Introduction

With each passing day, the Western world becomes increasingly multicultural, multiethnic, and multilingual. Statistics from the last census (2001) carried out in the UK revealed that 7.9% of the population (4.6 million people) were from a minority background, with the majority being from the Indian subcontinent or Africa and the Caribbean.[1] In comparison, in the USA, approximately 28% of the population at the present time are from a minority background (African Americans, Hispanics, Asians, Pacific Islanders, Native Americans, and Alaskan Natives representing the majority).

It is anticipated that immigrants and their descendents will continue to shape and alter the demographic landscape for several years to come. Consequently, it can be predicted that women from the ethnic minorities will form a growing proportion of the obstetric populations of many health districts. As clinicians assume responsibility for caring for an increasingly diverse population, genetic and ethnic connections to disease will become clearer. All health professionals must be prepared to meet the challenges such diversity will pose, if a uniform standard of health care is to be provided for all patients. It is important to be aware of the variations in need between individuals within similar communities, and not just across the population as a whole.

Prenatal screening allows women to make informed decisions about their reproductive choices. The vast majority of structural and chromosomal abnormalities arise in pregnancies without any risk factors. Therefore, aneuploidy and anomaly screening is offered to all women. However, certain genetic disorders occur with an increased frequency, or are confined to certain ethnic groups, and in these cases screening will be targeted at these individuals. It is important to ensure that prenatal screening is available and accessible equally to all women regardless of their background. In this chapter, we will be examining the influence of ethnicity on screening methods within the field of prenatal diagnosis, targeted screening in ethnic groups and finally the effect of ethnicity on uptake of screening.

Effects of ethnicity on screening methods

Down's syndrome

Down's syndrome is the commonest congenital cause of severe mental retardation.[2] In developed countries, there are approximately 100,000 deliveries per year, per 10,000,000 of the population. The birth incidence of trisomy 21 is about 1 in 500, and therefore, in such a population the total number of affected neonates is about 200.[3] The incidence of Down's syndrome rises sharply with increasing maternal age;[4] however, as the majority of children are born to women in their 20s and early 30s, 75% of babies with Down's syndrome are born to women in this age group. Screening women of all ages for Down's syndrome is now common practice in the West.

There is substantial variation in screening services for Down's syndrome throughout the world. Options for screening include nuchal translucency measurement (alone, in combination with first-/second-trimester biochemistry, fetal nasal bone assessment or ductus venous Doppler measurement), maternal serum screening in the second trimester or ultrasound for the detection of fetal defects and markers at 16–23 weeks. The influence of ethnic origin on screening efficacy by each of these modalities will now be examined in turn.

Nuchal translucency

Babies born with Down's syndrome show a distinct set of physical characteristics. Langdon Down first reported in 1866 that the skin of individuals with trisomy 21 appeared to be too large for their bodies.[5] This excess skin, in the form of nuchal translucency thickness, has formed the basis of one of the main non-invasive prenatal tests for this disorder since the early 1990s. Since

this time, the association between increased nuchal translucency at 11–14 weeks' gestation and chromosomal abnormality has been well established and documented.[6–8] For an invasive testing rate of 5%, about 75% of trisomic pregnancies can be identified using this method of screening alone. Two studies have shown that nuchal translucency screening can be effectively and equitably delivered to a multiethnic population. Thilaganathan *et al.* performed an observational study in a district general hospital with a large multiethnic population serving African, Asian, Caribbean, and Caucasian women.[9] In comparison, Chen *et al.* examined the effect of ethnic origin on nuchal translucency in a multiethnic Asian population comprising Chinese, Indian, Pakistani, Nepalese, and Filipino women.[10] Significant differences in the nuchal translucency measurement were obtained between the different ethnic groups in both studies. The magnitude of the differences was small, ranging from 0.08 to 0.22 mm. However, when compared to reported nuchal translucency intraobserver and interobserver variabilities of 0.54 and 0.62 mm, respectively,[11] the differences are clinically insignificant. No correction for ethnic origin is, therefore, required when first-trimester nuchal translucency screening for Down's syndrome is performed in multiethnic populations.

Ductus venosus

There is a clear association between abnormal Doppler flow in the ductus venosus (absence/ reversed) and fetal aneuploidy. The use of ductus venosus Doppler velocimetry in combination with nuchal translucency is better than either test alone, since it increases the sensitivity in the detection of Down's syndrome to 94% and decreases the likelihood ratio of a negative test to 0.08.[12] Although, the effect of ethnicity on ductus venosus Doppler indices are unknown, this screening method is so technically demanding that it is only likely to be performed on selected high-risk populations.

Nasal bone

In 2001 Cicero and colleagues demonstrated the possibility of using absence of the nasal bone at 11–14 weeks as a marker for Down's syndrome. They examined 701 routine ultrasound scans performed on women about to undergo prenatal diagnosis because of positive results on nuchal translucency screening.[13] The same group subsequently reported that nasal bones were absent in about 3% of chromosomally normal fetuses, in two-thirds of those with trisomy 21, and in about one-third of babies with other chromosomal defects.[14] The estimated likelihood ratio for trisomy 21 in the latter study was over 120 when the nasal bone cannot be seen. Given the significance of this ratio, and before nasal bone assessment is integrated into routine screening programs, knowledge about how to correct for ethnicity is required if this test is to be used equitably in multiethnic populations.

Table 79.1 The prevalence of absent nasal bones (NB) in normal and aneuploid pregnancies and their associated likelihood ratios (LR) for trisomy 21 (from Cicero *et al.*[18])

	Caucasian	Afro-Caribbean	Asian
Number	5284	170	201
Absent NB in aneuploid fetuses (%)	68.3	78.6	71.4
Absent NB in normal fetuses (%)	2.2	9.0	5.0
LR for trisomy 21 with absent NB	31.3	8.8	14.2
LR for trisomy 21 with NB	0.32	0.24	0.3

It is known that morphometry of the splanchnocranium, and of nasal bones in particular, differs between adults of various ethnic origins.[15] Likewise, ethnicity is known to influence whether the nasal bones are seen in second-trimester fetuses. It has been shown that second-trimester nasal bone hypoplasia is commoner in fetuses of Afro-Caribbean mothers than in Caucasian mothers.[16] More recently, studies have demonstrated a similar significant difference in the rate of visualization of the fetal nasal bones in the first trimester in chromosomally normal fetuses in mothers of different ethnic origins.[17]

In 2004 Cicero *et al.* produced data to update the likelihood ratio for trisomy 21 in fetuses with absent nasal bone at the 11- to 14-week scan. They examined 5918 pregnancies undergoing first-trimester karyotyping and found that the incidence of absent nasal bone was higher in fetuses of Afro-Caribbean and Asian origin than in Caucasians; it decreased with increasing fetal crown–rump length and increased with increased fetal nuchal translucency.[18] The authors provided data on the incidence of absent nasal bone in chromosomally normal and trisomy 21 fetuses and likelihood ratios according to ethnic group (see Table 79.1).

These data suggest that appropriate corrections may be applied for maternal ethnic origin and the absence of the nasal bones. However, as both parents contribute to a baby's phenotypic appearance, it remains to be determined whether any correction is also required for the father's ethnic origin.

Second-trimester maternal serum screening

In 1984, a major advancement in screening for chromosomal defects was made by Merkatz *et al.* who reported low levels of maternal serum alpha-fetoprotein (AFP)

in trisomy 21 pregnancies.[19] Since this time, prenatal screening for trisomy 21 based on the analysis of biochemical markers in maternal serum between 15 and 22 weeks of pregnancy has become an established part of obstetric practice. The principal markers found to be of value are AFP, total human chorionic gonadotrophin (hCG) (or its individual subunits: free β-hCG and free α-hCG), unconjugated estriol (uE_3) and dimeric inhibin-A. On average, in Down's syndrome affected pregnancies, the AFP and uE_3 levels are about three-quarters that of an unaffected pregnancy (multiple of the median, MoM < 0.84), whereas inhibin-A and free β-hCG levels are about double (MoM > 1.3 and > 1.6, respectively). Most screening programs use multiple markers in combination with maternal age to generate a risk. Performance is known to vary according to the choice of markers used and whether ultrasound has been used to determine the gestational age. When the latter is used in combination with maternal age, the detection rate for a 5% false-positive rate is estimated to be 59% for the double test (AFP and either total hCG or free β-hCG), 69% for the triple test (AFP, total hCG, and uE_3), and 76% for the quadruple test (AFP, hCG, uE_3, and inhibin-A).

The results of second-trimester maternal serum biochemistry are expressed as MoM values for gestation. MoM values normalize results for gestation to provide an equivalent measure between laboratories. The majority of published population data used to derive median values for the individual markers relate to European and American Caucasian populations. The degree of risk to an individual pregnant woman relies on combining the results with maternal age in a complex mathematical algorithm using commercially available software programs. The test is interpreted as positive or negative according to whether or not risk exceeds a fixed cut-off point. It is known that smoking, maternal weight, parity, previous pregnancy results, multiple pregnancy, and insulin-dependent diabetes can influence the concentration of the markers. It has been proposed that adjusting the risk algorithm, by taking into account these factors, can lead to an improvement in detection efficiency, although to what extent is not clear.

Another factor known to have an impact on the biochemical marker levels is ethnic origin. Gilbert *et al.*[20] raised the issue that racial differences existed in both age ranges for Down's syndrome and in the medians for biochemical markers. They proposed that outcome data on serum screening should be collected by ethnic groups, so that validated risk estimations could be formed, thereby making serum screening in ethnic groups more effective.

There have been several publications documenting differences in the marker levels in Afro-Caribbean, South Asian, Oriental, and Hispanic women compared to Caucasian women. Maternal serum AFP and hCG levels have been shown to be approximately 10–15% higher in black women compared to Caucasian women. In contrast, uE_3 levels hardly differ, and dimeric inhibin-A levels are about 8% lower in pregnancies in African Women. One of the largest published studies[21] evaluated data from more than 21,000 pregnancies to determine the extent of race-specific differences in median concentrations of analytes used in the triple test. This study found that at most gestational ages, median AFP, hCG, and uE_3 values for Caucasian, Afro-Caribbean, Hispanic, and other patients were all significantly different. Further, these differences remained significant even after the data were corrected for patient weight. For the individual analytes the extent of the variation was not the same at different gestational ages. It is important that screening laboratories follow the literature to keep abreast of new findings to ensure that they continue to provide the best possible screening service for women from minority backgrounds.

Correcting for ethnic origin has a small overall effect on screening performance. The detection rate increases by about 0.5% for a false-positive rate of 5%.[22] Having said that, the adjustment is worthwhile because it does not require resources and because of its established value in screening for open neural tube defects (NTDs) using serum AFP, where the false-positive rate is higher in Asian and Afro-Caribbean women compared to white women for a fixed AFP cut-off level. In fact, The American College of Medical Genetics recommends that a correction be made when screening for NTD also.[23] If Down's screening is being carried out in isolation and there is no risk of NTD for the mother, it could be argued that an adjustment for ethnicity need not be made because of the counterbalancing effect of the different analytes used in combination. For example, a Hispanic patient was screened at 16 weeks with median values (1.00 MoM) of AFP, hCG, and uE_3 when interpreted against a Hispanic patient-derived data set. If a primary Caucasian population data set had been used, her AFP value would have remained the same, hCG would have been 1.06 MoM and the uE_3 value 1.12 MoM. Although the higher hCG MoM would increase the Down's risk, the higher uE_3 MoM value would counteract to reduce the risk.

First-trimester maternal serum screening

All the serum markers used or considered in the second trimester have been assessed in Down's syndrome and unaffected pregnancies during the first trimester. Only two serum markers have stood out as being useful in screening at 11–14 weeks, namely, pregnancy-associated plasma protein-A (PAPP-A) and free β-hCG. Maternal serum PAPP-A levels are lower in pregnancies affected by trisomy 21, with the difference in PAPP-A levels between trisomy 21 and normal pregnancies decreasing with increasing gestational age. In comparison, the maternal serum-free β-hCG level is higher in trisomy 21 pregnancies, and the difference in levels between unaffected and affected pregnancies increases with advancing gestation.[24]

The consensus estimate of screening performance by using PAPP-A and free β-hCG in combination with maternal age is a 60% detection rate with a 5% false-positive rate. This is similar to the screening performance of second-trimester double markers, but not as good as the screening performance of second-trimester triple or quadruple markers. However, there is a significant improvement in screening efficiency when biochemistry analysis is combined with ultrasound in the first trimester. This form of screening can be provided in the setting of a one-stop clinic for assessment of risk (OSCAR), and is associated with a detection rate of about 90%, when the fetal nuchal translucency is also measured.

In 2000, Spencer *et al.* examined the influence of ethnic origin on first-trimester biochemical markers of chromosomal abnormalities. It was seen that the median maternal serum marker MoMs for free β-hCG and PAPP-A were 19% and 48% higher in Afro-Caribbean women, and 19% and 35% higher in Asian women compared to Caucasian women. Correcting for maternal weight made very little difference to the Afro-Caribbeans (21% and 57% higher after weight correction), but reduced the effect in Asians (4% and 17% higher after weight correction). Correcting first-trimester biochemical markers for maternal ethnicity and weight has little impact at the population level for detection rates (an increase in the overall detection rate by a mere 1.4%). However, the effect on the individual patient-specific risk can be substantial (up to a twofold increase), and can certainly make a difference to the patient's decision on whether to have an invasive test. For example, in a 67-kg, 25-year-old Afro-Caribbean, with an uncorrected free β-hCG of 2.10 MoM, and a PAPP-A of 0.65 MoM, the risk of trisomy 21 without correction for weight and ethnicity would be 1 in 540. After correction, the free β-hCG MoM would be 1.73, while the PAPP-A MoM would be 0.41, with a corrected screening risk of 1:260.[25]

It would appear that ethnic origin has a greater impact on first-trimester biochemical markers than second-trimester biochemical markers. However, further larger data sets are required to develop robust methods of correcting for ethnic origin and to assess the biological significance of such marker production between various ethnic groups.

Sixteen to twenty-three weeks' ultrasound scan

If the midtrimester 16- to 23-week scan demonstrates major structural defects, it is advisable to offer fetal karyotyping, even if these defects are isolated. The prevalence of these defects is low and therefore the financial cost implications are relatively small. Even if the defect is potentially correctable by surgery, such as exomphalos, it would seem appropriate to exclude an underlying chromosomal abnormality. The management policy for major fetal structural abnormality is unlikely to require changing on an ethnic basis. The same does not follow for the so-called 'minor' markers of chromosomal abnormality.

Minor defects or markers are common and they are not usually associated with any handicap, unless there is an associated chromosomal abnormality. Most practitioners adopt an individualized approach to the assessment of risk depending on the marker identified either using the appropriate likelihood ratio or a genetic sonogram score.[3] In high-risk populations as defined by advanced maternal age or positive maternal serum biochemistry, this approach has been shown to maintain a high sensitivity for fetal aneuploidy without significantly increasing the invasive prenatal testing rate.

However, routine karyotyping of all low-risk pregnancies with these markers would have major implications, in terms of both miscarriage and financial costs. As a general concern, this process of sequential screening assumes the unproven independence between the findings of different screening results. For example, second-trimester intracardiac echogenic foci are known to increase in prevalence when first-trimester nuchal translucency measurements are elevated in fetuses of normal karyotype.[26] Hence, prior screening test results should be followed until data evaluating the interdependence of such markers become available.

Additionally, only a few have attempted to evaluate ethnic variation in such minor markers for fetal aneuploidy. Despite this, they have all invariably established significant ethnic variations in prevalence of the markers such as nasal bone, intracardiac echogenic foci, humeral, and femoral length.[27–33] Hence, if these markers are to be used for modulating the risk of fetal chromosomal abnormality, the ethnic influence of the exact markers used need to be evaluated. In the long term, it would seem more reliable to use first-trimester nuchal translucency and maternal serum biochemistry, where corrections are not required or are easily made.

Neural tube defects

NTDs have a complex etiology in which both genetic and environmental factors appear to be involved. Analysis of recurrence patterns within families and of twin-concordance data provides evidence of a genetic influence in sporadic cases, but factors such as socioeconomic status and geographic area (independent of race or ethnicity) are also associated with variations in the incidence of NTDs. Furthermore, exposure during pregnancy to various drugs, most commonly antiepileptics, are associated with increased risk of NTDs. Recently, Rothenberg *et al.* demonstrated the increased prevalence of autoantibodies against folate receptors in serum of women with a current or previous pregnancy complicated by a fetal NTD.[34,35] It remains to be established whether there is a causative relationship between the presence of these antibodies and the development of NTDs.

Screening by midtrimester ultrasound appears to be superior to maternal serum AFP assessment, but the latter modality is still widely used as a prior screening modality before detailed ultrasound assessment. The ethnic variation in AFP levels are well established and corrective formulas may be applied to produce accurate risks for NTDs in various ethnic groups as recommended by the American College of Medical Genetics guidelines for the screening of NTDs.[23]

Targeted screening in ethnic groups

There are certain inherited disorders that occur more frequently in every ethnic, demographic, or racial group, than in the general population. Small genetic differences are known to exist between individuals from different ethnic groups. Certain ethnic groups have a higher risk of certain genetic conditions, especially autosomal recessive disorders, than the general population. Prenatal diagnosis is available for many genetic conditions, and a growing number of women are seeking advice regarding prenatal testing for a present or planned pregnancy. Knowledge of a patient's ethnicity can, therefore, help make a diagnosis, or help to identify individuals or couples at an increased risk of having a child with a specific genetic condition. The American College of Obstetricians and Gynecologists (ACOG) recommends genetic counseling for couples at increased risk of birth defects. Counseling enables the couple to become more informed about the disorders involved, the current availability of prenatal and postnatal testing, the accuracy and limitations of such testing, and their reproductive options.[36]

"Jewish" genetic disorders

The "Jewish" genetic disorders are a group of disorders that occur at a higher frequency among Jews compared to the general population, yet are not exclusive to the Jewish population. There is no official list of conditions; however, it is known that Mendelian disorders and diseases associated with predisposition genes have a higher incidence in an individual of Ashkenazi or Sephardic ancestry. As different Jewish groups are at risk of different disorders, it is important to establish not only a patient's religion, but also their ethnicity and ancestral countries of origin.

Ancestors of the Ashkenazi Jews lived in Central and Eastern Europe (Germany, Poland, Lithuania, and Russia). Approximately 95% of Jews living in North America are Ashkenazi. This population are more likely to carry genes for Tay–Sachs disease, Canavan disease, familial dysautonomia, Niemann–Pick (type A) disease, Fanconi anemia (group C), Bloom syndrome, Gaucher disease (the non-neuronopathic type), mucolipidosis type IV, and cystic fibrosis (CF; see Table 79.2). As these conditions can be severely incapacitating, tragically debilitating, or lead to death in infancy or early childhood, some orthodox communities encourage the use of premarital carrier screening to discourage the marriage of two carriers.

Table 79.2 Common genetic disorders and carrier frequency in the Ashkenazi Jewish population

Disease	Carrier frequency
Tay–Sachs disease	1 in 26
Canavan disease	1 in 38
Familial dysautonomia	1 in 30
Niemann–Pick disease (type A)	1 in 70
Fanconi anemia (group C)	1 in 89
Bloom syndrome	1 in 110
Gaucher disease	1 in 10
Mucolipidosis IV	1 in 100
Cystic fibrosis	1 in 25

In comparison, the Sephardic Jews ancestry can be traced to Spain, Portugal, North Africa (Morocco and Tunisia), and the Middle East. This Jewish population is more likely to be carriers for beta-thalassemia, familial Mediterranean fever, glucose-6-phosphate dehydrogenase (G6PD) deficiency, and Type III glycogen storage disease.

The Ashkenazi Jewish community is a unique and ideal population that provides screening of multiple diseases because detection rates are high (> 95%) when tested for a limited number of mutations. The ACOG recommends screening couples with European-Jewish ancestry at a minimum for Tay–Sachs disease, Canavan disease, and CF.[37,38] No standards of care have been set for the Sephardic population.

Hemoglobinopathies

Hemoglobinopathies are the commonest single gene recessive disorders in the world. They occur as a result of mutations in the globin gene and are primarily seen in populations whose ancestors are from Africa, the Middle East, the Caribbean, the Mediterranean, Asia, and the Far East. These disorders have appeared in the West due to global migration. In the UK, the NHS Sickle Cell and Thalassaemia Screening Programme are working toward a policy of universal antenatal screening that will allow the offer of sickle cell and thalassemia screening to all women as an integral part of early antenatal care.

The population of Cyprus (both Greek and Turkish) has one of the highest rates of beta-thalassemia carriers in the world, and in the past one of every 158 infants was born with the condition. Today in Cyprus, antenatal screening for thalassemia has been almost totally superseded by premarital screening. The religious authorities had ethical objections to screening during pregnancy, on the grounds that it excluded most options other than termination of affected pregnancies.

The church in Cyprus, therefore, insists on testing as a formal prerequisite to church weddings. The certificate required states merely that the partners have been tested and appropriately advised. In this way, the confidentiality of the test result is preserved and the couple can exercise an informed choice about reproduction. This societal approach to inherited genetic disorders is to be applauded, and it would be a suitable model for other communities to adapt.

Cystic fibrosis

CF is a common inherited condition that affects many systems in the body, most often resulting in chronic, progressive lung disease, problems with digestion, and subsequent malnutrition. CF is the most commonly inherited disease in Caucasians, affecting approximately 1:2500 individuals, but it has been identified in people of all races and ethnicities around the world. The incidence in other ethnic groups varies from 1:15,000 for African Americans to 1:90,000 in Asians. In 2001, the ACOG and the American College of Medical Genetics[38] recommended that CF carrier screening be offered to all Caucasian couples who are pregnant, or are considering pregnancy. These groups additionally recommended that carrier screening be made available to other ethnic populations with the understanding that the likelihood of being a CF carrier may be much lower in non-Caucasian populations (see Table 79.3).[39]

Although there have been over 1000 mutations identified that cause CF, only 25 have been recommended for carrier screening as additional mutations are rare, not well understood, and have minimal impact on the overall probability of affecting a child. Mutations of the CF also vary with ethnicity. The ΔF508 mutation accounts for 70% of the CF mutations in Caucasians of Northern European descents but only 30% of CF mutations in individuals of Ashkenazi Jewish descent. A different mutation, W1282X, is more common in the Ashkenazi Jews.

Glucose-6-phosphate dehydrogenase deficiency

G6PD deficiency is the most common human enzyme deficiency. G6PD deficiency can result in the rapid destruction of blood cells in the presence of infection or certain drugs. Different populations have different types of mutations, but within a specific population, common mutations are usually shared. There are a wide variety of normal genetic variants of the enzyme G6PD. The main races affected are in West Africa, the Mediterranean, the Middle East, and South East Asia. The degree of deficiency varies, often being mild in black Africans, more severe in Orientals, and most severe in Mediterraneans. Severe deficiency also occasionally occurs in Caucasians. Antenatal screening is available for at-risk patients.

Table 79.3 The detection rate for the cystic fibrosis ΔF508 mutation test in various populations, including carrier frequency before and after a negative ΔF508 mutation test[39]

Ethnicity	Detection rate (%)	Before test	After negative test
Ashkenazi Jewish	97	1/29	1/934
Caucasian (northern European)	90	1/25	1/241
Caucasian (southern European)	70	1/25	1/81
African American	69	1/65	1/207
Hispanic American	57	1/46	1/105
Asian	30	1/90	1/128

This is a pooled set of data based on ΔF508 deletion and requires additional information to accurately predict risk of specific Hispanic populations. Residual carrier risk after a negative test is further modified by the presence of a positive family history of CF and/or by mixed ethnicity

Effects of screening on ethnicity

Knowledge

The uptake of any screening test is influenced by knowledge of the condition being screened for. Parents need appropriate knowledge of Down's syndrome, what it is, and how it affects the child and adult, both mentally and physically. They also need appropriate knowledge of the screening test, together with the limitations of the test, so they can decide whether they wish to be screened. A study by Chilaka *et al.*[40] at Leicester General Hospital in the UK looked at the knowledge of Down's syndrome amongt pregnant women from different ethnic groups. The study showed that racial groups other than Caucasian had a poorer understanding of Down's syndrome. Fifty-one percent of Caucasians in the study had a good knowledge of Down's syndrome compared to 8% of Asians born outside the UK. The factors affecting knowledge included the quality of spoken English, knowing an affected child, parity, and religion. Only five women in the study could not speak English; however, none of these women had any reasonable knowledge of Down's syndrome compared to those who could speak English. The importance of the study results are highlighted by its main finding that knowledge of the condition was the most influential factor in the decision making process about accepting or declining a Down's syndrome screening test. In addition, information retention about prenatal screening also varies significantly by ethnicity and level of education.[41]

Access and equity

Women from ethnic minorities can experience financial, linguistic, and cultural barriers to access health care services, limiting utilization of genetic and other maternal child health services. Genetic conditions may go undetected with deleterious impact during prenatal, perinatal, and newborn periods. Society has an ethical obligation to ensure equitable access to health care for all, yet there remains a persistence of health disparities across race, income, and ethnicity.

The extent and quality of prenatal care is important for the health of women and their babies. Early prenatal care can encourage healthy habits during pregnancy, help to identify potential medical problems, facilitate screening and involvement with parenting support, nutrition, and other educational resources. Women from ethnic groups have been shown to use antenatal services less intensely with a high proportion booking too late for screening to be useful. Although the percentage of women receiving prenatal care during the first 3 months of pregnancy has increased over the past two decades for white, black, Asian, and Hispanic women, white women are still the most likely to receive prenatal care in their first trimester. Sadly, a significant proportion of women from the ethnic minorities still receive no care until the third trimester.

In some countries in the world, a substantial barrier to health care access for some people is the lack of either public or private health insurance. Another difficulty in accessing health services is the problem of communication and language barriers. The difficulties for the patient, if English is not the first language, with respect to screening can be divided into problems of recruitment into a screening program, of giving the patients enough information to allow informed consent, and of problems arising if detailed information needs to be provided in follow up. To counter language difficulties interpreters may be used and information leaflets can be produced in different languages. Interpreting skills continue to be a scarce resource in any health service. One way to cope with this problem has been the setting up of a language service, which enables remote interpreting via a shared telephone line. Another is by asking relatives to act as interpreters. However, this can be problematic as it is often assumed that they are knowledgeable in all aspects of both languages, and this may place them under a great deal of stress. Also, patients may feel uncomfortable with even close relatives knowing about their medical conditions, as it may have profound cultural implications such as impacting on marriage prospects for themselves or their close family.

In many cultures, the concept of having to go outside the family for health education or infant care is an alien concept, and would indicate an unacceptable lack of respect for the older women in the family who traditionally are an important part of the child care system, and who expect to instruct the young mother in the care of her baby. To be obliged to seek such education from members of another culture whose values and beliefs are different from one's own is almost bizarre. However, if the concept of instruction in parentcraft by a midwife is accepted, the actual attendance at parentcraft may present considerable difficulties. The 'usual' inhibitions to attendance experienced by young women, e.g. child care, the need to take time off work, may be further complicated by the need for a young woman to be escorted (particularly in the evenings), or by difficulties with communication or socioeconomic issues.

Despite these constraints, with an ethnically sensitive strategy, it is still possible to provide equal access to prenatal screening. For example, in a previous study on ethnic differences in nuchal translucency measurement, it was noted that the ethnic balance of the population accepting and declining prenatal Down's syndrome screening was not significantly different in an obstetric population from one of the most socially deprived regions of the UK, where over 15% of the women did not speak English.[42]

Culture and religion

Understanding and valuing cultural diversity is critical to ensure the best possible care. For example, a woman is likely to decline prenatal screening and diagnosis because of fears that she may be divorced by her partner or shunned by her in-laws in the event that a fetal abnormality is diagnosed. The difficulties such attitudes create are further amplified by the fact that such women may well have a poorer understanding of the local language, be financially insecure, and be reliant on their partner for right of residency in the country. This maternal perception, often unbeknown to the clinician, may be interpreted by health care workers as denial or lack of knowledge.

It is also important not to make the assumption that all women from a particular community follow the same customs and religion. For example, attitudes to termination vary even within the Muslim community. Some Muslim parents do not see termination as 'halal' (permitted) but as 'haram' (not permitted). They know their child is diseased but they choose to keep it believing that God's will (inshaallah) created that child and they expect to get their rewards in heaven. Even when termination of pregnancy is acceptable, there are different interpretations of the gestation up to which such a procedure may be carried out.[43]

Clinicians, therefore, need to develop an appreciation and respect for cultures and religions that differ hugely from their own. This may be often impossible to attain unless members of the local ethnic and religious communities are co-opted into health service delivery as health care workers of aides.

Consanguinity

In the West our knowledge and understanding of consanguinity is limited. While marriages between close

biological kin are preferred in many parts of the world, such unions are not commonplace in the West. First-cousin marriages are legal in countries such as the UK and Australia, but are against the law in others. The 1981 marriage law of the People's Republic of China prohibits marriage between couples related as first cousins or closer, and in the USA, consanguineous unions are prohibited in 30 States. Irrespective of prevailing legislation, a future decline in the prevalence of consanguineous unions can be predicted, accompanying the expected reduction in family sizes. Regardless, it is important that health care providers have an understanding of the potential genetic consequences of such unions. This was recognized by the National Society of Genetic Counselors (NSGC) in America, who developed guidelines providing recommendations on counseling and screening for consanguineous couples defined as being second cousins or closer.[44]

Most of the genetic fall-out of consanguinity is in the form of autosomal recessive disorders, which in fact adversely affect only a minority of such families. The more closely two people are related, the more genes they share, and the more likely that both will carry a copy of the same recessive mutation, thereby increasing their chances of having a child affected by that disorder. Although it is not possible to come up with one number for all populations of consanguineous couples, the risk is not as high as was previously envisaged. It is estimated that the additional risk of significant birth defects, including mental retardation or genetic disorders, above the general population risk is about 1.7–2.8% for first-cousin unions. The consensus from the NSGC is that beyond a thorough medical family history, with follow-up of significant findings, no additional preconception screening is recommended for consanguineous couples. Consanguineous couples should be offered similar genetic screening as suggested for any couple of their ethnic group.

Conclusions

Ethnic differences in the delivery of health care are prevalent across various domains of health, including mortality, morbidity, behavior, and utilization of health services. This chapter highlighted some areas of ethnic differences and potential inequalities in access to prenatal testing. The elimination of health inequality will first require a reliable assessment of the disparity in care provision as well as a clear understanding of differences across populations identified in terms of race/ethnicity. Further research is required to improve our understanding of why testing may not be offered, the reasons for failure to take up testing when offered, and to identify whether there are other social inequalities in the access to prenatal testing.

80 Ultrasound screening of congenital heart defects

R. Chaoui

Introduction

Congenital heart defects (CHD) are one of the most common anomalies in human fetuses (5/1000 livebirths) and are the leading cause of death due to malformations in the first year of life. Heart abnormalities and soft markers are present in a substantial amount in fetuses with chromosomal aberrations and fetal echocardiography and are thus an intrinsic part of the genetic scan.[1]

A prenatal diagnosis can be reliably achieved by means of ultrasound during pregnancy and the accurate prenatal diagnosis improves in many conditions of the fetal outcome by delivering the baby at a specialized tertiary center. In this chapter the examination of the fetal heart is reviewed, focusing on the role of screening and how to imply the heart into the genetic scan.

Examination techniques of the fetal heart

No organ in the fetus can be examined with as many diagnostical techniques as the heart. Detailed information on structure, function and time-related events has become available thanks to the development of sophisticated tools.[1] However, this has not been accompanied by a significant increase in prenatal detection rate of anomalies, but rather in the increasing reliability of precise diagnosis.

Real-time gray-scale ultrasound and two-dimensional (2D) echocardiography

Gray-scale 2D ultrasound is still the gold standard for the structural evaluation of the fetal heart. Resolution has continuously increased over the last two decades in step with the huge progress in the development of computer technology and fast processors. In most sophisticated (and expensive) ultrasound machines there is an ideal setting for fetal heart examination, which is based on a high image resolution (using scan heads with 250-1012 acoustic lines), a high frame rate and good penetration. Visualization of very tiny structures like the coronary arteries using real-time ultrasound has become possible as well as of other structures such as the fetal thymus that has not been seen before. The increased resolution using 5–7-MHz transducers has also led to the identification of new details like the echogenic intracardiac focus with the discussion on whether or not it is associated with chromosomal or other anomalies (see below).

Two main features, however, have facilitated enormously the fetal heart examination and are now standard even on mid- to low-range machines: the cine-loop and the zoom functions. The magnification of the image allows better assessment of the structures of interest and visualization of the different cardiac cycle phases image by image facilitates assessment of the structures during systole and diastole. In recent years, image resolution in gray scale was increased by completing the native image with harmonic and/or compound imaging.

Time motion or M-mode

Time motion application in the fetus was not possible until simultaneous real-time visualization became available. Cardiac biometry first performed with M-mode was very soon abandoned since such measurements became easier using cine-loop technique to image selectively diastole and systole.[2,3] Two main fields of interest are still in the domain of M-mode: one is the classification of fetal arrhythmia and the other is the calculation of indices used in cardiology to assess contractility, e.g. shortening fraction, ejection fraction, etc.

Spectral Doppler flow velocity waveform

Doppler ultrasound enables a non-invasive quantification of perfusion across different fetal cardiac valves and vessels. Peak velocities can be assessed and indices calculated. By measuring the area of a valve the perfusion can then be calculated either as

stroke volume or involving the heart frequency as cardiac output. The advent of color Doppler enabled a more reliable use over spectral Doppler across the known valves, but also the evaluation of more difficult otherwise not assessable regions, as pulmonary arteries and veins, ductus arteriosus, foramen ovale and even coronary vessels.

Color Doppler

In addition to the gray-scale examination of the fetal heart, color Doppler is now considered as the second part of a complete cardiac evaluation. The method allows rapid orientation within the fetal heart and completes the evaluation supplied by gray-scale information. Once abnormal flow is suspected, quantification becomes mandatory using spectral Doppler. The advent of color Doppler did not contribute to a huge increase in detection rate of CHD but increased the reliability of screening when routinely applied and in the detailed fetal echocardiography in suspected heart diseases.

We described a few years ago how most congenital heart anomalies could be detected in only three planes using color Doppler: the four-chamber view, the five-chamber view and the three-vessel-trachea view.[4] The exact examination in gray scale completed by the expected typical flow in color Doppler became the basis of diagnosis of fetal CHD.

Three-dimensional fetal echocardiography

As soon as the first 3D ultrasound equipment became available, an attempt to examine the fetal heart was undertaken. It was hoped that 3D information of the fetal heart could facilitate understanding of orientation, especially the assessment of the great vessels' anatomy, which is difficult for many examiners. However, since the heart is beating the main challenge is still the gating of the signals and the acquisition of information during systole or diastole.[5] The advent of spatio-temporal image correlation (STIC) technology a few years ago allowed a reliable acquisition of a 3D with systole and diastole as off-line 4D fetal echo.[6] STIC can be used in gray scale[6] or in combination with color or power Doppler mode.[7] A detailed description of 3D of heart and vessels is described elsewhere in this book and I refer to the reader to this chapter. The technique is however too new to be evaluated for its role in screening for fetal heart defects or in genetic scan.

Screening of the fetal heart or targeted examination based on indications

CHD have a multifactorial etiology and therefore prenatal detection cannot be achieved solely by concentrating on the high-risk population defined by patient history. Therefore, seeking for heart abnormalities should be part of the midtrimester ultrasound screening. In many countries such a general screening is not established (no insurance or mother care coverage), but is often performed either on indication of risk or because of the willingness of the patient.

Signs of cardiac disease are often subtle, necessitating careful targeted examination. In the 1980s, the four-chamber view was proposed as the most important plane for screening, allowing a greater detection rate for anomalies. Recently, however, incorporation of views of the great vessels has been recommended as part of the routine screening examination.

Many studies in the last 10 years have emphasized the importance of cardiac screening, but they have achieved widely divergent results, with reported detection rates varying from 5 to 92%.[8] However, it should be noted that these studies employed different approaches and are therefore not directly comparable (see Chaoui [8] for details).

There is a list of indications, generally accepted as referral reason for fetal echocardiography, which are presented in another chapter. The percentage of detection of heart anomalies within single groups (the yield) differs from 3–5% (i.e. diabetes, drugs and genetic ultrasound) to more than 50% (i.e. suspicious four-chamber view). In some indications fetal echocardiography is performed to calm the pregnant woman (low recurrence risk in positive family history) and in other conditions to seriously rule out a heart anomaly (non-immune hydrops and extracardiac malformations).

Fetal cardiac examination in a low-risk population and targeted fetal echocardiography in a high-risk population

It is generally agreed that the 'four-chamber view' should be part of every routine ultrasound in pregnancy. However, there are different reasons why this plane was not successful in improving the detection rate of CHD in the recent past. In order to achieve an accurate assessment of this plane we recommend following a step-by-step checklist on every single cardiac examination, including the list in Table 80.1.

