atypical of Turner syndrome.[40,41] The XIST locus is required for inactivation of the second X chromosome, and deletion or deficient transcription of XIST may result in failure of X inactivation. The severe phenotype in girls with a small rX or with unbalanced Xp translocation is thought to be due to functional disomy of certain Xp loci that are normally inactivated.[42]

About 5% of clinically diagnosed Turner syndrome patients have a significant Xp deletion, denoted 46,X,del(X)p, with or without mosaicism for a 45,X cell line. Xq deletions are associated with clinical features of Turner syndrome mainly in patients with 45,X/46,X, del(X)q mosaicism; women with terminal Xq deletion without 45,X cells do not usually have short stature or other features aside from premature ovarian failure.[43]

Conventional karyotyping reveals mosaicism for 45,X/46,XY or 46,X,fragmentaryY cell lines in about 10% of clinically diagnosed girls with Turner syndrome.[11] In cases where the Y chromosome is intact, it is likely that the proportion of normal 46,XY cells was too low in the developing gonad to induce normal testis development and male differentiation. Phenotypic males with 45,X/46,XY chromosomal constitutions may have short stature and congenital cardiovascular malformations similar to those with Turner syndrome[44,45] but are considered under the diagnostic category of Disorders of Sexual Differentiation. In girls with Y chromosome structural abnormalities, the sex determining gene SRY may be deleted or inactivated, resulting in absent male differentiation.[46] The presence of Y chromosome material is clinically relevant because of the risk for development of a gonadoblastoma in females with Y chromosome material.[47] The diagnostic issues related to Y chromosome detection and clinical implications with regard to gonadoblastoma are discussed later in sections on "Diagnostic Tests" and "Gonadoblastoma."

X Chromosome Genes and Turner Syndrome

In a classic article published in 1965, Ferguson-Smith analyzed the karyotypes of 307 patients with various forms of gonadal dysgenesis in relation to their clinical findings.[48] He proposed that monosomy for the short arm of the X chromosome was responsible the short stature and congenital malformations found in Turner syndrome, and he noted that Yp deletion was associated with a similar phenotype. Based on this analysis, Ferguson-Smith hypothesized that some Xp genes escape from X-inactivation in 46,XX females and that homologous genes were located on the Y chromosome short arm.[48] In addition, he reported that patients with mosaicism for a normal 46,XX line (i.e., 45,X/46,XX) tended to have fewer phenotypic abnormalities.[48] These observations were confirmed in subsequent chromosomal banding[35] and molecular studies.[49]

As predicted, genes currently implicated in the Turner phenotype are located on the X chromosome short arm, escape the process of X inactivation, and have functional homologs on the Y chromosome.[50] The human sex chromosomes share homologous gene encoding regions located at the termini of the short and long arms. They are termed *pseudoautosomal* because genes in these regions behave like autosomal genes and do not undergo

X inactivation. These regions ensure that X-Y meiotic pairing and recombination takes place, which is essential for male meiosis. The major pseudoautosomal region (PAR1) is located at the Xp and Yp terminal regions and includes at least 25genes.[51] Two groups independently identified a PAR1 gene, which when deleted was associated with skeletal deformities and short stature.[52,53] This gene is termed *SHOX*, for "short stature homeobox" and is located ~500 kb from the telomere of the sex chromosomes at Xp22.3 and at Yp11.3 (Figure 16-3). SHOX encodes a transcription factor that is highly expressed in human bone morphogenetic tissue.[54] SHOX haploinsufficiency due to mutation or microdeletion causes Leri-Weill dyschondrosteosis, characterized by mesomelic short stature and shortening and bowing of the radius with a dorsal subluxation of the distal ulna (Madelung deformity).[55] Homozygous SHOX deficiency causes Langer mesomelic dysplasia, producing extreme short stature, profound mesomelia, and limb deformity. SHOX mutations or deletions are found in 2% to 15% of children with idiopathic short stature, without obvious skeletal dysmorphology.[55,56] These observations have established the view that SHOX haploinsufficiency due to deletion of Xp or Yp terminal regions causes the skeletal anomalies and short stature occurring in Turner syndrome.

Isolated SHOX haploinsufficiency in Leri-Weil or Langer syndromes has not been linked to nonskeletal features of Turner syndrome such as lymphatic obstruction, congenital heart defects, renal anomalies, or hearing loss. It seems likely that haploinsufficiency for other, as yet unknown PAR1 gene(s) contributes to these important defects. This is inferred from the fact that rats and mice that lack PAR1 genes on the sex chromosomes are normal in size, fertile, and without apparent somatic or visceral defects.[16] In contrast, canine, feline, and equine species that share a conserved PAR1 region with humans exhibit dwarfism, infertility, and aortic coarctation in X monosomy.[50] Several Xp genes outside of PAR1 escape X-inactivation and have Y-homologues, and thus may play a role in Turner syndrome, as recently reviewed.[50] Xp deletion mapping data suggested that distinctive neurocognitive characteristics of Turner syndrome are linked to haploinsufficiency for PAR1 or nearby loci.[57] Ogata and colleagues ascertained a "lymphedema critical" region at Xp11.4,[58] although this localization was not confirmed in a more recent study.[59] Bondy and associates have demonstrated that the locus for bicuspid aortic valve and aortic coarctation is telomeric to Xp11.4.[60] Hearing loss also maps to Xp deletion.[61,62] Genes located on the X chromosome long arm (Xq) are not likely candidates given that girls with normal Xq constitution (e.g., 46,X,del(X)p) and girls that actually have an extra copy of Xq (46,X,i(X)q) have the consistent Turner phenotype.[63]

X Chromosome Genomic Imprinting

Although haploinsufficiency for Xp genes is clearly implicated in major features of Turner syndrome,[64] it is also possible that the exclusive expression of maternally or paternally derived X chromosome may differentiate 45,X girls from the 46,XX population that express an equal ratio of X maternal to X paternal genes secondary to random X inactivation. Important male-female differences such as adult height, brain size, risk for autistic spectrum disorders, abdominal adiposity, and atherosclerosis are independent of gonadal effects and could be influenced by X chromosome genomic imprinting.[65] Skuse and colleagues reported impaired social and verbal skills among girls with Turner syndrome who were monosomic for a maternal X chromosome compared to a group monosomic for a paternal X, and they suggested that imprinting of X-linked genes contributes to sex-based differences in risk for autism spectrum disorders.[66] Subsequent studies have not supported this view[67]; however, one MRI study found that brain volumes are greatest in prepubertal girls monosomic for X-maternal, intermediate in 46,XX girls, and smallest in girls monosomic for X-paternal, consistent with a maternal X chromosome dose effect on brain volume.[68]

Adult height is a sexually dimorphic trait; however, there is no apparent height difference between Turner groups monosomic for either parental chromosome.[69-73]

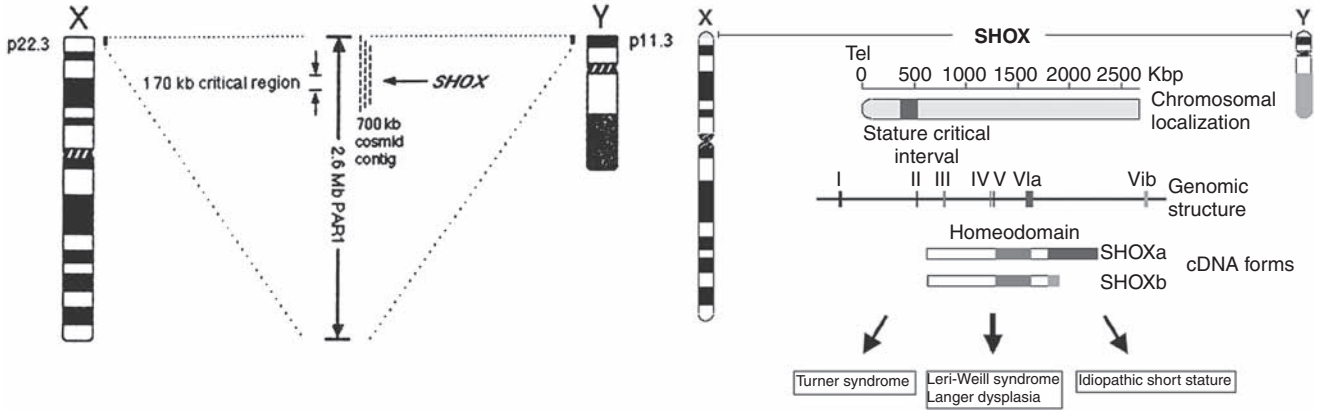

FIGURE 16-3 ■ X and Y chromosome ideograms showing the terminal pseudoautosomal regions (PAR) at Xp22.3 and Yp11.3 where the SHOX gene has been mapped, (A&C) and X chromosome regions historically associated with aspects of phenotype. (From Zinn, A. R. (1997). Growing interest in Turner Syndrome. *Nat Genet, 16,* 3. Reprinted with permission from Macmillan Publisher Ltd.)

Interestingly, adult height in women with Turner syndrome, regardless of X parental origin, tracks maternal but not paternal height.[29,70,72-74] One study suggested that response to growth hormone treatment was influenced by the parental origin of the single X chromosome,[74] but this has not been confirmed in larger, more recent studies.[37,75] Male-pattern abdominal adiposity is observed in females with monosomy for the maternal X chromosome and is associated with an atherogenic lipid profile,[76] which may contribute to greater risk for atherosclerosis among women with Turner syndrome and among the general male population, as males are constitutionally monosomic for a maternally derived X chromosome.

Diagnostic Tests

A chromosomal karyotype has been required for the definitive diagnosis of Turner syndrome.[77,78] This test usually entails obtaining a fresh blood sample from which mononuclear cells are extracted and placed into culture medium. A mitogen such as phytohemagglutinin is used to stimulate lymphocyte proliferation, and after several days, colchicine is used to arrest the cells in metaphase. After fixation, cells are spread on glass slides and treated with Giemsa stain to produce the G-banding pattern, which allows chromosome identification and characterization of major structural anomalies under the light microscope (see Figure 16-2A). Fluorescent-labeled molecular probes corresponding to specific DNA sequences are used to further identify chromosomal deletions or translocations in a process termed fluorescent in situ hybridization or FISH (Figure 16-2B).

For the diagnosis of Turner syndrome, the American College of Medical Genetics recommends scoring a minimum of 20 metaphases from peripheral blood cells.[37] If there is a high degree of clinical suspicion but the initial karyotype is normal, another 10 metaphase spreads should be analyzed. In addition, a standard metaphase karyotype may be performed on cultured fibroblasts or interphase FISH may be used on available cells or tissue, although such tests are not well established. In fact, all the clinical and prognostic information guiding standard practice is based on diagnosis using the standard 20-cell karyotype from peripheral blood mononuclear cells. In some cases the standard karyotype reveals small fragments of chromosomal material known as marker or ring chromosomes that cannot be identified as derived from X or Y chromosomes based on morphology. These fragments require identification using FISH with X and Y chromosome specific probes. Some authors suggest further screening for potential Y chromosome sequences using FISH or polymerase chain reaction (PCR) in girls that have a nonmosaic 45,X karyotype.[37] This approach has not been widely adopted because of uncertainty about the diagnostic reliability and the unclear clinical significance of "cryptic" Y chromosome sequences.

One study showed that measuring the allelic expression of X chromosome single nucleotide polymorphisms (SNPs) by high throughput sequencing of DNA samples from buccal swabs was able to confirm cytogenetic diagnoses of girls with Turner syndrome.[79] The conceptual basis for this approach is that individuals with a single X chromosome will demonstrate lack of heterozygosity for polymorphic X sequences. This method could be used for noninvasive screening of newborns, although the diagnosis would have to be confirmed by standard karyotyping.

A new diagnostic technology relevant to Turner syndrome and other chromosomal disorders uses array-based hybridization to assess both chromosomal sequence copy number and SNP diversity across the entire genome. This new technology provides high resolution virtual, or *in silico* karyotype analysis (Figure 2C) and is performed on stored blood or tissue samples without need for cell culture. These arrays are able to demonstrate X monosomy, X chromosome deletions, and detect Y chromosome presence equivalent to conventional metaphase karyotypes.[80] Their accuracy in detecting low level mosaicism needs further evaluation, however, and additional studies are needed to confirm a correlation between clinical features of Turner syndrome and array-based hybridization diagnoses in a prospective manner.

Indications for Karyotype Testing

There is a distinct biphasic pattern in the diagnosis of Turner syndrome with a substantial proportion being diagnosed around the time of birth and another large group diagnosed around 12 years of age (Figure 16-4). During infancy, the most common indication for karyotype screening is lymphedema. Residual signs of fetal lymphedema include neck webbing, low hairline, malrotated, low-set ears, and drooping eyelids. Swelling or puffiness of the hands and feet accompanies peripheral lymphedema, which is common in infants with Turner syndrome. Skeletal features and growth delay may be present but difficult to appreciate during the first few years. Another important indication for karyotype analysis is the presence of congenital cardiovascular malformation, especially aortic coarctation and aortic valve disease in a female infant or young girl.

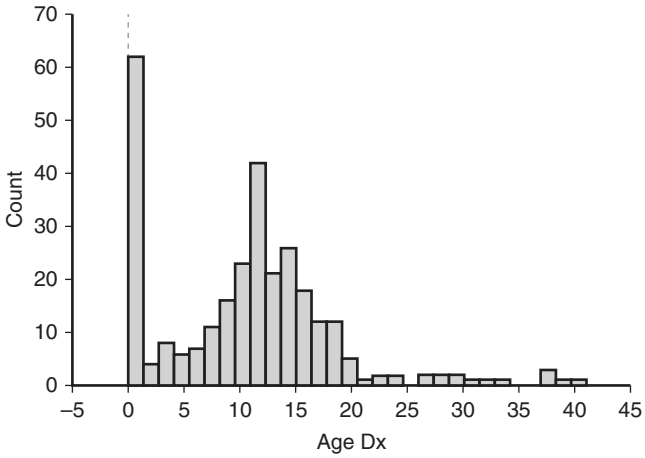

FIGURE 16-4 ■ Age of Turner diagnosis. The histogram shows the age of diagnosis for 292 patients evaluated in the NIH Turner natural history protocol between 2005 and 2010. The median age of diagnosis was 11 years.

A karyotype should be considered in the evaluation of girls with short stature, especially if associated with typical skeletal features such as micrognathia, high-arched palate, short metacarpals, or cubitus valgus as described later (skeletal anomalies and growth failure). Girls and young women presenting with delayed or absent puberty associated with elevation of gonadotropins should have a karyotype analysis. Finally, Turner syndrome is not infrequently discovered by karyotype analysis in women with infertility or premature menopause, as illustrated by the late age of diagnosis for 7% of the National Institutes of Health (NIH) cohort (see Figure 16-4).

Differential Diagnosis

The standard karyotype analysis plays an essential role in differential diagnosis of Turner syndrome. Noonan described male and female children with neck webbing, short stature, and congenital heart disease,[81] and in the past boys with this disorder were classified as "male Turner syndrome." Noonan syndrome is a genetically heterogeneous autosomal dominant disorder with no sex predominance and is associated with a normal karyotype. The Noonan congenital heart defects include pulmonic valve stenosis and hypertrophic cardiomyopathy[81]—in contrast to the Turner cardiovascular phenotype that includes mainly left ventricular outflow tract defects. Puberty may be delayed, but girls are usually fertile whereas boys may have cryptorchidism. The nomenclature, evaluation, genetic counseling, and endocrine management that are appropriate to the girl with Turner syndrome do not apply to patients with Noonan syndrome. Another consideration in the differential diagnosis of a girl undergoing evaluation for short stature with some skeletal features associated with Turner syndrome and similarly affected siblings is SHOX mutation/deletion or Leri-Weill syndrome. Girls with delayed or absent puberty, normal height, and 46,XX or 46,XY karyotypes are thought to have isolated mutations/deletions of genes involved in gonadal differentiation. These patients were historically grouped with girls with Turner syndrome under the category "gonadal dysgenesis," but they clearly have very different genetic, medical, and psychosocial issues.

Prenatal Diagnosis

The prognosis for prenatally detected Turner syndrome depends in large measure on the indications for the testing. When an abnormal fetal ultrasound showing cystic hygroma or fetal hydrops leads to genetic testing and demonstration of nonmosaic 45,X fetal karyotype, there is virtual certainty of a clinically significant diagnosis of Turner syndrome and a high risk of fetal demise.[82] A characteristic ultrasound of a 14-week-old Turner fetus with a cystic hygroma is shown in Figure 16-5. In contrast, an incidental prenatal diagnosis of Turner syndrome with a normal fetal ultrasound is often associated with a mild postnatal phenotype.[83] The postnatal outcomes for fetuses mosaic for 45,X and normal 46,XX or 46,XY cell lines are quite variable and correlate poorly with phenotypes of children ascertained on clinical grounds with Turner syndrome or mixed gonadal dysgenesis.[84] Over 90% of 45,X/46,XY cases ascertained by amniocentesis or villous chorionic sampling appear to be normally developed males at birth.[85] The outcome for fetuses with 45,X/46,XX karyotypes appears to be similarly mild.[83,86] Given these observations, it is important that prenatal counseling inform families that 45,X/46,XY and 45,X/46,XX gestations with normal fetal ultrasound may present a milder phenotype than that of patients diagnosed clinically. Moreover, even the 45,X fetus with cystic hygroma may be viable and enjoy a good quality of life. Importantly, prenatal diagnoses of

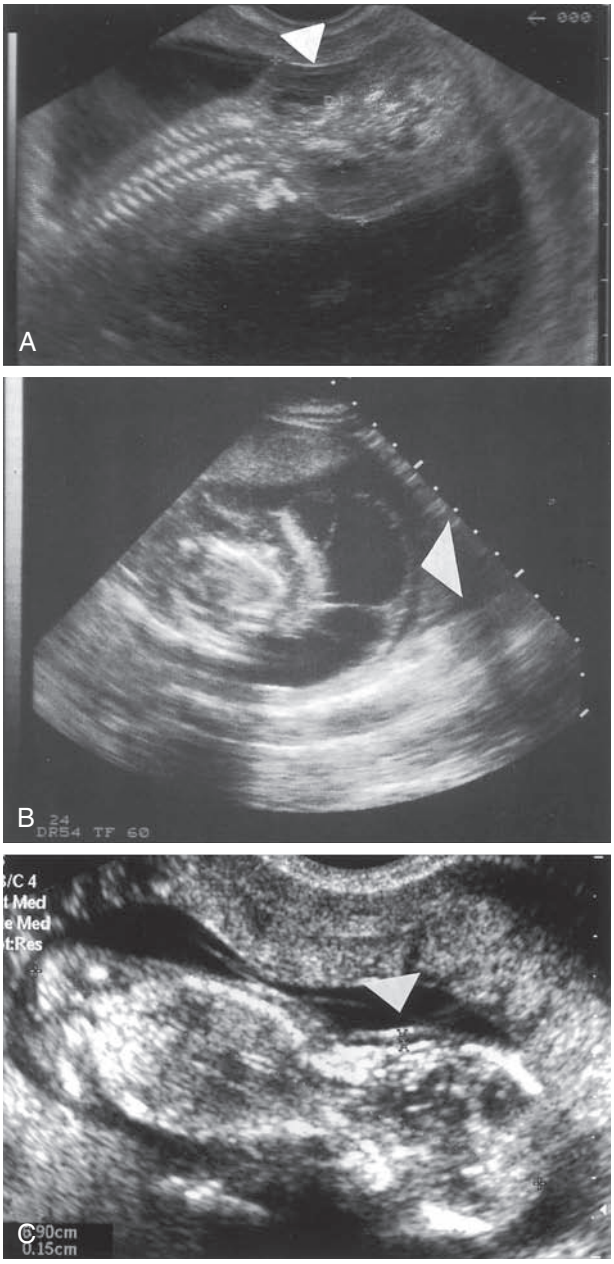

FIGURE 16-5 ■ **A,** A 14-week-old fetus with Turner syndrome and a cystic hygroma (arrow). **B,** A 13-week-old fetus with a normal karyotype and normal nuchal translucency of 1.5 mm (arrow). **C,** Same fetus as in view **A** in transverse plane. Large septated cystic hygroma (arrow) can be seen around the fetal neck. (Courtesy of Pekka Taipale, MD, PhD, Kuppio University Hospital, Finland.)

sex chromosome anomaly should be reevaluated postnatally with a standard peripheral blood karyotype in all cases.

As genomic technology advances, we are seeing new approaches to prenatal screening for genetic abnormalities. Massively parallel genomic sequencing is able to characterize small amounts of cell free fetal DNA in the maternal blood stream by 10 weeks' gestation, and this approach may eventually supplant the use of the maternal "analyte" screen. However, suspicions of aneuploidy based on cell free fetal DNA, maternal analytes or fetal ultrasound still require direct confirmation of the chromosomal complement from in situ fetal tissue obtained from amniocentesis or chorionic sampling. More advances on the genomic technology front may replace the traditional karyotype of fetal tissue. Comparative genomic hybridization (CGH) arrays are equal to traditional karyotype in identification of trisomy 21 and sex chromosome anomalies, including 45X from fetal samples obtained by amniocentesis or chorion samples.[87] CGH is more sensitive to microdeletions or duplications compared to traditional karyotype analysis, but it may not detect balanced translocations or cell line mosaicism associated with Turner syndrome, for example, 45,X/47,XXX. The clinical outcomes of pregnancies identified by the new genomic technologies have not yet been studied.

PHENOTYPIC FEATURES

Since the original description of Turner, it has been recognized that there are a multiplicity of findings in patients with Turner syndrome and that phenotypic features vary remarkably between patients with the same karyotype (Figure 16-6). Table 16-1 summarizes the most common features determined by physical diagnosis and standard medical screening.

FIGURE 16-6 ■ Phenotypic variability in Turner syndrome. Both of these 7-year-old girls with short stature have Turner syndrome with a 45,X karyotype confirmed in analysis of 50 lymphocytes. The girl on the left was diagnosed at birth due to prominent neck webbing and low-set and posteriorly rotated ears. She also has micrognathia and a low posterior hairline. In contrast, the girl on the right was diagnosed at age 7 due to short stature without "classical" stigmata of Turner syndrome, and she is more typical of the clinical presentation of the majority of girls with Turner syndrome diagnosed in the 21st century. *(This image can be viewed in full color online at ExpertConsult)*

TABLE 16-1 **Clinical Features in Girls with Turner Syndrome**

Physical Diagnosis		Percentage Affected
Skeletal	Short stature	100
	Short neck	40
	↑ Upper:lower body ratio	97
	Cubitus valgus	47
	Short metacarpal	37
	Scoliosis	12.5

	Type 1 diabetes	0
	Celiac	5
	Inflammatory bowel	3

"Physical Diagnosis" describes findings from physical examinations of more than 200 girls seen by Drs. Barbara Lippe and Paul Saenger between 1985 and 2000. Information on pubertal development is not included because many girls were not old enough to assess. The "screening evaluation" data are from 100 girls aged 7 to 17 who underwent standardized imaging and lab testing as part of the NIH natural history study performed between 2001 and 2008. The cardiovascular evaluation included MRI and cardiac echo. Under the cardiovascular listing, the "Other" category included partial anomalous pulmonary veins, aberrant right subclavian artery, and atrial septal defects. Blood pressure was measured on 24-hour ambulatory monitors. All patients also had renal and hepatic ultrasound studies. Abnormal liver function was defined as greater than 10% elevation of aminotransferase(s). Hashimoto's was defined by history of clinical hypothyroidism or elevation of circulating thyroid antibodies.

Lymphatic Obstruction

The appearance of the 45,X fetus illustrated in Figure 16-7 dramatically shows the fetal edema that occurs in many conceptuses with Turner syndrome. The edema appears to result from lymphatic malformations and obstruction.[88] The cystic hygromas are due to delayed formation of communications between the jugular and central lymphatics draining into the heart that normally develop between the fifth and sixth weeks of gestation. Peripheral lymphatic hypoplasia or aplasia has also been demonstrated using lymphangiography in adult patients with Turner syndrome.[89]

Webbed neck, or pterygium colli, is the most obvious consequence of nuchal lymphatic obstruction and this is seen in approximately 25% of patients diagnosed currently. The tenting of developing scalp and facial

FIGURE 16-7 ■ A 45,X abortus demonstrating generalized lymphedema. Note the distended cervical region. With resolution of the edema, the redundant skin may cicatrize, resulting in a webbed neck. The edema of the hands and feet may persist and be present at birth. (From Gellis, S. S., & Feingold, M. (1978). Picture of the month. *Am J Dis Child, 132*, 417. Copyright © 1978, American Medical Association.)

structures is believed to cause low-set, rotated auricular structures, down-sloping eyes, drooping eyelids, and low posterior hairline (see Figure 16-6). It has been suggested that this mechanical distention during fetal development may be responsible for lush hair growth, including eyelashes and eyebrows. Edema of the dorsum of the hands and feet at birth signals peripheral lymphedema, which usually resolves, although some patients demonstrate chronic involvement. Others may complain of intermittent or recurrent edema, often after the institution of estrogen replacement therapy.

Skeletal Anomalies and Short Stature

The most common physical abnormality associated with Turner syndrome is short stature. The impairment is most pronounced along the longitudinal body axis. This gives affected individuals the visual appearance of being stocky or squarely shaped and accounts for the predominantly illusory finding of widely spaced nipples.[90] The short neck is secondary to hypoplasia of one or more of the cervical vertebrae.[91] Long bone growth is selectively impaired, resulting in relatively short legs and an increased upper-to-lower segment ratio.[92] Individual bones are affected to varying degrees. For example, cubitus valgus is commonly appreciated and can be measured as the angle of intersection of the long axis of the upper arm with the long axis of the supinated forearm when the elbow is fully extended. Normally, in adult women this angle is approximately 12 degrees—whereas in adult men it is approximately 6 degrees.[93] The major determinant of the angle is the depth of the inner lip of the trochlea of the ulna relative to the outer lip. In many patients with Turner syndrome the angle is between 15 and 30 degrees (Figure 16-8) as a consequence of developmental abnormalities of the trochlear head.

A shortened fourth metacarpal is visible on a bone age radiograph (Figure 16-9A) and is visible on exam by depression of the knuckle when the patient makes a fist. The Madelung deformity is found in 7% to 8% of patients and is caused by bowing of the radius coupled with dorsal subluxation of the distal ulna (Figure 16-10).[94] This anomaly also occurs as part of the Leri-Weill syndrome.

Spinal scoliosis or kyphosis is reported in a significant number of patients[95] and may be secondary to vertebral anomalies or leg-length inequality. Micrognathia or receding chin and high arched palate are common and thought to be due to disturbances of the development of facial bones.

Bones of the hand and wrist on bone age radiographs often demonstrate osteopenia,[96] associated with ballooning of the tips of the terminal phalanges.[97] Both findings are illustrated in Figure 16-9B.This osteoporotic appearance is observed in childhood, suggesting that it may be more related to the developmental role of SHOX than to primary estrogen deficiency. In support of this view,

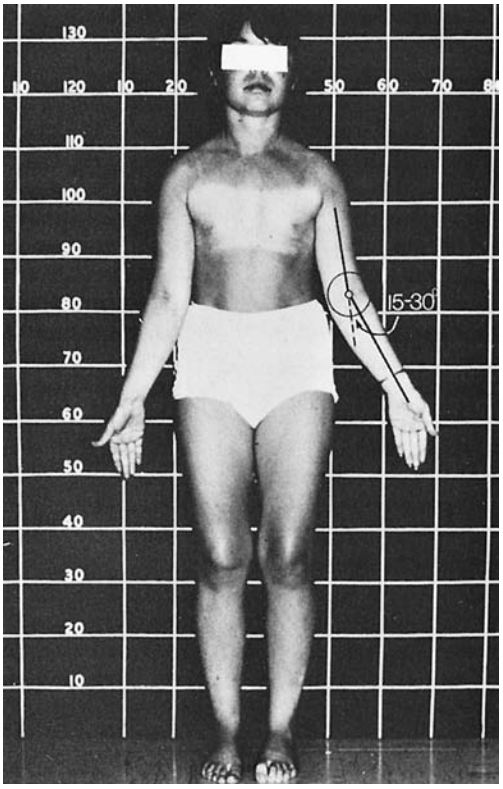

FIGURE 16-8 ■ A 16-year-old girl with Turner syndrome and absence of puberty. Note absence of most characteristic stigmata save short stature and an increased carrying angle (cubitus valgus).