It is agreed further that the assessment of the great vessels belongs rather to an extended fetal cardiac examination. We expect, however, that in future this will be part of a basic cardiac examination as well, since many anomalies of the great vessels are not detectable in the simple four-chamber-screening and their detection has been demonstrated to improve the outcome in various CHD. Whereas the four-chamber view can be examined in a single plane, the great vessels can be only assessed by a dynamic scan, i.e. by tilting and moving the transducer.[9] The checklist for assessing the great vessels will include the list as presented in Table 80.2.

Table 80.1 Checklist for the basic cardiac examination and the targeted fetal echocardiography for the four-chamber view

	Basic Examination	Targeted Fetal Echo
Upper Abdomen	Stomach and heart on the same side of the fetus	Same
Descending aorta/ Inferior Vena cava		– Aorta on the left side of the spine – Normal arrangement of Aorta and Inferior vena cava in the upper abdomen
Heart Size	about 1/3 of the thoracic cavity	Same
Heart Position	2/3 of the heart is in the left hemithorax	Same
		Same
Heart Axis	septum at an angle of about 45° to the midline	Same
Heart rhythm	120–180 Beats/min, no arrhythmia	Same
Ventricles	Two equally contracting ventricles, of approximately equal cavity size and wall thickness	Right Ventricle is shorter than the left and has the moderator band at the apex. Heart apex is build by the left ventricle
Atria	Two atria of approximately equal size with foramen ovale defect in middle third of atrial septum	Same
Valves	Two opening atrioventricular valves	Same
Crux of heart	Intact	Intact and slightly lower insertion of the tricuspid valve than to the mitral valve
Ventricular septum	Intact from apex to crux	Same
Pulmonary vein(s)		at least one should be seen by colour flow mapping connecting to the left atrium
Color Doppler flow shows		– antegrade perfusion across atrioventricular valves – no aliasing (turbulences) – no regurgitation – no crossing over the ventricular septum

Targeted fetal echocardiography should be performed by those familiar with the prenatal diagnosis of CHD and the wide spectrum of possible anomalies. In this chapter I cannot recommend whether the examiner should be an obstetrician or a pediatric cardiologist, as this may be decided by the local specificities of the country. I recommend, however, a close cooperation between both groups, especially while counseling a pregnant woman with a suspected heart anomaly in the fetus.

Often the expectations are bigger and therefore the time, equipment and expertise needed for an examination are greater. In these conditions the use of color and pulsed Doppler techniques increases the accuracy of the examination. In cases of arrhythmia M-mode or pulsed Doppler should be used to demonstrate the relationship between atrial and ventricular contractions.

The checklist in these conditions is longer and the dynamic examination of the heart in different planes[9] is mandatory, as shown in Tables 80.1 and 80.2.

Fetal echocardiography and the detection of a congenital heart defect

There are two steps in the detection of a fetal heart defect, namely, first, the suspicion of an abnormality and second, the detailed precise description and classification of the heart defect. Generally, the first is easily achieved when the examiner is able to get the four-chamber view and the great vessels in nearly all patients as described in Tables 80.1 and 80.2 and he/she knows the typical hints for an abnormal heart in these planes. The second step can be solved chiefly by getting experience of many CHD and knowing the spectrum of the different diseases. In many countries the latter examination is either achieved together with a pediatric cardiologist or by referring the pregnant woman to a pediatric cardiologist specialized in fetal echo examination.

Table 80.2 Examination of the great arteries as part of an extended basic cardiac examination or as targeted fetal echocardiography

	Extended Basic Examination	Targeted Fetal Echo
Aorta	arises from the left ventricle	arises from the left ventricle continues toward the aortic arch
Ventricular septum	continuous with ascending aorta	Same
Pulmonary trunk	– arises from the RV – is slightly larger than aorta – crosses over the ascending aorta – bifurcates to give the left and right pulmonary arteries – connects to the ductus arteriosus	Same
Duct and aortic arch		– are of approximately equal size – point to the left side of the spine – the trachea is on the right of both vessels – Thymus is present – No left superior vena cava on the left of the pulmonary trunk
Color flow shows		– antegrade perfusion across both semilunar valves – no aliasing (turbulences) except in the ductus region in third trimester – no regurgitation – no reverse flow in either the ductus arteriosus or the aortic arch

Table 80.3 Common suspicions leading to referral to targeted fetal echocardiography

Common suspicions in the four-chamber view	Cardiomegaly Arrhythmia Heart to the right/heart-stomach on different site Single ventricle One small ventricle (right or left) Discrepant size of the ventricles Defect in the ventricular septum, AV-junction One common AV-valve Echogenic focus in the LV Tumors in the heart
Common suspicions in the great vessels assessment	Perimembraneous VSD in the five-chamber view VSD with overriding aorta Dilated aortic root Discrepant calibre of ascending aorta and pulmonary trunk Hypoplastic or non-continuing aorta or pulmonary trunk Parallel great vessels arrangement One single vessel only visualized Aortic arch on the right side of the spine (and trachea)

It is important to know the most common 'abnormalities' detected during fetal cardiac scan and leading to a referral. In my experience the most common signs detected in the four-chamber view and the great vessel planes are summarized in Table 80.3. The differential diagnosis of most common suspicions of referrals is summarized in Table 80.4.

Fetal echocardiography in genetic scan

Fetal examination allows detection of fetuses at high risk for chromosomal aberrations owing to malformations or signs called soft markers.[10] The latter

Table 80.4 Differential diagnoses of some common suspicions

Single ventricle	Mitral atresia Tricuspid atresia Double inlet ventricle Large Atrioventricular septal defect
Small left ventricle	Hypoplastic left heart syndrome Coarctation of the aorta Mitral atresia with VSD Double outlet right ventricle
Small right ventricle	Pulmonary atresia with intact septum Tricuspid atresia with VSD
Ventricular Septum Defect	Isolated VSD Atrioventricular septal defect Double inlet ventricle Interrupted aortic arch Aortic coarctation Conotruncal anomalies (see overriding aorta)
Overriding aorta over the VSD	Tetralogy of Fallot Pulmonary atresia with VSD Truncus arteriosus communis Absent pulmonary valve syndrome Double outlet right ventricle
Parallel Vessels	Double outlet right ventricle Complete Transposition of the great arteries Congenitally corrected Transposition of the great arteries
Tiny ascending aorta	Hypoplastic left heart syndrome Aortic coarctation Tubular hypoplasia of the aortic arch Interruption of the aortic arch
Two normal appearing ventricles, but one single great vessel recognized	Double outlet right ventricle (vessels over each other) Transposition of the great arteries (vessels over each other) Truncus arteriosus communis Dilated Aorta (in pulmonary atresia with VSD)

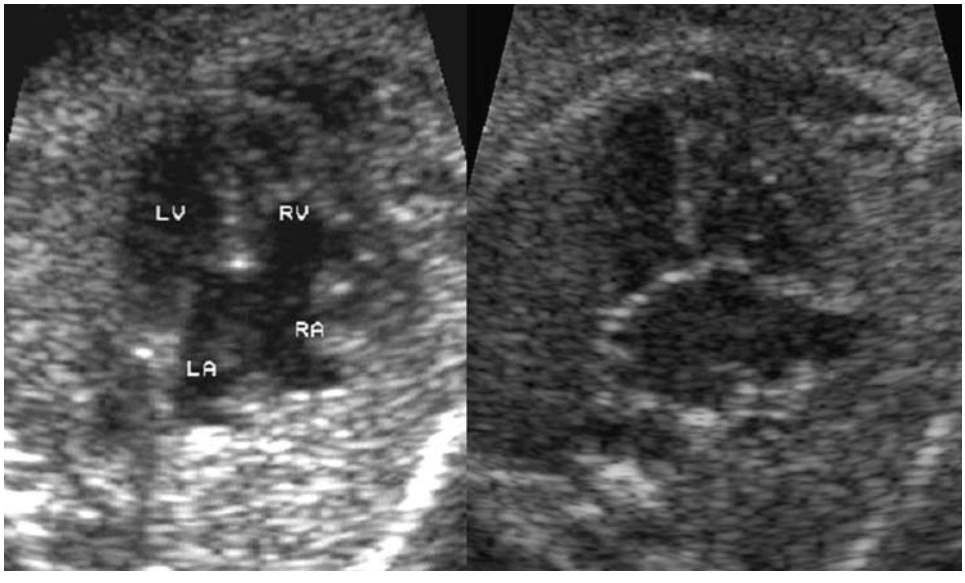

Figure 80.1 Fetuses with atrioventricular septal defect during diastole (left) and systole (right). In the left image the gap in the crux of the heart is easily recognized. On the right side on the one hand both AV valves are linear and on the other the measurement of atrial to ventricular length reveals a ratio 0.6 suspicious for an AVSD.

increases the risk to a specific malformation, without being obligatorily *per se* a structural malformation. The fetal heart belongs to the organs often evaluated carefully when looking for a chromosomal anomaly, either the common numerical aberrations such as trisomy 21, 18, 13 or monosomy X or more specific deletions such as the microdeletion 22q11 involving often the heart. In numerical aberrations except

Down's syndrome, the other anomalies have many extracardiac signs leading to an invasive procedure independent from the heart finding.

Structural heart anomaly

Atrioventricular septal defect (AVSD) (Figure 80.1) is the most common heart anomaly associated with a chromosomal aberration, mainly trisomy 21 and 18. The diagnosis can be achieved by detecting the gap in the crux of the heart (the combination of defects within the interventricular and interatrial septa). The association with trisomy 21 or 18 is between 50 and 80%; however, when in AVSD the left ventricle is small as in combination with aortic coarctation, the rate of aneuploidy is lower (10% or less) and if there are signs of isomerism (i.e. stomach on the right side) there is no association with chromosomal aberrations.

We proposed recently a new simple cardiac measurement the atrial to ventricular length (AVL) ratio,[11] in order to increase the detection rate for AVSD on routine scan. After a standardized four-chamber view, the ratio of the atrial length to the length of the ventricle in the midline is measured. Whereas the normal AVL-ratio during the second trimester is constant around 0.5, almost all fetuses with AVSD had a ratio exceeding 0.6.[11]

Other anomalies that are found in association with trisomy 21 are the ventricular septal defect (VSD) and the tetralogy of Fallot. Typical anomalies for trisomy 18 are besides the VSD and AVSD, the overriding of the aorta (Figure 80.2) with or without the pulmonary stenosis, a double-outlet right ventricle and occasionally a left outflow tract obstruction. Trisomy 13 cardiac anomalies are besides the VSD, left outflow tract obstructions such as aortic coarctation of the aorta and occasionally a hypoplastic left heart syndrome (HLHS). Turner syndrome has in almost all cases been detected prenatally, generally in combination with a cystic hygroma, also the left ventricular outflow tract obstruction, typically the aortic coarctation, and also occasionally the HLHS.

Figure 80.2 This is an overriding of the aorta over a VSD (*), which can be detected in the visualization of the five-chamber view. This is a sign and its differential diagnosis is listed in Table 80.4.

Cardiac soft markers

Intracardiac echogenic focus

The debate on this unspecific sign will not be discussed in this chapter. There are controversial data in the literature supporting the echogenic focus (EF) as a sign for Down's syndrome[10] as well as a benign sign with no relationship to chromosomal anomalies.

As most cases (around 90%) are found as isolated EF in the left ventricle (Figure 80.3), it is to be emphasized that EF in the right ventricle or two EF in the left

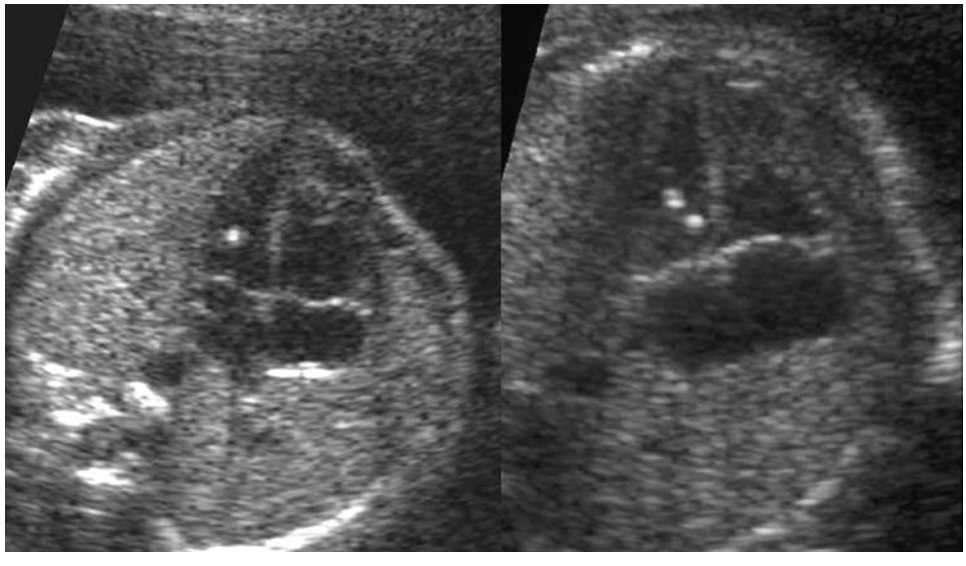

Figure 80.3 Two fetuses with echogenic foci. On the left the echogenic focus is present in the left ventricle and is the most common condition found. In the right figure two echogenic foci are present in the left ventricle. This fetus had a heart defect associated with a del.22q11.

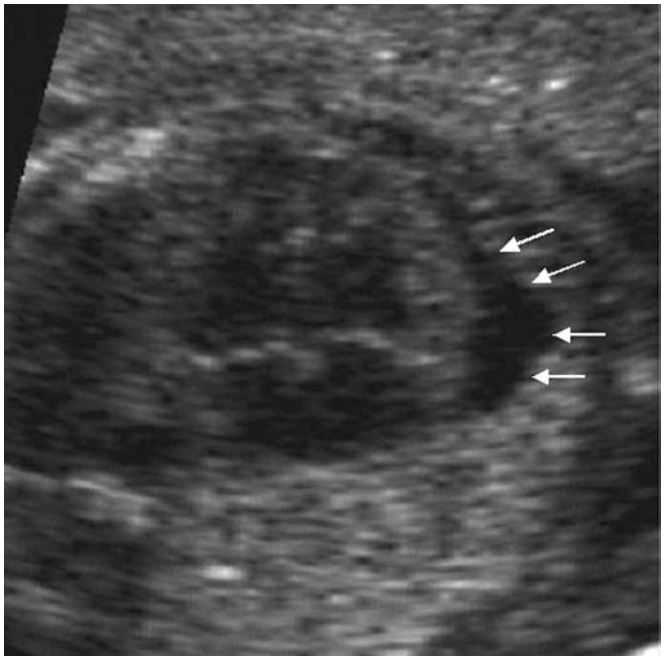

Figure 80.4 In this fetus with Down's syndrome there is a pericardial effusion at 20 weeks.

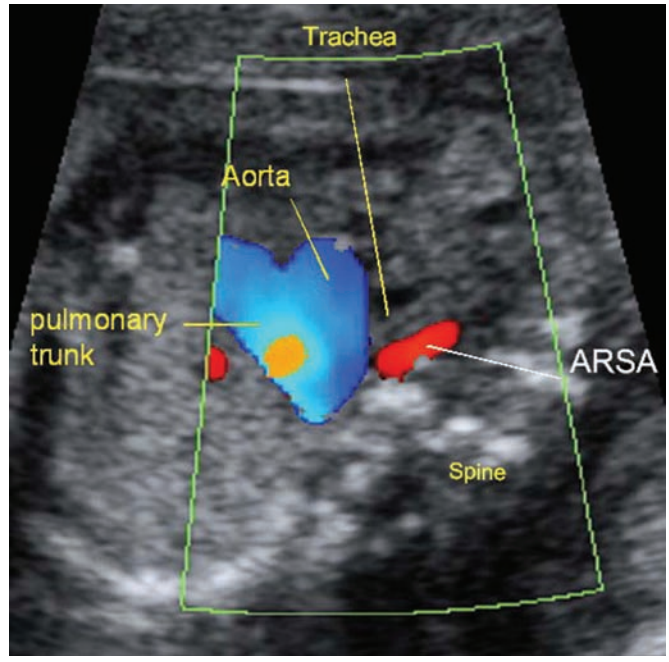

Figure 80.5 In this fetus with Down's syndrome at 20 weeks, an aberrant right subclavian artery (ARSA) is present. It is demonstrated in the three-vessel-tracheal view as a vessel with a course behind the trachea toward the right arm.

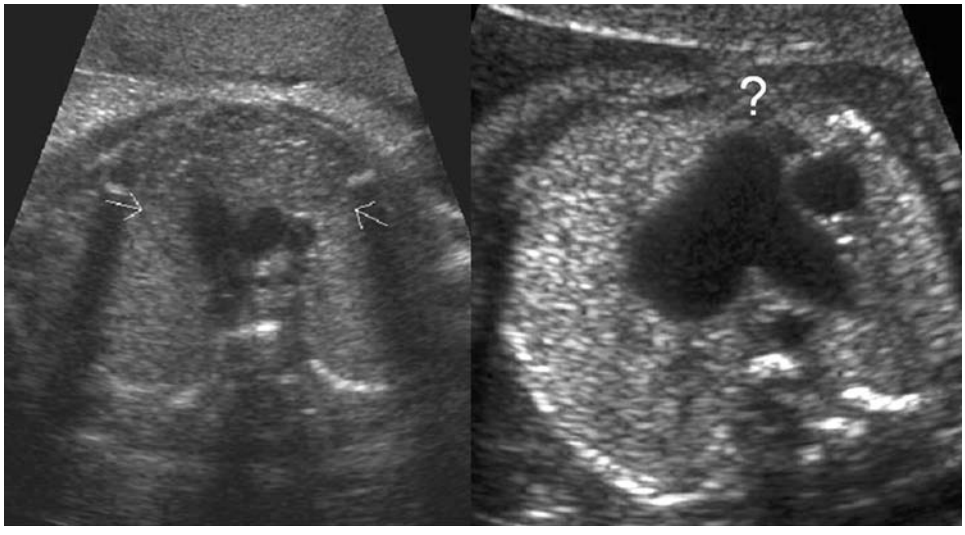

Figure 80.6 Thymus sign in predicting fetuses with del.22q11. In the left figure the thymus is recognized (arrows) as a slightly echogenic structure in front of the three-vessels and behind the sternum. In the right figure the fetus had an absent pulmonary valve syndrome with gross dilated pulmonary arteries. No thymus was visualized between the vessels and sternum (?) and FISH technique revealed the suspected del.22q11.

(Figure 80.3), right or both ventricles increase significantly the risk for chromosomal anomalies. The isolated EF in the left ventricle was accepted in the past year as increasing the background risk of a factor of 1.5 or even only 1. This led recently to a debate whether the findings of an EF should be told to younger women or not.[12,13]

In an observation of a series with CHD we found that 11% of all cardiac defects were associated with an EF,[14] some with malformations not detectable in the four-chamber plane such as the tetralogy of Fallot or a transposition of the great arteries (TGA). A total of 50% of all the cases were, however, not isolated left ventricular EF. Therefore, not only chromosomal anomalies but also cardiac defects should be ruled out in fetuses with a detected EF.

As the use of nuchal translucency (NT) in the risk assessment for chromosomal anomalies, the importance of second-trimester soft markers is reduced, especially the EF.

Discrepant LV/RV width

Devore[15] described an increased risk for trisomy 21 in early second-trimester fetuses with a narrow left ventricle compared with the right ventricle, without the additional signs of an aortic coarctation.

Tricuspid regurgitation

Isolated tricuspid regurgitation detected by the routine use of color Doppler is present in ca. 4% of all normal fetuses at the 20–22-week scan.[16] Tricuspid regurgitation was, however, also discussed as associated with Down's syndrome when detected at 16–18 weeks[15] or at the 11–14-week scan.[17]

Pericardial effusion

An isolated pericardial effusion was described to increase the risk of association with Down's syndrome (Figure 80.4).[18] It is not known whether in these cases, the effusion is the remaining of early hydrops with a thickened NT in early pregnancy. This sign was unfortunately not evaluated in recent years in the age of NT measurement.

Linear insertion of the AV valves

This is an interesting new sign presented by a French group a few years ago. Fredouille *et al.*[19] found on autopsy specimens of hearts from fetuses with Down's syndrome that in some cases, even with the absence of structural heart anomalies both atrioventricular valves (AV valves) inserted at the same level and not the tricuspid valve inserting lower in the right ventricle as under normal conditions. This is a very subtle and interesting sign, used also in the detection of AV-septal defect, but it should be evaluated by other groups.

Aberrant right subclavian artery (ARSA): the new cardiac sign for Down's syndrome

The normal right subclavian artery arises as a first vessel from the brachiocephalic artery and courses ventral of the trachea. An aberrant right subclavian artery (ARSA) arises separately from the aortic arch in the region of the junction of the aortic arch and the ductus arteriosus. It courses to the right arm behind the trachea and is thus detectable with color Doppler in the three-vessels-trachea view[20] (Figure 80.5).

In a few pediatric cardiology studies it was described that an ARSA (also called lusorian artery) is found in 1% of the normal population but is as high as 35% in persons with Down's syndrome with or without heart defects.

We were the first to describe this sign in fetuses with Down's syndrome in a paper published recently,[20] where we found that 5/14 (36%) of consecutive fetuses with Down's syndrome had this aberrant vessel, which we detected prenatally. Only one had it as an isolated sign, three in association with an EF in addition to extracardiac signs, and in only one case was it associated with an AVSD.

Personal experience and communication from pathologists support the fact that this sign is also common in trisomy 13, 18 and recent reports emphasized the occurrence in Turner syndrome and in microdeletion 22q11.

Further observations from other groups are necessary to confirm our new finding.

Cardiac signs for microdeletion 22q11

The del.22q11 is reported to have a frequency of 1:4000 livebirths and is considered to be after trisomy 21 the second most common chromosomal anomaly in liveborn children with a CHD. The earlier used and now abandoned acronym CATCH-22 summarizes the combination of finding in these patients: C = cardiac anomaly, A = abnormal facies, T = thymus hypo or aplasia, C = cleft palate, H = hypercalcemia and 22 for del.22q11. Prenatally, the clinical features of an abnormal facies are generally very subtle and we can mainly rely on the heart anomaly and, as we showed a few years ago, also on the thymus sign.

Among the heart anomalies, conotruncal and aortic arch malformations are the leading defects permitting a concrete suspicion of a del.22q11. The occurrence of this deletion is present in ca. 50% of all cases with interrupted aortic arch, 40% of absent pulmonary valve syndrome, 30% of Truncus arteriosus communis, 20% of pulmonary atresia with VSD, 15% with tetralogy of Fallot, and in around 5% in other anomalies such as complex transpositions, double-outlet right ventricle and others.[21]

A few years ago we examined a group of 147 fetuses with CHD, including 76 with conotruncal defects. In this study we examined the role of analyzing the absence or hypoplasia of the thymus in predicting a del.22q11. Ten of the 147 cases had a del.22q11, all being in the group with conotruncal anomaly. Nine of the 10 fetuses with microdeletion had an abnormal thymus detected prenatally (sensitivity 90%, specificity 98.5%). In our experience the examination of the thymus region helps in defining a group at high risk for del.22q11[21] (Figure 80.6).

According to other studies additional signs were described to increase the risk of 22q11 (in predefined high-risk groups) and some of these are increased NT in early pregnancy, intrauterine growth retardation, polyhydramnios, renal or facial abnormality, right aortic arch, aberrant right subclavian artery, aberrant pulmonary artery, etc.[22,23]

81 Ultrasound screening of chromosomal abnormalities by nuchal translucency

M. A. Zoppi and G. Monni

Introduction

Nuchal translucency (NT) is the term that has been used for 10 years to describe the echo-free space behind the fetal neck visible by ultrasound in almost all fetuses at 10–14 weeks[1] (Figure 81.1). Before this gestational age the NT is not clearly evident in all cases and after 14 weeks the NT reduces, becoming less transonic and turning into the nuchal fold space visible in the second trimester.

The NT is in fact the ultrasound image of some soft tissues that cover the occipital bone and cervical spine (muscles, connective tissue, lymphatic vessels, subcutaneous tissues and cutis).

In physiological condition these tissues can accumulate more or less fluids and as a result the thickness of the NT is expected to differ among normal fetuses.

Moreover, during the 11–14-week period, the thickness of the NT increases with the crown–rump length (CRL) and with the age of the fetus. Tables of reference for NT thickness in normal fetuses have been generated by cross-sectional studies. Some studies have calculated the ranges by using linear regression formula; however, the quadratic regression approach seems to better fit the trend of nuchal thickness.[2–5]

Other studies have shown that longitudinal assessments of NT in the same fetus showed a tendency toward increase of the thickness to a peak that is reached individually and differently by each fetus, mostly around 12 weeks, followed by a decrease.[6]

It is evident that due to local contingent conditions (operators, machines, approach to the ultrasound technique and ethnicity), there are subtle differences among different centers that perform the measurement of the NT. Therefore, it has been suggested that local reference ranges for normal NT be preferred to assess the thickness whenever it is possible.[7]

Figure 81.1 Nuchal translucency.

At 10 weeks, essentially, the NT thickness in normal fetuses most frequently measures around 1–1.2 mm, and at 13–14 weeks, around 1.7–1.9 mm.

The visualization and measurement of the NT is not included among the main identified objectives of first-trimester ultrasound as recommended in most guidelines issued by ultrasound scientific societies. Ascertaining the presence of the gestational sac in the uterine cavity, the number of fetuses, the embryonic or fetal heartbeat and the duration of pregnancy is usually done in the first-trimester scan.[8–10]

Therefore, during the first-trimester ultrasound examination, only if it is specifically requested is a normal NT visualized and measured. Because of the implications that the measurement of the NT can carry for the pregnancy (reducing or increasing the risk of chromosomal abnormalities, opening a scenario for invasive prenatal diagnosis), it is advisable to perform the measurement only in the correct setting (by a

skilled operator and in a certified screening program, after a request for screening by the informed patient).[11]

The enlarged nuchal translucency

Sometimes there can be a surplus accumulation of fluid in the nuchal tissues (Figure 81.2). The accumulation of nuchal fluid can be caused by either an increased amount of fluid directed in the nuchal region or some difficulty in the drainage of the normal quantity of fluid present in the neck.

Regardless of the underlying cause of the accumulation of fluids, what is apparent on the ultrasound is the increased thickness of the echo-free space behind the fetal neck, which has been labeled 'enlarged NT'.[12] This space can be absolutely transonic or faintly echogenic, and can be limited to the neck or extended the whole length of the fetus as a 'space suit'[13] (Figure 81.3).

When the NT is very enlarged at 10–14 weeks, it can easily be visualized during the scan without especially looking for it. This is a situation comparable with that which occurs with some soft markers for chromosomopathies in the second trimester (hyperechogenic focus, hyperechogenic bowel, dilated renal pelvis, etc.),[14] when these signs are evident, without our having to look for them. Although these signs are not malformations, and they can be visible during an ultrasound examination, which does not have the finality of chromosomopathy screening, the guidelines of some scientific societies that have faced this problem recommend disclosing the presence of evident soft markers to the patient, in order to offer the opportunity for adequate genetic counseling.[8]

It has been noticed since the early 1990s that fetuses with trisomy 21 can show an enlarged NT at first-trimester examination[15] (Figure 81.4).

When an ultrasound scan is performed with the specific intention of measuring the NT, it is essential to correctly visualize the fetus and to perform the NT measurement in an adequate way in order to compare the actual measurement with the reference values. The range of NT thickness varies with CRL, so that the 95th percentile for a CRL of 45 mm is quite different from that for a CRL of 82 mm, and it is evident that a fixed cutoff for NT measurement cannot be used efficiently to assess the enlargement of an NT.[16]

It has been noted that the majority of fetuses with trisomy 21 show an NT greater than the 95th percentile of ranges obtained for normal fetuses with a standard technique of NT measurement. Fetuses with chromosomal abnormalities other than trisomy 21 (trisomy 18, trisomy 13, Turner syndrome, Klinefelter syndrome and triploidy) can have an enlarged NT[16] (Figures 81.5–81.7).

In fetuses with normal and abnormal chromosomes the enlarged NT is frequently a transient sign. In an early study of trisomies 21, at the beginning of the second trimester, a reabsorption of the nuchal edema has been longitudinally described in six cases.[17] A study of the evolution of enlarged NT during the first trimester described a decrease in the thickness that occurred in both chromosomally normal and abnormal fetuses. In the second measurement performed in the same fetus, the frequency of decreasing NT was greater in the normal than in the abnormal karyotype fetuses.[18]

In fetuses with Turner syndrome the evolution of first-trimester enlarged NT is frequently described as a cystic hygroma (cystic malformation of the lymphatic system) in the second trimester[19] (Figure 81.8).

Figure 81.2 Enlarged NT.

Figure 81.3 'Space suit' nuchal translucency.

Pathophysiology of enlarged NT

The term 'enlarged NT in the first trimester' that is used in ultrasound practice may indicate many different background conditions.

An accumulation of fluids in the neck is presumed to come from either an abnormal local composition of the tissues that tend to capture more fluids or a situation of hampered reabsorption of a normal quantity of fluids regularly passed from the vessel to the

Figure 81.4 Trisomy 21 fetus with enlarged nuchal translucency.

interstitial spaces, or from a condition of increased passage of fluids from the vessel to the connective, due to an abnormal hydrostatic pressure as a consequence of impairment of the arterial or venous circulation.[20–26]

In trisomy 21, some alteration in the composition of the skin, with an increased expression of type VI collagen and a rise in the quantity of hyaluronic acid, could justify an increased entrapment of liquids that for reasons not yet explained, in the first-trimester fetus, is evident only in the nuchal region.[23,24] An extra accumulation of fluid that exceeds the normal capacity of the mechanism deputed for drainage may be the cause of enlarged NT in trisomy 21 fetuses.[26]

In Turner syndrome, the accumulation of fluid in the nuchal region seems to be related to a failure in the drainage by the lymphatic system, because of an abnormal structure that involves the minor lymphatic vessels in the skin, and the greater vessel, with a lack

Figure 81.10 Multiplanar view of a trisomy 21 fetus with enlarged jugular lymphatic sacs.

of definitive connections between the jugular lymphatic sacs and jugular veins system, as an expression of a failure in the development of the lymphatic system, due to the underlying karyotype anomaly[22,26] (Figure 81.9). In fetuses with Turner syndrome, the first-trimester translucencies are typically large, bilateral and septated, occupying the lateral and posterior regions of the neck of the fetus. In Turner syndrome, the first-trimester NT is in fact often not transient, with a tendency to evolve into a second-trimester 'cystic hygroma colli'.[26]

A different mechanism related to a temporary lymphatic failure due to a delay in the connection with the venous system has been considered in trisomy 21 and normal fetuses. In these cases, the evolution toward a reabsorption in the second trimester is frequent.[26]

Pathological studies carried out on fetuses with enlarged NT with normal karyotype and trisomies 21 and 18 have in fact shown in the posterior side of the neck of the fetus, exactly where the NT is visualized by ultrasound, the presence of some cavities, negative for immunohistochemical markers for lymphatic vessel endothelium and arteries. These cavities seem to be the result of coalescence of edematous mesenchymal spaces (due to an edematous mesenchymal). In these cases, a lymphatic distension of jugular lymphatic sacs in the lateral side of the neck has been shown to occur prior to the manifestation of the nuchal edema (Figures 81.10 and 81.11). The hypothesis was that the first occurrence would be the delay in the lymphatic drainage, which may then cause the accumulation of mesenchymal fluid and nuchal edema. At 14 weeks, when the jugular lymphatic sacs are fully developed, making definitive connections with the venous system, both nuchal edema and dilatation of lymphatic sacs finally resolve.[26–27]

In trisomy 21 another mechanism has been postulated to cause the accumulation of fluids and enlargement of the NT, due to an increase of the perfusion of the vessel directly to the neck and the upper part of the fetus. In pathology studies, a narrowing of the

Figure 81.11 Three-dimensional surface rendering of a trisomy 21 fetus with enlarged jugular lymphatic sacs.

isthmus of the aorta, associated with a dilatation of the supravalvular portion of the vessel, has been described. An increased passage of fluids into the connective tissue due to an increase in hydrostatic pressure could be involved in the enlargement of the NT.[28]

An accumulation of extravascular liquids, as it is present in adults with an impairment of cardiac function, can also be present in fetuses with chromosomal abnormalities or normal karyotype fetuses with structural heart abnormality. The subcutaneous edema depends on an impaired reabsorption of fluids due to an increase of the hydrostatic pressure in the venous system. A wide spectrum of heart defects has been described to be present in fetuses with chromosomal abnormalities and normal fetuses with enlarged NT, but a clear connection between specific cardiac diseases and the development of the enlarged NT in the

Figure 81.12 Heart defect in a first-trimester fetus with normal karyotype and enlarged NT.

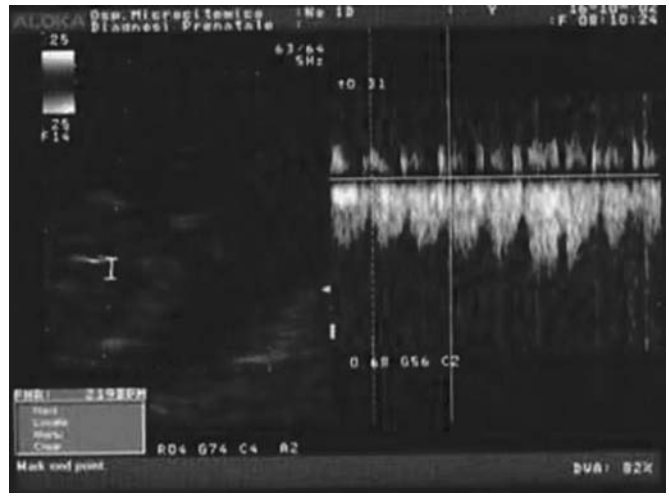

Figure 81.14 First-trimester tachycardia in a first-trimester fetus with normal karyotype and enlarged NT.

Figure 81.15 First-trimester second-degree heart block in a normal karyotype fetus with enlarged NT.

first trimester of pregnancy has not been demonstrated[28,29] (Figures 81.12–81.15).

A relationship between an impaired diastolic function and enlarged NT has been hypothesized on the grounds of some alteration signs on the velocimetry of the ductus venosus in fetuses with abnormal karyotype, cardiac defects and NT thickness.[30–31] The ductus venosus is a vessel that connects the umbilical circulation with the right atrium. In the first trimester of pregnancy the pulsed Doppler waveform of this vessel is characterized by a forward flow with a peak during systole, a second peak in diastole and a forward velocity during atrial contraction (Figure 81.16). In cases where the pressure in the atrium at the end of the diastolic phase is increased (which could be a sign of cardiac dysfunction due to several factors, including some structural malformations of the heart), the velocity during the atrial contraction in the ductus venosus decreases: it can be zero or reversed (Figure 81.17–81.18). In fetuses with chromosomal abnormalities that are suspected to have a greater occurrence of cardiac abnormalities and that show frequently an enlarged NT, the velocimetry of the ductus venosus is frequently altered (70–90%), with an absent or reversed atrial contraction velocity.

Another parameter that has been used to evaluate the alteration of the velocimetry in the ductus venosus is the pulsatility of the wave form, which in chromosomal abnormalities appears increased.[32] If there is a single cause that determines at the same time two parallel consequences such as the altered ductus venosus flow and the enlarged nuchal thickness, or if there is a consequential connection between the two findings, which of these findings occurs first needs to be demonstrated.

An impairment in the diastolic function has been shown in fetuses with enlarged NT in the first

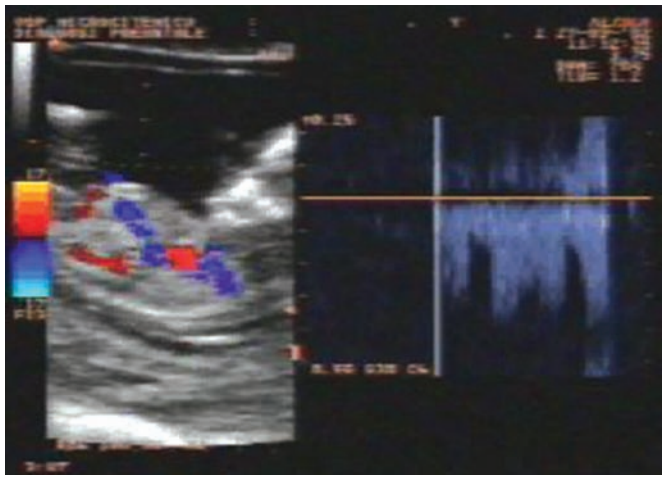

Figure 81.16 Normal velocity flow in the ductus venosus in a first-trimester fetus.

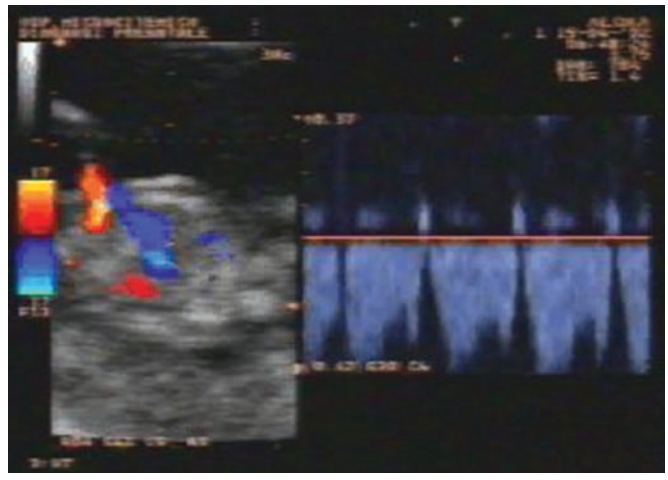

Figure 81.18 Reversed velocity during atrial contraction in the ductus venosus.

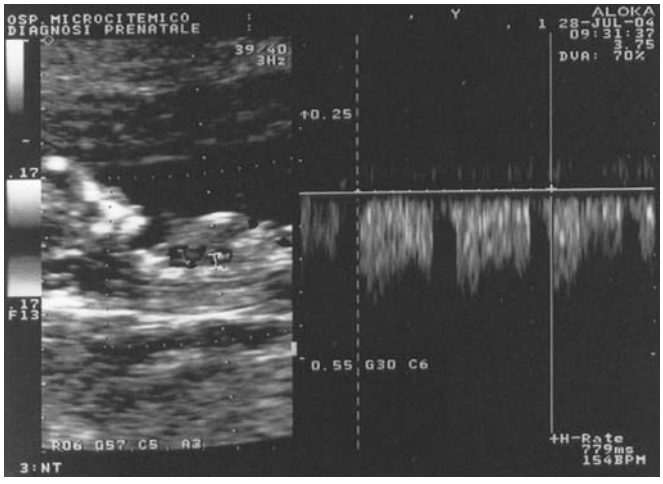

Figure 81.17 Absent velocity during atrial contraction in the ductus venosus.

trimester and normal karyotype, which persists in the second trimester, and this is demonstrated by an alteration of the velocimetry of the atrium-ventricular valves.[33]

In fetuses with enlarged NT, no impairment in the ventricular systolic function has been described. In fact, no difference of umbilical pulsatility index in the first trimester has been shown in normal karyotype fetuses with normal and enlarged NT and in trisomy 21 fetuses with enlarged NT.[34]

A mechanism of increased hydrostatic pressure in the thorax has been postulated to be involved in cases of first-trimester enlarged NT and venous congestion as in cases of diaphragmatic hernia and skeletal dysplasias.[21]

Enlarged NT for trisomy 21 screening

Amniocentesis and chorionic villus sampling (CVS) are invasive prenatal diagnosis techniques for fetal karyotype analysis, which carry a procedure-related risk of abortion of about 1%. Since the introduction of invasive prenatal diagnosis, karyotype analysis has been offered only to high-risk cases due to medical and financial reasons, and the maternal age-related risk of Down's syndrome was the older and most commonly used approach to prenatal screening. The aim of the screening is to select those women who are at high enough risk of Down's syndrome to justify an invasive prenatal diagnosis procedure.[35]

In the last 20 years, prenatal ultrasound examination has been able to identify some of the malformations in trisomy 21 fetuses and other aneuploidies, and some of the anatomical features that differ slightly from those of normal fetuses. The ultrasound approach has been proposed for identification of cases at a higher risk.[14] In the mid-1980s the first finding of trisomy 21 that has been identified by ultrasound as a marker for trisomy 21 was the increased nuchal fold thickness in the second-trimester fetuses.[36] Later, in the mid-1990s, the association between first-trimester increased NT thickness and trisomy 21 and other chromosomal abnormalities was described.[1]

For NT, an algorithm for the calculation of individualized risk and a specific quality control for the test have been proposed since its introduction, while for serum markers for trisomy 21 this is a consolidated approach, for ultrasound in prenatal diagnosis was relatively new.[2]

Frequencies of trisomy 21 cases and normal fetuses were compared for the deviation of the measured NT from the normal expected values, in order to calculate likelihood ratios.[2] Two principal methods have been used to calculate the deviation from the normal: the Delta value and the multiple of the median (MoM).[2,37] The Delta value approach is considered to give some advantages.[38] Delta value in millimeters indicates the difference between the measured NT and the expected median of NT calculated for normal fetuses

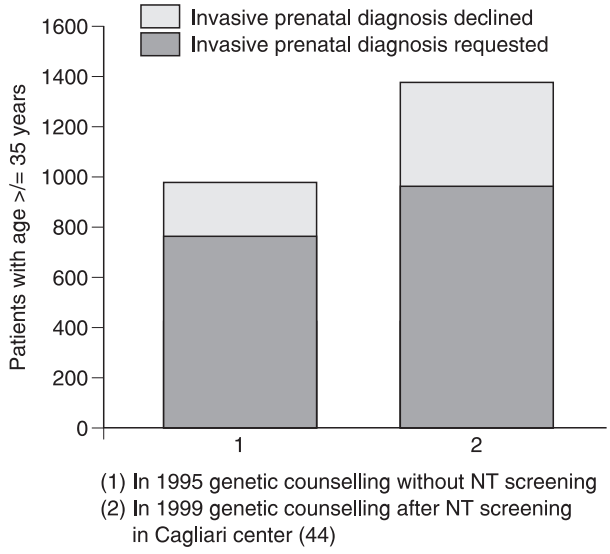

Figure 81.19 Acceptance of invasive prenatal diagnosis.

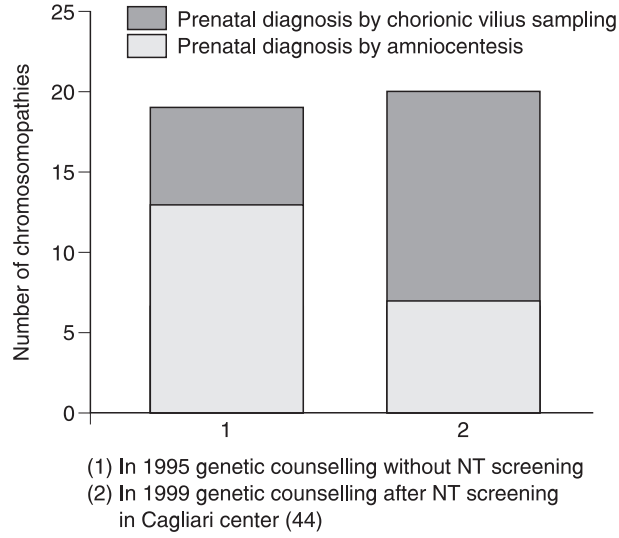

Figure 81.20 Procedure used for prenatal diagnosis of chromosomopathies.

for a given CRL. An estimate of the risk for trisomy 21 was calculated by multiplying the maternal age-related risk for trisomy 21 by the likelihood ratios obtained from the NT thickness, giving a new individual numerical risk.[16] The risk estimate for trisomy 21 based on the ultrasound measurement of NT is based on a few but important principles. First of all, the maternal background risk is the essential factor of the screening test for trisomy 21, and each time it needs to be considered in the calculation. Second, the results are not given as 'tested positive' or 'tested negative' on the ground of an arbitrarily chosen cutoff, but the patient is faced with a numerical result, on which she can base her decision according to her wishes and anxieties. Third, a quality control method is applied to ultrasound measurement (this is new for this field of medicine, although it has been used for decades, e.g. laboratory serum markers). There is evidence that the NT test is reliable, because the interoperator and intercenter variability can be reduced and comparable results are obtained, in cases where the measurement is performed according to a defined technique, with adequate training of operators and constant audit of the results.[39] Using this approach, in a multicentric study (22 centers involved), performed over 100,000 cases, with an average maternal age of 28 years, for a risk greater than or equal to 1 in 300, the sensitivity for trisomy 21 has been estimated to be 82%, with a false-positive rate of 8%.[40] With these performance results the NT test was considered to be the most effective prenatal screening to identify cases at risk of trisomy 21. Comparable results were obtained by other centers where guidelines for NT screening were observed.[5]

Fetuses at higher risk of trisomy 21 because of enlarged NT were at the same time found to be at higher risk of other chromosomopathies such as trisomies 18 and 13, triploidy and sex aneuploidies.[40]

Clinical importance of NT screening

The availability of an accurate screening test in the first trimester, such as NT, is useful to recognize cases at a higher risk of trisomy 21 at an early stage, in order to offer an early invasive prenatal diagnosis that could be performed preferably by CVS. It is true that when the performance of NT test is considered, the spontaneous intrauterine mortality of affected fetuses from the first trimester to term has to be taken into account. A number of those fetuses identified to be at high risk in the first trimester, and on which an invasive prenatal diagnosis procedure is performed, would be spontaneously demised in the uterus before birth, without all the trouble and anxiety that the prenatal screening procedure can carry. About 30% of trisomy 21 fetuses that are detected by first-trimester NT screening are destined to die during the pregnancy. This percentage is about 10% greater than the lethality of fetuses detected by a second-trimester screening test, which is about 20% to term.[41]

However, there is evidence that for pregnant women there are some aspects of prenatal screening that are of value. A test that gives the result early in pregnancy, and that obviously has at the same time a low rate of false negatives and false positives, with a reduced number of invasive procedures and fetal demises due to procedure-related risk, is considered to be better.[42,43] Enlarged first-trimester NT could identify, at the same time, fetuses at higher risk of abnormalities other than chromosomopathies. Cardiac defects, some structural abnormalities and genetic syndromes can occur more frequently in fetuses with enlarged NT than in the general population.[29]

Women at high risk of trisomy 21 because of advanced age can gain some advantage from having the NT test done. In fact, a more precise estimate of individual risk for trisomy 21 can be made, with the

opportunity to decide about prenatal diagnosis with more autonomy. Reduction in requests for invasive prenatal diagnosis in women aged 35 years or over and earlier detection of cases at risk by first-trimester CVS are the chief advantages of the NT screening test over invasive prenatal diagnosis due to maternal age[44] (Figures 81.19 and 81.20).

NT screening can be used for screening of chromosomal abnormalities with the same accuracy in twin and multiple pregnancies.[45,46]

Recent developments in NT screening

At its introduction in clinical practice, it was proposed that the NT screening test be performed from 10 weeks 3 days (a CRL of 38 mm). With evidence that at around 12 weeks a better evaluation of fetal anatomy could in most cases be achieved, it was suggested that screening be performed after the CRL reaches 45 mm, so that at the same time, structural abnormalities can be detected early.[47]

In order to decrease the false negatives and the rate of invasive testing, the risk obtained by maternal age and NT has been combined with other markers, which occur more frequently in trisomy 21 cases than in normal fetuses, but are not related to the increase of the thickness of first-trimester NT. First-trimester maternal serum markers, pregnancy associated plasma protein-A (PAPR-A) and free beta human chorionic gonadotropin, combined with the NT test, increase the sensitivity to 90% and decrease the false-positive rate to about 3%.[48]

The combination of NT test with the sign of absent nasal bone in the first trimester is still under assessment.[49,50] The integration of the NT test with maternal screening markers of the first and second trimesters has been shown to improve the accuracy of the test, but it is necessary to wait until the second trimester to disclose the result and eventually to offer the diagnosis.[51]

With the possibility of combining and integrating different tests, a new scenario for prenatal screening for trisomy 21 is now emerging. Different tests can be performed at different times (one stop, two step, one step), the results can be disclosed after every single test or integrated, successive tests can be performed only in established cases, for example, only in borderline cases (contingent test), and each test could obtain different performances.[35] Some tests carry a greater sensitivity, others a greater specificity. There are many options to screen for trisomy 21, but the choice of the direction in which to move is delicate. If the screening test for trisomy 21 is performed on a financial basis, and the national health care system is the purchaser, it can offer a policy of screening that is more cost-effective after a rigorous cost–benefit analysis.

When a screening program concerns a disease for which the definitive diagnosis exposes a human being to a potential lethal risk, and, in case of ascertained disease, there is no cure as there is for trisomy 21 at prenatal diagnosis, many ethical problems come to light and they put doctors and patients in a great dilemma.

In this specific case of screening, the principle of self-determination for the patient, for decades applied to the field of invasive prenatal diagnosis, should be the fundamental issue of the entire process, and should be the goal to be achieved.[11] From the start, all the steps of the screening procedure should be accurately considered, leaving nothing to chance, such as, for example, the first apparently innocent question about how old she is, that everyone asks a completely unaware (about prenatal screening troubles) prospective mother.

82 First-trimester ultrasound screening for Down's syndrome in multiple gestations

G. Monni and M. A. Zoppi

Introduction

In the last decades, the older maternal age at conception and the more frequent use of assisted reproductive techniques have moved to a constant increased rate of multiple pregnancies. Some specific prenatal and perinatal problems make these pregnancies at higher risk.[1–4] Neonatal mortality and morbidity are higher in multiple pregnancies, and maternal complications are more frequent.

Moreover, mostly because of the advanced maternal age, multiple pregnancies are at higher risk for chromosomal defects. At the same time, as these pregnancies (frequently obtained after years of infertility) are especially precious to the prospective parents, there is no unanimous acceptance of the need of invasive prenatal diagnostic procedures, which are more difficult to perform than in singleton pregnancies.[5,6]

Non-invasive screening tests for chromosomal abnormalities in multiple pregnancies are more acceptable. Maternal serum biochemistry for trisomy 21 in multiple pregnancies has been proposed.[7,8] However, interpretation may be difficult because of the interference between serum marker concentrations and assisted reproductive therapies, and the identification of which of the fetuses is positive at the biochemical test is of great concern.

For invasive prenatal diagnosis, the risk of miscarriage related to the procedure is increased, depending mostly on the number of needle insertions.[9,10] Prenatal diagnosis of a chromosomal abnormality in multizygotic multiples allows an informed decision about the management of the pregnancy. Therefore, an accurate estimate of individual fetal risk for chromosomal abnormality is advisable in multiple pregnancies.

Ultrasound screening for trisomy 21 by first-trimester nuchal translucency (NT) measurement is correctly applicable for twins and multiples.[11–13] The test gives an individual risk for each fetus and it is comparable in the accuracy to the screening test for trisomy 21 in singleton pregnancies.[14–17]

Type of multiples

Zygosity depends on the type of conception.

Monozygotic pregnancies originate from the division of a single zygote, and account for about 30% of twin pregnancies. The frequency of monozygotic pregnancy is stable in the world and among different populations at around 1 in 250 deliveries. The origin of monozygotic pregnancy is unknown. Next to the theory of an accidental event, a delay in the implantation of the zygote, with a reduction of oxygen transport, has been hypothesized.[18]

Multizygotic pregnancies originate from the fertilization of two or more oocytes by two or more spermatozoa (Figure 82.1). Dizygotic pregnancies account for about 70% of the total twin pregnancies. The frequency of dizygotic pregnancy varies among population, and the origin appears to be multifactorial. High levels of follicle stimulating hormone (FSH), advanced maternal age, high grade of parity, tall maternal stature and proportionate maternal weight (reflecting a good nutritional maternal status and probably higher levels of FSH), ethnical and familiar inherited factors, seasonality (peak of those kind of conceptions in summer), the application of technologies of assisted reproduction and the use of drugs for the induction of ovulation support an increased frequency of multiple conceptions.[1,2,18] The *in vitro* manipulation of embryos in techniques of assisted reproduction and the use of special culture mediums seem to induce a greater frequency of iatrogenic monozygotic pregnancies.[19] (Figure 82.2).

The chorionicity depends on the type of placentation. Dizygotic and multizygotic pregnancies are always dichorionic and multichorionic (Figure 82.3).

Figure 82.1 A dichorionic diamniotic twin pregnancy at 9 weeks.

Figure 82.2 A dichorionic triamniotic triplet pregnancy obtained by *in vitro* fertilization.

Figure 82.3 3D rendering of a multizygotic pregnancy (nine fetuses).

Figure 82.4 A monochorionic diamniotic pregnancy at 9 weeks.

Monozygotic pregnancies can be dichorionic or monochorionic, and the chorionicity depends on the time of the division of the conceptus (Figure 82.4).

If the division occurs by the third day from fertilization (and this happens in about 30% of monozygotic pregnancies), two placentas are generated. If the division occurs between the fourth and the eighth days from fertilization (and this happens in about 70% of monozygotic pregnancies), the placenta will be single with two amniotic cavities (monochorionic, diamniotic pregnancy). If the division occurs between the 9th and 13th days from fertilization (it happens in less than 1% of monozygotic pregnancies), the placenta and the amniotic cavity will be only one (monochorionic, monoamniotic pregnancy). In very rare cases, the division occurs between the 14th and 16th days from conception, and the result is conjoined twins.

Monozygotic twins are at higher risk for structural anomalies than multizygotic ones because of higher potential errors in the division of the zygote and pre-embryo.[1]

Prenatal ultrasound determination of chorionicity

Prenatal diagnosis of chorionicity can be made easier by ultrasound in the first trimester. By transvaginal ultrasound, gestational sacs can be seen at 5 weeks of gestation (from 4 weeks plus 2 or 3 days), and the

Figure 82.5 First-trimester lambda sign in a dichorionic pregnancy.

Figure 82.7 Second-trimester dichorionic pregnancy: the lambda sign has disappeared.

Figure 82.6 Absence of lambda sign (T sign) in a monochorionic twin pregnancy.

Figure 82.8 The ipsilon sign in a trichorionic pregnancy.

number of sacs indicates the number of placentas (monochorionic, dichorionic, trichorionic, etc.). As the gestation proceeds, the septum between the sacs become thinner, and only a triangular structure, the 'lambda sign' or 'twin-peak sign' remain from 10 to 14 weeks (Figure 82.5). In monochorionic pregnancy there is no chorionic tissue between the two amniotic sacs, and the joint of membranes to the chorionic sac is called the 'T sign' (Figure 82.6). In dichorionic pregnancies, later in pregnancy, the 'lambda sign' is difficult to visualize in all cases, and it can completely disappear around 20 weeks (Figure 82.7).[20]

The visualization of the 'lambda sign' is an unequivocal sign of dichorionicity, while the absence in the second trimester is not sufficient to exclude the presence of two placentas. In triplet trichorionic pregnancies, the junction of interfetal membranes is called 'ipsilon zone' (Figure 82.8).[21]

The accurate identification of chorionicity is one of most important goals of obstetric ultrasound in multiple gestations, and in all cases it should be ideally performed in the first trimester so that the risk of each individual pregnancy can be assessed.

Monochorionic pregnancies are at higher risk than dichorionic pregnancies for prenatal and perinatal problems, as they are monozygotic and because of the occurrence of specific problems due to transplacental circulation imbalance, which is the twin-to-twin transfusion syndrome. This complication occurs in about 20% of monochorionic pregnancies and frequently manifests itself at 16–22 weeks, by polyhydramnios in one sac and oligoanhydramnios in the other sac. If untreated, the mortality is about 90%. Amniodrainage or laser coagulation of arterovenous connections in the placenta is the therapy proposed in the second trimester, allowing a survival of about 50% of cases.[22]

Risk of chromosomal abnormalities in multiples

To calculate the risk of chromosomal abnormalities in multiple pregnancies, it is fundamental to estimate the zygosity.

For monozygotic pregnancies, if cases with mitotic non-disjunction that determine 'heterokaryotypia' are excluded, the karyotype in both fetuses would be the same.[23] Fetuses can be discordant for anomalies that are generated by the splitting phenomenon, but are concordant for anomalies genetically determined. Both fetuses have the same karyotype either normal or abnormal.

For multiple pregnancies derived from multizygotic conception, discordant karyotypes are expected. Therefore, prenatal sonographic estimation of zygosity is fundamental in the process of risk calculation.[9,24] In prenatal life, ultrasonographic evaluation of the placentas can give information in this direction. DNA analysis of the fetal or neonatal sampling allows a definitive diagnosis of zygosity.

When a monochorionic pregnancy is diagnosed by prenatal ultrasound (whether monoamniotic or diamniotic), monozygosity can be supposed, and an equal risk for trisomy 21 for both fetuses, similar to the maternal age-related risk, can be calculated. When dichorionic or multiple placentas are evidenced, a little probability of monozygotic pregnancy cannot be excluded, but the most frequent condition is multizygotic pregnancy. If the assessment is made in a period when it is possible to define by ultrasound the fetal gender, and the placentas are multiple, in cases with discordant sex, the probability of multizygosity is validated. The risk for the pregnancy of having one fetus with trisomy 21 is calculated by the sum of the risk for each fetus. For example, in a triplet trizygotic pregnancy, if the maternal trisomy 21 background risk is 1 in 150, the final risk for the entire pregnancy is 1 in 150 + 1 in 150 + 1 in 150. For calculations, risks can be expressed as odds (that is 1:149 + 1: 149 + 1:149), that is about 3:149 or 1:47, for a final risk for the pregnancy to have one fetus with trisomy 21 of 1 in 48. In multichorionic pregnancies, the risk for all fetuses to have trisomy 21 is very rare, this being calculated by multiplying the maternal age risk for one fetus by the risk of the other. For example, in a dichorionic and 'hypothetical' dizygotic pregnancy, where the maternal age risk for trisomy 21 is 1 in 150, the background risk of the entire pregnancy is calculated by multiplying 1:149 × 1:149, then 1:22,201, that is a risk of 1 in 22,202.

A sort of uncertainty is originated by the presence of those cases of monozygotic dichorionic pregnancies that are unrecognized in prenatal life, where the background risk of the pregnancy would be the same as the age-related risk for trisomy 21 of the pregnant woman.

Invasive prenatal diagnosis procedures for karyotype analysis in multiples

When a multiple pregnancy is discovered, extra counseling is due regarding procreative risks, pregnancy-related risk for the mother, prenatal management of the pregnancy, screening and prenatal diagnosis of fetal anomalies and chromosomal abnormalities.[9,10]

When an invasive procedure for prenatal diagnosis is planned, whatever be the approach considered (chorionic villus sampling, amniocentesis, fetal blood sampling), some fundamental conditions should be fulfilled.

The knowledge of the type of placentation is imperative (mono- or multichorionic placenta). Each sample obtained from a distinct twin should be defined (or checked by biological tests that analyze the fetal phenotype or genotype); each fetus should be mapped carefully by ultrasound during the procedure to later allow the precise identification when the result from diagnosis becomes available. We should consider the increased risk of procedure-related abortions, of invasive diagnosis in multiples, compared to singles, which depends among others factors mostly on multiple needle entrances through the uterus.

When the operators are faced with invasive procedures in multiple pregnancies, a specific experience and skill in this particular field of prenatal diagnosis is required.

Selective fetocide and multifetal embryo reduction

The diagnosis of a single affected twin after a procedure of invasive prenatal diagnosis can lead to consent to plan a selective termination of the affected fetus and to continue the pregnancy of the normal fetus.

Multifetal embryo reduction is an option that could be considered for therapeutical options in cases of high-order multiple pregnancies. Maternal and fetal risks (related to high prematurity) are increased in these pregnancies. The neonatal and pregnancy outcome have been shown to improve in cases of four or higher multiples reduced to twin, because of a significant increase of the gestational age at delivery and a better maternal outcome. At present, the role of embryo reduction for the management of triplet pregnancies is under discussion.[25,26]

Embryo reduction is usually performed in the first trimester, because it carries fewer complications than in the second, by intrathoracic or intracardiac injection of potassium chloride at 11–13 weeks, under ultrasonographic continuous guidance. When the number of fetuses is high, it is preferable to perform the reduction by steps.

At the beginning, when performing this procedure, the choice as to which fetus to reduce was based fundamentally on technical considerations (the fetus nearest to the uterine surface or the one easier to reduce for the operator). The likelihood of reducing a normal fetus while maintaining some abnormal cases (affected by structural anomalies or chromosomopathies) was considered. Therefore, it was proposed to offer invasive prenatal diagnosis for karyotype by chorionic villus sampling in all cases before performing embryo reduction.[27] Because of the difficulties and costs of such invasive prenatal diagnosis in multiples, and the greater risk of miscarriage related to the numerous procedures carried out, this approach has not been universally approved and performed.

To avoid a non-selective reduction and to decrease the use of invasive procedures, NT screening before embryo reduction has been considered. In fact, the finding of an enlarged NT, allowing the possibility of calculating the individual risk for trisomy in each fetus, can identify cases at higher risk for chromosomal abnormalities and for structural malformation in multiple pregnancies.[28]

Figure 82.9 Nuchal translucency.

Figure 82.10 Absent nasal bone in a trisomy 21 fetus.

NT in multiples

The ultrasound measurement of the soft tissues behind the fetal neck (NT thickness or NT) (Figure 82.9), and the combination of the likelihood ratios obtained with the maternal background risk for trisomy 21, is a valid test of screening to identify fetuses with chromosomal abnormalities.

In multiple pregnancies an individual risk for trisomy 21 can be calculated for each fetus, and, as for the background risk due to maternal age, the risk for the entire pregnancy can be considered.

In twin and multiple pregnancies, screening for chromosomal abnormalities by NT can be performed and it is as accurate as in singleton pregnancies.[14–17]

In a large collaborative study on 448 twin pregnancies, Sebire *et al.* have found an enlarged NT in 7.3% of all cases and in seven out of eight cases of trisomy 21.[15]

NT measurement can be used in high-order multiple pregnancies and in those cases obtained by assisted reproductive technologies because no evident difference has been found in the rate of enlarged NT than in spontaneous multichorionic pregnancies, and the sensitivity was the same.[17]

The increased accumulation of fluid in the fetal nuchal, leading to the ultrasound finding of an enlarged NT, can be determined by several different mechanisms: cardiac failure, abnormal or delayed development of the lymphatic vessels, altered composition of the connective tissue of the skin or venous congestion due to an increased pressure in the fetal thorax.[29,30]

The presence of an enlarged NT is associated with an increased rate of chromosomal abnormalities, but the risk for structural malformations and mostly cardiac defects in fetuses with normal karyotype is increased.[31,32]

It has to be considered that a higher frequency of fetal malformation per pregnancy is expected in multifetal pregnancies than in singleton pregnancies, and in a dizygotic twin pregnancy there is a slight chance of a double risk per pregnancy for fetal malformations (because of the independent probability that is carried by each fetus).

In multiple pregnancies, the absence of nasal bone visualization, which is another accurate soft marker for trisomy 21 in the first trimester, can be used with the same efficiency as in singleton pregnancies (Figure 82.10). About 70% of trisomy 21 and an important percentage of other chromosomal abnormalities such as trisomy 18 and 13, 45, X0, can manifest the sign of the absent nasal bone at ultrasound examination performed at 11–14 weeks[33,34] (Figures 82.11–82.13).

Figure 82.11 Dichorionic pregnancy with a normal fetus and a fetus with trisomy 21.

Figure 82.16 The same fetus with enlarged NT in the monochorionic diamniotic twin pregnancy with discordant NT showed an enlarged bladder.

Figure 82.17 The fetus with normal NT in the monochorionic diamniotic twin pregnancy with discordant NT.

Figure 82.18 The same fetus with enlarged NT in the monochorionic diamniotic twin pregnancy with discordant NT showed a normal bladder.

The case of enlarged NT in monochorionic pregnancies

In monozygotic pregnancies the rate of Mendelian disorders and chromosomal abnormalities are identical to those of singleton pregnancies, while there is an increased risk of structural malformations. Malformations due to disruption mechanisms such as midline facial, heart and abdomen anomalies are more frequent.

A higher rate of enlarged NT has been described in monochorionic pregnancies. The enlarged NT has been described in both fetuses or in one. The enlarged NT in monochorionic pregnancies can indicate fetuses at higher risk for chromosomal abnormalities or structural defects or can be a possible early manifestation of heart failure due to twin-to-twin transfusion.[35]

When in a monochorionic pregnancy, the NT is discordant between fetuses, a consideration should be made (Figures 82.14–82.18). An enlarged NT in only one fetus may indicate a greater risk for chromosomal abnormality for the entire pregnancy. The chromosomal abnormality if present, should be present in both fetuses (in the fetus with enlarged NT and in the fetus with normal NT). In fact, excluding the extremely rare case of heterokaryotypia, due to a mitotic non-disjunction, where a normal karyotype can co-exists with a 45, X0 or a trisomy fetus, it should be considered that the two fetuses of the monochorionic diamniotic pregnancy have the same karyotype, either normal or abnormal.

However, in the same pregnancy, there is evidence of a fetus that shows a normal NT, that gives a very small risk for chromosomal abnormality, for the entire pregnancy. To rule out this kind of problem, it has been recently suggested in monochorionic pregnancies with discordant NT, to calculate the risk for Down's syndrome by using the average NT measured in the two fetuses.[36]

Moreover, it should be considered that an enlarged NT could be indicative for a structural anomaly that could be present in only one of the monozygotic fetuses, both with normal karyotype. Concordance for the most common structural abnormalities that occur in monochorionic-monozygotic twins is rare.

In monochorionic diamniotic pregnancy, an enlarged nuchal translucency could be caused by placental circulation problems, rather than chromosomal abnormalities. This early imbalance of fluids between the fetuses can anticipate in the first trimester the inter-twin-to-twin transfusion, that manifest the most important diagnostic sign after only 16 weeks.

83 Maternal hemodynamic changes of pregnancy

J. Nizard

Introduction

Adaptation to pregnancy begins rapidly after conception. Most probably, all described modifications of maternal hemodynamics are triggered early every menstrual cycle, before conception, but are too small to be detected. These modifications are reversible, either at the end of the cycle with menstruations, or within the first weeks or months after delivery. Physiological modifications are only detectable when the amplitude of changes is sufficient, thus most of the time at the end of the first trimester of pregnancy. Functional as well as anatomical changes are observed in most systems, of which the cardiovascular and volume homeostasis systems are among the most important.

These changes in maternal physiology are asymptomatic in normal pregnant women, resulting from an adapted process. They are nevertheless important to know for their implications in pathology and its treatment. Most data we have derive from radioactive molecules and cells, or dye techniques previously used in pregnant women. Modern non-invasive techniques do not provide the same reliability. If echocardiography, for instance, can replace invasive measurements of cardiac output, we still lack non-invasive techniques for parameters, such as plasma volume.

Cardiovascular system

Blood volume

Plasma volume increase starts as early as 6 weeks and reaches a maximum volume of 5200 ml by the end of the third trimester, which represents an increase of 1200–1600 ml or 45% from non-pregnant values.[1,2] Although absolute volume values vary from individual to individual, and among studies, the overall percentage of increase is constant, between 45% and 50%.[3] It is not clear whether the importance of plasma volume is constant for an individual.[2,3] or depends on parity.[4,5] Interestingly, plasma volume increases throughout pregnancy, even when indexed to weight.[2]

The plasma volume increase is greater in multiple gestations and the increase is proportional to the number of fetuses.[6–8] More fetuses also means more placental volume. It is probable that the amplitude of these changes is proportional to placenta volume, since the plasma volume increase is greater, on average, in cases of molar pregnancy.[9] In the study of Pritchard on hemodilution in patients with molar pregnancies, after accounting for blood loss associated with the pathology, he describes in five out of eight patients anemia associated with significant hypervolemia.[9] The increase in blood volume ranged from 25% to 51% at 9–24 weeks when compared with non-pregnant values in the same patients. This is consistent with the increase in cases of multiple pregnancy or increased fetal weight, where placenta volume is proportionally increased.

On the other hand, in cases where placenta volume is likely to be decreased, such as pre-eclampsia and intrauterine growth restriction, plasma expansion is reduced.[10–12]

What happens at the very end of the third trimester of pregnancy is largely debated in the literature. Contradictory data on whether maternal plasma volume declines in the last month of pregnancy seem to be related to maternal positioning. The increase in plasma volume seems to continue even in the last month of pregnancy when mothers are in the left lateral position, at least in twin pregnancies. According to some authors, plasma volume reaches a plateau at around 32 weeks in singleton pregnancies, but continues to increase in twin pregnancies.[6] This peculiarity explains the increased risks of pulmonary edema in twin pregnancies when using β-mimetics or plasma expansion in the third trimester.

Why does plasma volume expand?

There are several theories to explain why plasma volume expands during pregnancy

- *Hyperaldosteronism*: Physiologic hyperaldosteronism during pregnancy can be responsible for plasma increase. Primary hyperaldosteronism is responsible for hypervolemia in non-pregnant

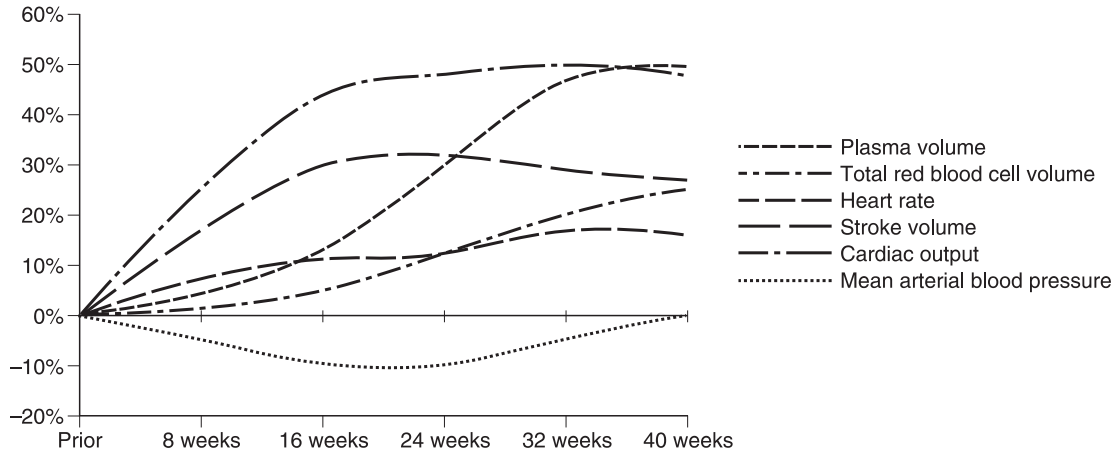

Figure 83.1 Evolution of different parameters throughout pregnancy. Adapted from Ayala *et al.*,[40] Capeless and Clapp,[36] Robson *et al.*,[33] Thomsen *et al.*,[8] and Pitkin.[17]

patients, with an increase in plasma volume of 48% and 76% in the two cases described by Briglier and Forsham, with no changes in total red blood cell volume.[13]

- *Influence of estrogens*: Estrogens affect plasma volume in many circumstances. Plasma volume expansion has been described in women using oral contraception or hormonal replacement therapy (i.e. estrogens in postmenopausal women).[14,15] Estrogens are responsible for an increase in renin levels, which are responsible for an increase in aldosterone level.
- Placental growth hormones implications are uncertain.
- *Placental circulation*: The placenta acts like a low-pressure maternal arterio–venous shunt, affecting arterial blood pressure and cardiac output. Placental circulation could thus explain part of the plasma expansion by induced hyperaldosteronism.

Red blood cells

Total red blood cell mass increases by 20–40% by term, which represents an absolute increase of 250–450 ml. The rise is the consequence of greater production of red blood cells, not longer lifetime, since iron supplementation increases even more the red blood cell mass.[1] The increase in total red blood cell volume is proportional to the weight gain in singleton pregnancies as opposed to plasma volume, which increases more than the weight gain.[2] The lesser increase in total red blood cell volume than the physiologic plasma volume expansion is responsible for pseudoanemia (Figure 83.1). Biologically, women have hemoglobin values at one standard deviation below the mean, but the value should always be above 10.5 g/dl.[16] Hematocrit can physiologically go as low as 33%.[17] The increase in red blood cell mass starts, or is detectable, later than plasma volume, by the end of the first trimester. Twin pregnancy is responsible for an increase in total red blood cell mass, but is not as proportional to weight gain as in singleton pregnancy. This increase in erythropoiesis is probably influenced by placental secretion of placental chorionic somatomammotropin, progesterone, or prolactin.[18] This increase in erythropoiesis increases maternal needs for iron by about 500 mg.[18] Moreover, maternal hemoglobin, by an increase in 2,3-diphosphoglycerate concentrations in red blood cells, has less affinity for oxygen to facilitate dissociation across the placenta to the fetus.[19]

This hemodilution, as a result of a greater increase in plasma volume than total red blood cell mass, has beneficial effects:

- It limits hemoglobin loss in cases of prepartum or postpartum hemorrhage
- It facilitates heart function by limiting blood viscosity
- It facilitates placental microcirculation by limiting blood viscosity
- It facilitates venous circulation to limit thromboembolic events[16,20]
- It limits impaired venous return, reduction in cardiac output, and hypotension in the supine position.