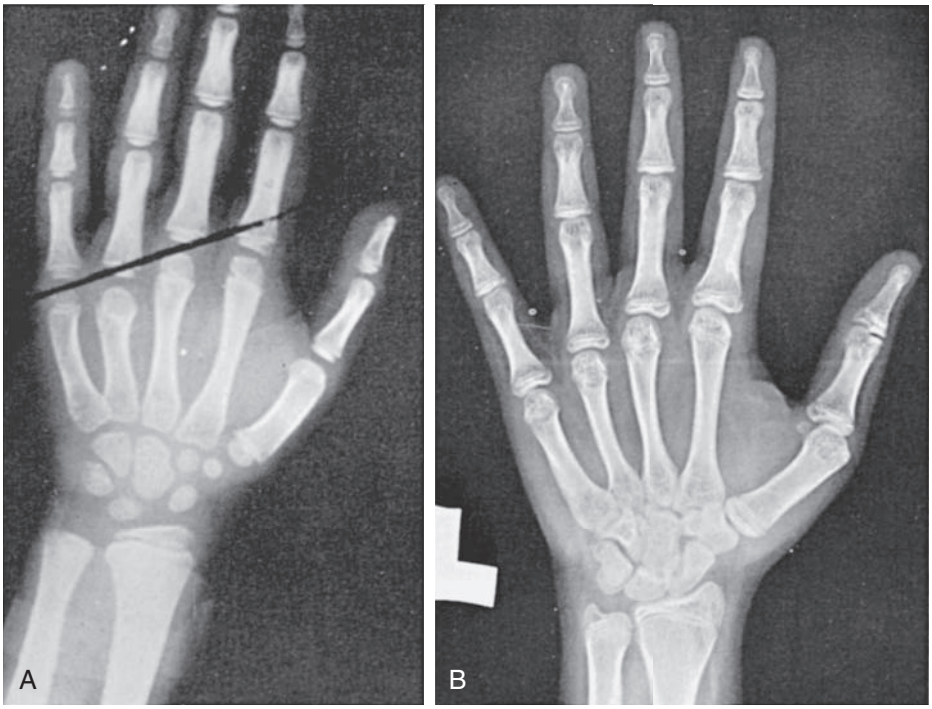

FIGURE 16-9 ■ Two characteristic hand radiographs. **A,** Short fourth metacarpal, the tip falling below a straight line drawn between the third and fifth metacarpals. **B,** Generalized lacy ("fish net") appearance of the carpals and tufting of the distal phalanges, characteristic of the osteoporotic appearance of the bones of patients with Turner syndrome.

FIGURE 16-10 ■ A 19-year-old-patient with Turner syndrome and bilateral bayonet-like Madelung deformities of the wrists.

cortical bone mineralization is selectively reduced in girls and women with Turner syndrome, independent of estrogen exposure.[98] Long bone fractures associated with minimal trauma appear to occur more frequently among girls with Turner syndrome.[99]

Short stature is the most common phenotypic feature of Turner syndrome. The first comprehensive assessment of skeletal growth deficits was reported by Ranke and colleagues in 1983.[100] Patterns of growth are illustrated in Figure 16-11, which shows cross-sectional height and velocity data from a series of 150 Turner children who had not received therapy to promote growth. The observations were supplemented by Davenport and coworkers,[101] who distinguished stages of growth deficit: mild intrauterine growth retardation with average birth length 1 standard deviation (SD) below the mean; a period of mild growth deceleration from birth to age 3.[102] After age 3, there is continued deceleration, so that between ages 3 and 13 years Turner syndrome girls fall farther and farther away from the normal height curves and, if untreated, fail to experience a pubertal growth spurt but continue to grow at a slow rate for several more years.

A positive correlation is found among height at diagnosis,[103] ultimate height achieved, and midparental height.[104] The final height deficit, using comparative data on adult heights in patients with different ethnic backgrounds, is approximately 20 cm.[105] Lyon and associates[106] used the data from Ranke and colleagues and from three other European centers to synthesize a series of growth curves for Turner syndrome. The curves provided mean height and SD values for age and determined a mean adult height 143.1 cm. Lyon and colleagues also noted a strong correlation between the initial height on these Turner curves and the adult height essentially independent of bone age at the time of the first height. Thus, they concluded that one could project the adult height of a girl with Turner syndrome based on her height at an

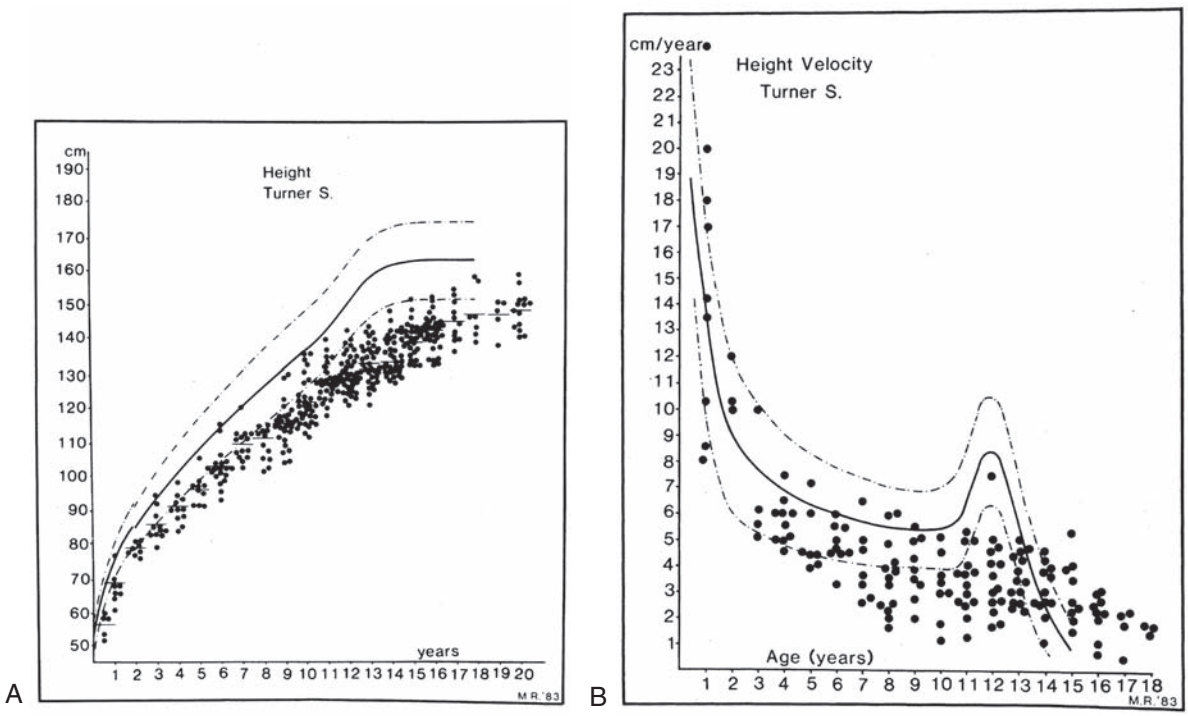

FIGURE 16-11 ■ Height and height velocity in Turner syndrome. **A,** Three hundred eighty-four single measurements of height for 150 children with Turner syndrome. **B,** Height velocity from a total of 159 measurements. Turner syndrome: spontaneous growth in 150 cases and review of the literature. *Eur J Paediatr, 141,* 81.)

earlier age. The deficit in longitudinal bone growth in Turner syndrome has been attributed to the deleterious effect of SHOX haploinsufficiency, and a similar deficit is seen in isolated SHOX defects such as Leri-Weill syndrome. Growth hormone deficiency is not implicated in Turner short stature.

Ovarian Insufficiency

The earliest studies of ovarian pathology in women with Turner syndrome described fibrous streaks devoid of oocytes and follicles, and thus initially it seemed that gonads failed to develop or were "dysgenetic." Subsequent studies revealed that early stages of ovarian development appeared normal, with expected numbers of oocytes and primordial follicles at 14 to 16 weeks of gestation in Turner fetuses.[107] However, at later stages of development, Turner ovaries were relatively depleted of oocytes and had few developing follicles, suggesting an accelerated rate of oocyte demise and follicular atresia,[108,109] although follicles in various stages of development are detected in some teenage girls with Turner syndrome.[110] The cause for the high rate of oocyte attrition in most girls with Turner syndrome is unknown. It has been suggested that aneuploidy contributes to oocyte demise due to meiotic mishaps.[111] Another possible explanation for oocyte loss is that diploid expression of unknown X chromosome gene(s) is required for normal oocyte generation or survival. The chromosomal location of putative fertility genes has remained elusive, with gonadal failure frequently observed in Xp deletions with intact Xq complement and in some cases of Xq deletion with normal Xp complement.[112] Terminal Xq deletions have been associated with premature ovarian failure in women who have few if any features of Turner syndrome.[113]

Ovarian function and potential for spontaneous puberty and even pregnancy are variable and sometimes difficult to assess among girls with Turner syndrome. An important Swedish study using ovarian biopsy has shown that a karyotype with mosaicism for 45,X and 46,XX cell lines is the most significant positive predictive factor for the presence of ovarian follicles, whereas karyotypes indicating nonmosaic 45,X or structural defects of one X chromosome were significant negative correlates for the presence of follicles.[114] Clinical factors such as normal follicle stimulating (FSH) and anti-Mullerian hormone (AMH) levels and spontaneous start of puberty were also significant positive predictors of follicle presence, although less robust than the blood karyotype.[114] According to a large, multicenter Italian study that included more than 500 girls with Turner syndrome, spontaneous puberty occurs in about 15% of those with pure 45,X and in 30% of girls with a second cell line with more than one X chromosome (i.e., 45X/46XX; 45X,47XXX).[36] Puberty may fail to progress to menarche in some girls, and menarche may be followed by oligomenorrhea or anovulatory cycles in others, so that the actual percentage of young women that maintain normal menstrual cycles by age 20 is less than 5%.

Spontaneous pregnancy occurs in 2% to 3% of women with Turner syndrome.[36,115,116] This is more common among women with mosaicism for 46,XX or 47,XXX cell lines, but there are several well-documented reports of spontaneous pregnancies in 45,X women who had no evidence of mosaicism despite intensive investigation.[24,116,117] An early case series reported a high frequency of fetal mortality or malformation for spontaneous pregnancies among women with Turner syndrome.[118] However, this has not been observed in more recent, population-based studies[116,119] nor in women with X monosomy.[116,120] If the mother has Turner syndrome due to a sex chromosome structural abnormality, the abnormal chromosome may be passed on to her offspring. The risk of maternal complications with spontaneous or assisted pregnancies is very high for women with Turner syndrome. These concerns are discussed at the end of this chapter in the "Reproductive Options" section.

Gonadoblastoma

The gonadoblastoma is a benign tumor that consists of large germ cells surrounded by small cells with variable granulosa, lutein, or Sertoli-like morphology. This type of tumor strongly resembles the histology of a developing gonad, hence the appellation "gonadoblastoma." This proliferative island of tissue within the dysgenetic gonad has a potential for steroid production and for malignant transformation into dysgerminoma.[47] The gonadoblastoma is found in approximately 40% of females with 46,XY mixed gonadal dysgenesis; the frequency among girls with Turner syndrome and Y chromosomal material is between 10% to 30%.[47] These frequency data are based on a histologic examination of ovaries that were "prophylactically" removed from girls with Y chromosome material in their karyotype. There are no studies showing morbidity or mortality related to gonadoblastoma in Turner syndrome. Analyses of Danish health registry data did not find increased morbidity or mortality related to any type of ovarian tumor among women with Turner syndrome.[20,121] A large British registry study ascertained gonadoblastoma diagnoses in 8% of women with Y chromosome in their peripheral blood karyotype, but it did not report any clinical data associated with the diagnosis.[122]

Prophylactic gonadectomy has been standard practice since the time that an excess of gonadal tumors was first appreciated in females with Y chromosomes and intra-abdominal gonads. Supporting this approach was the view that the gonads in these cases were nonfunctional, essentially contributing nothing to the patient but risk. However, we have learned that spontaneous puberty and even pregnancy may occur in individuals with Turner syndrome and Y chromosome material.[32,123,124] For example, Portnoi and colleagues reported the case of a girl diagnosed with Turner syndrome at age 8 because of short stature who was found to have translocation of Y chromosome material onto the X chromosome (see Figure 16-2B). The patient's family declined the advice for castration and the girl went on to develop spontaneous puberty and eventually had a well-supervised successful pregnancy.[32] All the clinical experience with gonadoblastoma/dysgerminoma in girls with Turner syndrome derives from cases where the karyotype included visible Y chromosome material or the patient had clinical evidence of virilization, hence the recommendation for gonadectomy was applied only to individuals with visible Y chromosome material or virilization.[125,126] With the advent of molecular amplification technology, several studies have reported detection of Y chromosome sequences in 45,X girls without evidence of Y chromosome material on their karyotype, sometimes with a histologic demonstration of gonadoblastoma after gonadectomy. Some authors suggest that all 45,X patients undergo molecular screening for cryptic Y chromosome material. On the other hand, PCR amplification may yield false positive results[127] and immature ovaries may contain nests of germinal cells resembling the benign gonadoblastoma, so the risk of overtreatment is a real concern.

Unfortunately, there is little information on the use of imaging or serum markers for surveillance of potential gonadal tumors in Turner syndrome. In any case where Y chromosomes/sequences are detected and gonadoblastoma is suspected, there needs to be education and counseling of patients or family concerning gender identity, sexual functioning, and reproductive consequences relevant to the decision for gonadectomy. Moreover, preservation of follicles or oocytes may be an option for some patients undergoing gonadectomy. Further discussion of gonadoblastoma issues is found under the "Y Chromosome" section presented later in the chapter.