Heart anatomical changes

Ventricles

End-diastolic ventricular volume and ventricular mass increase throughout pregnancy. These modifications, which include anatomical modification of the maternal heart during pregnancy, take place without end-systolic volume or end-diastolic pressure increasing.[21,22] The combination of increasing end-diastolic ventricular volume and stable end-systolic volumes

and end-diastolic pressure are the consequences of an increased compliance of the myocardium. It is not clear when cardiac compliance starts to increase during pregnancy.

Ventricular mass increases as soon as the first trimester[23] and the end-diastolic volume increase is detectable only in the second trimester,[21] and although the changes are not detected at the same moment, they are part of a continuum.

Atria

Left atrial diameter increases during pregnancy to reach a plateau at around 30 weeks.[24] Left atrial diameter is related to vascular filling. The increase in left atrial diameter during pregnancy is in relation with physiologic plasma volume expansion.

Vessels

Changes are observed in large vessels during pregnancy. Aortic compliance increases, which, combined with decreasing vascular tone, results in lower afterload and enhanced left ventricular performance.[25] Venous distensibility increases throughout pregnancy from the first trimester.[26] Increasing capacity of the venous system is essential to the physiological adaptation to plasma volume increase. It allows stability in venous pressure and protects the right heart from too high preload pressure. The fall in vascular resistance occurs at the same time as increasing compliance of large arteries and veins as early as the fifth week of gestation.[27] The causal relation between increased vascular compliance, fall in vascular resistance, physiologic plasma volume expansion, and increasing cardiac output during pregnancy are yet to be determined.

Cardiac output

Cardiac function was initially studied using invasive techniques. It has even been used in term pregnancies more recently.[28] Echocardiography combined with pulse- or continuous-wave Doppler measurements of cardiac output was validated against invasive techniques in non-pregnant patients.[29] These techniques were later validated in pregnant women.[30,31] Since then, most available data collected have used non-invasive techniques.

Cardiac output depends on heart rate and stroke volume. Stroke volume increases throughout pregnancy as demonstrated by the mid-20th-century invasive procedures and more recent non-invasive ultrasound examinations.[32–34] The major causes responsible for stroke volume increase are:

- A moderate increase in preload and greater venous return
- A decreased afterload, increased arterial compliance, and fall in vascular resistance
- An increased cardiac compliance and an intrinsic myocardial contractility increase that is independent of loading conditions.[35]

Cardiac output increases by 30–50% during pregnancy.[28,30,32–35] The increase in cardiac output is detectable as early as the fifth week of gestation. Early in pregnancy, the cardiac output increase is mostly the result of a stroke volume increase.[33,36] Heart rate increase occurs later in pregnancy and contributes, then, to the increase in cardiac output observed in the second half of pregnancy[33,37] (Figure 83.1).

Caval syndrome in pregnancy was described by Holmes in 1960.[38] Maternal position influences hemodynamics. When in the supine position, the uterus compresses the inferior vena cava, affecting venous return to the right atrium. The reduction in preload affects all hemodynamic parameters. Ueland *et al.* compared stroke volume, heart rate, and cardiac output at three different intervals in pregnancy, 20–24 weeks, 28–32 weeks, and 38–40 weeks.[39] They performed their measurements in the supine, lateral decubitus, and sitting position. Their main findings were:

- In the lateral decubitus, there is a fall in cardiac output by the end of the third trimester, as a result of the fall in stroke volume.
- In the supine position, cardiac output values at the very end of pregnancies are lower than non-pregnant values, as a result of a major fall in stroke volume partly compensated by an increase in heart rate.

Evolution of cardiac output in late pregnancy was not clearly described in the literature. This issue seems settled by the work of Clark *et al.* in 1989.[28] In a study on 10 healthy singleton pregnant patients between 36 and 38 weeks of gestation, using invasive central hemodynamic assessment, they found a 44% increase in cardiac output, with a 17% increase in heart rate and 27% increase in stroke volume.[28] They concluded that cardiac output does not fall in late pregnancy. Therefore, the variations in cardiac output measurements in late pregnancy observed in older studies were probably related to maternal positioning during measurements.

Blood pressure

Arterial blood pressure

Arterial blood pressure declines from the seventh week.[36]

Using 24-h mean blood pressure measurements in normal pregnancies, Ayala *et al.* found a steady decrease of systolic blood pressure, diastolic blood pressure, and mean arterial pressure up to the 21st week of gestation, followed by an increase to near non-pregnant values by the end of pregnancy[40]

(Figure 83.1). When the circadian variations of blood pressure were studied, the lowest pressures were measured at 4–5 h, and the highest at 12–21 h.[41] The magnitude of the difference between the highest and the lowest blood pressure within the same circadian period is maximal in the second trimester. These modifications in blood pressure are influenced by maternal age, but not by parity.[42]

Vascular systemic resistance

The total vascular resistance drop early in pregnancy is probably due to the low-resistance placental vascularization. It seems actually to be the first parameter to be significantly modified in early pregnancy.[43] Duvekot *et al.* performed serial weekly measurements from 5 to 8 weeks of gestation. They unfortunately did not have non-pregnant values and compared the results with the 5 weeks' gestation data. It is not clear if this drop in total vascular resistance, due to the placental low-resistance effect on the maternal circulation, is a cause or a consequence of plasma expansion and hyperaldosteronism. The only significant changes observed from the sixth to the eighth week of gestation compared to the fifth week were a rise in plasma 17-estradiol and a drop in plasma 17β-hydroxyprogesterone. Interestingly, Walters and Lim described in 1969 a fall in total vascular resistance when estro-progestative contraceptives were given to women.[15] The total vascular resistance remains low throughout pregnancy and is still 21% lower than non-pregnant values at 36–38 weeks of gestation.[28]

Conclusion

Pregnancy is characterized by early modifications in most hemodynamic parameters. These modifications are a consequence of normal adaptation to pregnancy and serve as control values for inadequate adaptation of pathologic pregnancies.

84 Pathophysiology of pre-eclampsia

T. Podymow, P. August and D. Skupski

Pre-eclampsia is a hypertensive condition unique to pregnancy with both maternal and fetal manifestations. The maternal disease is characterized by vasospasm, endothelial dysfunction, activation of the coagulation system and high blood pressure. The maternal pathophysiologic changes are mainly ischemic, affecting the vasculature of the placenta, kidney, liver and brain. Pre-eclampsia is diagnosed in a woman with new onset of hypertension >140/90 mmHg after the 20th gestational week accompanied by proteinuria >300 mg/day. Other common clinical and laboratory abnormalities include facial and peripheral edema, thrombocytopenia, elevated uric acid levels (greater than 5.5 mg/dl or 327 mmol/L) and elevated transaminase levels (greater than twice the normal). The greatest concern is that pre-eclampsia can progress to eclampsia, which is life-threatening convulsions associated with cerebral hemorrhage, or to hemolysis, elevated liver enzymes and low platelets (HELLP) syndrome. Eclampsia is frequently preceded by severe headaches, visual disturbance (halos or auras) and hyper-reflexia, while HELLP syndrome is frequently preceded by right upper quadrant or epigastric pain. The consequences of pre-eclampsia for the fetus are a result of decreased placental perfusion and include intrauterine growth restriction and fetal loss. Delivery is the only definitive cure of pre-eclampsia/eclampsia, and in order to prevent serious maternal complications premature delivery is often necessary; as such hypertensive disorders in pregnancy are the leading cause of indicated premature delivery. In this chapter, the pathophysiology of pre-eclampsia and the pathogenesis of these manifestations will be examined.

Pathophysiology

The pathophysiology of pre-eclampsia has been described divided into two stages:[1] alterations in placental perfusion (stage 1) and the maternal syndrome (stage 2).

Placenta – Stage I

The pathophysiology of pre-eclampsia begins with abnormalities in the development of the placenta, leading to the production of abnormal vasculogenic substances, which upon reaching the maternal circulation produce the maternal clinical syndrome. There is considerable evidence for the importance of the placenta in the pathogenesis of pre-eclampsia; pre-eclampsia can develop without a fetus in the case of molar pregnancies (a rapidly growing placenta with trophoblastic tissue) and in multiple gestations (increased placental mass). There are also case reports of twin pregnancies where pre-eclampsia is reversed upon termination of the severely growth-restricted twin and involution of the pathologic placenta.[2]

In normal gestation, the uterine artery's terminal branches, the spiral arteries, invade the placenta and are transformed from muscular arteries into relaxed flaccid vessels to accommodate an eventual 10-fold increase in uterine blood flow. This transformation is dependent on the placental trophoblasts that invade and surround the uterine spiral artery's vascular walls.[3] The placental trophoblasts, normally epithelial cells, replace their adhesion molecules with those of endothelial cells to assume vascular endothelial cell phenotype prior to invading the uterine arteries,[4] a process termed pseudovasculogenesis. This vascular remodeling results in increased blood flow and supply of nutrients and oxygen to the fetus by the end of the first trimester. In pre-eclampsia, pseudovasculogenesis is defective; cytotrophoblast invasion from the placenta is shallow, the arteries remain small and muscular[5] and the ensuing placental ischemia is thought to trigger the release of placenta-derived factors (Figure 84.1). Of considerable interest is the increased incidence of pre-eclampsia in women with medical conditions associated with microvascular disease such as hypertension, diabetes and collagen vascular disease, as the impaired placental perfusion leading to ischemia may be the common source of this disease.[1]

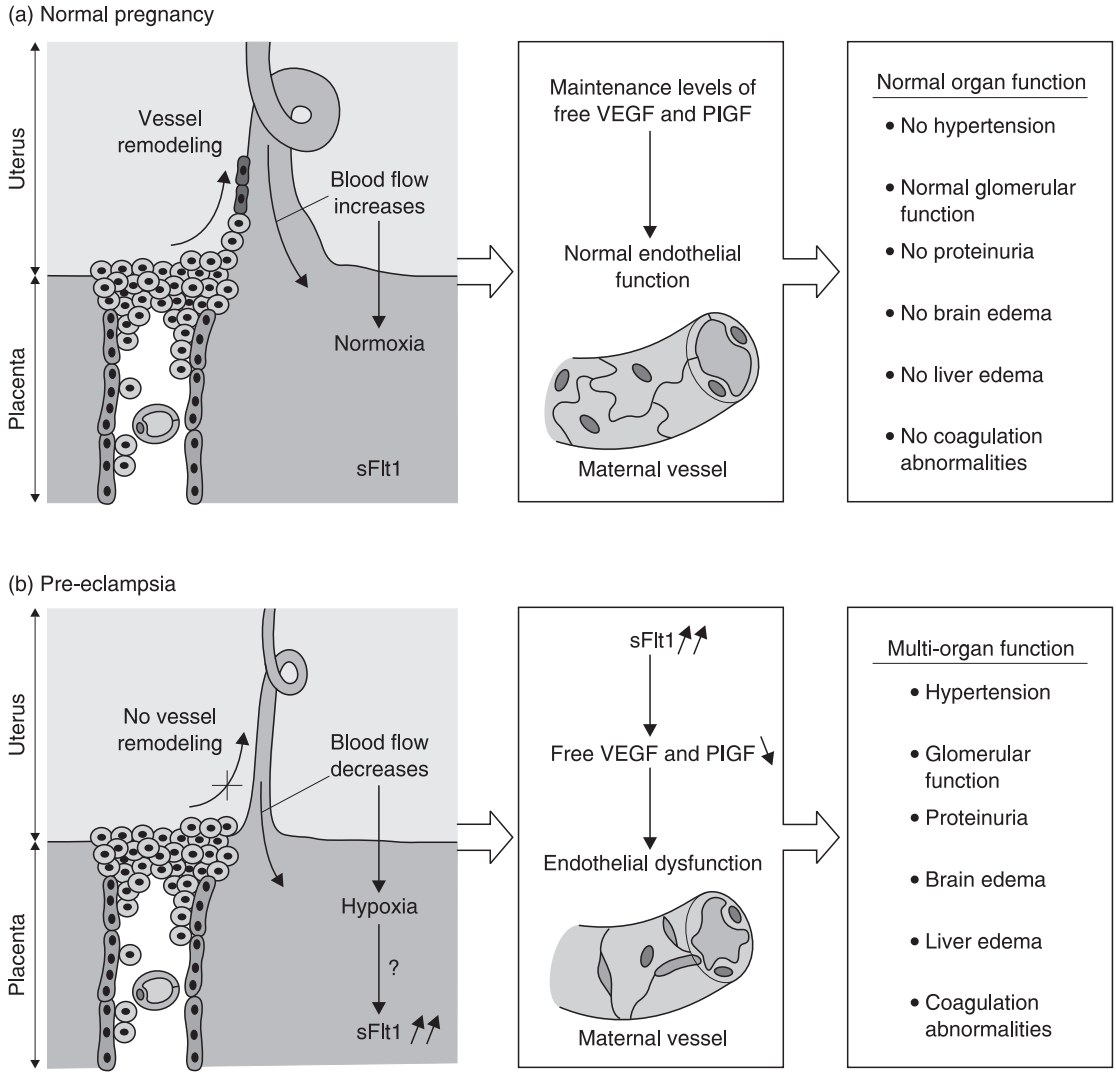

Figure 84.1 Hypothesis on the role of sFlt-1 in pre-eclampsia. (a) During normal pregnancy, the uterine spiral arteries are infiltrated and remodeled by endovascular invasive trophoblasts, thereby increasing blood flow significantly in order to meet the oxygen and nutrient demands of the fetus. (b) In the placenta of pre-eclamptic women, trophoblast invasion does not occur and blood flow is reduced, resulting in placental hypoxia. In addition, increased amounts of soluble Flt1 (sFlt-1) are produced by the placenta and scavenge VEGF and PlGF, thereby lowering circulating levels of unbound VEGF and PlGF. This altered balance causes generalized endothelial dysfunction, resulting in multi-organ disease. It remains unknown whether hypoxia is the trigger for stimulating sFlt-1 secretion in the placenta of pre-eclamptic mothers and whether the higher sFlt-1 levels interfere with trophoblast invasion and spiral artery remodeling. Adapted from Luttun and Carmeliet[8] with permission.

The idea that impaired placental perfusion leads to release of 'factors' into the maternal circulation to cause the clinical manifestations of pre-eclampsia is not new, although the precise nature of these 'factors' awaits ultimate description. The placenta-derived pre-eclampsia factors causing systemic endothelial dysfunction have for decades been elusive. Maynard *et al.* have reported that angiogenic proteins such as placental growth factor (PlGF) and vascular endothelial growth factor (VEGF) are both required for normal angiogenesis and endothelial function in pregnancy, and are reduced in women with pre-eclampsia. Recent studies report elevated maternal serum levels of a protein, which in pre-eclampsia appears to scavenge these factors and induce endothelial dysfunction: a soluble fms-like tyrosine kinase 1 (sFlt-1) (also called soluble vascular endothelial growth factor receptor 1, sVEGFR-1). This molecule is a circulating modified VEGF receptor, whose function is to neutralize VEGF and PlGF, and is found in excess quantities in both the placenta and the serum of pre-eclamptic women[6,7]. When administered to pregnant rats, sFlt-1 has been shown to induce a pre-eclampsia-like phenotype with albuminuria, hypertension and renal pathologic changes of glomerular endotheliosis.[6] In human studies, increased serum levels of sFlt-1 and reduced levels of PlGF have been found to predict the subsequent development of pre-eclampsia,[7] and decreased

urinary PlGF in the early second trimester is strongly associated with subsequent early development of pre-eclampsia.[9] The mechanism for the upregulation of sFlt-1 and whether normalization of VEGF and PlGF levels might halt progression of pre-eclampsia are yet unknown.

Other factors that may be derived from the placenta and are postulated to be related to pre-eclampsia are substances that increase oxidant stress, leptin and a variety of cytokines including tumor necrosis factor α. Oxidative stress due to hypoxia-driven free-radical generation at the fetal–maternal interface has been suggested as a cause of pre-eclampsia. The by-products of increased oxidative stress, possibly released by the placenta in response to hypoxia or ischemia, have been implicated in endothelial cell damage in pre-eclampsia.[10,11] Small studies using antioxidants to prevent pre-eclampsia have been encouraging and vitamins E and C are under study in larger trials to determine their potential role in prevention.[12]

Pathologically, the lesion of the placenta in pre-eclampsia is termed acute atherosis and is characterized by an accumulation of fat-laden macrophages and infiltrates in the arteries not invaded by trophoblast cells. In a study of 400 placentas from pre-eclamptic women, vascular lesions in the placenta correlated with the severity of clinical disease.[13] Pre-eclampsia is also associated with a greater degree of placental infarction than in normal gestation; however, the placenta has considerable reserve, explaining why some infants are growth-restricted or die but more often are normal for gestational age.

Pathophysiology of the maternal syndrome of pre-eclampsia – Stage II

Blood pressure in pre-eclampsia

High blood pressure in pre-eclampsia is due mainly to a reversal of the vasodilatation of normal pregnancy, replaced by a marked increase in peripheral vascular resistance.[14] Pre-eclamptics do not develop overt hypertension until late gestation (after 20 weeks, and usually not until the third trimester), but vasoconstrictor influences may be present much earlier. For instance, longitudinal and epidemiologic surveys show that women destined to develop pre-eclampsia have slightly higher 'normal' blood pressure (e.g. diastolic levels >70 mmHg) as early as the second trimester.[15–17]

The precise mechanism of pre-eclamptic hypertension is obscure. During normal pregnancy the renin–angiotensin system is stimulated, most likely in response to vasodilatation and lower blood pressure. In contrast with normal pregnancy, women with pre-eclampsia have suppressed plasma renin activity, aldosterone, urinary aldosterone excretion and angiotensin II levels. There is evidence that the renin–angiotensin system is stimulated early in pregnancy in women who later develop pre-eclampsia and that the developing vasoconstriction and hypertension turn off renin secretion. This decrease in renin has been used as a screening test to identify gravidas in midgestation who are at risk for the development of pre-eclampsia.[18]

Blood pressure in pre-eclampsia is also characteristically labile, and exaggerated responses to norepinephrine and angiotensin despite normal plasma levels have been noted.[19] There is a reversal of the normal circadian rhythm, with blood pressures often being higher at night.[20] In addition, increases in peripheral vascular resistance and blood pressure that characterize pre-eclampsia have been found to be mediated partly by a substantial increase in sympathetic vasoconstrictor activity, which reverts to normal after delivery.[21] These observations lend mechanistic support for the use of methyldopa, which is metabolized to α-methylnorepinephrine and replaces norepinephrine to decrease sympathetic tone centrally.

Changes in eicosanoid metabolism occur in normal pregnancy, particularly prostacyclin (PGI_2) and thromboxane (TXA_2) production, and further alterations arise in pre-eclampsia. Prostaglandins such as PGI_2 are increased in normal pregnancy, particularly vasodilatory prostanoids (mostly PGI_2) by vascular endothelial cells,[22] and this may contribute to the generalized vasodilatation characteristic of pregnancy. Reduced PGI_2, but not TXA_2, has been found to occur months before the clinical onset of pre-eclampsia.[23,24] There is substantial literature suggesting that alterations in prostaglandin metabolism underlie the pathogenesis of pre-eclampsia.[22–26] Manifestations such as increments in vascular reactivity and blood pressure, as well as intravascular coagulation, have been proposed to be due to an imbalance between PGI_2 and TXA_2 synthesis, resulting in a relative or absolute PGI_2 deficiency. These findings are consistent with evidence that pre-eclampsia is characterized by generalized vascular endothelial cell dysfunction, leading to diminished production of PGI_2, as well as other vasodilatory endothelial cell products.

In spite of the large body of evidence supporting a role for alterations in prostaglandin metabolism in pre-eclampsia, it is important to emphasize that these substances are difficult to measure, and act locally, so measurements from peripheral blood may not reflect local effects. Nevertheless, the notion that pre-eclampsia is characterized by a deficiency of PGI_2 with stable or increased TXA_2 production has been the basis of several large multicenter randomized trials evaluating low-dose aspirin (which inhibits platelet TXA_2 generation but spares vascular PGI_2 production) in the prevention of pre-eclampsia. Despite early, relatively small studies that reported striking reductions in the risk of pre-eclampsia in women treated with low-dose aspirin, a recent Cochrane review including data from 36,500 women

did not reveal the overall beneficial effect of aspirin on pregnancy outcome.[27]

Endothelial cell function

In recent years, the role of the vascular endothelial cells in the modulation of vascular smooth muscle contractile activity, as well as in coagulation and regulation of blood flow, has increased the understanding of endothelial cell function in the pathophysiology of pre-eclampsia and other chronic cardiovascular conditions, such as atherosclerosis and essential hypertesion. Endothelial cells, which have receptors for numerous vasodilators and constrictors, produce hormones, autacoids, and mitogenic cytokines, including PGI_2, nitric oxide and endothelin. The pathophysiologic changes of pre-eclampsia, particularly those present before clinically apparent disease, support the hypothesis that altered endothelial function contributes to many of the changes observed in the pre-eclamptic syndrome.[28] Women with pre-eclampsia manifest increased circulating markers of endothelial activation (von Willibrand Factor, cellular fibronectin, thrombomodulin, endothelin, V-CAM).[29] Pre-eclamptic blood vessels demonstrate reduced endothelial-mediated vasodilation *in vitro*,[29] and *in vivo* studies have shown that flow-mediated (endothelium-dependent) dilatation is impaired in women with previous pre-eclampsia.[26] Most recently, raised plasma concentrations of asymmetric dimethylarginine (ADMA), the endogenous inhibitor of endothelial nitric oxide synthase, has been shown to be elevated in women with evidence of abnormal endothelial function prior to the development of pre-eclampsia.[30]

There are numerous reports of a hypertensive syndrome produced by inhibiting nitric oxide synthase in various experimental models of gestation, with some features similar to human pre-eclampsia.[31,32] Results from women with pre-eclampsia are conflicting, with reports of increased as well as decreased serum and urinary metabolites of nitric oxide in pre-eclampsia.[33–35]

Endothelins represent other vasoconstrictors postulated to play a role in pre-eclampsia.[36–39] In this respect, circulating levels of endothelin-1 are generally (but not universally) reported as increased in this disorder, but it is unclear if such levels have pathogenic significance or are a by-product of endothelial damage.

The evidence for endothelial cell dysfunction in the pathogenesis of the maternal manifestations of pre-eclampsia is strong, and its cause continues to be actively investigated. As mentioned, circulating factors of placental origin, e.g. sFlt-1, are likely involved. Indeed, sera from women destined to develop pre-eclampsia have the capacity to alter endothelial cell function or cause endothelial cell activation *in vitro* (assessed by nitric oxide and PGI_2 generation).[40] Sera from pre-eclamptic patients are also mitogenic and increase messenger RNA for, as well as production of, the platelet-derived growth factor β in culture.[41] There is also a growing body of evidence implicating increased lipid peroxides as well as by-products of increased oxidative stress, possibly released by the placenta in response to hypoxia or ischemia, in the genesis of endothelial cell damage in pre-eclampsia.[10,42–44]

Metabolic disturbances in pre-eclampsia

Hyperinsulinemia, obesity, glucose intolerance and dyslipidemia (e.g. increased triglycerides, reduced high-density lipoproteins) are associated with cardiovascular disease and essential hypertension. Insulin resistance and hyperinsulinemia (mediated by hormonal changes) are also characteristic of normal pregnancy, and are maximal in the third trimester.[45] Several laboratories have reported exaggerated metabolic disturbances in patients with pre-eclampsia, including hypertriglyceridemia, increased levels of free fatty acids, decreased levels of lipoprotein a, increased insulin levels, and glucose intolerance.[46–50] These observations are intriguing, particularly because they may be related to the evidence for increased oxidative stress in pre-eclampsia (lipid abnormalities may result in increased oxidative stress.

Obesity remains an important risk factor for pre-eclampsia, with strong positive association between maternal prepregnancy body mass index and the risk of pre-eclampsia.[51] Early pregnancy dyslipidemia[52] and gestational diabetes[53] are also associated with an increased two- to threefold risks of pre-eclampsia. At this time it is uncertain if these are the cause or markers for endothelial dysfunction, or if they may represent oxidative stress in pre-eclampsia.

Cardiac function in pre-eclampsia

Blood pressure normally declines in early pregnancy, systolic pressure changes little, while diastolic pressure falls by 10 mmHg at 13–20 weeks and then rises again to prepregnancy levels in the third trimester. Normal pregnancy is characterized by primary vasodilatation and increased cardiac output is due in part to the decreased afterload. As noted, high blood pressure in pre-eclampsia is due mainly to a reversal of the vasodilatation of normal pregnancy, replaced by marked increases in peripheral vascular resistance. Most studies of cardiovascular hemodynamics in women with pre-eclampsia have been performed in women with established disease and may be confounded by ongoing treatment. Invasive hemodynamic monitoring of untreated pre-eclamptics as well as limited careful echocardiographic studies demonstrate that women with pre-eclampsia have either normal or slightly decreased cardiac output in association with increased systemic vascular resistance and increased afterload. Serial echocardiographic studies throughout gestation have shown that in women who eventually

developed pre-eclampsia, increased cardiac output and decreased peripheral vascular resistance were found early in pregnancy followed by high-resistance low cardiac output states when pre-eclampsia developed.[54] Other studies of nulliparous gravidas with pre-eclampsia in the third trimester using pulmonary artery catheter, show decreased cardiac output in pre-eclamptic patients compared with controls.[14,55] Peripheral vascular resistance was increased and pulmonary capillary wedge pressure was below normal. This has been confirmed in other studies, and amounts to a normal ventricle contracting normally against a markedly increased afterload.[56] Peripartum heart failure can occur in this setting, though it is usually a complication of pre-existing heart disease.[57]

Plasma volume and red blood cell mass are increased in normal pregnancy, as physiologic vasodilatation leads to stimulation of the renin–angiotensin system, and volume retention ensues. In pre-eclampsia, however, plasma volume is decreased, which is documented by measurement with Evans blue dye.[58,59] The decrease in plasma volume may be secondary to vasoconstriction and hypertension, although there are some reports that decreases in plasma volume may precede hypertension.[58,60,61] These latter reports have led to the use of volume expansion therapy with vasodilator drugs in the treatment of pre-eclampsia. In view of the suppressed renin–angiotensin system in pre-eclampsia, the decreased plasma volume seems likely secondary to vasoconstriction and a 'smaller' intravascular compartment. Reports that the decreased plasma volume may have preceded hypertension[61] led to the experimental use of volume expansion therapy, although in Cochrane analysis, this treatment remains unproven.[62]

Renal changes in pre-eclampsia

Consistent with the effects of pre-eclampsia on the endothelium, the renal lesion characteristic of pre-eclampsia is glomerular endotheliosis.[19,63,64] The glomeruli are enlarged and swollen but not hypercellular, due primarily to hypertrophy of the intracapillary cells (mainly endothelial but mesangial as well), which encroach on the capillary lumina, giving the appearance of a bloodless glomerulus. The basement membrane is usually not thickened and foot processes are usually well preserved, even when severe proteinuria is present. Interestingly, sFlt-1, which is elevated in women with pre-eclampsia, has been administered to pregnant rats and induces hypertension, proteinuria and glomerular endotheliosis, the classic lesion of pre-eclampsia.[6] Similarly, these renal alterations are also observed in experimental models that are characterized by reduced VEGF levels in the case of VEGF knockout mice.[65]

Localized lesions resembling those of focal and segmental glomerulosclerosis (FSGS) are present in about 20% of women with pre-eclampsia. The significance of this finding is not clear; some consider it to be a sequelae of pre-eclampsia, a form of secondary FSGS, whereas others consider that it may be a manifestation of pre-existing subclinical nephrosclerosis.

In pre-eclampsia, both glomerular filtration rate and renal blood flow decrease, the former more so than the latter, leading to a decrease in filtration fraction.[19] The decrement is usually modest (25%) even when morphologic changes are pronounced. Because renal function normally rises 35–50% during pregnancy, creatinine levels are usually still below the upper limits of normal. The basis for the altered renal hemodynamics is not certain and renal histological and hormonal changes are probably involved. Recent evidence suggests that the hormone relaxin, a natural vasodilator produced by the corpus luteum and placenta, is reduced in women with pre-eclampsia and may contribute to the renal changes observed.[66,67] Fractional urate clearances decrease, often before overt disease is apparent, with a uric acid level greater than 5.5 mg/dl (327 mmol/L) being an important marker of pre-eclampsia. This appears to be a sensitive marker of decreased renal clearance and glomerular filtration. Proteinuria > 0.3 g/day (but in some cases nephrotic range, i.e. > 3 g/day), is another hallmark that may appear late in the clinical course of the disease. Rarely, renal insufficiency may develop due to acute tubular or cortical necrosis associated with pre-eclampsia.[68]

Sodium excretion appears to be impaired in pre-eclampsia, documented in studies of renal excretory ability after saline infusion,[69] though the reduction in intravascular volume and decreased placental perfusion are major reasons to avoid diuretics in pre-eclampsia.[19] Renal handling of calcium is also abnormal in pre-eclampsia, with hypocalciuria, low plasma 1,25-dihydroxyvitamin D3 and high parathyroid hormone noted.[70,71]

Coagulation system

Pregnancy is associated with an increase in hemostatic factors and decrease in fibrinolytic proteins; factors II, VII, X, VIII, XII and fibrinogen increase 20–200% whereas the fibrinolytic protein S has a 40% decrease during pregnancy.[72] The inherited coagulopathies are major causes of thromboembolic disease in both pregnant and non-pregnant individuals; the most common are autosomal dominant deficiencies of antithrombin III, protein C, protein S, as well as activated protein C resistance due to the factor V Leiden mutation, and a function-enhancing mutation in the prothrombin gene (prothrombin G20210A) and hyperhomocystinemia. The pregnancy-associated changes in hemostatic and fibrinolytic proteins exacerbate the clinical effect of heritable coagulopathies. A postulated mechanism for pre-eclampsia in relation to the coagulopathies is the development of microthrombi in the placental circulation, with decreased placental perfusion leading

to pre-eclampsia, hypertension and proteinuria.[73] Factor V Leiden mutation is the most common heritable coagulopathy, affecting 5–9% of European populations, though it is rare in Asian and African populations.[74,75] A recent meta-analysis suggests that factor V Leiden is associated with a twofold increased risk for pre-eclampsia.[76] The risk of the prothrombin 202210 polymorphism though suggestive as a risk factor is less clearly so, and the MTHFR genotype (leading to hyperhomocystinemia) does not appear to confer an increased risk.[76] Increased incidence of pregnancy-related complications including pre-eclampsia has been found for deficiencies in protein C, protein S, antithrombin III, but determination of the specific odds of developing pre-eclampsia with these thrombophilias is ongoing.[77] Clinically, some advocate screening for thrombophilias in women with early (< 34 weeks) or severe (> 160/110 mmHg) pre-eclampsia with consideration of heparin treatment in those found to be positive. Primary preventive treatment for women with known thrombophilic mutations but no clotting history is less certain until more trial data are available.

Falling platelet counts are a known manifestation of pre-eclampsia. The precise mechanism is unclear, but it appears that microangiopathy and endothelial cell damage stimulate platelet activation and consumption.[78,79] When severe, this may lead to disseminated intravascular coagulation.[80] Platelet activation may lead to increased generation of TXA_2, which may in turn increase vasoconstriction and platelet aggregation.[81] Increased release of platelet products such as serotonin may also contribute to vasoconstriction, and pharmacologic agents that inhibit serotonin such as ketanserin have been used successfully in the treatment of pre-eclampsia.[82]

Hepatic abnormalities

The liver dysfunction that may accompany pre-eclampsia is correlated to the histological findings, which include periportal hemorrhages, ischemic lesions and fibrin disposition. These are consistent with both endothelial damage and activation of the coagulation system leading to some amount of liver tissue edema or necrosis. Involvement may range from mild enzyme abnormalities to HELLP with markedly elevated transaminase levels, to subcapsular bleeding or hepatic rupture. HELLP syndrome is well described in the clinical literature[83] and requires the presence of hemolysis on peripheral smear and platelet counts below 100,000/mm^3 and transaminase levels greater than twice the normal for diagnosis. Liver involvement in pre-eclampsia generally signifies more serious disease and is associated with an increased risk of maternal complications compared to pre-eclampsia alone.[84]

Central nervous system

Eclampsia and seizures in pre-eclampsia that cannot be attributed to another cause are the most common central nervous system complication and are responsible for the most maternal deaths in this disease. In one small series, seizures were preceded by headache in 64% and by visual changes in 32%.[85] Visual disturbances include blurred vision, scotomas and, rarely, reversible cortical blindness (reversible posterior leukencephalopathy). In these cases, CT and MRI studies showed extensive bilateral white-matter abnormalities suggestive of vasogenic edema without infarction in the occipital and posterior parietal lobes of the cerebral hemispheres.[86,87]

Postmortem pathologic specimens of eclampsia reveal hemorrhages and petechiae, vasculopathy and ischemia with microinfarcts.[88] The cause of cerebral hemorrhage is debated; vasospasm, thrombosis and rupture have been postulated and transcranial Doppler studies document increased cerebral blood flow velocity consistent with vasospasm in women with pre-eclampsia and eclampsia.[89–91] Convulsions have been observed in women with only mild to moderate hypertension; the mechanisms for the seizures are not known, though by computed tomography and magnetic resonance imaging[92,93] cerebral edema has been described, as have hemorrhage and edema in the vascular watershed areas of the posterior hemispheres.[94] Predominance of posterior lesions may explain the increased incidence in pre-eclampsia–eclampsia of visual disturbances. Rarely, hemorrhages may be major and associated with permanent neurologic sequelae. Cerebral edema observed on some computed tomography studies may be a consequence of excess administration of fluids in patients with low oncotic pressure due to hypoalbuminemia. Rarely, reversible posterior leukoencephalopathy may develop in patients with eclampsia, which is transient blindness that resolves completely in most cases.[86] The findings on neuroimaging are characteristic of subcortical edema without infarction.

Long-term sequelae of pre-eclampsia

The pathophysiologic changes of pre-eclampsia appear to confer a long-term risk for cardiovascular disease in the mother. In an analysis of follow-up of over 30,000 hypertensive pregnant women, gestational hypertension, mild pre-eclampsia and severe pre-eclampsia were associated with 2.8-, 2.2- and 3.3-fold greater risks for premature cardiovascular events;[95] a magnitude of excess risk that is on par with smoking. Severe pre-eclampsia was also associated with a 2.3-fold greater risk for thromboembolic events[95] and in a separate study the rate ratio for later death from stroke for the pre-eclampsia/eclampsia group was 3.59.[96] Whether this is a result of permanent endothelial injury or if pre-eclampsia is a manifestation of an underlying predisposition to vascular disease is not known.

85 Physiological changes of the uterine cervix during pregnancy and delivery

V. N. A. Breeveld-Dwarkasing and F. K. Lotgering

Introduction

During most of human pregnancy, the uterine cervix is a dynamic anatomical structure that serves as a barrier between the fetus in its intrauterine environment and the vagina as the portal to the outside world. In the prelude to parturition a process called ripening takes place in which the cervix changes from a structure that is firm and rigid to one that is soft and elastic that can be pulled open by uterine contractions, allowing passage of the fetus. It functions reliably, but is not foolproof: in preterm delivery the cervix opens prematurely and in cervical dystocia it may fail to dilate adequately. Recent work has improved our understanding of the mechanisms that underlie these changes, but current knowledge still cannot truly explain its dysfunctions. From the many factors and cells that are involved, it is now concluded that cervical ripening and softening are caused by an inflammatory-like mechanism. In this chapter we summarize what is known and not known about the physiological changes of the uterine cervix in pregnancy and delivery, with emphasis on the remarkable remodeling of its viscoelastic properties.

Anatomy

The cervix is positioned between the muscular body of the uterus and the vagina, connecting the uterine cavity with the vagina through its canal, which can dilate during delivery. The cervix consists predominantly of fibrous connective tissue (collagen 80% of total protein content) and 10–15% smooth muscle fibers.[1] The proportion of smooth muscle cells is higher near the myometrium (28%) than near the vagina (6%).[1] Through most of gestation the cervix is a firm structure but the fibrous tissue which is responsible for this has to change its structure to become soft and pliable during delivery. This process of cervical ripening is characterized by a gradual phase which starts in the early third trimester, preparing the cervix for the second phase (during delivery) in which it becomes soft and pliable in a few hours time. During the first phase of cervical ripening, both collagen synthesis and denaturation increase, with denaturation dominating the process. During this stage the cervix may already feel soft to the touch but the highly denatured collagen network still provides sufficient resistance against uterine contractions. During dilatation further digestion of denatured collagen leads to loss of collagen and, consequently, of firmness.[2] The cervical ripening takes place mainly in the deep stromal layer of the cervix, a fact that emphasizes the importance of tissue sampling sites in biochemical studies of cervical ripening.

The cervix receives its blood supply primarily from the cervical branch of the uterine artery and anastomoses with the vaginal arteries are common. Blood flow increases markedly in the first trimester, when blood flow of the portio vaginalis uteri in healthy pregnant women was found to be increased to 69 ml/min/100 g.[3] The cervix contains abundant autonomic and sensory nerves, and they are derived from the hypogastric (T13-L4), splanchnic (L6-S2) and vagus nerves.[4] The sensory information transmitted through the vagus nerves includes pain and other reflex information from the cervix during labor and delivery that seems to bypass the spinal cord.[5] In addition, afferent unmyelinated C-fibers of these nerves which are associated with cervical vasculature and smooth muscle cells produce neuropeptides that play a role in the local neurogenic inflammatory processes associated with cervical ripening such as causing the vasculature to leak, edema and migration of inflammatory immune cells.[4] However, the cervix apparently functions normally to retain the fetuses during pregnancy even in the absence of neuronal connections, as in the transplanted uterus in the

mouse,[6] and in women with a preexisting spinal cord lesion.

Clinical considerations

The readiness of the uterine cervix to dilate not only after pharmacological induction of labor, but also in spontaneous preterm or term labor, is traditionally assessed with the use of the modified Bishop score.[7] The score takes into account the dilatation, length, consistency, and position of the cervix. The ripeness of the cervix increases with advancing dilatation, reduction in length, progressive softening, and a more anterior position of the cervix. These changes are the result of the changes in viscoelastic properties, uterine contractions, and descent of the fetus. Although clinicians use these variables to predict the risk of preterm delivery and/or the chance of successful induction, the subjectivity of the assessment and interobserver variability limit their predictive value. As a consequence, investigators have sought methods to measure the same variables objectively.

Cervical dilatation has been measured with the use of ultrasound crystals attached to the vaginal surface of the cervix, close to the cervical canal in humans[8,9] and in cows.[10] Because the propagation velocity of the ultrasound pulse in cervical tissue is approximately 1500 m/s and remains constant, the distance between the two ultrasound crystals can be calculated from the time it takes for the pulse to travel from one to another. The method is somewhat limited in that it measures dilatation at the external opening of the cervix, instead of at the internal os where softening and opening (funneling) may begin. Both species demonstrate a similar picture, as represented in Figure 85.1 for nulliparous women.

Initially, during the latent phase, uterine contractions do not result in an increase in distance between the crystals attached to the vaginal cervix. The first measurable response, during the early dilatation phase, is an increase in distance during a contraction followed by an almost complete rebound after the contraction. During the acceleration phase, the distance increases with each contraction and does not return to its prior position, thus resulting in progressive dilatation. A deceleration phase, as originally reported by Friedman,[12] does not normally occur.[8,13] The initial cervical response to a uterine contraction as well as the onset of the acceleration phase occur at a smaller cervical diameter in parous than in nulliparous women. The initial response in parous women occurs at 2.9 cm and in nulliparous women it occurs at 3.6 cm. The onset of acceleration begins at 3.4 cm in parous and at 4.8 cm in nulliparous women.[8] As a consequence, calculated myometrial work per cm of cervical dilatation in parous parturients is less than in nulliparous parturients, which means that less force is needed to dilate the cervix in parous than in nulliparous women.

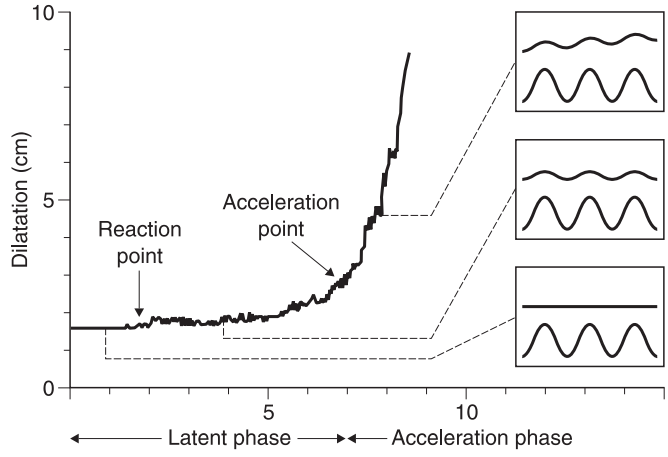

Figure 85.1 Cervical dilatation in women as measured with ultrasound crystals attached to the cervix. In the early latent phase the cervix does not respond to contractions by dilatation, in the late latent phase dilatation increases temporarily with contractions, in the acceleration phase the cervix dilates progressively with contractions. From van Dessel[11] with permission.

Cervical length has been measured extensively in recent years with the use of transvaginal ultrasound transducers. The method is limited in that there is substantial intra- and interobserver variability in measurements of cervical length, even when experienced observers perform the measurements under standardized conditions.[14] In singleton pregnancies, the uterine cervix on average is 40 ± 7 mm at mid-gestation and only slightly less at 30 weeks' gestation.[15] A short cervical length in asymptomatic women before 20 gestational weeks is a successful predictor of preterm delivery before 34 weeks' gestation, with a likelihood ratio of a positive test (cervical length < 25 mm) of 6.3 (CI 3.3–12.0) and that of a negative test of 0.8 (CI 0.65–0.95).[16] Likewise, a short cervical length is a useful predictor of successful labor induction, with a total rate of cesarean sections of 21% in women with a cervical length of ≤ 25 mm and 43% in women with a longer cervix.[17] Transvaginal sonographically measured cervical length itself was found to be a better predictor of successful labor induction than the traditional Bishop score,[17] with the notion however, that the differences were significant only in those women with an unripe cervix (Bishop score ≤ 5), which suggests that other factors, including the viscoelastic properties, are also important.

Softening of the cervix has been difficult to quantitate. However, light-induced fluorescence (LIF) of collagen has been used to investigate the changes in collagen content of the cervix during gestation and following labor induction with sodium nitroprusside, a nitric oxide donor, in the guinea pig[18] and in humans.[19] Collagen fluorescence decreased towards delivery and increased gradually postpartum, and treatment with sodium nitroprusside caused a significant reduction in fluorescence. Collagen gives a characteristic

fluorescence spectrum with a peak around 390 nm. One of the major cross-links of collagen, pyridinoline, is believed to be the intrinsic fluorophor. A decreased fluorescence suggests a reduction in collagen cross-links, associated with cervical ripening.

In the unripe cervix the cervical lips are positioned against the posterior fornix, and while ripening and softening, the cervix gradually moves forward so that the cervical canal lines up with the vagina. It has been attempted to study the position of the cervix with transvaginal ultrasound. However, the anterior cervical angle was found not to be either a useful predictor of induction success (sensitivity 22%, positive predictive value 40%) or of preterm birth.[20,21]

The cervix is always involved in cases of preterm delivery, even if the primary cause is not the cervix. In the case of cervical insufficiency, or cervical incompetence, a preexistent weak cervix is unable to retain a pregnancy in the absence of uterine contractions. Historically, cervical incompetence is a clinical diagnosis based on a history of two or more second-trimester pregnancy losses, after painless dilatation up to 4 cm.[22] The incidence of cervical incompetence has been estimated as 2/1000 births in Denmark.[23] Such an intrinsic weakness of the cervix may be surgically treated by a cerclage. Cervical incompetence may be suspected in case of Mullerian abnormalities [cervical hypoplasia, as with *in utero* diethylstilbestrol (DES) exposure], surgical trauma as in prior late abortion, cone excision, trachelectomy, obstetrical trauma, or in the case of connective tissue disease (Ehlers–Danlos syndrome). A cervix which appears to be short by transvaginal sonography is also a risk factor for preterm delivery, but is not always caused by cervical incompetence. Therefore, the entities that could lead to preterm delivery should not be used interchangeably with cervical incompetence. Cervical incompetence may vary in degree and it may be expressed differently in subsequent pregnancies and although a short cervix may indicate a higher risk for preterm delivery it does not discriminate between underlying pathologies.[24] In normal pregnancies the cervix also shortens progressively between the 10th and the 40th week.[25] That is why the American College of Obstetricians and Gynecologists recommends not to screen women at low risk routinely and to perform serial cervical length measurements only in women with a historical risk factor for preterm delivery.[26] These, include bacterial vaginosis, placental and intra-amniotic infections, extreme uterine distension as in multiple pregnancies, blunt abdominal trauma leading to placental abruption, diabetes, and smoking. When these causes lead to preterm delivery, irrespective of the etiology, a common biochemical pathway has to become active that will lead to cervical effacement and dilatation just as in normal delivery. Strategies to prevent preterm deliveries that are less invasive than cerclage, such as reduction of physical activities or even the application of vaginal pessaries are likely to be effective in the mere presence of risk factors, when clinical symptoms or a typical obstetrical history are absent.[27]

The change in cervical function from retaining the fetus *in utero* during pregnancy to allowing the fetus a smooth passage during delivery requires an extensive and intriguing remodeling of the viscoelastic properties of the cervix, as we will discuss in greater detail.

Tissue remodeling

Proper timing of the tissue remodeling in the cervix may make the difference between a severely premature, a healthy term, or a postterm infant, and between spontaneous delivery, a cesarean section, or a failed induction. Our understanding of the intriguingly complex mechanisms that underlie this remodeling process is still far from complete. We will first describe the physiological changes that occur in the extracellular matrix (ECM) which is responsible for both the strength and plasticity of the cervix, subsequently the cellular events that are responsible for the changes in the ECM, and finally the hormonal changes that induce the invasion of cells and regulate the actions of both the resident and the invasive cells.

Extracellular matrix

The cervix is not a static tissue but a dynamic organ and the ECM plays a major role in the dynamic changes in strength and plasticity of the cervix during pregnancy and parturition and the different phases of the menstrual cycle. The ECM constitutes collagens, proteoglycans, and elastin, which are synthesized by the smooth muscle cells and fibroblasts that represent the majority of the cells that are usually present in the cervix. During ripening the structural integrity of the ECM changes as a result of structural changes in the collagen network, a shift in the composition of the total proteoglycan content and possibly a change in the arrangement of elastin fibers. During ripening the resident cells are mostly involved in releasing inflammatory mediators and proteolytic enzymes, while during labor an additional number of neutrophils and macrophages invade the cervix and release the enzymes stored in their granules, which are responsible for the much faster softening. We will discuss the dynamic regulation of collagen, elastin, and other constituents of the ECM in more detail.

Collagen

The fibrous connective tissue of the cervix consists largely of collagen type I (70%) and type III (30%), and taken together they represent 80% of the total protein content of the cervix. Collagen molecules are three stranded molecules typically arranged in a triple helical configuration. Their strands are bound together by disulfide bridges and the molecules are

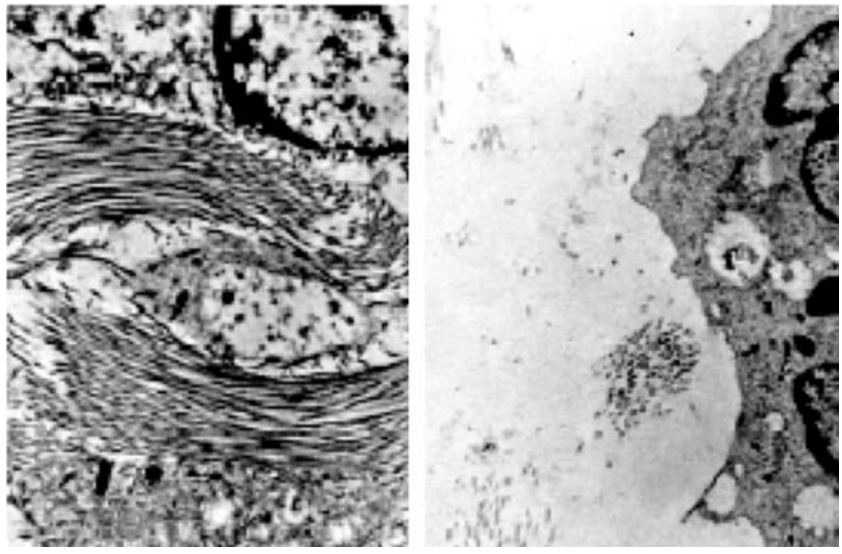

Figure 85.2 Electron micrographs of the cervix of pregnant guinea pigs obtained before term (left) and following ripening at term (right). Note the large number of collagen fibers present during early pregnancy and the decrease in fibers during ripening. From Garfield *et al*.[31] with permission.

cross-linked by pyridinoline side chains to form strong nonextendable fibers. The synthesis of collagen triple helices is complex in that it requires co-translational and posttranslational steps in addition to the protein synthesis *per se*. Two relevant co-factors are vitamin C and copper. Copper is a co-factor for peptidyl-lysine oxidase, an enzyme involved in the cross-linking of collagen fibers that is inhibited by smoking.[28] Normally, the synthesis and degradation of collagen are in a dynamic balance, depending on the stage of pregnancy.

In the nonpregnant state, the collagen bundles are densely packed together. During pregnancy the collagen is gradually remodeled, during the process of ripening that prepares the cervix for labor and dilatation. Yet, even during the first trimester of pregnancy the collagen fibers become less tightly packed.[29] Through these changes, the pregnant cervix feels softer than the non pregnant cervix, while a more parallel alignment of the fibers assures proper closing function.

As long as the helical conformation of the molecule remains intact, collagen is not readily accessible for proteolytic enzymes. Even when the collagen molecules are denatured, they can still maintain their three-dimensional network conformation through cross-bridges and still offer considerable resistance to physical stress, as is the case during cervical ripening.[2] Unwound, denatured, collagen is subject to further digestion by proteolytic enzymes, including collagenases which may result in a greater solubility of collagen,[30] and this could be responsible for the decreased collagen content of the cervix shortly before delivery as observed in cows.[2] In pathologic conditions, including cervical incompetence and *in utero* diethylstilbestrol exposure, a too extensive ripening process may occur in mid-pregnancy.[29] The difference between an unripe and a maximally ripened cervix are clearly demonstrated in Figure 85.2. Subsequently, during parturition macrophages and neutrophils progressively invade the cervix, release their catabolic enzymes that dissolve the dispersed collagen fibers, and allow the cervix to dilate within hours.

Immediately after delivery, the involution of the cervix is accompanied by a two- to threefold increase in the synthesis of collagens I and III,[32] thereby starting the repair that will allow the successful carrying of a subsequent pregnancy.

Elastin

Although elastin constitutes only 1% of the total connective tissue and its content does not appear to change with the stage of pregnancy, it is an important component of the ECM of the cervix.[33] Elastin does not offer the same resistance against the mechanical forces of uterine contractions and the fetal presenting part as collagen does,[34] but it adds to the cervix the quality of elasticity. Added to the strength of the collagen, the elastic component may serve to keep the cervix closed during pregnancy, while allowing it to dilate during labor. But maybe even more importantly, it may enable the cervix to bounce back to its original diameter after delivery. Elastin is localized to specific regions of the cervix and is not dispersed through the cervical stroma. Elastin seems to be concentrated at the external os and from there on it spreads to the periphery in a band upwards to the internal os where it becomes sparse in the muscular area below the internal os.[33] The elastin fibers of the cervix are made up of membranes and fibrils which are organized in a fishnet-like structure[34] so they can be stretched in any direction. They are likely to be responsible for the

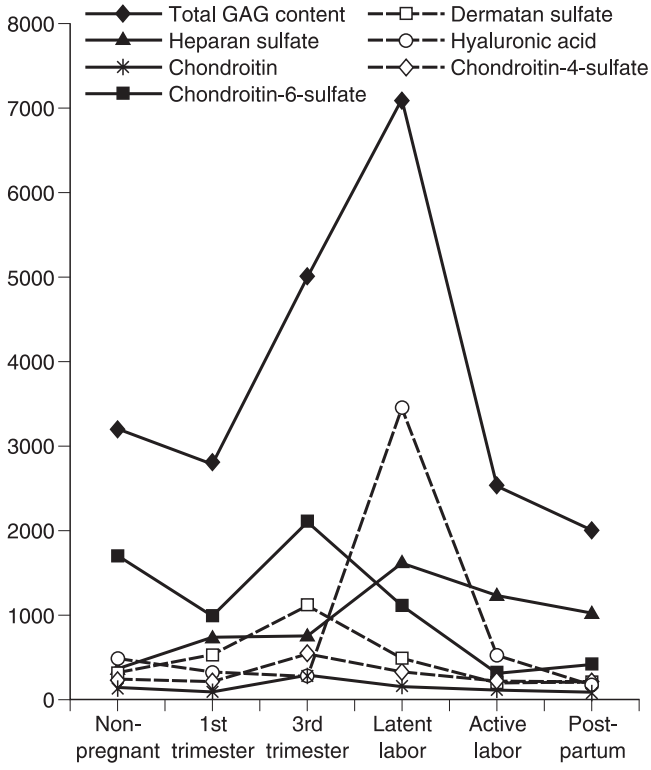

Figure 85.3 Pregnancy-induced changes in the total glycosaminoglycans (GAG) content and the content of the individual GAGs (nmol/g dry weight) in the cervix of pregnant women at delivery and postpartum. Adapted from Osmers *et al*.[37] with permission.

dynamic changes in cervical length and temporary funneling at the internal os of the cervical canal that occur during pregnancy in response to maternal positional changes, fetal movements and uterine contractions as observed by ultrasound.[35] Biopsies from incompetent cervices have shown a reduction in total elastin, fragmented fibers and an abnormal arrangement of the elastin compared with those of uncomplicated term pregnancies.[36]

Proteoglycans and hyaluronic acid

Proteoglycans play an important but complex role in the spatial arrangements and stabilization of the ECM. In addition, they regulate the induction of cytokines. Proteoglycans are glycoproteins that contain one or more glycosaminoglycan (GAG) side chains in addition to a protein core. In the past, the nomenclature of the proteoglycans was based on these side-chains and studying the changes in content of the various GAGs during pregnancy showed a complex pattern (Figure 85.3).

The changes in GAG concentrations (nmol/g dry weight) are most pronounced during late gestation and labor. The change in total GAGs content is already pronounced in the third trimester and is caused predominantly by an increase in chondroitin-6-sulfate, while the further increase during labor is largely caused by an increase in hyaluronic acid. From a functional point of view, however, the relevance of these changes in total and individual GAG concentrations may be questioned as the complete proteoglycan molecule and its spatial arrangement rather than the content of side chains is important with regard to their role as building blocks of the ECM. Thanks to modern gene technology, a new appreciation of the molecular design has lead to a new and simplified nomenclature based on homologies of the protein core and to the grouping of distinct gene families and subfamilies, often with similar or identical structural and functional relationships.[38] Members of at least two proteoglycan subfamilies are present in the cervix, i.e., the small leucine-rich proteoglycans (formerly called small dermatan-sulfate proteoglycans) that include decorin and biglycan,[32,39] and the hyalectan (hyaluronan and lectin interacting) proteoglycans that include versican (a large chondroitan/dermatan sulfate proteoglycan), aggrecan (a chondroitin sulfate proteoglycan), and a large (220 kDa) keratan sulfate proteoglycan.[40] Decorin seems relevant as it coats and stabilizes the collagen fibrils through a tight alignment of the fibrils, by binding its protein core with different sites of the collagen fibrils. The decorin concentration is lower in the cervix of term and parturient women than in nonpregnant and early pregnant women[41] and the decorin to collagen ratio correlates inversely with the softness of the cervix. This suggests that the dispersion of collagen near term is in part mediated by loss of decorin. Biglycan interacts with collagen via its GAG side chains and like decorin its concentration decreases during cervical ripening.[32] The hyalectans probably enhance the water binding capacity of hyaluronic acid. The concentrations of versican and the large keratin sulfate proteoglycan increase in the ECM during labor,[32,40] when a significant increase in the hyaluronic acid content also occurs.[37] Hyaluronic acid is a glycosaminoglycan which is produced by fibroblasts; it is hydrophilic and attracts water to the ECM, and helps to disrupt the collagen. In addition, it is involved in PGE_2 synthesis and cytokine production,[42] while its breakdown products have angiogenic, inflammatory, immune-stimulating, antiapoptotic and heat-shock protein-inducing properties,[43] all of which may contribute to accelerated ripening of the cervix in early labor. In the immediate postpartum period, uterine involution and cervical retraction are associated with a two- to threefold increase in mRNA not only for collagen I and III but also of the small leucine-rich proteoglycans, including decorin and biglycan, as part of the repair process.[32]

Mediators

Matrix metalloproteinases

Matrix metalloproteinases (MMPs) are the primary mediators of ECM degradation in the cervix during

pregnancy and parturition.[44–47] These zinc-dependent enzymes have been divided into four subgroups, collagenases, gelatinases, membrane type MMPs (MT-MMPs), and stromelysins. They are capable of degrading collagen and elastin, as well as other ECM components, including proteoglycans. All cell types present in the cervix are capable of producing MMPs. The physiologically important collagenases MMP-1 and MMP-8 are produced by the resident fibroblasts (MMP-1) and the invading neutrophils (MMP-8). They cleave the triple helices of the intact undenatured collagen, degrading it into smaller fragments. MMP-1 preferentially cleaves type III collagen, and MMP-8 type I collagen.[48] MMP expression is regulated at several levels, including gene transcription, gene translation, latent enzyme secretion, pro-enzyme activation and, importantly, inactivation by endogenous inhibitors. Some MMPs, e.g., MMP-1 are synthesized on demand in response to hormones, cytokines, growth factors, and physical stress.[49] They may be secreted as latent enzymes into the ECM, or bound to the cell surface and become activated by proteinases, including other MMPs.[50] Other MMPs such as MMP-8 are synthesized by leucocytes, such as neutrophils and macrophages and stored in their granules as latent enzymes to be released when these cells are stimulated. At the onset of labor, neutrophils are attracted to the ECM. The MMPs present in neutrophil granules as well as in the ECM are activated, in response to increased cytokine activity resulting from hormone induction. As a consequence, during labor, MMP concentrations are increased both in the cervical tissue and in the circulation.

The ECM degrading activity of the MMPs is counterbalanced by the activity of tissue inhibitors of metalloproteinases (TIMPs). These inhibitors are present in the cervix throughout gestation[29] and prevent it from becoming too severely damaged by the MMPs. The synthesis of TIMPs varies with the level of MMP activity, which in turn is dependent of the stage of cervical ripening and dilatation.[51] Other suppressive factors of MMP expression include TGF-β and glucocorticoid.[52]

Cytokines

Cytokines, including the interleukins (ILs) IL-1 (α and β), IL-6, and IL-8, are causally linked to preterm and term labor. Cytokines attract neutrophils to the cervix, stimulate their extravasation, and the subsequent release of MMPs from their granules and also stimulate fibroblasts to synthesize and secrete MMPs. IL-1α stimulates MMP-1 secretion by human cervical fibroblasts and iNOS mRNA expression in these cells,[53] while IL-1β, IL-6, IL-8, and tumor necrosis factor alpha (TNFα) expression is linked to invading neutrophils.[54] When IL-1β or IL-8 are administered intracervically, they induce premature ripening and delivery.[55,56] IL-1β, IL-6, and IL-8 are also found to be increased during bacterial vaginosis or intra uterine infections, and then they play a causal role in early cervical ripening and premature delivery.[57] Interleukin-levels in the lower uterine segment,[58] placental blood, maternal serum, and amnionic fluid[59] are also found to increase progressively with the increase of the cervical diameter in normal labor at term.

TGF-β is an immunosuppressant and a potent chemo-attractant for monocytes and neutrophils.[60] It stimulates fibroblasts to synthesize collagen and proteoglycans. TGF-β increases after delivery,[32] and may thereby contribute to the involution of the cervix.

Nitric oxide

Nitric oxide (NO) is a short-lived free radical gas that is produced by nitric oxide synthases (NOS) in a reaction in which arginine, oxygen, and NADPH are converted into citrulline, NO, and NADP. There are three forms of NOS, all of them have been identified in the cervix. They are the constitutive calcium-dependent isoforms bNOS (brain NOS) and eNOS (endothelial NOS) and an inducible Ca-independent isoform (iNOS).

An important effect of NO is smooth muscle relaxation and therefore it is believed to aid in myometrial relaxation during pregnancy and possibly in cervical relaxation during delivery,[61] as may be concluded from the observations in rats, where during active labor NO production is upregulated manifold in the cervix, it is simultaneously downregulated in the myometrium.[62] Interestingly, the relaxing effect of NO on the myometrium appears to be mediated through an effect on calcium-activated potassium channels and not through cGMP as has been previously assumed.[63,64]

The increase in cervical NO during labor is mediated mainly by the increased expression of inducible nitric oxide synthase (iNOS)[65] in cervical stromal cells and invading neutrophils, macrophages, and mast cells.[66] In addition to being a smooth muscle relaxant, and probably functionally more important, NO is also involved in the regulation of several inflammatory mediators that induce cervical softening. NO-donors such as sodium nitroprusside induce a rapid and significant softening of the cervix in early pregnant women, when it is applied into the cervical canal.[67] Sodium nitroprusside given intracervically to term pregnant guinea pigs induced changes in the ECM that were similar to those observed in guinea pigs that delivered spontaneously.[18] NO stimulates the release of prostaglandin (PG) E2 and PGF2α by human cervical fibroblast, through stimulating cyclo-oxygenase. It also stimulates the synthesis of proteoglycans, probably through a PGE2-dependent pathway. NO increases the production of MMP1 in human fibroblasts.[53] High concentrations in the cervical tissues may cause cell death.[68] The view that NO is actively involved in the pathways that lead to ECM degradation which contributes to cervical ripening is

supported by the observation in pregnant rats that the NOS-synthesis inhibitor L-NAME significantly reduces the distensibility of the cervix.[62]

Endothelial NOS (eNOS) and brain NOS (bNOS) provide low background levels of NO in the cervix. The concentration of bNOS is significantly increased in active labor[69] while reports with regard to eNOS concentrations are contradictory. Both constitutive isoforms are believed to be more involved in smooth muscle relaxation, while the massive increase in NO synthesis which is caused through the greatly increased iNOS expression may be more important for its involvement in immune and inflammatory response.

Cellular compartment

The cervix contains epithelial cells, smooth muscle cells, and fibroblasts, as well as a variable population of migratory cells, neutrophils, macrophages, and mast cells. All the various cell types in the cervix participate in one way or the other in the process of cervical ripening. The epithelial cells not only provide local protection against invading organisms, but secrete inflammatory modulators, including iNOS.[66] The resident fibroblasts and smooth muscle cells in the cervix are not only the source for collagens and proteoglycans and several growth factors, they also take part in the inflammatory-like response of the ripening cervix through the secretion of cytokines and proteolytic tissue-degrading enzymes. Early in gestation, smooth muscle cells and fibroblasts proliferate. Late in gestation, especially in early labor, the rate of proliferation is reduced, physiologic cell death (apoptosis) increases, and neutrophils and macrophages are attracted to the cervical stroma. Most of the information about the contribution of the individual cell types to the process of cervical ripening has been derived from *in vitro* studies, i.e., cell cultures and in a lesser amount from immunohistochemical or *in situ* hybridization studies, so the possible effect of interactions between different cell types in most cases cannot be specified. Based on these studies, hormones or inflammatory mediators given to patients may not always induce the desired effect. In the following sections we will discuss what is known about the cellular components of the cervical stroma and their role in the physiological changes that occur during pregnancy and delivery.

Stromal cells

Smooth muscle cells are present in the muscular outer layer of the cervix and in the stroma. Smooth muscle cells in the cervix may have two functions, one of muscle contraction and one of secretion of catabolic enzymes. Although the literature does not offer any clear guidance in this matter, it may be perceived as logical that muscle contractions may be the more important function in the outer layer, because of the arrangement of muscle fibers in bundles while in the stroma the more dispersed smooth muscle cells may contribute to the inflammatory-like mechanisms of the cervix. However, these two functions may not be completely separated because of the observation that an electromyogram (EMG) derived from the cervix is higher in women with a clinically unripe compared to a ripe cervix.[70,71] During parturition contractile activity of the cervix diminishes in response to increased levels of NO.[72]

The proposed mechanism by which NO exerts its relaxing effect on the myometrial smooth muscle cells has recently been revised. Previously it was thought that the relaxing effect of NO was mediated through soluble guanylyl cyclase (sGC) activation and cGMP accumulation, like in vascular and gastrointestinal smooth muscle cells. More recent studies, however, have shown that NO-induced relaxation is independent of this pathway.[64] It has been proposed that the NO-induced relaxation in the myometrium is mediated through the activation of calcium-activated potassium-[63] or PKG-independent regulation of myosin phosphatase.[64] Although it has been reported that an analog of the cGMP inhibits contractile activity of the cervix,[73] further studies are clearly needed to determine just how NO exerts its effect on cervical smooth muscle relaxation.

Besides contributing to the ECM by synthesizing collagens and proteoglycans,[38] cervical smooth muscle cells also participate in the inflammatory-like mechanism that leads to degradation of the ECM. They do so through the production of cytokines, including IL-1β and TNF-α, which in turn, induce expression of MMP-1 and MMP-9.[74] They also produce IL-8, upon lipopolysaccharide- and cytokine-stimulation, which stimulates neutrophil invasion and degranulation and, consequently, the release of proteolytic enzymes, including MMPs.[75]

In some aspects cervical fibroblasts are similar to cervical smooth muscle cells in that they both contribute to the ECM by synthesizing collagens and proteoglycans and they are both capable of producing cytokines, proteolytic enzymes such as MMPs and proteolytic enzyme inhibitors such as TIMPs. However, there are some fundamental differences in the way they react to stimulation by pro-inflammatory cytokines. For example, both cervical smooth muscle cells and fibroblasts increase their gene expression of MMP-1 and not of MMP-2 when stimulated by IL-1β or TNF-α, but fibroblasts also react by increasing TIMP expression, and cervical smooth muscle cells do not.[74] So fibroblasts have the primary function to provide the cervix with strength through the secretion of collagen and proteoglycans. Upon proper stimulation, they produce MMP-1, MMP-2, and MMP–9 as well as cytokines, including IL-6 and IL–8,[76,77] which are effective on the other side of the balance. Cultured human cervical fibroblasts respond to mechanical stress or the administration of PG-F2α, IL-1α, or NO with the production or secretion of MMP-1.[49,53]

Invading cells

Inflammatory cells of all kinds are present in cervical stroma throughout gestation[41] as they are in all organs that are in contact with the exterior. Shortly before the onset of labor the cervix is invaded by a large number of neutrophils, and to a lesser extent by macrophages. They contribute to the increased levels of NO, cytokines, and MMPs that are actively involved in cervical ripening and dilatation.

In pregnant women, neutrophils are thought to be the main source of the increased levels of collagenolytic enzymes, including MMPs.[78] During labor, neutrophilic infiltration of the lower uterine segment increases with cervical dilatation, as do the concentrations of MMP-8 and IL-8. At 2–3 cm dilatation, neutrophils are present close to the endothelium of the blood vessels but have not yet invaded the tissue. When dilatation progresses, the process of neutrophil invasion is associated with increased expression of adhesion molecules, including intercellular adhesion molecule-1, endothelial leucocyte adhesion molecule-1 and vascular cell adhesion molecule-1.[79] Shortly after delivery, the neutrophil concentration shows a marked further increase, and with it the expression of IL-1β and IL-8.[80] This may represent an anti-infectious property rather than being associated with cervical involution.

Macrophages are present in somewhat higher numbers in the cervical stroma of women during parturition,[80] while other inflammatory cells, including mast cells, T-cells, and plasma cells that are present in small numbers during gestation, do not increase appreciably during labor.[41] Mast cells play a role in angiogenesis during the first half of gestation, through mast cell degranulation that causes the release of vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), IL-1, and IL-6.[81] Macrophages and mast cells do not seem to play an important role in the initiation of labor.

Hormonal regulation

Progesterone and estrogen

Progesterone keeps the myometrium from contracting and the cervix from softening. Spontaneous labor is preceded by a reduction in the circulating concentration of progesterone and/or an increase in estrogen in several but not in humans, and premature labor can be induced successfully by estrogen injection in sheep.[82] This underlines the concept that progesterone dominance is important to maintain uterine quiescence, while estrogen dominance would lead to labor. The fact that parturition in humans is not preceded by a drop in serum progesterone concentration or a shift in serum progesterone/estrogen balance does not necessarily mean that the concept of the progesterone/estrogen balance is invalid in humans as circulating hormone concentrations are only part of the picture in which receptor quantity and sensitivity also plays a role. In the guinea pig, progesterone receptor expression decreases shortly before parturition, whereas estrogen receptor-α (ER-α) remains high throughout late gestation and parturition.[83] Humans seem to be similar to guinea pigs in that the responsiveness of their cervix to progesterone and estrogen is likely not to be mediated through changes in circulating blood levels but by changes at the receptor level. The fact that progesterone antagonists effectively induce cervical ripening and labor in women supports the functional importance of progesterone blockade in the onset of labor.[84,85] In addition, progesterone may upregulate the production of TIMPs,[51] and inhibit the IL1- (α and β) mediated induction of MMP-9 in cervical fibroblasts of term pregnant rabbits,[86] by which it blocks the MMP-induced degradation of the ECM. Estrogen stimulates the infiltration of eosinophils in the rat[87] and the enzymatic activity of the procollagenases in cell cultures from the guinea pig cervix.[88,89] Furthermore, estrogens enhance the cytokine-induced attraction of neutrophils to the cervix, an effect that is blocked by progesterone,[90,91] and the presence of ER-β in neutrophils suggests that estrogens may attribute to the release of MMPs from the neutrophils in the cervix.[92] Overall, the progesterone to estrogen ratio at the tissue and cellular level is likely to be of major importance for uterine quiescence and cervical closure during pregnancy as well as for the initiation of cervical ripening and delivery.

Prostaglandins

Prostaglandins (PGs) are unsaturated cyclic fatty acids derived from arachidonic acid in a reaction catalyzed by cyclo-oxygenase (COX)-1 and COX–2. COX-1 is expressed constitutively and COX-2 is induced by cytokines and growth factors.

Local (vaginal and intracervical) application and systemic administration of PGs (PGE_1, PGE_2, and $PGF_{2\alpha}$) and their synthetic analogs induce clinical ripening of the cervix and the onset of labor. In current obstetrical practice PGE_2-gel applied vaginally is routinely used to induce cervical softening. Collagen extractability from cervical biopsies of women treated with PG increased significantly compared to the cervix of nonpregnant women[93] or term pregnant women with an unfavorable cervix.[94] However, incubating biopsy samples with PGE_2 from pregnant women at different stages of pregnancy revealed that pregnancy stage has a major influence on the response of cervical tissues to PGE_2. For example, in the early first-trimester collagen synthesis is stimulated, and proteoglycan synthesis is decreased, by PGE_2. In cervical tissues obtained from late first-trimester pregnancy until term the effect of PGE2 on the synthesis of proteoglycans and collagen is reversed, while in tissues obtained at the start of labor, incubation with PGE_2 causes a decrease in both collagen and proteoglycan synthesis.[95]

Several mechanisms are activated by PGs. PGE_2 enhances the effect of IL-8, a potent neutrophil chemoattractant,[96] which is abundantly present in the cervix and whose concentration in this tissue increases progressively with cervical dilatation.[97]

If endogenous PGs play a role in the physiological ripening and dilatation of the cervix it is to be expected that PG levels should rise in cervical tissue at late gestation and labor. However, analysis of cervical mucus samples shows no increase in PGE_2 and $PGF_{2\alpha}$ content during the period of cervical ripening.[98] This suggests that if PGE_2 and $PGF_{2\alpha}$ are active during normal labor, their levels are under tight temporal and spatial control and that they would be synthesized locally in the tissues, acting in a paracrine way. Incubated cervical tissues obtained from patients during the first trimester of pregnancy produced PGs and prostaglandin metabolites, an effect that may at least in part be mediated by NO.[99] Functional LH and hCG receptors have been localized in the cervix of women and treatment of endocervical tissue with hCG induced a significant decrease in COX-2 expression and thus could inhibit PG synthesis. During the last few days prior to labor in the baboon, PGE_2 receptor expression in the cervix increases and thereby sensitizes the cervix to PGE_2.[100] The PGE_2 receptor, EP_4 is also present in human cervical fibroblasts and seems to mediate GAG synthesis.[101] PGE_2 may also cause an increase in cervical MMP-9 concentration in rats, by a cAMP-dependent mechanism.[102] Oxytocin infusion is widely used to augment labor by stimulating increased frequency and intensity of myometrial contractions, although in two randomized clinical studies intravenous infusion of low doses of oxytocin seemed to be as effective as local application of PGE_2 gel in inducing cervical effacement.[103,104] In cows, oxytocin-receptor expression in the cervix increases markedly during late gestation, predominantly in the mucosal cells.[105] In sheep, cervical oxytocin receptor levels during pregnancy are low [106] and remain low during late gestation and labor.[107] However, in sheep oxytocin is able to induce marked cervical softening in the estrus period because the oxytocin receptor is maximally present. The observations in sheep and the fact that in clinical practice oxytocin infusion is not always as effective in prelabor ripening of the cervix of pregnant women, suggests that high oxytocin receptor levels are necessary to make the cervix sensitive to oxytocin. In cows it has been shown that oxytocin stimulates COX expression and by this way the release of PGE_2.[108] It could be possible that in women the effect of oxytocin is generated through an increased PGE_2 synthesis at the uterine level since oxytocin receptor expression in the uterus is increased during labor.[109] Preinduction with PGE_2, which is commonly practiced when oxytocin infusion is used to induce labor, may overcome the critical period when oxytocin receptors at the uterine or the cervical level have not yet increased to sufficiently high levels to induce endogenous PGE_2.