Cardiovascular System

Spectrum and Etiology of Congenital Cardiovascular Malformations

Congenital cardiovascular malformations (CVM) are the most serious, life-threatening consequences of X chromosome monosomy.[20,122,128] Coarctation of the aorta in Turner syndrome was documented many years ago[5,48,129]; however, early series reporting the spectrum of CVM in Turner syndrome included patients with Noonan syndrome,[130] which has a different cardiovascular phenotype.[81] The frequency and spectrum of Turner-specific CVM was established in more recent studies using chromosomal karyotyping and cardiovascular imaging (Table 16-2). Obvious CVMs occur in approximately 75% of spontaneously aborted Turner fetuses and 30% of living patients. Obstructive lesions of the left ventricular outflow tract predominate, ranging in severity from nonstenotic bicuspid aortic valve to aortic stenosis, coarctation of the aorta, aortic aneurysm, and mitral valve anomalies (see Table 16-2). The most severe form of left-sided hypoplasia (hypoplastic left heart syndrome) also occurs in Turner syndrome and has a very poor prognosis.[131,132] The association of Turner syndrome and left-sided cardiovascular malformation is distinctive among malformation syndromes.

Clark described a significant association between neck webbing and aortic coarctation in girls with Turner syndrome.[133] This association was supported by observations on aborted fetuses[134] and additional clinical studies reporting a significantly higher prevalence of aortic

coarctation and bicuspid aortic valve (BAV) in girls with neck webbing.[135,136] Clark proposed that engorged fetal lymphatic channels might compress the ascending aorta and alter intracardiac blood flow, resulting in the spectrum of left ventricular outflow tract (LVOT) defects.[133] However, in a study of 45,X fetuses with severe aortic arch defects and aortic valve abnormality, Miyabara and coworkers described a generalized hypoplasia of fourth branchial arch tissues, which in their view was more consistent with defective migration of neural crest cells, as opposed to mechanical effects due to lymphectasia.[137] Moreover, LVOT defects occur in Turner patients without neck webbing, and neck webbing is found in some girls with normal cardiovascular structure and function demonstrated by advanced imaging,[138] which seems inconsistent with a cause-and-effect relationship. It may be more likely that haploinsufficiency for sex chromosome gene(s) causes central fetal lymphedema *and* aortic heart defects independent of each other, with penetrance conditioned by autosomal genetic variation and possibly environmental effects.

Interestingly, nonsyndromic LVOT defects such as aortic coarctation and BAV in the general population are not associated with lymphedema or neck webbing and are more common in males than in females by a ratio of approximately 3:1. The cardiovascular phenotype is found in patients with Turner syndrome with deletion of just the short arm of the X or Y chromosome,[48,139] suggesting that loci important for LVOT development are present on Xp and Yp. The putative candidate gene would escape X inactivation in females and be expressed from both the X and Y chromosomes in males. The Yp allele may be more prone to disruption in males as a consequence of inherent Y chromosome mutability.[140] PAR1 localization of an LVOT related gene(s) may explain the greater prevalence of these defects among males, as the meiotic recombination rate for this region is sevenfold greater in males than females,[141] increasing risk for Yp gene disruption.

Aortic Complications

Complications of congenital cardiovascular disease are the leading cause of morbidity and premature mortality in Turner syndrome.[128,142,143] The major cardiovascular complications include aortic valve disease and aortic dilation, dissection, or rupture. The aortic valve is congenitally abnormal in approximately 30% of life-born girls with Turner syndrome, but it is not detected in many individuals until the third decade of life or later due to inadequate screening.[139,144] Among 74 patients with bicuspid aortic valve studied at the NIH (median age 30 year, range 7 to 67), 55% had normal aortic valve function, 30% had mild aortic regurgitation, and 15% had moderate to severe aortic regurgitation.[139] Aortic stenosis was present in only 2/74 patients with BAV in this series. BAV prevalence was equal in pediatric and adults groups, but the likelihood of valve dysfunction was higher among adults. Interestingly, the large NIH screening study utilizing advanced imaging confirmed an early small study by Miller and coworkers indicating BAV in 34% of girls with Turner syndrome.[145] It is clearly important to screen for aortic valve pathology in all girls and women with Turner syndrome, because the valve may deteriorate over time, leading to heart failure. Moreover, the presence of aortic valve abnormality is linked to aortic pathology with increased risk for aortic dilation, dissection, and rupture.[146-153]

The presence of an abnormal aortic valve is associated with relative dilation of the ascending aorta, using age and body surface area nomograms, in girls and women with Turner syndrome.[139,151] The degree of dilation is greatest in patients with abnormal aortic valve function[139,151] but may be present in individuals with normal valve function as well. Moreover, mild-moderate ascending aortic dilation is found in approximately 10% of Turner patients who have a normal tricuspid aortic valve and normal blood pressure.[139,151] There is some evidence for a generalized vasculopathy in adults with Turner syndrome with enlarged diameter of carotid and brachial arteries[154] and aneurysms of other arteries.[155] The term *aortopathy* has come into wider use to describe aortic disease of diverse etiologies including Marfan syndrome and related vascular disorders that are not associated with valvular disease, in addition to aortic disease associated with BAV. It is unknown at present whether the risk for aortic complications in Turner syndrome is more similar to the former or the latter. This is a critical issue, because indications for intervention, the most effective type of surgery, and therapeutic responses to pharmacologic treatment are likely to be different in these categories.

The risk for serious aortic complications is increased in girls and women with Turner syndrome by 100-fold or greater compared to the general female population, estimated from an epidemiologic study of Danish registry data.[150] The median age of dissection was 35 years, with

the few pediatric cases clearly associated with severe clinically evident aortic valve disease or coarctation often related to surgical complications. Aortic valve abnormalities and aortic coarctation, with or without surgical repair, are important predisposing factors. Hypertension is a risk factor for aortic disease in the general population as well as in Turner syndrome, and fortunately it is readily diagnosed and treated. The presence of aortic dilation is a clear risk factor for aortic dissection in Turner syndrome, and thus direct measurements of ascending aortic diameters at the sinuses of Valsalva, sinotubular junction, and ascending aorta must be collected and recorded for all patients, together with body surface area and age.[156] Spontaneous and assisted pregnancies are associated with increased risk for catastrophic aortic complications in Turner syndrome, and the French College of Obstetrics and Gynecology[157] and the American Society of Reproductive Medicine[158] have issued stringent guidelines on preconception screening and maternal care aimed at reducing these risks.

Other Cardiovascular Issues

Although aortic valve disease and risk for aortic complications are major concerns in Turner syndrome, other congenital cardiovascular problems are common. Partial anomalous pulmonary venous connection (PAPVC) is increased in Turner syndrome,[159,160] with a prevalence estimated from 1% to 15%,[135,161-164] with the higher prevalence found using contrast cardiovascular magnetic resonance angiography (MRA).[163-164] This diagnosis should be pursued in girls with exercise intolerance, unexplained pulmonary issues, or evidence of pulmonary hypertension or right heart hypertrophy. The significance of incidentally discovered PAPVC in the screening of asymptomatic patients is unclear. Only 1 of the 11 cases reported in the NIH series and 1 of the 7 cases described from Cincinnati Children's Hospital had a clinically significant left-to-right shunt eventuating in surgery.[163,164] Aberrant right subclavian artery is another relatively common anomaly (5% to 10%; Figure 16-12) [163,164] that may compress the esophagus leading to dysphagia and chest pain.[165] Furthermore, the origin of an aberrant right subclavian artery from the descending aorta may mask the presence of aortic coarctation if the right upper extremity alone is chosen to measure upper versus lower extremity blood pressure difference. Atrial or ventricular septal defects and mitral valve disease are more common than in the general female population but less frequent than aortic defects and PAPVC (see Table 16-2).

Minor electrocardiographic findings including right axis deviation, T wave abnormalities, and QTc prolongation are significantly more common among girls and adults with Turner syndrome compared to age-matched female controls.[166-168] These findings are of uncertain significance; however, similar observations are reported in Marfan and other congenital cardiovascular diagnoses. Out of an abundance of caution, we advise screening electrocardiogram (ECG) on all patients with Turner syndrome and recommend those with a prolonged age-specific QTc to avoid medications associated with QTc prolongation.[78] Impaired autonomic responses are suggested by resting tachycardia, reduced heart rate variability, and the absence of the expected nocturnal dip in blood pressure.[169,170] Systemic blood pressure is consistently higher in girls and women with Turner syndrome compared to age-matched female controls,[171,172] and it is in the hypertensive range in approximately 25% of cases.[173] The high prevalence of hypertension appears independent of renovascular or aortic disease[174] and is not adversely impacted by usual estrogen treatment.[173,175] Thus, in the majority of patients the cause of the hypertension is unknown. Further studies are needed to determine ideal systemic blood pressures for girls and women with Turner syndrome given their smaller stature and increased risk for aortic and also atherosclerotic disease. Moreover, further investigation is required to identify beneficial pharmacotherapy for patients with hypertension or BAV and aortic dilation.

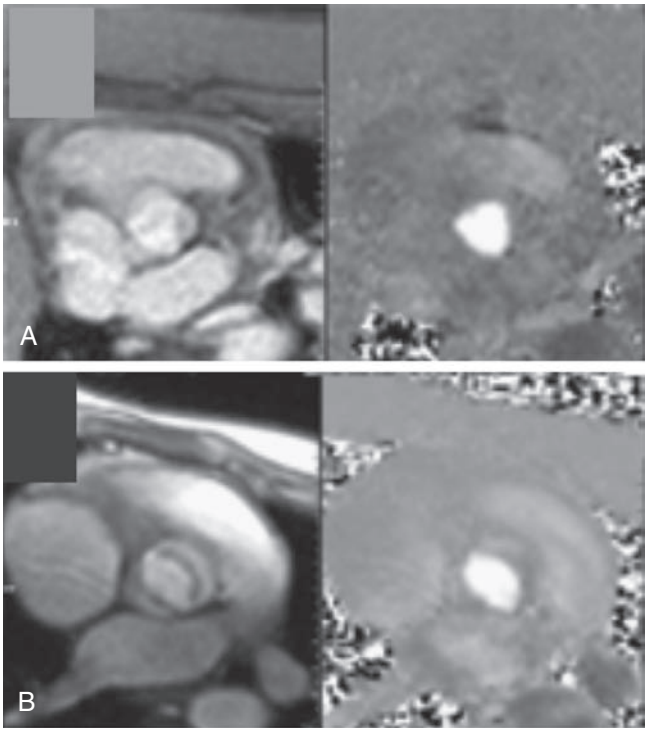

FIGURE 16-12 ■ Aortic valve structure shown by cardiac MRI. Anatomy is shown on the left and blood flow on the right side of each panel. Cardiac MRI is able to visualize the aortic valve more consistently than transthoracic cardiac echo. This figure shows normal tricuspid (A) and bicuspid (B) aortic valves.

Cardiovascular Screening in Turner Syndrome

Girls diagnosed with Turner syndrome associated with CVM in infancy and childhood need ongoing care by the pediatric cardiology team, ideally at a specialized tertiary care center. The mode of imaging and the frequency of follow-up are determined by the clinical situation in each case. Most girls are diagnosed with Turner syndrome in childhood or adolescence due to short stature without

clinically obvious cardiovascular disease. Close cardiovascular examination and consultation with pediatric cardiology are required at the time of diagnosis, with particular attention to blood pressure measurements in all extremities. Transthoracic echocardiography has been the standard approach to screening for congenital cardiovascular disease for decades, but this modality has important limitations related to operator dependency and limited acoustic windows, especially in the context of abnormal chest anatomy and obesity.[176] Cardiovascular magnetic resonance (CMR) imaging provides excellent visualization of cardiovascular anatomy and function, with dimensions of ascending, transverse, and descending aorta, in any desired imaging plane (Figures 16-12 and 16-13). Importantly, CMR consistently detects significant cardiovascular anomalies, including chronic aortic dissection, aortic coarctation and dilation, aortic valve abnormality, and partial anomalous pulmonary venous connection not demonstrated by routine echocardiography in girls and adults with Turner syndrome.[152,163,164,177,178]

In summary, asymptomatic BAV or aortic dilation and some cases of coarctation pose risks for aortic complications but may escape detection with standard evaluation and echocardiography, and hence we recommend more advanced imaging when possible without excessive risks of sedation or radiation exposure, usually by age 12.[78] The detection of asymptomatic BAV and aortic dilation in adolescents is important to assess the individual's risk for aortic complications and the need for continuous cardiac surveillance and care during the adult years. Moreover, knowledge of such underlying defects will enhance education of the young patient and her family about the risks of high-impact or high-resistance exercise and parenting choices.

The most recent consensus meeting agreed that dilation of the ascending aorta in girls and women with Turner syndrome may be defined by BSA-adjusted diameter at the sinus of Valsalva or ascending aorta exceeding two standard deviations (Z-scores) above age- and sex-matched controls.[78] This view was confirmed in large pediatric[151] and adult studies.[148]

Ongoing Cardiac Care

Pediatric patients with known cardiovascular disease require continued care by the pediatric cardiology team and transfer to adult congenital heart clinic when appropriate.[179] Patients who have had aortic coarctation repair in childhood are not "cured" and need continued surveillance for hypertension, aortic valve disease, and imaging of the aorta to monitor for restenosis or aneurysm formation.[180,181] Patients with BAV or aortic dilation need regular and continued monitoring for hypertension, valve function, and potential progression of aortic dilation. The optimal frequency of monitoring is unknown because it is unknown whether there is continuous progressive dilation of the

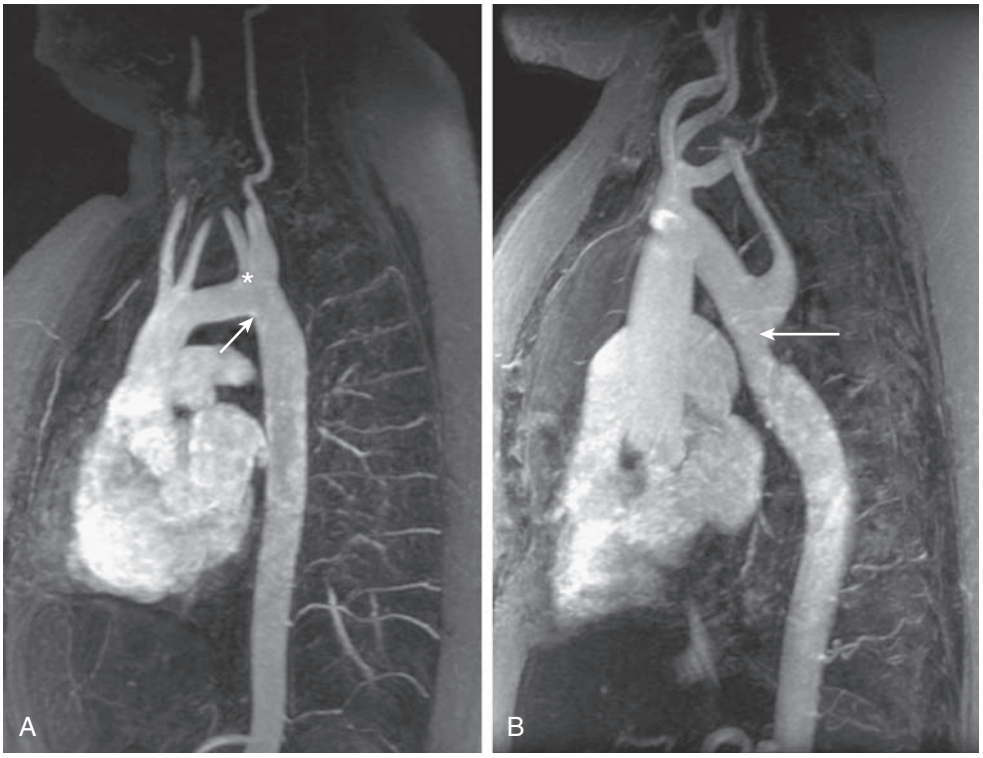

FIGURE 16-13 ■ Cardiac MRI aortograms in Turner syndrome. The image on the left (**A**) shows a squared off, elongated transverse aortic arch (ETA) with a kink in the lesser curvature (arrow). This kink has been called "pseudocoarctation" and is associated with risk for type B dissection. This patient also has a dilated origin of the left subclavian artery (*) and an aberrant origin of the right subclavian artery. The image on the right (**B**) shows a tortuous aortic arch with coarctation just below the take off of the left subclavian. There is moderate dilation of the ascending aorta and poststenotic dilation of the descending aorta as well. This image was obtained from a 41-year-old woman with long-standing hypertension who had been followed with cardiac echo over the years.

aorta as seen in Marfan syndrome, or whether there is a saltatory process,[182] perhaps associated with stressors such as motor vehicle accidents, high-resistance exercise, or pregnancy. Available evidence describes a small annual rate of dilation near the detection limit of current imaging methods.[183,184] Further studies are required to identify parameters that may be more useful in predicting imminent aortic decompensation, such as aortic wall thickness, compliance, or circulating markers such as brain natriuretic peptide (BNP).[185]

Beta-blockers and angiotensin receptor blockade have shown some efficacy in preventing aortic dilation in Marfan syndrome, but neither form of treatment has been investigated in cases of Turner syndrome. Children at increased risk for aortic dissection due to BAV and aortic dilation with or without hypertension and their families should be counseled about possible presenting symptoms (e.g., chest or back pain) and advised to wear a medical identification bracelet indicating the presence of aortic disease. This precaution is advised because delayed diagnosis is the most important cause of fatality in acute aortic dissection. Missed or delayed diagnosis is a major concern for girls and women with Turner syndrome, because the emergency department stereotype for aortic dissection is an adult male in his 60s.

For the patient with no identified cardiovascular defects after adequate cardiovascular evaluation and imaging, routine pediatric care with continued monitoring of blood pressure is advised. It seems also prudent to reevaluate aortic dimension at 5- to 10-year intervals. Heart-healthy moderate aerobic exercise is emphasized and should be encouraged. Eligibility for competitive sports for all those with Turner syndrome should be determined by a cardiologist after a comprehensive evaluation that includes magnetic resonance imaging (MRI) of the aorta.

Risk for Premature Atherosclerotic Disease

Epidemiologic analysis of registry data described a threefold increased risk of coronary and cerebrovascular disease among women with Turner syndrome in Denmark.[186] It was not determined from these data if the coronary disease and stroke were secondary to atherosclerosis or to underlying congenital cardiovascular disease. Adults with nonsyndromic aortic coarctation have increased risk of hypertension, coronary disease, and stroke—despite apparently successful coarctation repair.[140] Total cholesterol levels are elevated in untreated girls with Turner syndrome compared to age-matched females,[187] with improvement in metabolic profile in growth hormone–treated girls.[188] Atherogenic risk factors including abdominal adiposity and lipid profile are higher in women monosomic for the maternal X chromosome versus those with retained paternal X chromosome,[76] but they are not usually elevated into the atherogenic range.[172] Recommendations for preventing atherosclerosis apply equally to girls with Turner syndrome and the general pediatric population and include promoting a healthy lifestyle, monitoring blood pressure and obesity, and initiating metabolic screening by age 9 to 10 years.

Renal Anomalies

Renal abnormalities occur in 20% to 30% of girls with Turner syndrome[63,189] and include most commonly duplication of the pelvocaliceal collecting system, horseshoe kidney, and unilateral renal agenesis. The etiology of the renal anomalies is unknown. There seems to be no correlation between the renal anomalies and other features such as neck webbing or congenital heart defects.[190] The renal anomalies are typically associated with normal renal function during childhood, although pyelonephritis is a frequent complication of collecting system obstruction that requires surgical correction. It is currently recommended that all patients undergo ultrasound imaging of the urogenital system at diagnosis, and as needed in the case of urinary tract infections. Further studies are required to determine if the Turner renal anomalies are associated with deterioration in renal function or the development of proteinuria and hypertension during later life. Certainly renal function should be tested on a regular basis, and renal preservation is an ongoing medical concern for those with a horseshoe or single kidney.

Otologic Disorders

Perhaps the most common medical problem experienced by girls with Turner syndrome is bilateral otitis media. Anderson and coworkers[191] first described medically significant middle ear pathology in girls with Turner syndrome, with many recurrent episodes, spontaneous perforations, frequent need for surgical treatment, and significant hearing loss in about 25%. Additional studies confirmed the problem of recurrent often refractory otitis in Turner syndrome, usually associated with conductive hearing loss and correlated with karyotypes demonstrating loss of the X chromosome short arm, Xp.[61,192-194]

The chronic and severe otitis does not appear to be related to a specific or generalized immunologic dysfunction. Other types of infections and disorders of the mucous membranes do not occur with increased frequency in Turner syndrome. It seems rather that the frequent otitis may be the consequence of abnormalities in growth of the cranial base disturbing the relationship of the middle ear to the eustachian tube, which coupled with abnormalities in the shape of the palate create a predisposition to fluid collection and secondary infection.

Conductive hearing loss is most common and severe in children and is correlated with middle ear pathology,[61] whereas sensorineural hearing loss is more common in adults. This sensory defect is generally bilateral and characterized by symmetrical sensorineural dips in the audiogram in the midfrequency range (Figure 16-14). Thus, the sensorineural hearing deficit appears to progress over time and is not strictly a congenital abnormality. There remains a significant conductive component of hearing loss in adults with Turner syndrome that may signify an ongoing middle ear pathology.[61] The assiduous treatment of ear, nose, and throat (ENT) problems in childhood and avoiding potential injuries to the inner ear may reduce the risk of hearing loss.

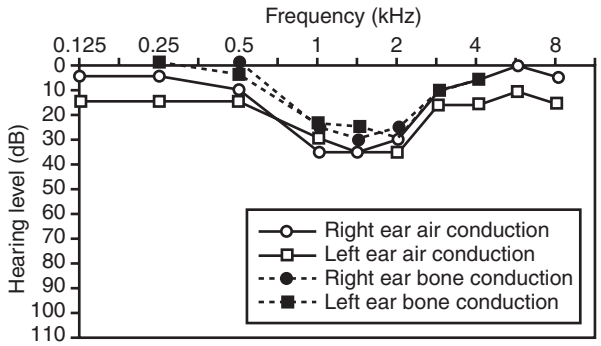

FIGURE 16-14 ■ Audiogram showing the typical dip with the peak of 35 dB in the 1.5-kHz frequency region in a 12-year-old girl with Turner syndrome (karyotype 45,X). This girl has no subjective hearing problems. (From Stenberg, A. E., Nylén, O., Windh, M., & Hultcrantz, M. (1998). Otological problems in children with Turner syndrome. *Hear Res, 124*, 85–90.)

Autoimmunity

Hashimoto lymphocytic thyroiditis is the most prevalent autoimmune disorder in Turner syndrome. Elevated titers of antithyroid antibodies (antithyroid peroxidase, antithyroglobulin) with or without hypothyroidism have been reported in as many as 50% of Turner patients, generally increasing with the patient's age.[120] This condition is most common in patients with the isoX chromosome,[195,196] but it is also prevalent in other karyotype groups.[197,198] The presence of elevated antibody titers may precede the appearance of hypothyroidism and may normalize after the onset of hypothyroidism. The most common finding is a positive antibody screen together with subclinical hypothyroidism with thyroid-stimulating hormone (TSH) mildly elevated and thyroxine levels within normal range.[197,198] The clinical picture of overt hypothyroidism in Turner syndrome may be different from the general population because it has been reported that even severely affected individuals may not show any signs or symptoms of the disease.[197] This, coupled with the high frequency, mandates periodic screening of all Turner syndrome patients.

Graves disease may also be slightly increased among girls with Turner syndrome.[199] In a longitudinal study, 24% of 84 children with Turner syndrome who were followed for about 8 years developed hypothyroidism and 2.5% developed hyperthyroidism.[200] Thyroid disease has been reported as early as 4 years[201]; therefore, all patients with Turner syndrome should be screened annually for autoimmune thyroid disease with a TSH and a free T4 level from 4 years of age onward. In the group of 84 girls followed longitudinally, two had vitiligo and three had alopecia. Other forms of autoimmunity such as Addison disease, hypoparathyroidism, and pernicious anemia are not increased in frequency in Turner syndrome. An association of juvenile rheumatoid arthritis and Turner syndrome was reported by Zulian and colleagues.[202] They surveyed 28 pediatric rheumatology centers and identified 18 girls with Turner syndrome among 15,000 juvenile rheumatoid arthritis patients, which they calculated represents a sixfold increase over what would be expected. A comprehensive clinical and immunologic evaluation of 204 adults with Turner syndrome at the NIH found a significantly higher prevalence of Hashimoto thyroiditis (37%), celiac disease (2.7%), and inflammatory bowel disease (4%) in the Turner group compared to age-matched women with karyotypically normal premature ovarian failure, and to the general female population.[198] There was a trend toward increased Graves disease (2.7%) and psoriasis (3.1%) but no evidence of higher rates of rheumatoid arthritis or any other autoimmune or inflammatory conditions.

Gastrointestinal Disorders

Liver Disease

Minor elevations of hepatic aminotransferases are common in girls and women with Turner syndrome, usually in the absence of signs or symptoms of liver disease. Approximately 20% to 25% of girls[203] and 40% of women[204] demonstrate abnormal liver function tests including aspartate-, alanine-, and gammaglutamyl-transferases and, less commonly, alkaline phosphatase. In some cases, liver enzyme elevations may be associated with pharmacologic estrogen, progestin, or oxandrolone treatments,[203,205] but over the long term estrogen treatment is associated with normalization of hepatic enzymes.[204] Among 100 girls from age 7 to 17 evaluated in the NIH natural history study between 2002-2007, 27% had modest transaminase elevation (see Table 16-1) that was not correlated with growth hormone (GH) or estrogen use, nor with fatty infiltration observed on liver ultrasound.[63] Aside from a rare case report, there does not seem to be any association between autoimmunity and hepatic abnormalities. Liver biopsies in adults with typical enzyme abnormalities have not consistently defined any unique or diagnostic pathology in women with Turner syndrome.[206] Roulot and coworkers have suggested the hepatic disorder may be linked to intrinsic vascular disease. Gravholt and colleagues reported an increased frequency (relative risk 5.7, CI 1.55 to 14.56) of cirrhosis in a Danish National Health registry study, but this has not been observed in clinical series on health in patients with Turner syndrome.

Gastrointestinal Bleeding

A number of reports have called attention to gastrointestinal bleeding occurring in patients with Turner syndrome.[207,208] The bleeding has been ascribed to intestinal telangiectasia, hemangiomatoses, or dilated veins and venules. It is not known which patients may be at risk for developing vascular bleeding, or whether these vascular abnormalities are a consequence of the same obstructive processes that result in the lymphedema. Management of these cases may be extremely difficult; a conservative approach is advised to avoid extensive bowel resections. These patients may require transfusions to maintain a normal hemoglobin concentration. Estrogen treatment may be problematic in such individuals, and treatment has to be individualized.[209,210]

Inflammatory Bowel Disease

As noted previously under "Autoimmunity," girls and women with Turner syndrome have increased risk for Crohn disease and ulcerative colitis.[211-215] Because growth retardation and delayed sexual maturation are characteristic manifestations of inflammatory bowel disease and of Turner syndrome, careful attention must be paid to the review of systems in these patients. Conversely, short girls with inflammatory bowel disease and growth and pubertal delay may need an assessment of gonadal function (measurement of gonadotropins) before their sexual delay is ascribed to their bowel disease alone. The prevalence of celiac disease is also increased in patients with Turner syndrome.[216-218] Considering that growth failure and pubertal delay can be manifestations of celiac disease and Turner syndrome, consideration has to be given to testing short girls with celiac disease with or without pubertal delay (especially if they are on dietary management and have not had catch-up growth) for Turner syndrome. Turner syndrome girls should be screened by measurement of tissue transglutaminase IgA antibodies beginning at age 4 years and repeated every 2 to 5 years.[219,220]

Carbohydrate Intolerance

Carbohydrate intolerance among patients with Turner syndrome was demonstrated in 1963 by Ann Forbes and colleagues at the Massachusetts General Endocrine Clinic.[221] The high rate of glucose intolerance was confirmed repeatedly, but the etiology of the metabolic defect has remained unclear over the years; early studies described insulin deficiency[222] and insulin resistance.[223] A survey of Danish health registry data reported an increased incidence of both type 1 and type 2 diabetes in Turner syndrome,[121] but a higher than usual rate of type 1 has not been observed in other countries or in clinical studies. Clinical studies have consistently shown hyperglycemia in response to glucose challenge with variable insulin responses, and most patients are not insulin dependent or ketosis prone. Elucidation of the metabolic etiology of Turner glucose intolerance has been hampered by the absence of appropriate control groups, as girls and women with Turner syndrome usually have greater adiposity and less exposure to natural ovarian hormones compared to age-matched females, and many use pharmacologic steroids or growth hormone that alter metabolic responses. Another confounding factor is that individuals with a maternally derived X chromosome have excess visceral adiposity whereas those with a paternally derived X appear to have a more beneficial fat distribution,[76] but the two genotypes are routinely lumped together in metabolic studies.