The conclusion is that although prostaglandins and oxytocin are able to induce cervical softening when used in labor induction, their role in cervical ripening and softening during physiological spontaneous deliveries at the cervical level is still disputed as the mechanisms that could possibly be involved have not yet been clearly established.

Conclusion

Since the concept of cervical ripening as a local inflammatory reaction has been introduced by Liggins,[110] the intriguingly complex remodeling of the uterine cervix in the onset of labor has shown to be an exciting field for continued research. Although many factors and mechanisms that could be involved in this process have been identified, mostly from animal models and *in vitro* studies, and have led to new concepts and ideas, not all of them have been shown to actually occur in the cervix of women that give normal birth. We have made a selection of those factors of which the clinical relevance is evident or could prove to be promising targets for pharmacological or mechanical interventions to prevent preterm and postterm delivery as well as failure of ripening and dilatation in response to pharmacological induction of labor.

86 Physiology of maternal sleep in pregnancy

K. Biedermann and R. Huch

Introduction

Pregnancy involves fundamental readjustment of the maternal organism, often associated with unpleasant changes, notably fatigue and reduced energy.[1,2] It is popularly believed to impair sleep. Pregnant women try to sleep more, but are still often tired and perform less efficiently.[3] Those affected tend to account for their residual fatigue in terms of progressive sleep deprivation, due to altered and fragmented sleep in pregnancy.[4] By means of a questionnaire on wrist actimetry in daily life and polysomnography in the sleep laboratory, we investigated the changes in sleep habit and quality in pregnancy and assessed their relationship to fatigue.

Background

Methods of sleep research

Polysomnography – a combination of electroencephalography (EEG), electromyography (EMG) and electrooculography (EOG) – is the gold standard for sleep investigation and arbiter of sleep stage division into rapid eye movement (REM) sleep and non-REM (NREM) sleep, which is itself subdivided into four stages of differing depths.[5]

The sleep EEG is the sum curve of the electrical vectors on the scalp produced by the discharge of thousands of neurons. This neuron activity consists of waves differing in frequency and amplitude. The sum curve is broken down by Fourier analysis into individual frequency bands. The proportion of waves at a given frequency (power density) is deduced from this spectrum; in particular, the slow waves (1–12 Hz frequency band) indicative of deep sleep are differentiated from intermediate (13–17 Hz, α-rhythm of the resting waking state) and rapid waves (18–25 Hz), which occur in NREM sleep stages 1 and 2. Whole-night spectral analysis shows waves of the whole frequency spectrum in all sleep stages, but with different power densities in the different frequency bands.

Figure 86.1 shows the different sleep stages (sleep structure) combined with Fourier analysis of the sleep EEG. The sleep stages are shown along the top, above the waves at different frequency bands over the entire sleep episode. Long-wave sleep (1–4 Hz) shows a marked increase in the first sleep cycles, with the maxima falling in NREM sleep stages 3 and 4. In the later sleep cycles long-wave activity decreases continuously until it eventually disappears almost completely.

Sleep stages and sleep control

NREM sleep

In stage 1 sleep, there is a decrease in the high-frequency EEG waves, but muscle tone and autonomic function (blood pressure, heart rate and respiration) remain at their waking levels or only decrease insignificantly. Dream-like experiences occur frequently and mostly relate to the thought content of the preceding waking stage. Stage 2 sleep follows after approximately 5 min. The EEG shows the characteristic spindles and spontaneous and evoked K-complexes. Muscle tone is markedly reduced, the eyes are quiet, and movement artifacts absent. Autonomic function decreases further compared to stage 1; the arousal threshold is raised. Consciousness and receptivity to external events are absent. Stage 2 NREM sleep accounts for over 50% of total sleep time and is hence the chronologically dominant sleep stage. This protracted stage is followed by the transition to deep sleep (stages 3 and 4), with the first occurrence of distinct σ-waves (0.5–4 Hz). Muscle tone is lower than in stage 2; tendon reflexes are preserved. The eyes are actively closed; eye movement is absent. Consciousness is extinguished and autonomic function further reduced. Low-frequency σ-waves dominate stage 4 NREM sleep (50%), and the EMG shows minimal muscle tone. Arousal from the deepest stage of sleep requires the strongest stimuli.

REM sleep

REM sleep, characterized by salvoes of REMs[6] is also termed paradoxical sleep because the EEG is dominated by high-frequency waking waves. However,

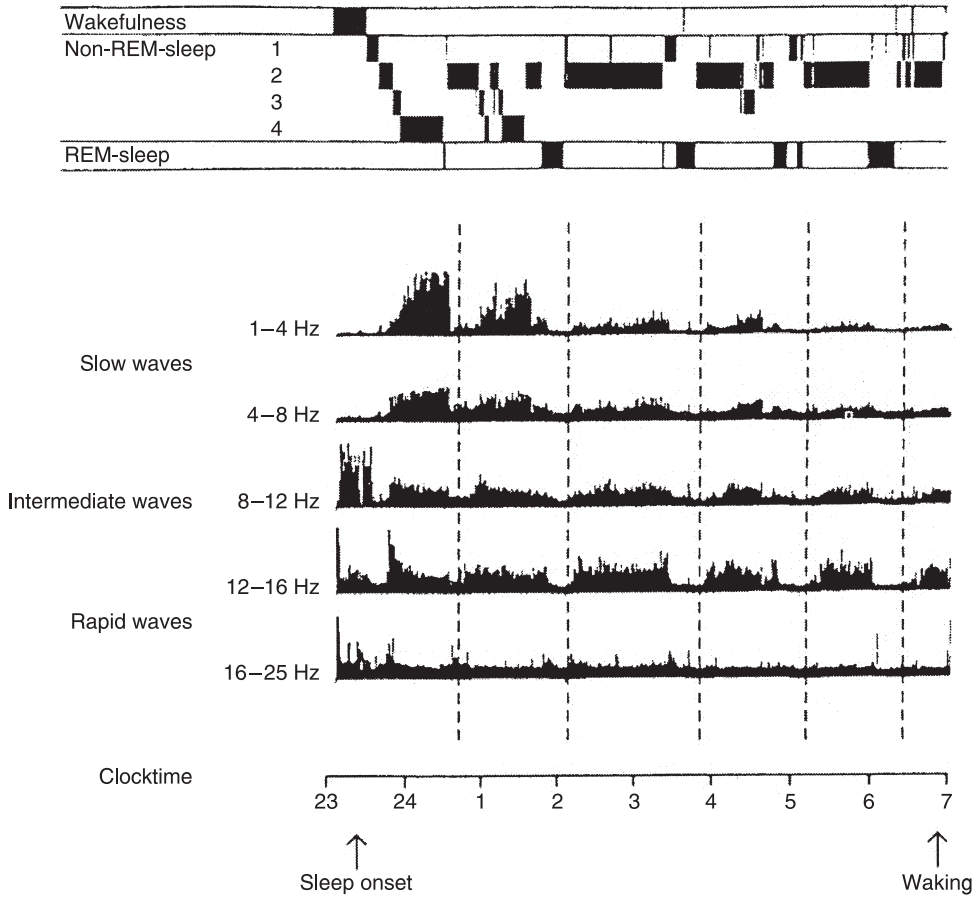

Figure 86.1 Sleep stages (sleep structure) (top) and spectral analysis (sleep architecture) in a whole-night polysomnogram (bottom).

muscle tone is almost entirely absent. REM sleep is dream intensive and altogether accounts for approximately 20% of the total sleep time, its share tending to decrease as the sleep episode progresses.

Internal clock

Like many physical functions, the sleep–wake cycle is subject to a circadian rhythm. Under normal conditions, this is set to a 24-h-day, but it also operates in experimental isolation, where it is set to a 25-h-day.[7] Animal experiments have identified the oscillator of the internal clock as a small neuron nucleus lying above the optic chiasma: the suprachiasmatic nucleus.

Sleep factors

Several sleep factors have been discovered to date, e.g. S factor,[8] sleep promoting substance,[7] σ-sleep-inducing peptide,[9,10] prostaglandin D_2,[11] immune polypeptides, such as interleukin-1, interferon and tumor necrosis factor, and neurosteroids.[12,13] None has yet been shown to play a central role. Sleep modulation and control is thus presumed to be multifactorial.[14]

Sleep and fatigue in pregnancy

Fatigue has been defined as a subjective and objective decrease in energy with respect to various spontaneous activities.[15] It is primarily the result of physical activity, or more precisely of inadequate recovery from such activity. Many other factors can cause or increase fatigue, e.g. psychological[16] and hormonal influences, in addition to anemia, hypotension, obesity, magnesium deficiency and infectious disease. Fatigue in pregnancy is multifactorial, involving psychological and emotional factors, marked hormonal changes and obvious biological determinants, such as weight gain, pregnancy anemia and the tendency to hypotension.

Sleep disturbance and decreased drive are the common complaints throughout pregnancy, present in 20% and 40% of women, respectively, in the first trimester, and increasing to 70% in the case of sleep disturbance at term.[17] A survey of 100 pregnant women at term found that mean sleep time increased in the first trimester and again in the third trimester; sleep was increasingly shallow and interrupted, while birth and baby themes came to dominate dream content at the expense of daytime experience.[18]

Clinical study

Structure and methods

A total of 189 women attending the Zurich University Hospital Obstetric Outpatients Clinic were recruited

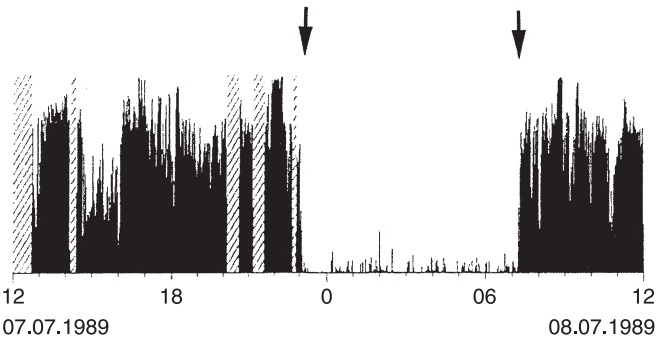

Figure 86.2 Printout of modified 24-h (noon–noon) activity data files. Arrows, onset and end of sleep; hatched areas, erased recording phases (excluded from analysis).

over 2.2 years. The inclusion criteria, in addition to informed consent, were a normal singleton pregnancy and the absence of sleep disturbance and relevant psychological or somatic complaints. At the booking visit, subjects were questioned by a (female) physician about their lifestyle and occupation and sleep behavior before pregnancy. At the end of each trimester and 6 weeks postpartum, they were reinterviewed about any changes. The questionnaires were drafted with the aid of the Institute of Pharmacology, Zurich University, and psychologists.

Activity was monitored in 70 of the subjects using wrist actigraphy:[19–21] a wrist-worn matchbox-sized monitor (Gähwiler Electronics, Zurich) converts movement to electrical signals via a piezoelectric transducer; the signals release an impulse if they exceed a set threshold (0.1 g m/s^2). Epochs were set to 1 min for optimal movement resolution compatible with the device's 1-week storage capacity. Subjects were asked to wear the monitor as far as possible continuously for 1 week on the wrist of the non-dominant hand, once per trimester and postpartum. They were also asked to record sleep times together with specific activities, e.g. driving, in a sleep and activity diary to enable blank phases and passive vibration to be excluded from the analysis. Monitors were downloaded onto an IBM PC and the raw data, comprising 10,080 measurements over the 7 days, were edited according to the diary entries. It was these modified data sets that were then analyzed (Figure 86.2).

In addition to interview and actigraphy, 10 subjects also underwent polysomnography (Grass, with online Fourier analysis) for two consecutive nights in each trimester (weeks 10, 20 and 30), commencing at lights out. Subjects could get up at their own discretion and were woken at the time they requested. The polygraphic data were manually scored according to the criteria of Rechtschaffen and Kales[5] for 20-s epochs and fed into the computer as data files for combined analysis of sleep stages and EEG spectra, in addition to conventional sleep stage analysis.

The Mann–Whitney U rank test and Wilcoxon's signed rank test were used for statistical analysis, and the significance level for longitudinal changes through pregnancy adjusted with Bonferroni's correction. The chi-squared test and Fisher's exact test were used for multiple comparisons.

Sleep study results

Population

The median age was 28 years (range 15–45 years). A total of 87 women (46.0%) were expecting their first child, 161 (85.2%) were married and 47.1% were in full-time employment at the start of the pregnancy. Median booking visit body weight was 56 kg (range 40–93 kg); median weight gain during pregnancy was 13.9 kg (range –4 to +28.5 kg), equivalent to 25.4% of baseline body weight (range –9% to +53%).

Of the women 37.6% had smoked until their pregnancy; 20% smoked more than 10 cigarettes daily. The remaining 62.4% described themselves as non-smokers. Forty percent consumed virtually no alcohol before their pregnancy, while 11% had a weekly alcohol intake equivalent to 180 ml of 100% alcohol, for example, in 1.5l wine, 4.5l beer or 0.5l spirits, assuming a medium alcohol content (12%, 4% and 36%, respectively).

Sleep times

The most reliable sleep–time data were obtained by actigraphy. These values were compared with the questionnaire answers provided by the same women and with control data for 20–40-year-old women from a representative 1983 Swiss population survey.[22]

Mean actigraphic time in bed in pregnancy was 8 h 22 min on weekdays and 8 h 42 min at weekends (Table 86.1). These values deviated somewhat from the questionnaire responses: Weekday time in bed was underestimated by 14 min, while weekend time in bed was overestimated by 25 min. The actigraphic weekday–weekend difference was only 20 min (8.42 vs. 8.22) vs. a subjective estimate of 59 min. Pregnant women reported 20 min more sleep during weekdays, and only 12 min more sleep during weekends, than the reference population. When averaged over the week, time in bed was longer in pregnancy by 18 min/night (+3.3%). This difference is slight and illustrates the fact that pregnant women, like their non-pregnant counterparts, adjust their sleep time to their occupational and social commitments. A general finding was that the pregnant women generally went late to bed, thereby failing to use a possible means of sleep compensation.(Table 86.1)

Sleep times showed no significant changes during pregnancy, but actigraphic time in bed tended to be longer in the first trimester, due to an earlier bedtime than later in pregnancy (Table 86.2). Bedtime differed significantly between the first and third trimesters ($P < 0.01$). It was surprising that many women (47.1%) were still working in the first trimester; their

Table 86.1 Whole pregnancy weekend and weekday bedtime (BT), rising time (RT) and time in bed (TIB) (h:min; mean ±SD) in the actigraphy population ($n=70$) vs. age-matched non-pregnant controls[19]

	Weekends			Weekdays		
	BT	RT	TIB	BT	RT	TIB
Self-rating	23:38 (1:14)	8:45 (1:17)	9:07 (1:13)	22:47 (0:52)	6:55 (1:00)	8:08 (0:59)

Non-pregnant controls	22:50 (1:53)	8:38 (1:33)	8:55 (1:23)	22:02 (1:35)	6:36 (0:56)	7:48 (1:07)

Table 86.2 Actigraphic bedtime, rising time and time in bed (h:min; mean ±SD; $n=70$) during and after pregnancy

	Trimester			
	First	Second	Third	Postpartum
Bedtime	22:59 (0:46)	23:08 (0:45)	23:15 (0:59)	23:14 (0:50)
Rising time	7:34 (0:51)	7:34 (0:57)	7:44 (0:59)	7:37 (0:56)
Time in bed	8:37 (0:50)	8:26 (0:47)	8:29 (0:46)	8:23 (0:49)

Figure 86.3 Mean time in bed in housewives ($n=21$) and full-time employees ($n=24$) on weekdays and weekends. Housewives spent longer in bed than employees on weekdays ($P=0.008$, Mann–Whitney test). Boxes: 25th, 50th and 75th centiles; T bars: 10th and 90th centiles.

proportion decreased progressively during pregnancy (20% in the third trimester). Rising time, on the other hand, did not change during pregnancy, ranging from 07:34 to 07:44 h.

Employment affected the total sleep time. On weekdays, housewives slept almost 1 h longer than employed women ($P<0.001$), went to bed at the same time but sleeping some 40 min longer in the morning (Figure 86.3). However, they reported fatigue with the same frequency as their employed counterparts. At weekends, employed women slept on average only 11 min longer than housewives (9 h 30 min vs. 9 h 19 min; not significant).

Dreams

Dream activity is typically more intense in pregnancy, centered on themes of pregnancy, birth and baby,[18] and frequently tinged with anxiety.[23] A total 22% of women reported more intense dreaming in the first trimester, rising to 30% in the second and third trimesters, and returning to prepregnancy levels days after delivery. The increase in dream activity in pregnancy and postpartum was unrelated to energy levels, despite nightmares being a frequent cause of waking in pregnancy. Pregnancy dream content is non-prognostic for pregnancy outcome or quality of subsequent mother–infant bonding.[24]

Daytime naps

Before pregnancy, only 37% of the women took an occasional or regular daytime nap. During pregnancy the proportion increased to 41% in the first trimester (mean 42.6 min) and 50% in the third trimester (mean 31.3 min). Only 26% took no nap at any time during their pregnancy. Napping had little effect on sleep behavior. In fact, total sleep time in 24-h periods that included a daytime sleep was approximately 1 h longer than in identical periods with no nap; nocturnal sleep times were therefore unchanged. Naps were more often associated with nocturnal sleep onset problems (21.7% vs. 10.0%, $P<0.05$). Napping had no effect on nocturnal motor activity (mean nil phase time and motor latency). Employment had no effect on napping.

Sleep quality

Women reported sleep changes in early pregnancy in 85% of the cases. Increases in sleep time and sleep

latency were reported by 43% and 36%, respectively. Sleep was shallower (44%) and also disturbed by arousal stimuli, which had not caused waking before pregnancy. In the second trimester, 68% reported improved sleep quality, followed by further deterioration in the third trimester when sleep was more easily disturbed (52%) and more fragmented. These data were confirmed by very similar values in a Japanese study.[25] The main causes of sleep disturbance are bathroom trips,[26] unaccustomed sleep position,[27,28] back pain,[29] fetal movement,[3] nightmares, hunger and thirst.

Sleep quality ran only partly in parallel with sleep time during pregnancy. Often the changes were mutually contradictory, greater fatigue being reported despite longer sleep or subjects describing themselves as more rested despite shorter sleep. Approximately 90% of women reported fatigue during pregnancy, from the first trimester onward; self-rated energy was lowest in the first and third trimesters, unaffected by the usual amplitude of sleep changes, and unrelieved by longer sleep. Fetal sex did not affect maternal sleep behavior or energy. Hypnotics were taken only in exceptional cases (0.5%, mostly benzodiazepines); approximately 10% of the women took 'natural' hypnotics (valerian, candy).

Sleep latency. Sleep latency (the interval between lights out and the first stage 2 sleep) can only be determined by polysomnography. However, we found a significant correlation between subjective sleep onset time and polysomnographic sleep latency. Difficulty in falling asleep was one of the commonest sleep disturbances, reported by 29%, including almost 10% reporting sleep latency exceeding 30 min. However, the great majority (63.7%) fell asleep in less than 10 min. Sleep latency decreased with increasing sleep pressure, i.e. the longer subjects had been awake the more quickly they fell asleep. Mean time in bed was longer in women taking a longer time to fall asleep: women falling asleep in $\leq$10 min slept 23 min less than those falling asleep in $>$ 10 min (8 h 43 min vs. 8 h 20 min, $P < 0.01$). The time taken to fall asleep showed only small changes throughout pregnancy, but was longest (not significantly) at term.

Actigraphic motor latency was defined similarly as sleep latency as the interval between lights out and the first nil activity phase lasting $\geq$5 min. It was longer in pregnancy than postpartum (6 vs. 5 min, $P < 0.01$), but unchanged during pregnancy itself. It was also longer on weekdays than at weekends (7 vs. 6 min, $P < 0.01$), probably due to the earlier bedtime. Restless sleep was associated with a longer motor latency as motor activity in women with restless sleep was also increased during sleep onset.

Nocturnal waking. Sleep in pregnancy was fragmented by nocturnal waking, reported by at least 40% of subjects once per night even before pregnancy. The most frequent causes were 'internal', e.g. bathroom trips or thirst (58%), external factors, e.g. noise and temperature (40%), and nightmares (21%); 9% had no explanation.

In pregnancy, the proportion of women generally waking at night increased to 78% in the first trimester, fell to 69% in the second trimester and increased again to 79% in the third trimester (vs. 23% postpartum). The proportion of women waking up more than once increased steadily from 30% in the first trimester to 52% in the third trimester. Employed women awoke less often than housewives (1.4 vs. 1.7 times per night, $P < 0.05$) who more frequently already had a young child to look after.

Nocturnal rising. Rising at night ran in parallel with waking at night during pregnancy, following 59–66% of waking episodes. Both sets of values were thus largely similar. Getting up at least once a night even before pregnancy was reported by 42.1% of women. In contrast to other studies,[16,30] this had no detectable impact on sleep quality. In the first and second trimesters, 58% and 51% of women rose at least once per night, respectively (increases of 15% and 8%, respectively); the proportion then increased in the third trimester to 76% ($P < 0.0001$). Improvement was only partial after delivery when, mainly because of the baby, rising was still more frequent than in the first and second trimesters (Figure 86.4). Bathroom trips were the commonest cause of rising at night even before pregnancy (43.8%), followed by caring for a small child (24.4%), hunger and thirst (14.6%) and uncomfortable environmental temperature and nervousness (Table 86.3). Bathroom trips remained the major cause throughout pregnancy, cited by 69.6% in the third trimester (Table 86.3), with a proportionate decrease in risings caused by a small child. The baby was, as expected, the dominant cause after pregnancy.

Fatigue and energy. Fatigue has been defined as the subjective and objective decrease in energy.[15] Fatigue and energy thus represent opposite poles of the same spectrum, describing the same reality in inversely proportional terms. Only 26% of women reported feeling rested on waking even before pregnancy; a good third described themselves as 'tired' on waking. Physical and mental energy is known to be decreased early in pregnancy. A total of 70.9% of women reported fatigue/decreased energy at the end of the first trimester; 18.5% reported feeling marked fatigue/markedly reduced energy (Table 86.4). Only a minority (3.7%) felt more energy in the first trimester than before pregnancy. Fatigue/decreased energy was thus a common complaint in early pregnancy, decreasing transiently to 34.6% in the second trimester before reascending in the third trimester to 65%. It improved postpartum in two-thirds of subjects, but was still reported in 31.6%.

Mean fatigue scores (1 = very tired, 6 = very energetic) were determined in 70 subjects throughout

pregnancy and were used to divide the population into three groups. Sleep parameters and clinical findings were then analyzed separately for the three groups. Only one sleep parameter (bedtime) and two clinical parameters (basal hemoglobin and minimal diastolic blood pressure) correlated significantly with fatigue in pregnancy (Table 86.5).

The mean difference in bedtime between tired and energetic women was 23 min ($P=0.026$) (Table 86.5). There were no differences in rising time or time in bed. Nocturnal activity [nil activity time, percentage nil activity and mean nil phase length (mNPL)] and nocturnal waking were unrelated to fatigue. Motor latency appeared longer (not significantly) in the tired group. Daytime napping was equally frequent in all three groups.

The reasons advanced as possible causes of fatigue on waking differed throughout pregnancy and postpartum (Table 86.6): the most frequent were bathroom trips, inadequate sleep or rest, evening coffee or tea, workload, personal problems, unaccustomed sleeping position, fetal movement and pregnancy complaints. Interestingly, pregnancy-specific effects on fatigue were not given; the causes were mostly those known to cause fatigue even outside pregnancy.

Employment had little impact on the fatigue reported by approximately 60% of housewives and employed women alike. Energy was not therefore increased by a reduction in workload. Instead, work was adjusted to energy as decreased energy in pregnancy leads to workplace stress and feelings of inadequacy. The increased emotional vulnerability in pregnancy also led many pregnant women to avoid such conflict by leaving their employment. The proportion of full-time employees fell from 47.1% in the first trimester to 20% in the third; the proportion of part-time employees stayed constant throughout pregnancy at 25%.

It is also interesting that performance was not improved by more sleep. Fatigue/decreased energy was no less frequent in women sleeping longer in the first trimester vs. before pregnancy than in those not sleeping longer. The fact that pregnancy fatigue was not made good by longer sleep indicates that sleep disturbance was not the cause, provided it remained within the usual limits. Other complaints, e.g. nervousness, irritability and headache, were also often attributed to sleep disturbance, although they may themselves also be its cause.

Pregnant women are often worried that their decreased energy could affect the course of pregnancy, birth or the baby. These fears can be allayed; prematurity, birth weight and neonatal adjustment were identical in women with markedly decreased energy and those with high or only slightly reduced energy. Duration of labor and spontaneous delivery rates were also identical in both the groups. We failed to confirm the association reported between birth weight and mean sleep time during pregnancy,[31] but confirmed the finding that employment does not affect the course of pregnancy or delivery.[32]

Motor activity during sleep. Like time in bed, the nocturnal nil activity time, i.e. the sum of minute measurement units showing nil activity, also remained largely unchanged throughout pregnancy (median 6 h 50 min). Individual fluctuation during pregnancy was slight, ±18% in 80% of all subjects.

The percentage of nil activity of time in bed was 75–85% in most subjects, but fluctuated markedly (56–93%) in individual cases. It increased from the first to the second trimester ($P<0.01$), evidencing more restless sleep in the first trimester. Other

Bold type, the three most frequent causes per interval

intertrimester comparisons showed no differences. The percentage of nil activity did not differ between weekdays and weekends, or between housewives and employed women.

The number of nocturnal nil phases (intervals of uninterrupted nil activity) was maximal (median 57) in the first trimester, then decreased in the second trimester (median 54) ($P < 0.001$), remaining unchanged (median 55) in the third trimester before falling to a minimum postpartum (median 44). The postpartum value was lower than the pregnancy values ($P < 0.0001$). Since total nil activity time remained unchanged

Significant changes ($p<0.05$)* vs. first trimester; †vs. second trimester

throughout pregnancy, it was broken during pregnancy into more individual nil activity phases by more frequent interruptions. Sleep was at its most restless and fragmented in the first trimester.

The increased number of nocturnal nil phases in pregnancy resulted in a shorter mNPL (Figure 86.5) in pregnancy vs. postpartum (7.36–7.59 min vs. 9.56 min, $P<0.0001$). In addition, the increase in mNPL from the first to the second trimester was significant ($P=0.0002$), but not that to the third trimester ($P=0.27$). Women with a low nocturnal percentage of nil activity had, as expected, a shorter mNPL ($P=0.0001$), also indicative of more restless sleep.

This means that during sleep in pregnancy, especially in the first trimester, motor activity was more frequent than in non-pregnancy. However, such increased motor activity had no effect on sleep quality. Motor latency was also significantly increased throughout pregnancy, indicating increased motor activity during sleep onset.

Daytime activity decreased continuously during pregnancy, in parallel with nocturnal activity, reaching a minimum postpartum, which differed significantly from the first trimester. Women with high daytime activity had higher night-time motor activity. There was a negative correlation between median daytime activity and mean night-time nil phase length ($r=0.6$), illustrated in Figure 86.6 (first trimester) and present in all recording periods.

Polysomnography

Conventional sleep analysis. Sleep structure, i.e. sleep stage distribution, remained largely unchanged over pregnancy (Table 86.7). The only significant

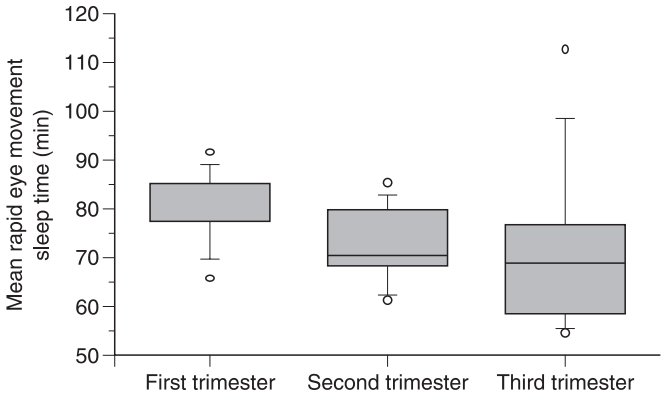

Figure 86.7 Mean REM sleep time in two nights per trimester (78, 70 and 69 min in trimesters 1, 2 and 3, respectively) in nine subjects, showing a significant decrease from the first to the third trimester ($P < 0.05$).

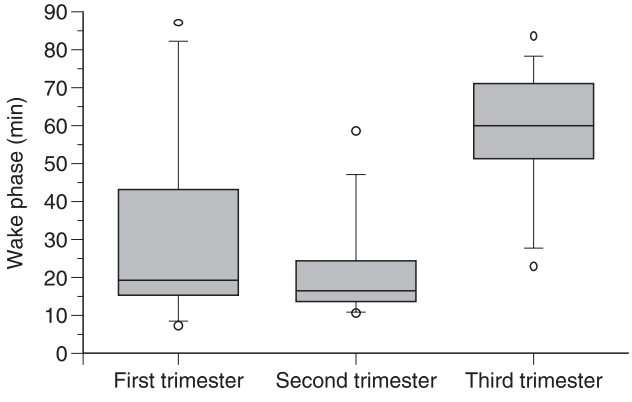

Figure 86.8 Wake phase after sleep onset (mean of two nights) per trimester in nine subjects, showing a longer wake phase in the third vs. the first and second trimesters ($P < 0.05$, Wilcoxon's test).

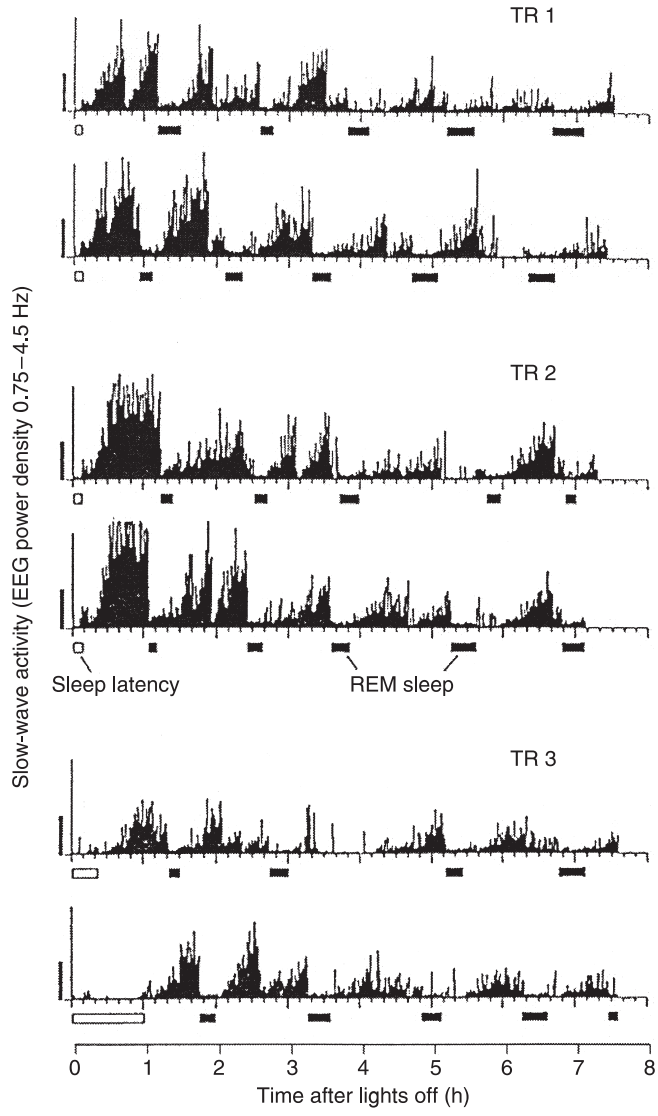

Figure 86.9 Power density of slow-wave activity (0.75–4.5 Hz) over six nights in the same pregnant woman (two nights per trimester, chronological order from top to bottom) showing decrease of slow-wave activity during pregnancy. TR1, first trimester; TR2, second trimester; TR3, third trimester; REM, rapid eye movement. From Levine *et al.*[30]

changes from the first to the third trimester were an increase in nocturnal wake phase time (from 32.5 to 58.3 min) – hence a decrease in sleep efficiency, defined as time asleep/time in bed (from 86.5 to 79.9%) – and a decrease in REM sleep time (from 79.7 to 70.5 min) (Figure 86.7).[33]

The same changes – decreased REM sleep and increased wake phase – have been found in previous studies.[34,35] An earlier report of an increase in paradoxical sleep during pregnancy[36] was based on the sleep staging criteria of Dement and Kleitman,[6] which differ from the Rechtschaffen and Kales criteria[5] in current use.

Median wake-phase time after sleep onset was longer in the third than in the first or second trimesters (60 vs. 20 min, respectively; $P < 0.05$) (Figure 86.8).

Median sleep efficiency decreased significantly from 88.6% in the first trimester and 90.5% in the second trimester to 79.9% in the third trimester, i.e. in the third trimester more than one-fifth of the time in bed was spent awake. These changes in sleep structure were of secondary significance as causes of fatigue in pregnancy. There was no difference in terms of time in bed, distribution of NREM and REM sleep, waking after sleep onset or nocturnal rising, between nights from which subjects awoke tired and those from which they awoke refreshed. The remaining sleep parameters (time

Table 86.8 Non-rapid eye movement (NREM) and rapid eye movement (REM) sleep frequency bands (Hz) showing significant power density changes during pregnancy

Trimester	NREM sleep	REM sleep

	14–17	
2–3	1–12	3–4
	13–16	5–6
		9–11

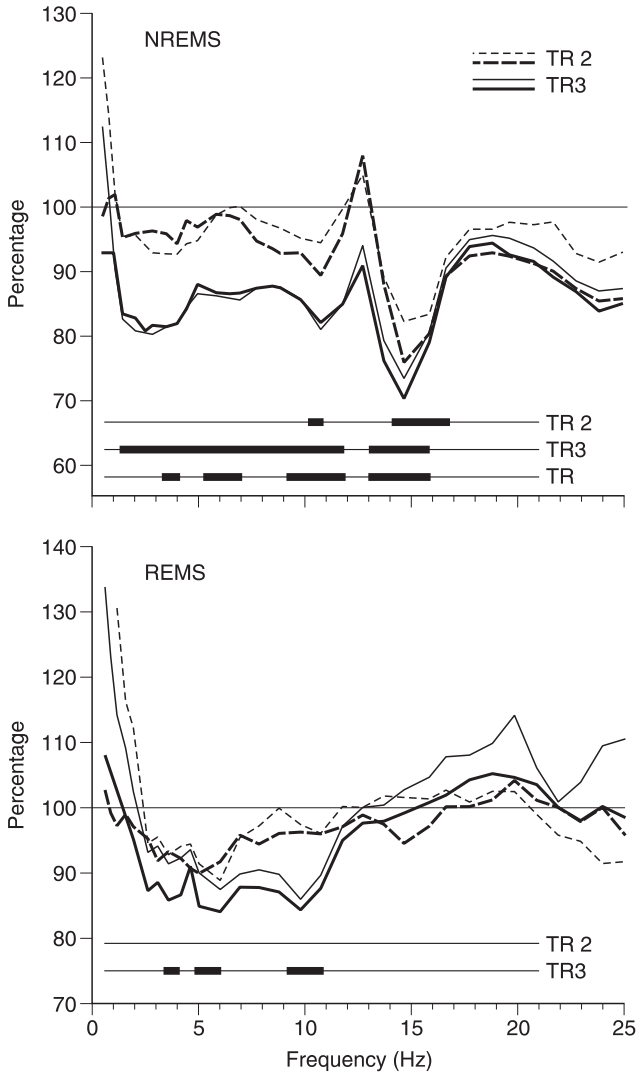

Figure 86.10 Changes (collective mean % deviation per trimester from first trimester baseline (100%) in power density in NREM sleep and REM sleep in nine pregnant women. Bold, frequency bands with significant changes; TR2, second trimester; TR3, third trimester. From Levine *et al.*[30]

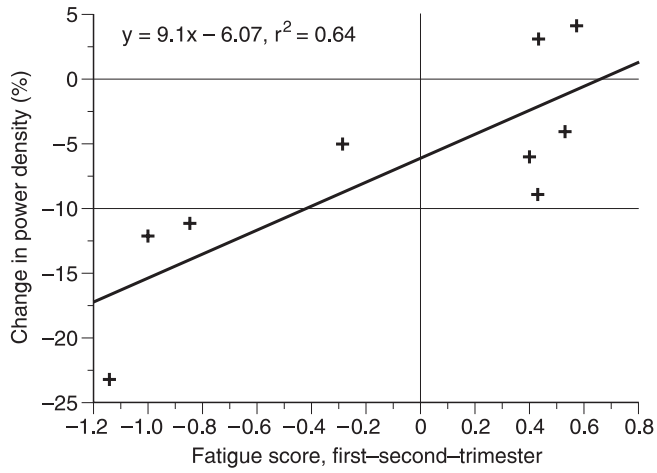

Figure 86.11 Correlation between fatigue and decrease in power density in 10.5 Hz frequency band from first to second trimester. $r=0.8$.

in bed, sleep latency, total sleep time, REM latency, REM sleep, stage 1 sleep, and sleep efficiency) also had no effect on the recuperative value of sleep. This indicates that sleep time and sleep stage distribution have little effect on fatigue in pregnancy, at least where the differences observed in this normal population are concerned. The same conclusion may not apply to larger differences in sleep parameters.

Whole-night spectral analysis. Sleep architecture analysis was focused on slow-wave EEG activity (0.75–4.5 Hz) as a measure of sleep depth. Slow-wave activity also occurs outside deep sleep, but is not recorded by conventional sleep staging. The contribution of whole-night spectral analysis is that it records power densities in the different frequency bands independently of the conventional sleep stages.

Power density decreased significantly from the first to the third trimester in the long-wave frequency band in NREM and REM sleep[33] (Figure 86.9), i.e. sleep was shallower overall in the third trimester vs. the first, even though the proportion of deep sleep was unchanged in the third trimester.

The first-trimester power density at each frequency band was used as the baseline (100%) in expressing the values in each subject during pregnancy; subsequent values were expressed as percentage deviations from this baseline. The collective deviations in the second and third trimesters (the mean of both nights in each trimester in nine subjects) are shown in Figure 86.10, which also shows the significant changes in power spectra during pregnancy as thick bars in the appropriate frequency band (Table 86.8).

There was a clear correlation between the decrease in power density at 10.5 Hz in NREM sleep and fatigue on waking from the first to the second trimester (Figure 86.11). Thus, women with a decrease in power density at 10.5 Hz of 10% all reported greater fatigue in the second vs. the first trimester, while all those feeling less tired in the second trimester showed a smaller decrease, or in some cases an increase, in power density in the same frequency band.

Hormonal effects on fatigue

The central depressant effect of progestagens causes symptoms such as fatigue, apathy, drowsiness, decreased libido, decreased drive, fluctuating mood, depressive mood and decreased energy,[37] i.e. many of the complaints typical of early pregnancy. But as serum progesterone levels up to 10 weeks' gestation do not differ significantly from luteal values,[38,39] additional mechanisms must be involved, notably changes in brain hormone metabolism (steroids in particular) and/or receptor status.

Neuroactive steroids, or neurosteroids, are progesterone derivatives, which bind not to the cytoplasmic steroid receptor of the typical end organ but to neuron

Table 86.9 Fatigue and maternal serum neurosteroid positivity in pregnancy

Fatigue	Neurosteroid positivity *n/N*	Neurosteroid positivity %	Pregnanolone equivalents (nmol/l)
None	0/8	0	–
Mild–moderate	1/6	17	185
Severe	6/9	66*	435 (255)†
Total	7/23	30	

n/N, fraction of pregnant women investigated: *$p = 0.02$ vs. no and mild–moderate fatigue (Fisher's exact test): non-significant vs. mild–moderate fatigue; expressed as mean (SD)

γ-amino butyric acid ($GABA_A$) receptors where they exert benzodiazepine-like activity.[40,41] The result is marked fatigue, shown with several steroid hormones.[13,42–44] We used a binding assay [with the ionophore ligand (^{35}S)-*t*-butyl-bicyclophospho-rothionate] to screen for neurosteroids in a pilot study in 23 pregnant women between 10 and 40 weeks' gestation.[45] The results showed a correlation between severe fatigue in pregnancy and the presence of neurosteroids in peripheral venous blood throughout pregnancy (Table 86.9): neurosteroid binding was present in six out of nine pregnant women with severe fatigue vs. none out of eight women without fatigue. The correlation requires confirmation in further studies.

The sleep EEG changes seen toward the end of pregnancy – a significant decrease in power density in the slow-wave frequency band – have also been described in association with benzodiazepine use.[46–48] The physiological function of endozepines (diazepam binding inhibitors or endogenous ligands of the benzodiazepine receptors) remains to be elucidated, though they have a demonstrated role in some disease processes, such as idiopathic recurring stupor[49] and hepatic encephalopathy.[50] No blood samples in the above neurosteroid pilot study showed any evidence of endozepine binding, making this an improbable explanation for pregnancy fatigue.[45]

Progesterone also contributes to the sleep changes in pregnancy. Experimental progesterone administration in men was associated with more frequent waking, decreased deep (stage 4) sleep and increased sleep latency.[51,52]

Pregnancy fatigue can be interpreted as a biological signal to the expectant mother to take things easy physically. Reduced physical activity reduces uterine contractions and increases uteroplacental blood flow.

Clinical impact of sleep impairment

Pregnancy, sleep and fatigue

The effects of pregnancy on sleep and fatigue can be summarized as follows:

(1) Sleep changes during pregnancy. These changes show little relationship with fatigue. Some sleep parameters correlate with fatigue: later bedtime, increased waking after sleep onset, decreased power density in the low-frequency band.
(2) As pregnancy fatigue does not respond to longer sleep or less work, sleep time and workload do not appear to be its principal determinants. More plausible candidates are endocrine causes, as in the case of neurosteroids.[45]
(3) Sleep disturbance and fatigue do not affect the course of pregnancy. The most frequent pregnancy complications – prematurity, low birth weight for gestational age, intrapartum asphyxia and cesarean section rate – were no more frequent in the women with severely disturbed sleep or excessive fatigue than in the overall population.

Sleep disturbance in pregnancy: management guidelines

Pregnant women who complain about fatigue and sleep problems should be made aware that such complaints are not only frequent but also have no demonstrable impact on the pregnancy or baby and are best viewed as the body's invitation to take things easy.

Symptomatic management is required for pregnancy complaints that may often cause sleep problems, e.g. restricted respiration (increase the number of pillows to leave the chest free), obstructed nasal respiration (humidifiers, vasoconstrictor nasal drops) or nocturnal carpal tunnel syndrome (splinting of the wrist overnight). Early morning nausea can be managed with drugs [vitamin B6, suppositories of meclozine dihydrochloride, pyridoxine hydrochloride and caffeine (Itinerol®, Vifor, Switzerland)], and nocturnal calf cramps with magnesium supplements. Nocturia may respond to compression stockings, which reduce dependent fluid accumulation during the day, and hence the diuretic response to recumbency.[53] Fatigue due to anemia can be treated with prophylactic iron.

Falling asleep and remaining asleep can also be assisted by further measures, such as discussing psychosocial problems and sensitizing the patient to the increased emotional vulnerability in pregnancy. A talk with the partner or employer may also be of benefit.

Tips for active sleep preparation include a regular bedtime, preceded by a short walk in the fresh air. Evening coffee and tea should be avoided, together with heavy meals and alcohol. It is also best to go to bed only when tired; otherwise, reading or a similar activity can be recommended and/or a warm bath.

Patients can also be helped by correcting their ideas about 'enough' sleep. They need to understand that the body basically gets the sleep it needs, if not today then tomorrow or the day after.[54] It must be emphasized that it is not sleep so much as rest that is important.

Some non-drug remedies have been shown to be harmless in pregnancy, e.g. valerian drops, which have a documented hypnotic action,[55] herbal tea (e.g. lemon balm), alcohol-free beer and milk and honey mixtures.

If none of the above are effective, a hypnotic can be prescribed in exceptional cases. All medication is contraindicated in principle during the first trimester. In the second or third trimester, benzodiazepines or barbiturates can be used as short-term symptomatic therapy. Both may have adverse neuropsychological effects on the child, especially with protracted use.[56–60] To reduce the risk of neonatal hemorrhage, vitamin K supplementation is recommended in the last three weeks of pregnancy in patients on long-term barbiturates (e.g. epileptics) because of increased vitamin K turnover due to hepatic enzyme induction.[61]

The fundamental message to get across is that women should be receptive and ready to respond positively to the signals, which their bodies emit during pregnancy. The sleep problems and fatigue associated with pregnancy are transient in all cases and resolve shortly after birth.

Summary

The main pregnancy-associated changes in sleep are a decrease in depth and an increase in fragmentation, primarily due to nocturnal bathroom trips. Some 50–75% of study women got up at night during pregnancy vs. only 8.5% of controls.[22] On average, pregnant women sleep approximately 18 min longer per night than non-pregnant women and do so throughout pregnancy with certain individual fluctuations. Yet despite longer sleep, significantly more pregnant than non-pregnant women rated their sleep quality as poor or very poor (40% and 27%, respectively, vs. 4%).

More intense dream activity was reported by approximately one-fifth of the women in early pregnancy vs. before pregnancy, and by one-third in the further course of pregnancy. Dream content frequently revolved around birth and baby themes often tinged with apprehension.

Sleep fragmentation was also shown by actigraphy. Nocturnal nil activity duration did not change through pregnancy; however, the number of nocturnal nil activity phases increased and the mean nil activity phase length decreased. Motor latency was also significantly increased throughout pregnancy, confirming the more-marked motor activity during sleep onset. However, increased motor activity had no effect on the recuperative value of sleep.

Daytime sleep, reported by only 37% of women before pregnancy, increased during pregnancy to a maximum of 58% in the third trimester. Women who took a daytime nap did not differ from the others in sleep times or employment status. Daytime napping was not associated with the quality of waking or sleep fragmentation by waking and rising. In summary, there was no evidence that daytime napping was a response to poor nocturnal sleep quality; rather, it was taken if the opportunity arose.

Sleep structure showed two significant changes during pregnancy: first, a decrease in REM sleep (from 79.7 to 70.5 min) and, second, an increase in nocturnal waking after sleep onset (from 32.5 to 58.3 min). The longer waking phase reduced sleep efficiency, from 86.5 to 79.9%, i.e. one-fifth of the total time in bed was spent awake, with α-EEG activity. The main casualty of the increased waking phase was REM sleep; NREM sleep stages did not change during pregnancy. Recuperative deep sleep decreased in pregnancy by approximately 10% (not significantly). These changes in sleep structure were only observed in late pregnancy and cannot account for fatigue in early pregnancy.

Whole-night spectral analysis during pregnancy showed a significant decrease in power density in the slow-wave frequency band (1–12 Hz) and intermediate band (13–17 Hz) in both REM and NREM sleep. The decrease in power density at 10.5 Hz in NREM sleep (from first to second trimester) correlated with increased fatigue. From the second to the third trimester, we found a correlation between decreased power density in the 13–16-Hz frequency band and increased fatigue. These sleep changes need to be qualified by the fact that fatigue was already present early in the first trimester. The low-grade sleep changes cannot explain the often marked fatigue. However, the correlation between fatigue and the decrease in power density in the slow-wave band suggests that changes in sleep architecture may be at least partial determinants of fatigue.

In our study population of 189 pregnant women, 89.4% complained of definite fatigue and decreased energy in the first trimester. The fatigue involved not just physical energy but also concentration ability and memory. Such complaints are common even before women know that they are pregnant, thereby largely excluding purely psychological causes triggered by the awareness of pregnancy onset.

Workload was reduced through to the third trimester by some 58% of full-time employees largely independently of fatigue. Fatigue did not decrease after the workload was reduced, indicating that the latter is not the major determinant of pregnancy fatigue. Complaints of fatigue were as frequent in housewives, despite being able to adjust their workload more easily, and sleep a mean 27 min longer than their employed counterparts.

Pregnancy fatigue thus appears multifactorial and largely independent of sleep. Later bedtime, low basal hemoglobin and low diastolic blood pressure showed an individually significant association with fatigue. Frequent rising at night, restless sleep and increased weight gain in pregnancy were not significantly associated with fatigue. Only the endocrine changes can account for early pregnancy fatigue. Neurosteroids may play a major role in this regard,[44,45] in addition to the recognized sedative effects of progesterone.

Acknowledgments

This study was supported by a grant of the Hartmann-Müller-Foundation (Zurich). The polysomnographies were carried out in the Institute of Pharmacology of the University of Zurich (Professor A.A. Borbely).

87 Immunology at the maternal–fetal interface

S. Scherjon and F. Claas

Introduction

The maternal acceptance of the semiallogeneic fetus seems to ignore the concepts of transplantation immunology. Elucidating the mechanism leading to this unique phenomenon is essential for our understanding of processes leading to normal and abnormal pregnancy, and may also result in important concepts in the field of transplantation, autoimmunity and, possibly, neoplasia control.

In 1953, Medawar explained the 'immunological paradox of pregnancy' by considering pregnancy a state of 'immunological neutrality'.[1] One of the three possible mechanisms he proposed was based on the idea that the fetus is antigenically immature. However, the idea of a complete absence of human leukocyte antigens (HLA) on fetal tissues appeared to be too simplistic. Billingham (a student of Medawar) showed in 1964 that non-classical transplantation (HLA) antigens could be found on embryonic tissue from very early gestational ages onward.[2] It was later understood that the presence of these non-classical HLA on trophoblasts are essential for the mother to recognize trophoblastic cells as 'self' and to prevent the normal immune response to non-self tissues.[3,4] Non-classical HLA were demonstrated – in direct contact with the deciduas – both on extravillous trophoblast (EVT) and on the (amnion) chorion. The second possible explanation by Medawar was based on a diminished maternal responsiveness to pregnancy. A decreased ability to elicit both a humoral and a cell-mediated immune response should lead to the acceptance of the 'foreign' fetus. Indeed, antibody titers do decrease during pregnancy, but this decrease is caused by the physiological hemodilution occurring especially during the first trimester of pregnancy. The variety of the antibody profile remains unchanged during pregnancy. On the other hand, cellular immune responses seem to be decreased during pregnancy,[5] as reflected by the improvement in some T-cell-mediated autoimmune diseases and an increased incidence of infections. In contrast, the innate defense mechanism is more prominent during pregnancy.[6] This increase in the function of the native immune system may be a compensatory mechanism for the decrease in specific T-cell reactivity.[7] Wegmann challenged the idea of a systemic immune suppression in pregnant women and suggested that cellular interactions within the placenta lead to a local immune response.[8] Also, a third possible explanation, that the uterus and especially the decidua is an immunologically privileged site, where mother and child are completely separated, cannot be the (only) explanation as even term pregnancies can be found outside the uterus with no decidua in place. Furthermore, it is now evident that during pregnancy there is cellular trafficking over the fetal–maternal interface.

Already very early after fertilization, there is direct contact between the blastocyst and the maternal decidua. From those very early days onward the immunological balance between mother and fetus has to be established and maintained as there is no doubt that the maternal immune system is certainly able to recognize the paternal antigens inherited by the fetus.[9,10] The lack of a destructive immune response mounted by the mother seems to be related to the presence of an active immune process essential for normal pregnancy. This concept is supported by findings that an increase in the number of HLA differences between mother and child reduces the chance of getting certain complications of pregnancy. Sharing of HLA between mother and fetus is associated with increased incidence of pre-eclampsia and fetal growth retardation. This was confirmed by others, suggesting that in women with a history of pre-eclampsia an unusually high degree of immunological compatibility with the fetus was found.[11–13] HLA-DR sharing between pre-eclamptic women and their partners is a risk factor for pre-eclampsia[14] and is also associated with a reduced birth weight, on average 200 g less.[15] Supporting this hypothesis is the observation that with more maternal–fetal HLA class II disparities, an improvement in rheumatoid arthritis during pregnancy and in the period thereafter was found.[16] This

improvement cannot be directly explained by the increase in Th2 cytokine bias occurring during normal pregnancy.[17] Also, priming of the mother by paternal antigens, e.g. by semen, might induce an immunological hyporesponsiveness, essential for the process of maternal acceptance of her 'foreign' fetus.[18,19] The studies by Robillard[20,21] showed that the immunological response to trophoblastic invasion is dependent on earlier confrontation with paternal antigens during sexual intercourse, suggesting that certain pregnancy complications might be related to 'primi-paternity'. Mucosal alloimmunization via repeated exposure to HLA occurring during unprotected sexual intercourse generates an active immune tolerance to paternal antigens.

It has become evident that in the immunological acceptance of the semiallogeneic or even fully allogeneic fetus – after oocyte donation – local immunomodulation at the maternal–fetal interface is of key importance.

Implantation

The endometrium has through every menstrual cycle a surprisingly high regenerating capacity. It constitutes many cell types including glandular epithelium, stromal (mesenchymal) cells and endothelial cells. Decidualization of the endometrium during the menstrual cycle implies the change of stromal cells of the endometrium into decidual cells. Although already in the 19th century William Hunter had given the first description of the *membrane decidua*, it was only recently accepted that the decidua is actually a maternal membrane surrounding the (two) fetal membranes.[22] The process of decidualization, initiated by the action of progesterone on estrogens induced endometrium, facilitates the apposition of the blastocyst and the acceptance and outgrowth of trophoblastic villi. Trophoblast cells by their production of human chorionic gonadotropin support the persistence of the corpus luteum and by that the production of progesterone by the ovary. This system is also supported by the production of prolactin by the pituitary and by estrogen, inducing leukemia inhibiting factor (LIF), which enhances the effect on progesterone production.[23] From 8 weeks onward the main source of progesterone production becomes the syncythiotrophoblast. Although decidualization is essential for implantation, it is independent of the blastocyst itself. The process depends on progesterone, but also cytokines such as transforming growth factor beta (TGF-β) and insulin-like growth factor binding protein (IGFBP)[24,25] play a critical role in decidualization.[26]

Trophoblastic cells can be divided into two subtypes, villous trophoblast and EVT. Villous trophoblast is located around the villi and is in direct contact with maternal blood in the intervillous space. The cytotrophoblastic cells form the inner layer and are stem cells for the syncythiotrophoblast, which forms the outer layer of the villous. EVT has a proliferative and a migratory phenotype.[27] It invades the decidua and the uterine wall and forms the anchoring cytotrophoblast. At the decidual layer behind the placenta, the decidua basalis, there is direct contact between the ingrowing trophoblast, forming the anchor villi (interstitial trophoblast), and the endometrium surrounding the endometrial capillaries. The trophoblast that replaces the smooth muscle (intramural trophoblast) and endothelial cells (intra-arterial trophoblast) of these capillaries is called endovascular trophoblast.[27] At the other site of the developing fetus, villous structures will gradually disappear as the growing fetus and amniotic cavity will obliterate the endometrial cavity and the chorion will attach to the decidua, which at that side is called the decidua parietalis. The decidua is also considered of essential importance in the limitation of trophoblastic growth, which is necessary to prevent the occurrence of clinical features such as placenta accreta and percreta.

Many biochemical active compounds are involved in the implantation process. Cytokines such as interleukin 1β (IL-1β) induce the synthesis of prostaglandins and IGFBP-1, both needed for sufficient trophoblastic invasion. Invasion is also dependent on cell adhesion molecules, such as integrins,[27,28] and on matrix metalloproteinases (MMPs).[29] The latter are produced by trophoblast cells. Fibronectin, produced upon promotion by TGF-β by the EVT and detectable in the extracellular matrix of the deciduas, plays a critical role in the attachment of trophoblast cells to the decidua and supports the formation of cytotrophoblastic cell columns.[30]

Implantation and the non-classical major histocompatibility complex (MHC) I molecules

King and Loke described in 1991 an attractive model for a controlled permission of trophoblastic invasion – and also for limiting this invasion – into the endometrium and myometrium of the uterus.[31] Trophoblastic cells express, besides the classical HLA class I molecule HLA-C, only the non-classical class I antigens HLA-G, HLA-E and HLA-F, which have a very limited polymorphism. MHC class II antigens are completely absent on trophoblasts.[32] HLA-G is expressed only on the invading extravillous cytotrophoblast and is not present on villous syncytiotrophoblast.[33,34] By the expression of the non-classical HLA molecules, fetal trophoblastic cells, in their interaction with decidual leukocytes, are recognized as 'self' and do not evoke an immunological response by natural killer (NK) cells. This allows the EVT to invade the uterus. HLA-G is expressed in five different spliced, membrane-bound or soluble isoforms.[35]

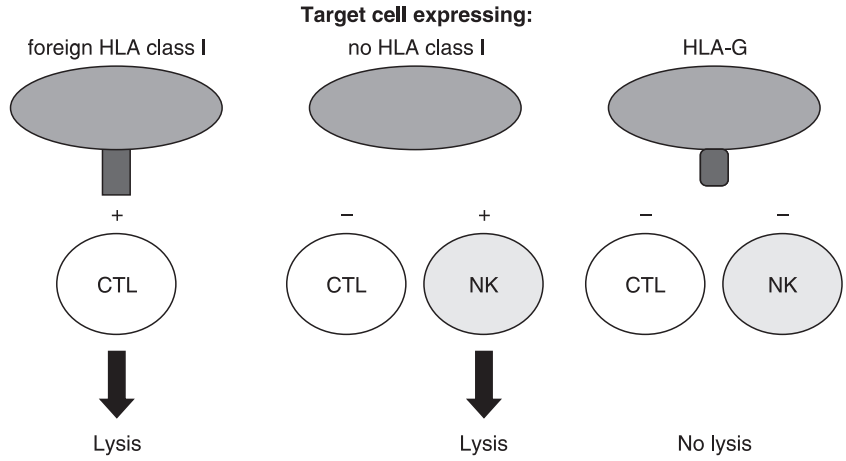

Figure 87.1 Cytotoxic T cells will react against HLA-mismatched target cells. Downregulation of the surface expression of the foreign HLA molecules will prevent this reactivity but will lead to activitation of NK cells that are triggered by the lack of HLA class I molecules on the target cell. Expression of HLA-G will prevent activation of NK cells by its interaction with KIR receptors.

Soluble HLA-G (sHLA-G) is secreted by the syncytio- and cytotrofoblast. HLA-G has the ability to present peptides derived from classical HLA class I molecules and other intracellular molecules. Although some data suggest that HLA-G expression at the maternal–fetal junction is decreased in pre-eclampsia,[36,37] this is not confirmed by others.[38]

Decidua infiltrating cells

The decidua contains many different types of (immune) cells, of which the frequency changes throughout the menstrual cycle and during pregnancy.

Uterine NK (uNK) cells

In the early proliferative phase of the endometrium, many small, round agranular cells with very little cytoplasm are found, which enlarge and become more granulated during the secretory phase. These cells, formerly called *uterine large granular lymphocytes*, turned out to be a special form of NK lymphocytes, uNK cells, with a different phenotype than NK cells found in peripheral blood. These cells do not express the classical NK marker CD16, while the CD56 surface density of these cells is more than 20 times higher compared to peripheral blood NK cells.[39,40] These uNK cells are bone marrow derived and replicate *in situ* in the endometrium.[41] Their number is maximal around ovulation and remains high around the period of implantation, accounting for at least 70% of the uterine lymphocytes.[40] uNK cells produce cytokines, like TGF-β, macrophage colony stimulating factor, tumor necrosis factor alpha (TNF-α), interferon gamma (IFN-γ), vascular endothelial growth factor, angiopoietin 1 (Ang1), Ang2, IL-3 and LIF, which are essential in trophoblast invasion and tissue remodeling.[42,40,43] On the other hand, appreciable amounts of granulocyte macrophage colony stimulating factor and IFN-γ are produced by uNK cells, possibly stimulated by IL-2, a factor related to trophoblast apoptosis, limiting the invasiveness of trophoblast cells.[44] Although there is a significant decrease of the uNK cells during the second trimester of pregnancy, at term age uNK cells are still present in appreciable amounts in the endometrium.[45]

sHLA-G is able to block uNK cell function and cytolytic T lymphocyte action, the latter possibly by an increase in apoptosis of activated $CD4^+$ and $CD8^+$ T cells.[35] By this effect on uNK cells and harmful $CD8^+$ T cells, trophoblast invasion is facilitated and endothelial cell reactivity is diminished.[46] In this context, it is essential to realize the principle difference in allorecognition between $CD8^+$ T cells and NK cells. $CD8^+$ T cells are activated by foreign HLA, while NK cells are programmed to lyse cells that lack self HLA molecules. The absence of classical HLA would be a trigger for NK cells, but the interaction of HLA-G with KIR receptors on NK cells prevents such reactivity (Figure 87.1).[47,48]

The interaction between uNK cells and HLA-G is basic for a normal, successful pregnancy, although it has been reported that women with a homozygous deletion in the HLA-G gene can have completely normal pregnancies. HLA-C is also expressed by the EVT cells and interacts with NK cells possibly in the same way as HLA-G. Although the existence of a specific receptor for HLA-G on the uNK cell is still discussed, HLA-C – and most probably HLA-G also – is recognized by receptors belonging to the KIR family, e.g. ILT3 and KIR2DL1.[49] HLA-G might, via binding of these receptors, influence cytokine secretion by T cells and modulate the Th1/Th2 balance.[46] HLA-E, also expressed by the EVT, is recognized by the NK cell by its CD94/NKG2A receptor. This interaction prevents cellular toxicity against the trophoblast.[50] It seems that HLA-E coexpression is at least necessary for the

prevention of trophoblast lysis.[51] KIR receptors are expressed besides by uNK cells and also by γδT cells.[52]

It seems that for implantation the cytokines produced as a result of the interaction between trophoblastic cells and uterine lymphocytes – especially uNK cells – are essential. The process has many features in common with an inflammation-like process, where cytokines play a pivotal role as well. In early pregnancy, the role of specific T cells is marginal as they seem not to be involved in the implantation process.

B and T cells

B cells and plasma cells are considered irrelevant for the regulation of trophoblast invasion as they are almost absent in the deciduas.[40] T cells form around 10% of the decidual leukocytes.[40] The number of CD8+ T cells and CD4+ (helper) T cells may change during pregnancy.[53] Recently, it was found that activated T cells are present at the placental site (decidua basalis)[40] and are even more numerous in the decidua aligning the fetal membranes (decidua parietalis).[54] Further functional characterization of T cells present in the decidua parietalis and basalis[45] should elucidate whether these cells play an active role in the (down) regulation of the maternal alloimmune response to the fetus.

Most *in vitro* studies of T cells isolated from maternal blood show a diminished T-cell activity and a concomitant increase in B-cell function. These findings are in line with clinical observations demonstrating an increased incidence of viral infections during pregnancy and the amelioration of T-cell-mediated autoimmune diseases such as rheumatoid arthritis. In contrast, the severity of antibody-mediated autoimmune diseases such as systemic lupus erythematosus shows an increase during pregnancy.

In peripheral blood a reduction of T-helper (Th) 1 cells is demonstrated, which is partly caused by progesterone, associated with a downregulation of nuclear factor (NF) κB, which has an inhibitory effect on Th1 cell differentiation.[17] The consequence of this is that the balance of Th cells is shifted to a Th2 bias, which is the reason why normal pregnancy is characterized by a dominance of the anti-inflammatory Th2-type cytokines such as IL-4, -6, -10 and -13. The Th1 proinflammatory cytokines such as IL-2, IFN-γ and TNF-α, which activate cytotoxic T cells, are thought to have a detrimental effect on the development of pregnancy. However, the relevance of a Th2 bias in pregnancy was disputed from the beginning as it cannot be excluded that the cytokines, beneficial for processes important during implantation like spiral artery development and local tissue remodeling, are detrimental later during pregnancy.[55] Th1 cytokines especially, such as IFN-γ, are involved in the local inflammatory response during implantation.[56] Moreover, in the mouse IL-10 (Th2) knockout model, no negative effect on pregnancy outcome, pregnancy rate, litter size or birth weight was observed. In contrast, uNK cell knockout mice showed that a maternal uNK cell-deficient decidua is associated with fetal demise and a reduction in birth weight.[57] These postpartum findings were related to abnormalities in the arterial and microvascular architecture of decidual vessels. Transplantation of these mice with normal bone marrow led to the development of uNK cells preventing this pathology, whereby the decidual arterioles looked normal and the placental became larger again. uNK cells probably exert these effects in vascular modification (dilatation, elongation and branching) via the production of specific cytokines like IFN-γ[41] The complex network of cytokines and the cells contributing to this balance during pregnancy still have to be investigated, whereby it has to be considered that not only T cells, but also uNK cells produce these cytokines.

During pregnancy the adaptive immune system is activated, as shown by the development in 30% of the pregnancies of long-persisting antibodies against paternal HLA and the activation of cytotoxic T lymphocytes specific for these HLA.[58] In the decidual environment T cells may be primed by paternal antigens, but the normally expected T-cell-mediated cytotoxicity of trophoblastic cells does not occur. Through both elimination and suppression of fetus-reactive T-cell clones and also because paternal antigens are presented via non-classical HLA, the balance of Th cells is shifted to a Th2 bias. For a successful pregnancy the immunological acceptance of the fetus is essential. This acceptance is considered more and more an active process leading to the induction of immunological regulation, whereby the fetus is not attacked. The development of blocking antibodies may play a protective role by inhibiting the effect of HLA antibodies and potential fetus-reactive maternal lymphocytes. From the term placenta, activated alloreactive T cells can be isolated.[59] Locally at the level of the placenta, these activated T cells are probably downregulated by regulatory T cells. With a high level of HLA compatibility between partners, this downregulation might be less effective, explaining the higher incidence of pregnancy complications in these couples.

Macrophages

Macrophages are the second most numerous type of leukocytes present at the interface and are found in greater numbers in the decidua basalis as compared to the decidua parietalis.[45] They are the main producers of cytokine and growth factors and contribute to an adequate balance between Th1 and Th2 cytokines in the placenta, either by producing cytokines such as IL-4, IL-10 and IFN-γ or by indirectly stimulating the IFN-γ production by uNK cells.[60] Placental apoptosis, orchestrated by macrophages, is a normally occurring phenomenon in the placenta. Apoptosis is higher in third-trimester placentas compared to first-trimester

placentas and it might also be higher in abnormal pregnancies, complicated by intrauterine growth restriction and/or pre-eclampsia.[61] Apoptosis is essential for the tissue remodeling occurring during implantation. The clearance of these apoptotic bodies is essential for placental homeostasis, preventing the release of potentially proinflammatory intracellular contents and of proteins that are foreign to the maternal immune system. The clearance of apoptotic debris is associated with the release of the anti-inflammatory TGF-β and possibly of other Th2-associated cytokines.

Recent evidence suggests that an even more important role for uNK cells lies in the production of cytokines (or other active substances), which prevent cytolytic actions by T cells, although these T cells are already present in an activated state.[54] LIF, and also IL-10, might control the transcription of HLA-G. In mouse, the absence of LIF is associated with total pregnancy failure. Also, human data support a pivotal role for LIF.

Apoptosis of EVT is related to the number of $CD56^+$ NK cells, while the number of uNK cells declines in parallel with apoptotic cells. The massive apoptosis of EVT is suggested to be the mechanism reducing invasiveness of the trophoblast.[62]

Fas-ligand (FasL) induced apoptosis

FasL expression on the trophoblast induces apoptosis of T cells or NK cells via their Fas receptors. In the trophoblast villi, FasL was found only on the cytotrophoblast, while the syncytiotrophoblast, which is in direct contact with the maternal blood, showed no expression of FasL. This FasL–Fas receptor interaction eliminates maternal lymphocytes specific for fetal/paternal antigens.[63–66]

The active process of tolerance induction

Several mechanisms may lead to an active downregulation of a destructive alloimmunity by the maternal immune system toward the fetus.

Dendritic cells (DCs) and regulatory T cells

DCs are important in the regulation of the immune response and have the unique opportunity to coordinate the innate and adaptive immune system. One can consider the endometrium as a mucosal surface, where DCs are confronted with trophoblastic antigens during pregnancy. DCs process and present these antigens to the maternal immune system for the induction of regulatory cells (Treg),[67] which may lead to the induction of regulatory T cells and may explain some of the findings of specific maternal tolerance to paternal antigens during pregnancy.[68] In humans in early first-trimester deciduas, DCs with a myeloid phenotype have been isolated,[69] although at a low frequency (1%). The dominance of plasmacytoid DCs in the decidua might be essential for polarizing the T-cell immune response to a Th2 bias.[70] DCs have been shown to produce TGF-α and also the T-cell inhibiting factor indoleamine 2,3-dioxygenase (IDO)[71] (see further). In the mouse model, immature DCs isolated from the decidua contain predominantly the pregnancy protective cytokine IL-10 and small amounts of the Th1 type cytokine IL-12.[72]

The family of regulatory T cells consists of the naturally occurring $CD4^+CD25^+$ T-regulatory cells (Treg) and the induced secondary Th3 cells and Treg type1 (T_R1) cells.[73,74] Treg cells are present in early pregnancy decidua.[75] Treg cells may develop after antigenic stimulation, under non-inflammatory conditions. Treg cells inhibit $CD4^+$ T cells to produce IL-2 and convert them into IL-10 producing T_R1-like cells and can also induce TGF-β producing Th3-like cells. This suppression is an important factor in the Th2 bias occurring during pregnancy.[76,77] IL-10 might be functional in three ways: suppression of cytotoxic T cells and their cytokines (IL-12 and IFN-γ), induction of regulatory T cells and inhibition of the maturation process of DCs leading to a more tolerogenic type of DC. Also, IL-6 and IL-1β are produced by these cells.[78,79] TGF-β is involved in the inhibition of trophoblast invasion by downregulation of collagenases and inhibition of metalloproteinases and integrins.[25,40] TGF-α is supposed to be a stimulator of trophoblast invasion. Some of these Th cells express the regulatory T-cell marker CTLA4[80] and have already been shown to induce the production of IDO by DCs after interaction between CD80 and CD86.[81] In the mouse, Treg cells, carrying the transcription factor FoxP3, are substantially increased in uterine tissue during pregnancy.[7] In venous blood during pregnancy, a doubling of $CD4^+CD25^+$ cells was found, which were increasing in parallel with the duration of pregnancy.[76] These expanding cells in the pregnant endometrium (both in mice and in humans) are pivotal for the suppression of the maternal immune reaction against fetal derived paternal antigens.[7,82]

Indoleamine 2,3-dioxygenase

Recently, a role for IDO regulating T-cell immunity during pregnancy has been suggested.[83] As a mechanism to prevent trophoblast lysis, IDO secreted by EVT, decidual macrophages and possibly DCs inhibits lymphocyte proliferation and survival via a decrease in extracellular tryptophan.[71,83,84] Its immunosuppressive effect might be exerted not only by a decrease of tryptophan but also by an increase of the tryptophane kynurenine metabolites. These metabolites might have a selective apoptotic effect on Th1 cells. IDO expression is induced by IFN-γ[85,86] and further stimulated by CTLA-4 expressing Treg cells.[76] It was shown

that placental tissue, with a particularly high expression of IDO, made maternal $CD8^+$ T cells specifically tolerant for paternal class I MHC.[83]

Crry protein

Crry protein, a murine protective cell surface protein and a component of the natural immunity system, is also expressed on trophoblast. This protein suppresses the ongoing complement activation, especially C3, after its deposition on the membranes at the feto–maternal interface. Complement activation, promoting inflammatory reactions to the placenta, resulting in embryonic lethality, is inhibited by the expression of the Crry protein.[87] It was shown in the Crry protein knockout mice, that Crry is necessary for embryonic development.[88] In human placenta, three other complement regulators, decay accelerating factor (CD 55), membrane cofactor protein (CD 46) and CD 59, are present in high concentrations. These regulators have the same function as Crry, preventing complement activation and placental inflammation at the interface.

Progesterone

Progesterone has immune modulatory activity because of its blocking effect on T-cell activity.[89] Peripheral T cells from pregnant women have a much higher progesterone sensitivity compared to non-pregnant women, due to an increased number of progesterone receptors (PR).[90] There is an overlap between the PR-positive T cells and $\gamma\delta$T cells.[91] PR receptors also exist on uNK cells.[92] PR-positive lymphocytes and uNK cells produce, on binding with progesterone, a progesterone inhibiting binding factor (PIBF). PIBF inhibits NK cell cytotoxicity by a failure in degranulation, to release perforin and granzymes,[93] and it might also induce the secretion of IL-10 by already activated lymphocytes.

Progesterone may also play an essential role in the local regulation of invasion. It regulates the genes, effecting an increase of factors essential for the local regulation of invasion like amphiregulin, IGFBP-3[25] and immune response gene-1.[23]

In animals, medroxyprogesterone rather than progesterone had the best anti-inflammatory properties by reducing the upregulation of type 2 cyclooxygenase (COX-2) messenger RNA.[94] COX-2 is essential for the production of the labor-associated prostaglandins. Also, other labor-associated genes are downregulated by progesterone: e.g. IL-1β, IL-8, NF-κB[94] and MMP8 and MMP9.