A small study assessed insulin sensitivity via the euglycemic insulin clamp technique in girls with Turner syndrome compared to age but not gender- or body mass index (BMI)–matched controls and found reduced insulin sensitivity in Turner girls.[224] Most recent data generally suggest that glucose intolerance in Turner syndrome is due to insulin deficiency rather than insensitivity,[225-227] although one report noted insulin resistance associated with obesity.[228] The NIH study compared nonobese women with Turner syndrome to age-matched women with 46,XX premature ovarian failure, with both groups off hormone replacement for 2 weeks prior and during the study.[229] Fasting glucose levels were normal in both groups, but glucose levels after oral and IV glucose challenges were significantly higher while fasting and glucose stimulated insulin levels were lower in the Turner group, suggesting that impaired insulin secretion rather than insulin resistance contributes to the risk for diabetes in Turner syndrome.

Of 400 participants evaluated during the NIH study 2001-2010, only one had type 1 diabetes.[230] Type 2 diabetes was not found in any children but was present in 25% of the adults in that study. Interestingly, diabetes was more than twice as frequent among women with an isoXq chromosome compared to those with pure 45,X or with Xp deletion.[230] A cross-sectional cohort study found that girls with Turner syndrome have reduced beta cell function associated with impaired glucose tolerance, and despite greater adiposity and blood pressure, they have normal insulin sensitivity.[231] Thus, it seems that many girls and women with Turner syndrome do not exhibit the typical insulin resistance associated with excess fat in non-Turner individuals.[232]

Neuropsychological Features

The consensus regarding the currently available evidence is that the intelligence of persons with Turner syndrome is normal and girls are similar to their siblings in overall intelligence. Mental retardation has been reported in several cases that were ascertained based on a severe neurodevelopmental phenotype without features typical of Turner syndrome, found to have a ring X chromosome.[40,233-236] It appears that a high risk of mental retardation is caused by the failed inactivation of the ring X from loss of the X inactivation center—thus creating disomy for unknown, normally X-inactivated genes.

Whereas most individuals with Turner syndrome have normal overall intelligence and verbal skills, many have selective impairments in visual-spatial information processing, arithmetic skills, and the coordination of motor and visual-perceptual skills[237-239] coupled in some with a degree of hyperactivity.[240] The discrepancy between verbal and performance IQ is confirmed by many studies and may range between 10 and 15 points—with verbal being higher than performance.[237-239,241-243]

The parental origin of the single normal X chromosome has been implicated in some aspects of the neurocognitive phenotype. Skuse and associates investigated 80 females with Turner syndrome, of whom 25 (the expected proportion) had an X chromosome of paternal origin (Xp). These girls showed satisfactory social adjustment and had higher verbal and executive functional skills than the larger group of girls with the retained X chromosome of maternal origin (Xm).[66]

In an extension of these studies, the Skuse group investigated the relationship of verbal and nonverbal memory with origin of the X chromosome.[244] They observed that 45,Xp Turner females matched controls in verbal memory, whereas this was not the case in the

45,Xm females. In contrast, the results of 45,Xm patients matched those of controls in visual-spatial memory tests, but the 45,Xp group did not. The authors concluded that these data indicate an imprinted locus for social cognition on the X chromosome that is silenced on the maternally derived X. This defect in social cognition may translate into difficulties or lack of understanding of social and nonverbal cues and risk for autism spectrum disorders. The X chromosome parental origin has not been correlated with cognitive or behavioral phenotype in more recent studies,[245-248] although brain size has been correlated with the maternal X chromosome.[68]

The role of estrogen deficiency and estrogen replacement therapy also needs to be considered in the context of organic causes for the cognitive, social, and functional profiles of girls and women with Turner syndrome. Indeed, estrogen replacement appears to enhance motor speed, nonverbal processing, and memory in estrogen-treated Turner syndrome patients compared with placebo-treated patients.[249,250]

The risk for psychiatric illness was systematically investigated in 100 women participating in the NIH natural history study between 2001 and 2003.[251] The incidence of major depression was 5% and that of anxiety disorder was 8%. Women with Turner syndrome reported a higher rate of lifetime depression compared with rates observed in community-based studies but similar to those obtained from gynecologic clinic samples. Affective symptoms among this group of 100 women were prospectively compared to age-matched women with karyotypically normal premature ovarian failure.[247] The two ovarian failure groups had similar levels of shyness and social anxiety that were higher than normal cycling controls, and similar levels of self-esteem that were lower than controls, suggesting that the experience of ovarian failure contributes to the neuropsychological profile of girls and women with Turner syndrome. The first systematic investigation of the personality of girls and women with Turner syndrome was conducted in the 1970s.[252] This and subsequent studies indicate that individuals with Turner syndrome had a high stress tolerance, a tendency toward overcompliance, and a higher degree of dependence and limitations in emotional competence.[240,253,254] Most women with Turner syndrome have a typically female pattern of psychosocial development with unambiguous female gender identification.[255] There may be a delayed sexual debut,[256,257] but sexual fantasies are similar in nature and frequency to average women and sexual activity among Turner women that are married is also similar to that reported by the general female population.[258]

Medical Management

Once the diagnosis of Turner syndrome has been established and a chromosomal confirmation established, additional diagnostic procedures are indicated. These diagnosis and management strategies have been published as recommendations from consensus workshops.[78]

Initial and Follow-up Evaluation

Screening studies at the time of diagnosis and ongoing monitoring for age groups are summarized in Boxes 16-1 and 16-2. All newly diagnosed patients require a thorough cardiovascular evaluation as described previously in this chapter (Box 16-3). Blood pressure should be measured in all four extremities, and 24-hour ambulatory monitoring may be helpful in detecting nocturnal hypertension in girls. Routine renal ultrasound may detect structural abnormalities in renal architecture or collecting system anatomy. If no abnormalities are present, follow-up studies are not routinely indicated. If significant abnormalities are detected, follow-up evaluation and therapy may be indicated and long-term screening for urinary tract infection may be necessary. Scoliosis and kyphosis are evaluated at diagnosis and during growth. If noted, the degree and cause of scoliosis should be determined radiographically.

Otologic and ophthalmologic consultations should begin by age 2 to 3 years and continue as clinically indicated. Otitis media is extremely common and should be treated vigorously. Myringotomy and polyethylene tube placement are considered the primary modes of therapy

BOX 16-1 Screening at Diagnosis of Turner Syndrome in Children and Adults

All Patients
- Cardiovascular evaluation by specialist*
- Renal ultrasound
- Hearing evaluation by an audiologist
- Evaluation for scoliosis/kyphosis
- Evaluation for knowledge of Turner syndrome; referral to support groups
- Evaluation for growth and pubertal development

Ages 0-4 Years
- Evaluation for hip dislocation
- Eye exam by pediatric ophthalmologist (if age ≥ 1)

Ages 4-10 Years
- Thyroid function tests (T_4, TSH) and celiac screen (TTG Ab)
- Educational/psychosocial evaluation
- Orthodontic evaluation (if age ≥ 7)

Ages ≥ 10 Years
- Thyroid function tests (T_4, TSH) and celiac screen (TTG Ab)
- Educational and psychosocial evaluations
- Orthodontic evaluation
- Evaluation of ovarian function/estrogen replacement
- LFTs, FBG, lipids, CBC, Cr, BUN
- BMD (if age 18)

*See Box 16-3.

BMD, bone mineral density; BUN, blood urea nitrogen; CBC, complete blood count; Cr, creatinine; FBG, fasting blood glucose; LFTs, liver function tests.

From Bondy, C. A., for the Turner Syndrome Study Group (2007). Care of girls and women with Turner syndrome. J Clin Endocrinol Metab, 92, *10–25.*

BOX 16-2 Ongoing Monitoring in Turner Syndrome

All Ages
- Cardiology evaluation as indicated*
- Blood pressure annually; consider 24-hour monitor
- ENT and audiology every 1 to 5 years

Girls > 5 Years
- Social skills at age 4 to 5 years

School Age
- Liver and thyroid screening annually
- Celiac screen every 2 to 5 years
- Educational and social progress annually
- Dental and orthodontic as needed

Older Girls and Adults
- Fasting lipids and blood sugar annually
- Liver and thyroid screening annually
- Celiac screen as indicated
- Age-appropriate evaluation of pubertal development and psychosexual adjustment

*See Box 16-3.

From Bondy, C. A., for the Turner Syndrome Study Group (2007). Care of girls and women with Turner syndrome. J Clin Endocrinol Metab, 92, *10–25.*

BOX 16-3 Cardiovascular Screening and Monitoring Algorithm for Girls and Women with Turner Syndrome

Screening (All Patients at Time of Diagnosis)
- Evaluation by cardiologist with expertise in congenital heart disease
- Comprehensive exam, including blood pressure in all extremities
- All require clear imaging of heart, aortic valve, aortic arch, and pulmonary veins
- Echocardiography is usually adequate for infants and young girls
- MRI and echo for older girls and adults
- ECG

Monitoring (Follow-up Depends on Clinical Situation)
- Patients with apparently normal cardiovascular system and blood pressure need reevaluation with imaging at timely occasions (e.g., at transition to adult clinic), before attempting pregnancy, or with appearance of hypertension; girls who have only had echocardiography should undergo MRI when old enough to cooperate with the procedure
- For asymptomatic adults, imaging every 5 to 10 years
- For patients with cardiovascular pathology, treatment and monitoring determined by the cardiologist

From Bondy, C. A., for the Turner Syndrome Study Group (2007). Care of girls and women with Turner syndrome. J Clin Endocrinol Metab, 92, *10–25.*

for serous otitis media in Turner syndrome. The high prevalence of hearing loss, either primary or secondary to residual serous otitis media, mandates that regular ENT evaluation with audiometry is needed for most patients. In infancy, feeding techniques such as those used for cleft palate patients may also be indicated. Because abnormalities in speech may be a consequence of a palatal deformity, speech evaluation may also be indicated. Orthodontic evaluation is needed for most girls by age seven, as the narrow palate and small jaw cause malocclusion and crowded dentition frequently requiring orthodontic treatment.

Ophthalmologic abnormalities including ptosis, strabismus, and amblyopia, are common and require pediatric eye consultation. X-linked red-green color deficiency is present in 8% of girls with Turner syndrome, a percentage similar to that found in males.

Screening for autoimmune thyroid and celiac diseases begins at age 4 and includes thyroxine, thyroid-stimulating hormone, antithyroid antibodies, and tissue transglutaminase antibodies. Subsequently, thyroxine and thyroid-stimulating hormone or thyroid-stimulating hormone alone should be determined at 1- to 2-year intervals. Celiac screen is usually repeated every few years or as indicated by sign or symptoms. Metabolic screening including liver function tests, renal function tests, fasting glucose, or hemoglobin A1c and lipids should commence at about age 10 or earlier in the context of excess adiposity or obesity.

Hypertension is common in Turner syndrome, and blood pressure should be measured at each visit. In addition, 24-hour ambulatory monitoring is ideal for detecting nocturnal or stress-related hypertensive episodes that may support the introduction of antihypertensive treatment.

The decision to seek consultation for plastic surgery to correct the webbed neck deformity or the forwardly displaced ears is individual. It must be pointed out to the patient and family that in addition to the webbing the neck may also be short. Therefore, cosmetic surgery may be somewhat disappointing. In some cases, however, satisfactory results are achieved.

If, or when, psychometric testing should be performed is an individual family decision. Nevertheless, a preschool evaluation to rule out major areas of cognitive dysfunction might be advisable. In light of the previous discussion, school performance should be monitored—and specific problems should be attended to with skilled cognitive specialists. Girls with hearing loss will benefit from preferential seating in the classroom, and those with attention deficit disorder (ADD) may benefit from untimed testing in school when appropriate. The Turner Syndrome Society of the United States (www.turnersyndrome.org) is an excellent resource.

Y Chromosome

As noted earlier in this chapter, the peripheral blood karyotype demonstrating Y chromosome material in a girl with Turner syndrome indicates a risk for development of gonadoblastoma. Pelvic ultrasound may demonstrate an adnexal mass (Figure 16-15), in which case

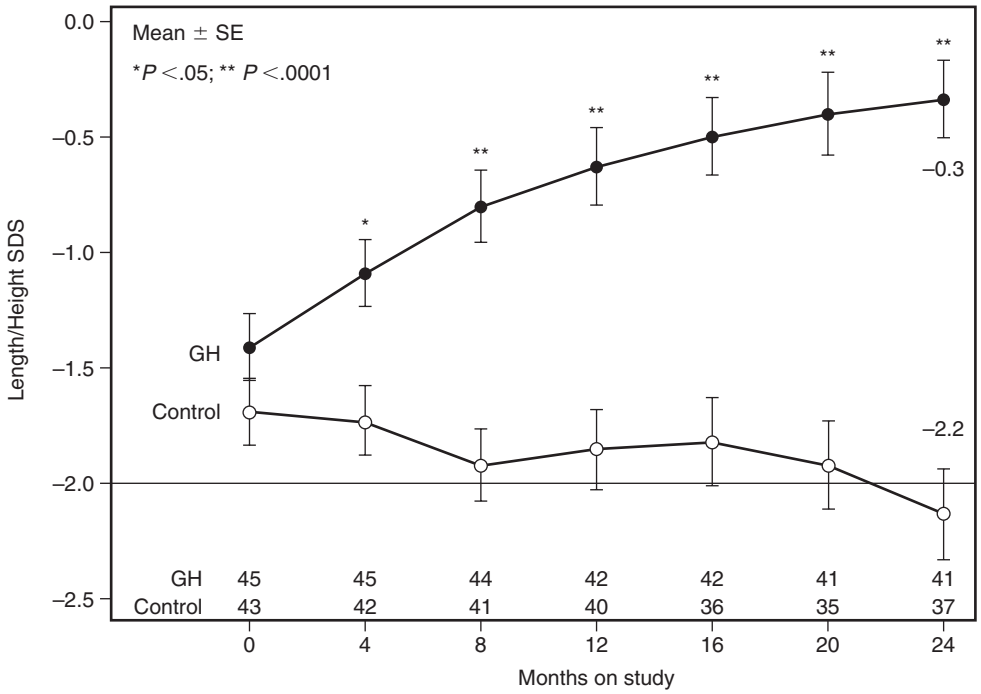

FIGURE 16-15 ■ GH treatment of toddlers with Turner syndrome. Length/height SDS for the untreated control group (open symbols) and the growth hormone treatment group (filled symbols) during the 2-year study. Between-group difference at end point was 1.6 + 0.6 SDS ($p < 0.0001$). Mean age at baseline was 24 + 12.1 months. (From Davenport, M. L., Crowe, B. J., Travers, S. H., et al. [2000]. Growth hormone treatment of early growth failure in toddlers with Turner syndrome: a randomized, controlled, multicenter trial. *JCEM*, *92*, 3406–3416, Figure 1.)

surgical removal of the bilateral adnexal structures is indicated. If pelvic imaging is negative and there is no evidence of virilization, the patient and family must be educated and counseled about the pros and cons of prophylactic gonadectomy versus monitoring by pelvic ultrasound. As discussed in the section on ovarian function, the uncertain risk for a gonadoblastoma that transforms into a malignant tumor must be weighed against possible spontaneous puberty and potential fertility. Cryopreservation of ovarian tissue should be offered if available.

Growth Hormone

In the 1990s, recombinant human growth hormone (GH) was shown to increase growth velocity and final adult height for girls with Turner syndrome. Rosenfeld and coworkers demonstrated a gain in height compared to historical controls,[259] and Sas and colleagues showed a clear dose-response effect with increasing GH doses associated with increasing height.[260] The first randomized study with an untreated contemporaneous control group showed that adult height was increased by about 7.3 cm after an average duration of 5.7 years of treatment, at a dose of 0.3/mg/kg/week,[261] which is lower than the current recommended dose of 0.375 mg/kg/week. Very young girls 9 months to 4 years of age treated with GH maintained normal growth rate compared to untreated Turner controls (Figure 16-16).[262] The results of a randomized, double-blind, placebo-controlled study begun at the NIH in 1987 showed an average gain in adult height of 3 cm with GH alone and 5 cm with GH combined with prepubertal treatment with ultra-low-dose ethinyl estradiol.[263] The ethinyl estradiol dose for girls younger than 12 in the NIH study was less than 1 μg/day, compared with 20 μg in the low-dose birth control pill. These findings are consistent with a growth promoting effect of low, nonfeminizing estradiol levels in the prepubertal years. The growth-enhancing effects of low-dose estradiol are in contrast to the growth-inhibiting effect of feminizing doses of estrogen used to induce pubertal development,[264] which is associated with epiphysial fusion. Ranke and colleagues analyzed height prediction for GH treatment in Turner syndrome.[265] Height at the start of treatment, GH dose, and duration of treatment are identified as important predictive factors.

GH treatment has been evaluated for safety in a group of approximately 5000 girls with Turner syndrome followed for 10 to 20 years in the Genentech National Cooperative Growth Study.[266] An increased frequency of intracranial hypertension (pseudotumor cerebri), scoliosis, and slipped epiphyses was noted, as well as an unexpected higher incidence in the diagnosis of type 1 diabetes. On the beneficial side, GH treatment tends to normalize body proportions, although foot size is disproportionately enlarged.[267] GH treatment has beneficial effects on body composition, as shown in a comparison of age-matched girls who have never received GH (n = 26) to girls treated with GH (N = 76) participating in the NIH natural history study. BMI and visceral adiposity were significantly greater and glucose tolerance significantly worse in the untreated group (off GH treatment for 2 weeks prior to and during the study), with effects apparent years after the discontinuation of therapy.[188]

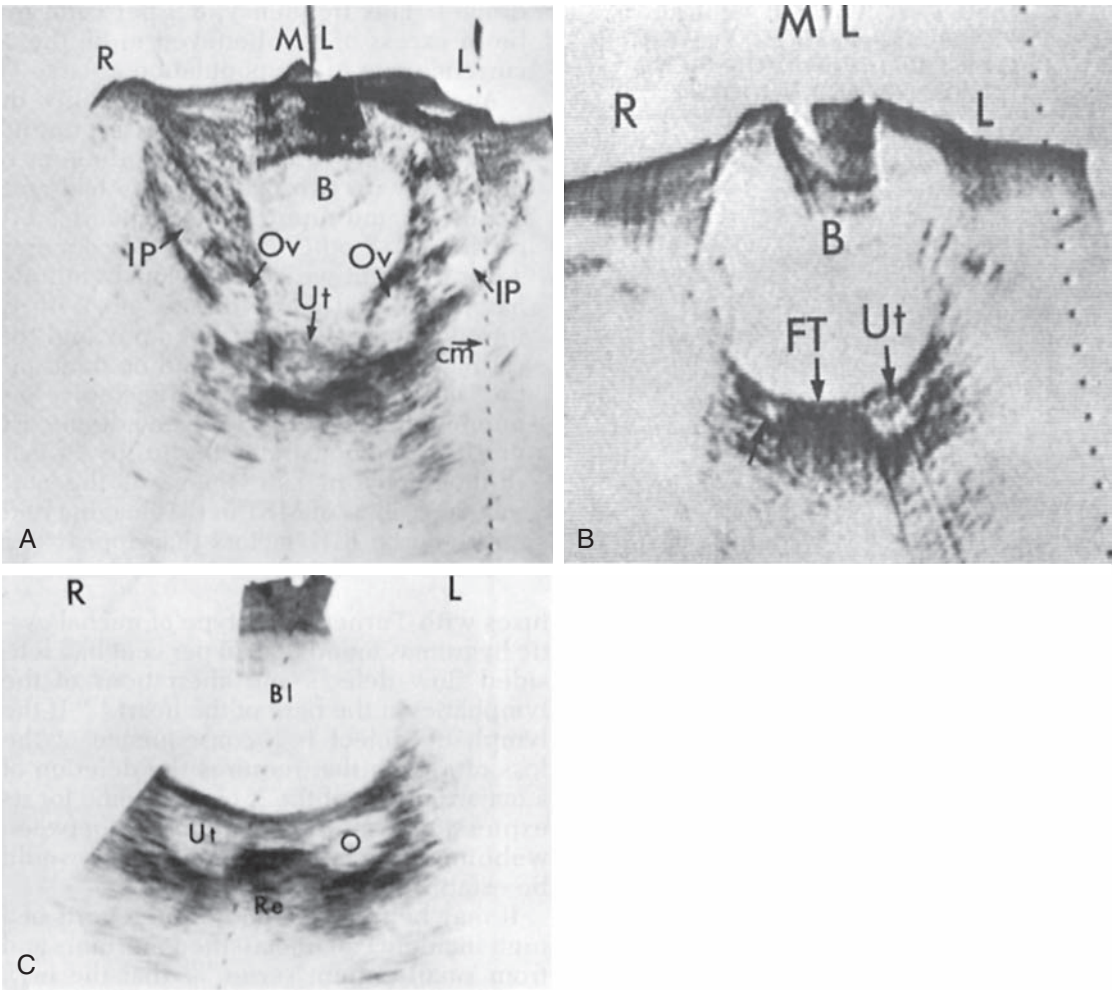

FIGURE 16-16 ■ Examples of pelvic ultrasound studies. **A**, Normal pubertal female demonstrating ovaries of adult size. **B,** Patient with Turner syndrome. The corpus of the uterus is seen slightly to the left of the midline. The fallopian tube can be followed into the right adnexa and observed to terminate in a small structure (arrow) believed to be the fimbriated end of the tube. No ovaries are identified. **C**, Patient with 45,X/46,XY Turner syndrome previously treated with estrogen. The corpus of the uterus is enlarged to adult size. In the left adnexa, a large gonadal mass (O) is seen. Histologically, this was identified as a gonadoblastoma. The images are transverse, oriented right (R) and left (L) of the midline (ML). The dotted scales are in centimeters. **B,** BL, bladder; FT, fallopian tube; IP, iliopsoas; O, gonadoblastoma; OV, ovary; Re, rectum; and Ut, uterus.

GH treatment seems to have no adverse effects on the cardiovascular system over short term follow-up, with body size adjusted ventricular and aortic dimensions similar in treated and untreated patients.[268,269] Moreover, systemic lipids and aortic compliance were relatively better in girls treated with high-dose GH. A comparison of cortical and trabecular bone in GH-treated and age-matched untreated controls with Turner syndrome reveals no apparent effect of GH treatment on bone mineral density.[98]

Late diagnosis of Turner syndrome in girls age 10 and older is a common problem (see Figure 16-4) that compromises attainment of optimal adult stature. In the past, such girls were treated with GH for several years and induction of puberty delayed to age 15 or older. Such a delay of puberty is now viewed as detrimental to social and sexual development and may impair optimal bone mineralization. Statural growth in these girls may be increased by treatment with the nonaromatizable androgen oxandrolone at a dose of 0.05mg/kg/day or less, in addition to GH, which may augment growth by up to 4 cm, usually without virilizing effects.[270,271] Oxandrolone is also used to enhance stature when GH is not available, but patients and families must be warned about potential adverse metabolic effects and diminution of breast development associated with androgen treatment.

GH treatment usually begins at the standard recommended dose of 0.05 mg/kg/day, with close monitoring for height velocity, IGF1 level, and potential adverse effects of intracranial hypertension, scoliosis, and slipped capital epiphyses. Treatment for 3 to 4 years is usually required to experience significant height gain and is discontinued when the target height is attained, when bone age is greater than 14 years, or when growth velocity is less than 1.5 cm per year. It is important to keep in mind that the safety data for GH in Turner syndrome represent intermediate range follow-up of girls in whom treatment

was typically initiated in mid-childhood and continued for several years at the preceding dosage. Although reaching an adult height of 5 feet or greater seems desirable from many points of view, there are as yet no proven medical or psychosocial benefits to this pharmacologic achievement, and hence safety should never be compromised to this end.

Puberty

As noted earlier, spontaneous puberty develops in 10% to 30% of girls with Turner syndrome. The higher rate applies mainly to girls with mosaicism for cells with more than one X chromosome, but a significant number of girls with less favorable chromosomal constitutions will also start puberty on their own. Aside from karyotype, the major indicators of potential natural pubertal onset are normal-range values for FSH and anti-Mullerian hormone (AMH) (Figures 16-17 and 16-18). AMH may be particularly informative, because hormone levels directly reflect the presence of developing ovarian follicles and hence potential fertility.[272] Pelvic ultrasound may be helpful, although failure to visualize ovarian tissue does not preclude the presence of follicles. Patients and families are often very interested in potential fertility, and the clinician needs to have this information to provide counseling about reproductive options (discussed later). In most girls over the age of 10, FSH will have elevated into the menopausal range, and AMH will be undetectable with pelvic ultrasound showing no evidence of ovaries and an immature uterus; these patients will need pubertal induction and maintenance estrogen/progestin treatment.

The aim of estrogen treatment in Turner syndrome is to mimic the beneficial effects of endogenous estrogen in breast and genital development, healthy fat distribution, and bone mineralization, while minimizing the risk for estrogen-associated gynecologic cancers and thrombogenic

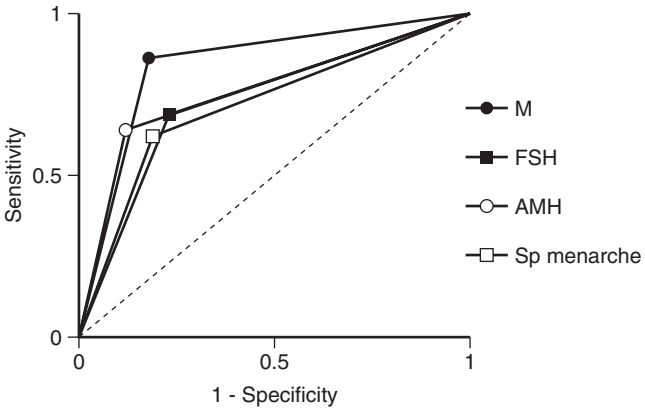

FIGURE 16-17 ■ Receiver operating characteristic curves showing the relationship between sensitivity and specificity regarding the four investigated variables with the highest sensitivity. (From Borgström, B., Hreinsson, J., Rasmussen, C., et al. (2009). Fertility preservation in girls with Turner syndrome: prognostic signs of the presence of ovarian follicles. *J Clin Endocrinol Metab, 94*, 74–80. Erratum in *J Clin Endocrinol Metab, 94*, 1478, Figure 2.)

complications. In the past, the choice for estrogen treatment was limited to metabolized estrogens purified from pregnant mare urine (conjugated equine estrogens [CEE], "Premarin"), and the highly potent, synthetic ethinyl estradiol (EE2). In recent years, transdermal patches containing the natural ovarian product, 17-beta estradiol, have become available and are the preferred delivery method. In addition to replicating the molecular action of the ovary's natural hormone, this formulation is directly absorbed into the venous circulation, bypassing first pass hepatic effects associated with excessive production of prothrombotic proteins. Moreover, the administration of transdermal estradiol allows measurement of estradiol levels in the circulation, which may be helpful for monitoring for adherence. Because estradiol levels vary widely throughout the monthly cycles in eugonadal females, target estradiol levels in pharmacologic treatment are not known. In sexually mature girls, the average daily ovarian estradiol production over the monthly cycle is 100 μg/day, which is approximated by transdermal patches delivering 100 μg/day. Physiologic estradiol repletion is not expected to normalize the FSH level, because FSH secretion is jointly regulated by estrogen and other ovarian products such as the inhibins. Thus, suppression of FSH is not a measure of adequate estrogen therapy.

Current recommendations for estrogen treatment for the induction of puberty suggest beginning the therapy at age 12 for most girls.[126] The suggested doses and rate of escalation are outlined in Table 16-3. The aim of treatment is to initiate development with the lowest possible dose so that sexual maturation will begin on par with peers, while avoiding premature fusion of the epiphyses that would limit growth in stature. Thus, breast development and bone age are evaluated at ~6-month intervals during estrogen treatment for pubertal induction. A sufficient phase of "unopposed" estrogen exposure is required for optimal breast development, and androgen or progesterone treatments may inhibit optimal development. Thus, oxandrolone should be discontinued prior to the initiation of estrogen treatment, and progestins should not be initiated until breast development is satisfactory. Some girls with prominent stigmata of fetal lymphedema may have damaged breast anlage and demonstrate minimal development in response to estrogen. These girls may benefit from breast implantation surgery, if so inclined.

Progestin treatment is necessary to suppress estrogen's proliferative effect on the uterine endometrium and should be introduced after 2 years of unopposed estrogen treatment, or sooner if breakthrough bleeding occurs. This recommendation is given because chronic exposure to estrogen treatment, in the absence of progestin effect, leads to endometrial hyperplasia and risk for hemorrhage and neoplasia. The most physiologic form of progestin is progesterone, which is available in micronized form for oral administration and in cream and gel form. Regrettably, there have been no controlled studies to establish the most effective form of estrogen/progestin treatment for girls with Turner syndrome. The accepted dose of oral micronized progesterone proven to protect the uterus is 200 mg taken at bedtime for the last 10 to 12 days of a monthly cycle, or the last 20 to 30 days of a trimonthly cycle. Progesterone is a soporific and hence

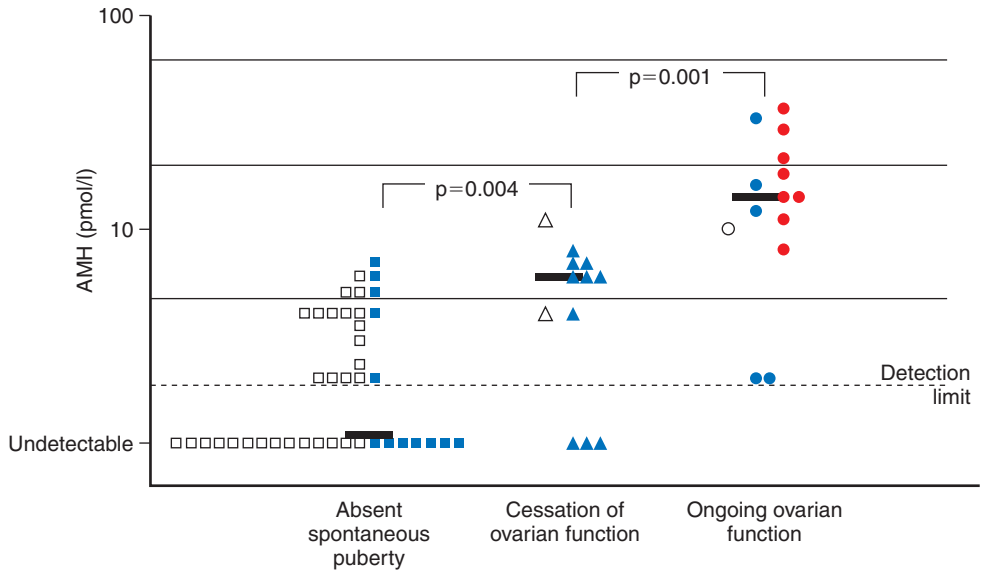

FIGURE 16-18 ■ AMH levels and ovarian function at time of AMH measurement in patients with Turner syndrome, aged 12 to 25 years. Dotted line represents the detection limit of the assay; squares represent patients with absent puberty; triangles represent patients with cessation of ovarian function; circles represent patients with ongoing ovarian function. Thick black bars, median of AMH; black, patients with 45,X; blue, miscellaneous karyotypes; red, 45,X/46,XX. (From Hagen, C. P., Aksglaede, L., Sørensen, K., et al. (2010). Serum levels of anti-Müllerian hormone as a marker of ovarian function in 926 healthy females from birth to adulthood and in 172 Turner syndrome patients. *J Clin Endocrinol Metab, 95*, 5003–5010. TABLE 16-3 **Ovarian Hormone Replacement Treatment in Turner Syndrome**

Age (in years)	Age-Specific Suggestions	Comments
10-11	Monitor for spontaneous puberty by Tanner staging, AMH and FSH levels	Low-dose estrogen treatment may not inhibit GH-enhanced growth in stature
12-13	If no spontaneous development and FSH elevated, begin low dose E2	Equivalent initial E2 doses: depot (im) E2, 0.2-0.4 mg/month; transdermal E2, 6.25 μg daily*; micronized E2, 0.25 mg daily by mouth
12.5-15	Gradually increase E2 dose over about 2 years (e.g., 14, 25, 37, 50, 75, 100, 200 μg daily via patch) to adult dose	Usual adult daily dose is 100 μg transdermal E2, 2 mg micronized E2, 20 μg EE2, 1.25 mg CEE
14-16	Begin cyclic progesterone treatment after 2 years of estrogen or when breakthrough bleeding occurs	Oral micronized progesterone best option at present; usual adult dose is 200 mg/day on days 20-30 of monthly cycle or days 100-120 of 3-month cycle
14-30	Continue full doses at least until age 30 because normally estrogen levels are highest between age 15 and 30 years	Some women may prefer using oral or transdermal contraceptive for HRT; monitor endometrial thickness
30-50	The lowest estrogen dose providing full protection versus osteoporosis is 0.625 CEE or equivalent	Monitor osteoporosis risk factors, diet, exercise; obtain BMD and begin regular screening mammography by age 45 years
> 50	Decision on estrogen use based on same considerations as for other postmenopausal women	New HRT options are appearing, and these recommendations may need updating in the near future

*The lowest-dose commercially available, E2 transdermal patches deliver 14 and 25 μg daily; it is not established whether various means of dose fractionation (e.g., administering a quarter patch as directed, or administering whole patches for 7 to 10 days per month) are equivalent.

CEE, conjugated equine estrogens; E2, estradiol; EE2, ethinyl estradiol; HRT, hormone replacement treatment.

the bedtime administration. The efficacy of topical progesterone in preventing uterine hyperplasia is unknown. More androgenic, synthetic progestins such as medroxyprogesterone or norethindrone may inhibit optimal breast and uterine development and have unfavorable metabolic effects in some individuals, although these agents are effective in endometrial protection.

Patients and families must be educated as to the importance of this physiologic hormone treatment regimen for healthy growth and development, especially with regard to building and maintaining strong bones. Discontinuation of hormone therapy during young adulthood is all too common and may result in irreversible loss of bone mineral especially in the spine, leading to

height loss, kyphosis, and chronic pain and disability (Figure 16-19). Families may have legitimate concerns about risks of heart disease and cancer associated with hormone replacement therapy, and it must be explained that these adverse effects were observed in postmenopausal women receiving less physiologic forms of treatment. It is also important to discuss "natural" hormones that are widely touted on women's health sites as alternatives to standard treatments, underlining the fact that these products are not known to be effective or safe. Many older girls and young women may prefer taking oral or transdermal contraceptive formulations for reasons of convenience, tolerability, or financial concerns. Although these are not the most physiologic choices and have greater thrombogenic risk, estrogen/progestin contraceptive formulations are effective in maintaining bone mineralization and protecting the uterus.

It is important to point out that spontaneous puberty, even with menses that appear cyclic, does not always mean that normal ovulatory cycles are occurring or will continue to occur. Some girls have anovulatory cycles that do not achieve normal endometrial maturation and predispose to endometrial hyperplasia, dysfunctional bleeding, or cancer. Irregular cycles may lead to discontinuation of treatment in many cases. Every effort should be made to educate patients and parents as to the importance of continuing hormone replacement, with openness to consultation with experts in adolescent gynecology and adoption of alternative regimens such as oral contraceptive treatment that may ensure continued adherence. Girls with irregular cycles may still have an occasional ovulatory cycle and, if sexually active, are at risk for unplanned pregnancy. For these girls, contraceptive formulations may the best choice for hormone therapy.

Hormone treatment requires regular breast examinations, and patients should be instructed about monthly self-examination. Girls who become sexually active need regular gynecologic follow-up with annual pelvic exams and Pap tests. Regular discussion of issues of concern related to sexual maturation and counseling on the need for ongoing hormone treatment to maintain strong bones will be of paramount importance. There is no need to measure bone mineral density during childhood or adolescence unless there is unusual clinical concern—for example, a low-impact or atraumatic fracture. Short stature is associated with underestimation of bone mineral density obtained by DXA and results need to be normalized for bone size.[273] Size-adjusted vertebral bone mineral density is usually normal in adults with Turner syndrome that have received routine hormone replacement treatment, but it may decline dramatically with discontinuation of treatment (see Figure 16-19).[274] Bone mineral density of the hip and wrist is often lower than normal, reflecting a selective reduction in cortical bone that is not sensitive to estrogen[275] but may reflect the SHOX defect in bone.

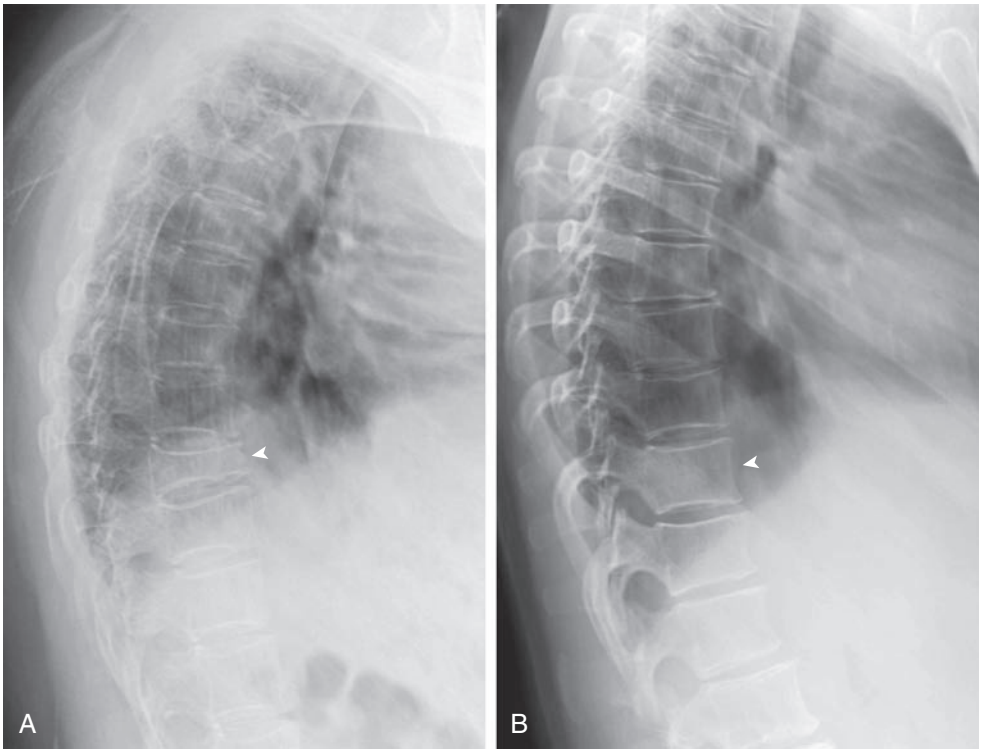

FIGURE 16-19 ■ Estrogen treatment prevents osteoporosis. These lateral chest x-rays are from two 30-year-old women with Turner syndrome. Both had a karyotype of 45,X, both received GH treatment for several years during childhood, and both were started on estrogen treatment at age 12. One patient stopped taking estrogen at age 18 (**A**), and the other adhered to treatment (**B**). The woman who discontinued estrogen treatment experienced height loss, dorsal kyphosis, and chronic pain due to collapse and wedging of vertebral bodies. The arrowhead points to T12 in each woman.

Reproductive Options

As discussed in the "Ovarian Insufficiency" section, about 2% of women with Turner syndrome may have spontaneous pregnancies. Assisted reproduction using donor oocytes with in vitro fertilization has been successful when the uterus has been given adequate hormonal preparation prior to embryo transfer.[276] However, both spontaneous and assisted pregnancies are associated with a high risk for maternal complications, including catastrophic aortic dilation, dissection, and rupture.[277] In most well-documented cases, the women had preexisting risk factors for dissection such as bicuspid aortic valve or aortic coarctation, although these problems were often not detected prior to pregnancy due to inadequate screening.[278] Patients known to have such defects should be counseled about alternatives to pregnancy such as adoption or surrogacy. If not already done, girls and young women with Turner syndrome should have a cardiovascular MRI prior to getting involved in counseling about reproductive options, because significant aortic malformations are often not detected on routine echocardiography and their presence would discourage planning for pregnancy. Girls with ovarian function may be candidates for cryopreservation of recovered oocytes or ovarian tissue obtained by laparoscopy,[276] given the very high probability of premature ovarian failure. This technology has been successful in preserving fertility for girls and women undergoing cancer treatment, although pregnancy resulting from this approach has not yet been reported in Turner syndrome. Girls and families interested in this possibility should be referred to reproductive endocrinology specialists associated with an academic medical center for consultation.

Transition to Adult Care

Pubertal induction treatment should be the occasion for starting the process of involving girls as partners in their care. After years of caring for a young child, a health care provider may overlook the fact that the patient is no longer a child and that new lines of communication need to be established with the patient as an emerging adult. The road to a successful transition involves educating the patient about her health care needs and goals, while developing a schedule for regular thyroid, liver, and renal function testing; annual gynecologic evaluation; and regular cardiology follow-up (see Box 16-2). The patient should be educated about the hormone treatments and other medications she is receiving and the need for regular evaluation of dosage and side effects. Target goals for weight, blood pressure, cholesterol, body fat proportions, and exercise regimen may be collaboratively established, and a portable health record maintained by the patient should be prepared prior to transfer out of pediatric care. Many of the major medical issues for adults with Turner syndrome—such as thyroid function, hormone replacement therapy, hypertension, metabolic status, and bone health—may best managed by endocrinology specialists with a background in internal medicine or gynecology. These providers should also supervise the regular evaluation of otologic/audiologic and cardiovascular systems. Psychosocial aspects of the transition to independence should also be addressed and the patient provided with sources for adult counseling services and support groups.