Recently, it has been shown that progesterone treatment results in a more than 40% reduction in the incidence of preterm delivery in a high-risk group.[95] Increased NF-κB levels have been found in preterm deliveries even without signs of an infection, whereas IL-10 has an inhibiting function on prostaglandin production. Even term delivery is associated with this inflammatory-like process.[96] There is no doubt that prolactin is produced by the decidua, partly controlled by the action of progesterone. Prolactin might have an immune modulatory role via receptors shown to be present on immunocompetent cells, e.g. the uNK cell.[97,98]

Cellular trafficking

There is a very intensive and reciprocal fetal–maternal trafficking, both actively and passively, of many different substances and cells through the placenta. This process is important for the maintenance of and maternal adaptation to pregnancy and also for the maternal recognition and immunological acceptance of pregnancy. The placental supply of maternal blood, via the endometrial/decidual spiral arteries to the intervillous space, bathes the fetal syncythiotrophoblast and its constituent immunocompetent cells. Fetal villous tissue and fetal cells within the villous capillaries are only separated from the maternal blood by the capillary endothelial wall, the mesenchyme within the villous trophoblast and the syncytiotrophoblast. Also, at other locations there is a very close cell-to-cell contact. At the decidua parietalis there is direct contact between the fetal membranes – e.g. the chorion leave – and the maternal decidua. The consideration that fetal and maternal circulations, and through them the cells of the fetus and mother, are completely separated during pregnancy has been challenged by the fact that chimerism, defined as the long-term persistence of a small number of allogeneic cells, both within the mother (maternal microchimerism) and within the fetus (fetal microchimerism), is a regularly occurring process. Chimerism is known to occur after solid organ transplantation, but especially after hematopoietic cell transplantation, where it can result in a (chronic) graft-vs.-host disease, a disorder that has a profound resemblance to autoimmune diseases.

During pregnancy, these trafficking cells have a haematopoietic progenitor cell character.[99] In the third trimester 80–90% of the mothers will have circulating fetal cells, with a proportion of around 1 fetal cell in 1000 maternal cells. The occurrence of cellular trafficking over the feto–maternal interface results from a cellularly imperfect placental barrier. This cellular trafficking confronts the mother with paternal antigens, resulting in activation of alloreactive T cells and HLA antibody formation, and possibly also the induction of tolerance. HLA compatibility between mother and fetus supports the persistence of fetal cells in the maternal circulation. The migration of these cells into maternal tissues like thyroid and bone marrow have possible long-standing consequences.[100,101] The suggestion has been made that the long-term persistence of fetal cells is associated with the development of autoimmune diseases including sclerodermia,

rheumatoid arthritis, thyroiditis, primary biliary cirrhosis, Sjögren syndrome, systemic lupus erythematosus and neonatal lupus syndromes. However, microchimerism might also have positive effects. The induction of tolerance to non-inherited maternal HLA (NIMA) during pregnancy[102] leads to a better acceptance of NIMA-mismatched transplanted organs[103] and a lower incidence of graft-vs.-host disease.[104]

Also, a neonatally occurring tolerogenic effect of soluble maternal HLA resulting from breast-feeding was shown.[105] The presence of chimerism might be used therapeutically, e.g. in bone marrow transplantation, where non-T-cell-depleted stem cells from haploidentical family donors are successfully used for transplantation provided that chimerism can be demonstrated.[106,107]

Conclusions

There are many immune mechanisms playing together at the fetal–maternal interface. These mechanisms are characterized by their redundancy and complexity. Any cytokine can be both down- and upregulated. The absence of B cells and the relative small numbers of T cells in the first-trimester decidua suggest that the adaptive immune system is not as important in that period of gestation as the innate system. NK cells and macrophages, representing the innate system, are more apparent in this period. As the number of NK cells in interaction with non-classical HLA (HLA-G) decreases substantially during pregnancy, other mechanisms resulting in maternal acceptance must become more important while pregnancy progresses.[108] Although trophoblast carries no HLA class II and no HLA-A and HLA-B, the mother and fetus might interact via HLA-C, as suggested by the distribution of particular HLA-C allotypes and specific KIR receptors in the population.[109]

However, it is important to realize that a successful pregnancy cannot be based on only one mechanism. In a murine model with class I expression on trophoblast and the absence of FasL, a normal tolerance to histoincompatible pregnancies was shown, without an adverse effect on pregnancy outcomes.[110] Also, the recognition of HLA-G by the NK cell is not essential for reproduction.[111] As Chaouat *et al.*[112] have stated, for a successful pregnancy, it is essential that there are 'sequential windows and extreme complexity mixed with very precise timing and tuning'.

The classical immunological model of the fetus being an allograft, which is not rejected, is less appropriate and newer models must be considered based on local immune regulation operating in parallel for the acceptance of the (semi) allogeneic fetal allograft.

88 Fetal behavior

J. G. Nijhuis

Introduction

For many years, the fetus has been considered to be developing in a relatively safe surrounding. However, this view changed dramatically when the accessibility of the human fetus increased with the introduction of ultrasonography. This was the start of an avalanche of fetal behavioral research.[1] Increasing insight into the developing human fetus made it clear that the growing fetus could only be judged properly if one took gestational age into account, and it also became clear that intrauterine life was not so safe as one had always assumed: 'After all, the fetus is but a human being, just as prone as a child or adult to have an accident, a disease or an iatrogenic problem!'[2]

In this chapter, we will review the most important data on fetal behavioral variables and behavioral states and then discuss the clinical consequences of this knowledge.

Basic studies

Fetal heart rate patterns

Electronic monitoring of the fetal heart rate in combination with contractions, if present, is used worldwide for the assessment of fetal condition (cardiotocography, CTG). The technique was introduced for intrapartum use by Caldeyro-Barcia *et al.* in 1966,[3] Hammacher and Werners in 1968[4] and Hon in 1968.[5] In 1969, Kubli *et al.*[6] also introduced the technique for antepartum use. Although the intra- and interobserver variability is still large, the specificity is such that clinicians rely on the method.[7,8] The sensitivity, however, is rather poor. In general, good bandwidth or beat-to-beat variability in the presence of accelerations is indicative of a good fetal condition, a silent pattern (small bandwidth, no accelerations) is indicative of fetal distress, certainly in the presence of late decelerations. One of the problems is that many scores that were developed to improve the interpretation of the CTG did not take the age of the fetus into account, while Visser *et al.*[9] had already shown a clear developmental trend during gestation in the amplitude and duration of the accelerations. Timor-Tritsch *et al.*[10] pointed out that the fetal heart rate pattern (FHRP) was dependent on the fetal behavioral state. In 1982, we defined four different FHRPs, A, B, C and D, which were then used to define behavioral states in combination with the presence or absence of body and eye movements[11] (Figure 88.1). It was also found that not only the form of the accelerations changed during gestation but also during gestation the length of silent heart rate patterns (FHRP A) increased, i.e. without any sign of fetal distress.[11,13] More recently, automated antepartum baseline fetal heart rate determination and detection of accelerations and decelerations has been introduced.[14]

Fetal body movements

> 'and the children struggled together within her'
>
> Bible, Genesis 25:22

This is probably one of the first descriptions of fetal movements. In 1976, Reinold[15] was the first to show that the fetus was already moving spontaneously in the first trimester of pregnancy. He also showed that absence of body movements might indicate impending fetal death, while the presence of body movements is very reassuring. With modern ultrasound techniques the very first 'fetal activity' that can be observed is the fetal heart rate.[16] In 1982, de Vries *et al.*[17] published their results on the observation of fetal somatic activity in the first half of pregnancy. They introduced a categorization of movement patterns and described how the individual movements were performed in terms of speed, force and amplitude. This work clearly shows that the majority of the repertoire of movements that can be distinguished in the third trimester and after birth are already present at 14 weeks' gestation.[17]

In the second and third trimesters, much attention has been paid to the presence of gross body movements,[18] but only in the last weeks of pregnancy does the fetus exhibit quite clearly prolonged periods of presence and absence of fetal movements. As gestational age progresses, the periods during which body

(a)	State criteria			
State criteria	State 1F	State 2F	State 3F	State 4F
Body movements	Incidental	Periodic	Absent	Continuous
Eye movements	Absent	Present	Present	Present
Heart rate pattern	A	B	C	D

(b)

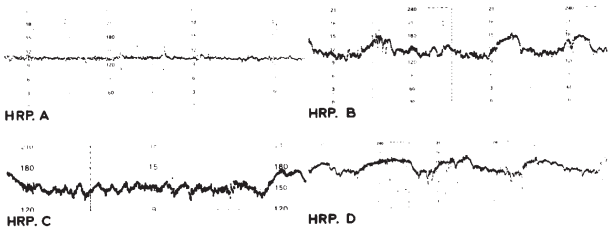

Figure 88.1 (a) Definition of the four behavioral states. (b) Examples given for each of the fetal heart rate patterns (HRP) A–D, at a recording speed of 3 cm/min. Reproduced from van Vliet *et al.*[12] with permission.

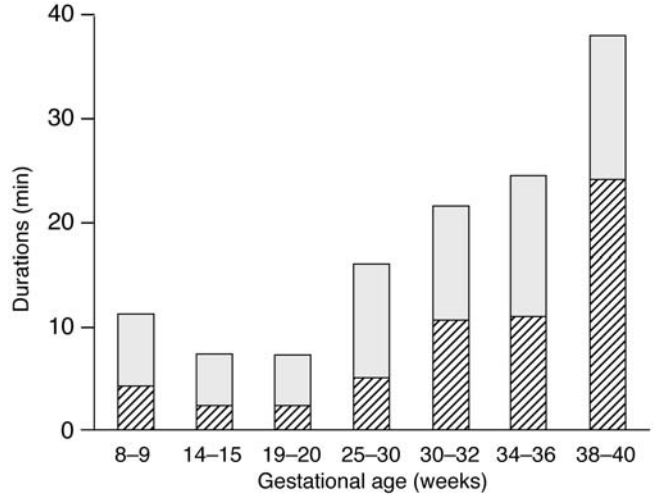

Figure 88.2 Maximum and median duration (in minutes) of periods in which body movements can be absent at different gestational ages.

movements can be absent increase dramatically. This is nicely illustrated in Figure 88.2.

This observation emphasizes again that the fetal age should be taken into account: what is normal in a fetus at 20 weeks may be abnormal in the same fetus at 38 weeks! Over the past decade it has also become clear that counting the number of movements is not very useful: even the mildly hypoxic growth-retarded fetus will still make body movements. It seems to be of much more importance to look at the quality of the movements, the speed and amplitude, etc. De Vries *et al.*[17,19] started to use the concept of quality in the first trimester and Bekedam *et al.*[20] looked for this aspect in 10 intrauterine growth-retarded fetuses between 29 and 35 weeks.

Fetal eye movements

Bots *et al.*[21] published their first observation on fetal eye movements using ultrasound and they recorded them by means of M-mode ultrasonography in 1981. Their findings were confirmed in the same year by Birnholz.[22] The possibility of observing and recording eye movements created a change allowing the study of fetal motility in relation to a new variable. Of course, at this stage fetal and neonatal data appeared to be rather similar. It is, however, not always possible to compare the fetal data with those of the neonate, because in the neonate it is not the eye movements that are used in behavioral studies but rather the criterion 'eyes open' or 'eyes closed'.[23]

Fetal breathing movements

It was Ahlfeld[24] in Germany who published the first observation of fetal breathing movements in 1888. His observations were almost unanimously neglected until the issue was reintroduced by Dawes *et al.*[25] in 1970, who described breathing movements in fetal lambs, and by Boddy and Robinson[26] in 1971 in the human fetus. Bots *et al.*[27] published a detailed analysis of human fetal breathing movements and described them as 'paradoxic' because the ribcage made an inward movement during 'inspiration' when the diaphragm made a downward movement. Originally, it was thought that breathing movements could be used as a perfect indicator for the detection of fetal distress, but soon it became apparent that breathing movements are not continuously present and are influenced by many conditions. A postprandial increase in breathing movements has already been described from 20 to 22 weeks onward,[28] and Nijhuis *et al.*[29] showed an increase after glucose intake by the mother at 24 weeks. Furthermore, smoking diminishes the incidence of fetal breathing and breathing is not only much more likely to be absent during fetal rest periods,[30] but also much more regular.[31,32] During the last weeks of pregnancy, the incidence of fetal breathing decreases and breathing movements are absent during labor.[33] The duration of periods in which breathing movements can be absent increases enormously during pregnancy, and near term it is not unusual for breathing movements to be absent for as long as 120 min.[34] In general, for behavioral studies, fetal breathing should not be studied as an independent variable but always in combination with other variables and preferably under highly standardized conditions.

Fetal mouth movements

With modern ultrasonographic equipment, the fetal mouth is easy to visualize. Specific mouthing or sucking behaviors can be observed: recurrent clusters of

'regular mouthing movements' can be observed during quiet states (state 1F), while during state 3F 'sucking movements' can be observed (for an overview, see van Woerden and van Geijn[35]). Both activities, regular mouthing and sucking, are able to entrain a fairly specific heart rate pattern, which may confuse the clinicians.[36,37]

Fetal behavior

Certainly in the second half of pregnancy, the observation of fetal activity can be combined with the simultaneous recording of the fetal heart rate and such a combined recording is then called the registration of 'fetal behavior'. In the beginning, it is as if all sorts of movements occur more or less independently of one another and they do not elicit specific FHRP. However, with the increase of gestational age, an increasing linkage can be observed between periods with 'absence of eye movements', and periods with 'absence of movements' and with a silent heart rate pattern, FHRP A.[38] This increasing linkage, which has been noticed by Drogtrop *et al.*[39] at 25–30 weeks and by Visser *et al.*[40] at 30–32 weeks, is crucial for the development of recognizable behavioral states.

Behavioral states in the neonate

'Behavioral states are constellations of physiological and behavioral variables (e.g. eyes closed, regular breathing and no movements: quiet sleep) which are stable over time and recur repeatedly, not only in the same infant, but also in similar forms in all infants' (modified from Prechtl *et al.*[23]). In the neonate, Prechtl *et al.*[23] defined five behavioral states: state 1 [quiet sleep, similar to non-rapid eye movement (REM)-sleep], state 2 (active sleep, similar to REM-sleep), state 3 (quiet awake), state 4 (active awake) and state 5 (vocalization). Three major requirements have to be fulfilled before a behavioral state can be recognized. First of all, a specific combination of certain variables must occur at the same time ('coincidence', 'linkage'), e.g. presence of body movements, eyes open and irregular breathing for state 2. Second, to be able to recognize this combination, it should be stable over time (by definition at least 3 min). Third, it must be possible to see a clear change from one state into another, a 'state transition'. If the transitional periods become too long (i.e. longer than 3 min of 'no coincidence'), it is no longer possible to clearly distinguish behavioral states.[13]

Fetal behavioral states

Following the concept of behavioral states in the neonate, Nijhuis *et al.*[11] described four fetal behavioral states. They recorded fetal behavior with two ultrasound scanners and a simultaneous registration of the FHRP. To emphasize the similarity with the neonatal states they were called 1F ('F' for fetal) to 4F, respectively.

State 1F (similar to state 1 in the neonate): Quiescence, which can be regularly interrupted by brief gross body movements, mostly startles. Eye movements are absent. The FHRP A is a stable pattern with a small oscillation bandwidth and no accelerations, except in combination with a startle (Figure 88.1).

State 2F (similar to state 2 in the neonate): Frequent and periodic gross body movements – mainly stretches and retroflexions – and movements of the extremities. Eye movements are present. FHRP B has a wider oscillation bandwidth and frequent accelerations during movements (Figure 88.1).

State 3F (similar to state 3 in the neonate): Gross body movements are absent. Eye movements are present. FHRP C is stable but with a wider oscillation bandwidth than FHRP A and no accelerations (Figure 88.1).

State 4F (similar to state 4 in the neonate): Vigorous, continual activity including many trunk rotations. Eye movements are present. FHRP D is unstable, with large and long-lasting accelerations, often fused into a sustained tachycardia (Figure 88.1).

After the introduction of the definitions, many other research groups were able to confirm the same findings.[41–43] The introduction of the concept of states had a great influence on the research that was performed in both animal and human research. As an example, it appeared to be the case that breathing movements were largely absent during state 1F,[30] but if they were present they were much more regular.[32] Therefore, to study the influence of a certain stimulus on breathing, it is now clear that such a study needs to be standardized for states. Otherwise one might think that the stimulus used abolishes breathing while, in fact, only a state transition from 2F (with breathing) into 1F (without breathing) has been induced.

Following the description of fetal behavior under normal conditions, many studies have been looking for changes in behavior in growth-retarded fetuses,[20,44,45] fetuses of diabetic mothers[46] and of mothers who used antiepileptic drugs,[47] cocaine,[48] methadone[49] and corticosteroids.[50] For reviews see Richardson,[51] Groome and Watson,[52] Koyanagi *et al.*[53] and Romanini and Rizzo.[54] Furthermore, Doppler measurements in several fetal vessels also appeared to be state related, although in compromised fetuses this state dependency plays a minor role.[55]

Clinical experiences

Studying fetal behavior is very time-consuming. This means that a behavioral study will only be performed if simpler techniques do not answer the question that is posed. Fetal heart rate monitoring is the most frequently used method, but insight into fetal behavior has had a certain influence on the interpretation of CTGs. The two most important examples are the

Table 88.1 Differential diagnosis and proposed management in silent heart rate pattern and sinusoidal heart rate pattern

Differential diagnosis	Management
Silent heart rate pattern	
State 1F	Extension of recording time
Effect of drugs	Exclusion of use of drugs
Tachycardia	Inspection of baseline
Anomalies	Ultrasonographic examination, behavioral study
Hypoxia	Contraction stress test
Brain death	Cordocentesis
Sinusoidal heart rate pattern	
Fetal mouth movements	
Sucking ('major' or 'marked')	Behavioral study
Regular mouthing ('minor')	Behavioral study
Effect of drugs	Exclusion of use of drugs
Congenital anomalies	Ultrasonographic examination
Fetal asphyxia	Biophysical profile testing
Fetal anemia	Cordocentesis

'silent' heart rate pattern and the 'sinusoidal' heart rate pattern. Obviously, a silent FHRP may indicate fetal distress, but it may also reflect a physiological behavioral state 1F. It is therefore of crucial importance that one considers a differential diagnosis if a silent heart rate pattern is recorded[56] (Table 88.1). The most extreme example of a silent heart rate pattern is entrained by the 'intrauterine brain death syndrome'. In such a case the FHRP is silent over a long period of time, with a somewhat elevated baseline and the fetus does not move (Figure 88.3). At birth – mostly via a cesarean section due to 'fetal distress' – a floppy infant is born and artificial ventilation will be needed. An electroencephalogram will be isoelectric and a diagnosis of 'brain death' will then finally be made.[56,57] This 'intrauterine coma' is probably the consequence of a hypoxic accident that is mostly not recorded. Hence, there has been a period of severe asphyxia during which the fetus almost died, but then recovered. In such a situation a cordocentesis would reveal a normal pH value.

We have already mentioned that a fetus makes regular mouthing movements during state 1F,[58] while sucking movements can be seen during 3F.[36,37] Both categories of mouth movements may entrain a 'sinusoidal-like' FHRP, a heart rate pattern that can also be recorded in combination with severe fetal anemia. Again, also for this FHRP, a differential diagnosis can be made (Table 88.1). We have only made a beginning

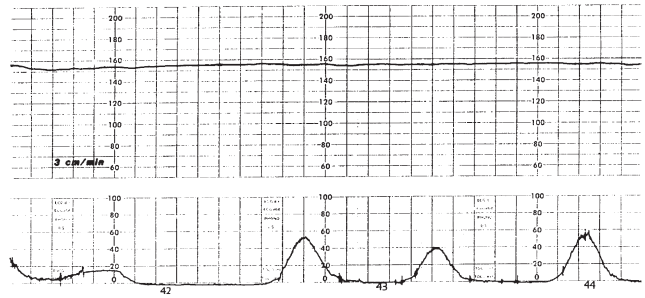

Figure 88.3 An example of a persistently silent fetal heart rate pattern without decelerations, and absence of fetal activity. Note the relatively high baseline of 155 bpm, this recording indicates fetal brain death. Reproduced with permission from Nijhuis *et al.*[56]

with the understanding of the human fetus in its natural environment, but these examples make perfectly clear how important it is to be aware of these behavioral states.

Another step forward was made by Mulder *et al.*,[50] who showed a clear effect of betamethasone on fetal behavior. This drug, which is used for the stimulation of lung maturation, decreases heart rate variability and the number of movements. Dexamethasone seems to have a similar effect, but to a much lesser degree.[59]

Visser *et al.*[60] have considered the change of consecutive variables in a deteriorating fetal condition, and proposed that changes in fetal behavior and quality of fetal movements are among the first signs, while a terminal heart rate pattern is of course the final step.

Future clinical aspects

In normal post-term pregnancies, van de Pas *et al.*[61] showed that the fetus continues to mature further, similar to the neonate already born. In the post-term fetus, the amount of states 3F and 4F increased significantly at the expense of state 2F, implying that the fetus is more 'awake' *in utero*. If one accepts that the fetus exhibits clear behavioral states, similar to the neonate, then it is perfectly understandable that birth by itself does not seem to alter the developmental pathway of this output of the central nervous system. However, most neonatal tests are not applicable for the fetus. It has already been noticed that fetuses with congenital anomalies may show bizarre behavior[62] or dissociation of heart rate and movements.[63] Other authors have been studying state transitions rather than behavioral states,[64] but still it is difficult to draw conclusions from a single behavioral recording in a single fetus. Perhaps, it would be more promising if we could develop a 'neurological examination' for the fetus, knowing that we have limited possibilities. A first step has been made by Tas *et al.*,[65] who were able to evoke an intercostal-to-phrenic inhibitory reflex (IPIR): compression of the ribcage results in apnea. In

a second series of experiments, they were not able to find a different result in a group of growth-retarded fetuses, defined as growth below the 10th percentile.[66] Another possible approach is the study of fetal habituation, i.e. the fetal learning pattern. A normal fetus will habituate to a certain stimulus, which means that it will cease to respond to repeated exposure to the stimulus. For example, Hepper and Shahidullah[67] demonstrated that fetuses with Down's syndrome take longer to habituate than normal fetuses. Recently, Leader[68] concluded in a commentary, 'It seems likely that no single, isolated aspect of behavior alone will evolve but rather a combination of behaviors to form a prenatal neurological examination'.[68]

Summary

The study of fetal behavior also plays an important role in the understanding of normal fetal well-being and in the evaluation of the possibly compromised fetus. It has introduced a completely different way of looking at the developing human being. It also has become more apparent that birth by itself is not the major cause for the neonatal neurological morbidity. Morbidity does not, in the majority of cases, originate from an (hypoxic) accident during birth, but rather from an (hypoxic) accident somewhere during gestation, or it may even be genetic. Most of these mild cases will not be detected at birth and may therefore be attributed to a difficult birth, which is seldom the real cause.[69] It may well be that 'difficult birth in itself in certain cases is merely a symptom of deeper effects that influenced the development of the fetus' (Sigmund Freud[70]).

The study of fetal behavior is still very time-consuming and therefore mostly used in research protocol. In the forthcoming years, we should aim at the development of a more appropriate way to analyze fetal behavior because there is a definite need to get a better insight into the condition of the fetus before birth and in particular the condition of the fetal central nervous system. The development of an adequate and practical intrauterine neurological examination should have high priority in clinical perinatology. The fetus can no longer be regarded as a 'growing organism' that will react independently of age and state. If one wants to say something about the condition of the fetus or to learn something about its development in its intrauterine environment, then one should start to do so under standardized conditions with respect to fetal age, time of the day, relation to maternal meals, etc. and last but not least, certainly in the last trimester one should be aware of fetal behavioral states.

89 Fetal and neonatal hearing

B. Arabin and H. L. M. van Straaten

Introduction

The phenomenon that the sensory development of the prenate is a quiet process of gradually responding to the extrauterine world has been anticipated by mythological and religious stories, artists, writers and many philosophers since ancient times.[1] Aristotle argued that the individual first acquires sensation during pregnancy and might experience the extrauterine environment. However, doubts remained about prenatal sensory capabilities. Jean Jacques Rousseau referred to the fetus as a 'witless tadpole' and even the first scientific approaches by Preyer[2] in 1885 led to doubtful conclusions about fetal hearing capacities.

Hearing is one of the primary modalities of human beings for communicating and a prerequisite for the development of language. Serious efforts to explore prenatal recognition began in the 1920s and 1930s. Peiper[3] performed sonic stimulation with the aid of a car horn to study movement responses of the fetus. Forbes and Forbes[4] were able to acknowledge the amodal link between movement and sound by stimulating a pregnant mother lying in a water bath which was struck with a metal object. Ray[5] attempted to measure fetal reactions to the smacking of two boards together. All these authors reported habituation responses following the stimulus presentations.

Habituation and conditioning became more focal as researchers attempted to tighten scientific controls for analysis. Sontag and Wallace[6] tried to experiment with increased numbers and greater control of the involved variables orientated to a stimulus– response method by measuring physical responses towards external stimuli. It became obvious that auditory maturation does not solely function in isolation but is part of an integrated development. The hypothesis was put forward that intrauterine conditioning accounts for certain behavioral characteristics of the newborn and the refractory times of the habituation–dehabituation processes were studied.[7] Fetal movement (FM) responses to sound stimulation were observed as one major focus for fetal conditioning.[8–10] New methods of perinatal medicine such as Doppler registration of fetal heart rate (FHR) and FM, as well as ultrasound, became extremely helpful to objectify fetal responses to external stimuli.

The unborn is involved in a perceptual world with increasing specification and differentiation. During the first trimester self-generated movements are combined with somatosensory awareness resulting in coordination of early FM patterns. Later sensory challenges may derive from two environments. The 'intrauterine world' includes the emotional state and daily rhythms of the mother, touch with the umbilical cord, the uterine wall and acoustic stimuli caused by maternal circulation, digestion, movements, breathing and, finally, her voice. As birth approaches, stimuli from the 'extrauterine world' are increasingly responded to. Neurological development allowing preparatory interaction involves a considerable number of genetic actions, which might be autoregulatory as well as activated or inhibited by positive- or negative-feedback mechanisms.

Different disciplines have therefore become interested in the field of prenatal maturation of the auditory system such as embryology, genetics, neurophysiology, psychoanalysis and developmental psychology. Since pregnant mothers and most of the current methods used to register immediate responses are in the hands of obstetricians, research and clinical investigations in perinatal medicine have been directed towards this field.

Embryology and developmental anatomy

The special status of the ear is supported by the observation that the ossicles in the middle ear are of adult size by 8 months of gestation,[11] and thus the only bones to attain their final form in the prenatal period.[12] Conventionally, the ear is described in terms of the outer, middle and inner ear. Knowledge about the complex development of the ear helps in understanding its integrated function and disturbances of the auditory system.[13–28]

External ear and tympanic membrane

The external ear is divided into the pinna and the external auditory canal. From 4 weeks' gestation onwards the mesoderm from the first and second branchial

Figure 89.1 Embryo of 10 weeks with a crown–rump length of 36 mm and an 'ear length' of 2.6 mm.

arch gives rise to six outgrowths, the hillocks of His, condensing by 12 weeks to form the pinna. From 10 weeks onwards the future ear can be visualized (Figure 89.1). The external auditory canal develops from the first branchial groove. At 8 weeks the cavum conchae deepens, growing towards the middle ear which can be demonstrated by ultrasound in advanced pregnancy (Figure 89.2). Adult size of the external auditory canal is reached only by 9 years of age.

The tympanic membrane develops from structures associated with both the external and the middle ear. The completed tympanic membrane has three layers: an outer epithelial layer, a middle fibrous layer and an inner mucosal layer, continuous with the lining of the tympanic cavity. The tympanic membrane inserts into the tympanic ring which is complete at 16 weeks, and can be visualized by ultrasound at the end of the external auditory canal (Figure 89.2). The maximal diameter is of adult size in the term fetus.

Middle ear, temporal bone and facial nerve

The middle ear consists of the tympanic cavity, three ossicles (malleus, incus and stapes), the tensor tympani and the stapedius, tendons and the Eustachian tube.

The ossicles develop between 4 and 6 gestational weeks from the mesenchyme of the mandibular and the hyoid arches; full size is reached by 18 weeks. Only then do they become ossified and might be visualized located cranially of the mandible (Figure 89.3a). Extension of the first and second pharyngeal pouch, lined with endoderm, forms the tubotympanic recess. At week 7, constriction of the mid-portion leads to the formation of the Eustachian tube and the tympanic cavity. During further development the tympanic cavity is filled with mucoid mesenchymal tissue becoming vacuolated. By 30–34 weeks the tympanic cavity is pneumatized.

The temporal bone derives from four separate elements: the tympanic bone, the squamous portion, the

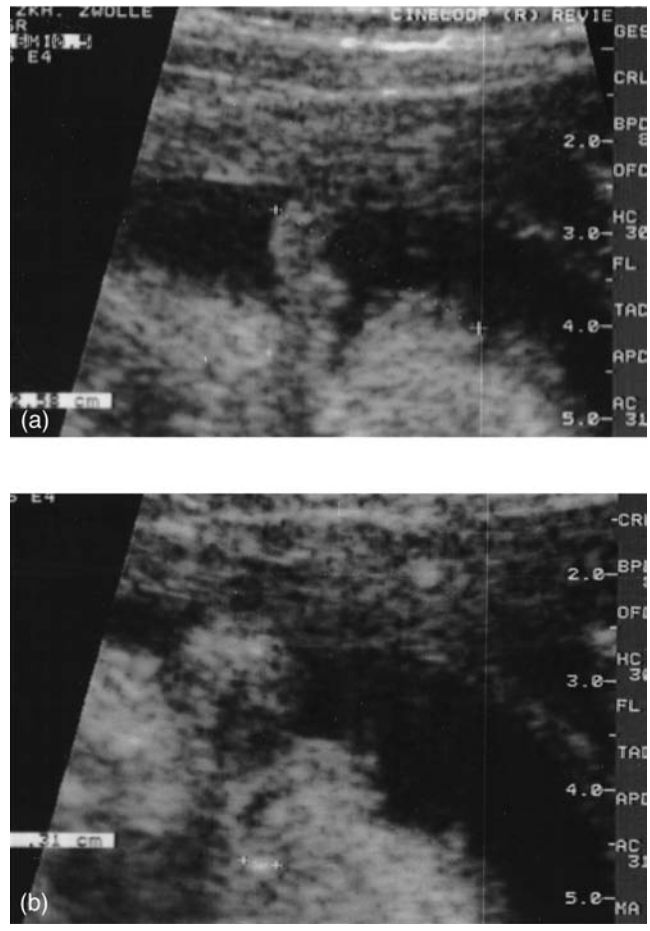

Figure 89.2 (a) Pinna of a fetal ear at 34 weeks (2.6 cm) with external auditory canal. (b) The same external auditory canal obtained by scanning towards the midline with the tympanic membrane (ring) at the central end of 31 mm.

styloid process and the petromastoid. Only the first three parts have formed and ossified at birth. Postnatally, there is still no complete bony ear canal and no mastoid process. The facial nerve derives from the second branchial arch. At the end of the third gestational week the acousticofacial ganglion can be identified; by the end of the embryonic period its neuroblasts form the main trunk of the facial nerve and the chorda tympani nerve. The fully developed facial nerve transverses the internal acoustic meatus, the middle ear and, finally, exits superficially from the stylomastoid behind the tympanic membrane, where it can be injured by obstetric manipulations.

Inner ear and auditory nerve

The inner ear lies in the petrous portion of the temporal bone consisting of a membranous labyrinth inside a bony labyrinth. The bony labyrinth includes the cochlea, three semicircular canals, the vestibule enclosing the utricle, the saccule and part of the cochlear duct, as well as the perilymphatic spaces. Development of the bony labyrinth occurs in three stages: cartilage formation, the formation of the perilymphatic spaces, the calcification and ossification. By 24 weeks, all centers

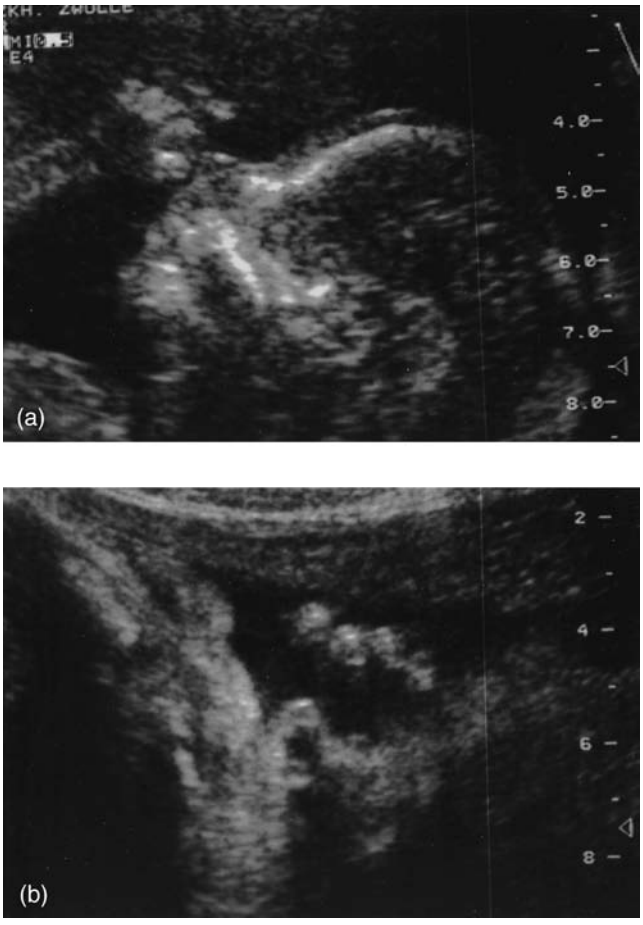

Figure 89.3 (a) Sagittal view of a fetus. Note the three ossicles superior of the mandible in front of the pinna. (b) Frontal view of a fetus 'attempting to listen', in spite of amniotic fluid in the outer ear canal, sound attenuation and internal background noise.

have fused to form a complete bony capsule. Ossification of the inner ear does not occur until each portion has attained adult size. The configuration of the membranous labyrinth is recognizable by 10 weeks and completed at around 24 weeks. Its neurosensory elements develop from the ectodermal otic placode in the 23-day-old human embryo giving rise to the otocyst. The differentiation of the vestibular and cochlear end organs takes place during the second month of pregnancy.

Light microscopy demonstrates that the first sign of differentiation of the organ of Corti in the wall of the cochlear duct starts at 10 gestational weeks. At 14 weeks, rows of inner and outer hair cells can be observed. At around 20 weeks, the human cochlear morphology is similar to what is considered the stage corresponding to the onset of cochlear function. The organ of Corti contains sensory and supporting cells. Ultrastructural development includes hair cell differentiation of inner and outer hair cells, synaptogenesis and ciliogenesis.

The eighth nerve ganglion also derives from the otocyst. After 4 weeks these cells form the auditory ganglion, dividing later into superior and inferior branches of the vestibular nerve and the cochlear nerve. The nerve cells remain bipolar throughout life, the peripheral processes terminating in the sensory areas of the inner ear and the central processes in the brainstem.

Auditory pathways

In the auditory system the second neuron is the brainstem. Structures in the human auditory pathway, from the proximal end of the cochlear nerve to the inferior colliculus, undergo myelination between 26 and 29 gestational weeks. The density of myelination increases in all pathways up to 1 year of age. Though code transmission is improved in myelinated pathways, myelination is not prerequisite for transmission. Primary and secondary crossed and uncrossed pathways ensure that each ear is represented on both sides of the brain.

In mammals the pathway proceeds to the auditory center in the cerebral cortex. The auditory pathway in human beings transforms the code represented by a mechanical response of the ear into a signal which can be utilized by higher centers. The codes are changed from level to level. Through maturation infants develop an information-processing capacity, the development of which has not yet been sufficiently studied. This knowledge, however, is essential for understanding how speech and language develop, and may have implications concerning auditory behavior, reaction to sound and diagnostic testing.

Physiological basis of hearing, encoding and transmission

Sound is created by a vibratory source that causes molecules to be displaced. It is designed for gaseous and liquid media, while oscillation in solids is mostly referred to as vibration. The quantification of sound requires measurement of the amplitude and the frequency. The amplitude is measured in units of sound pressure called pascals (Pa) proportional to the acoustic intensity or loudness. The measurement of sound pressure levels is given in decibels (dB), which are logarithmic numbers favored due to the inherent compression of the linear scales. The frequency of sound is measured in cycles per second, namely Hertz (Hz). The range of 20–20,000 Hz is accepted as the bandwidth of human hearing. Beyond these limits high sound pressure levels are required to evoke auditory responses and there is also decreased discrimination ability. Frequency and magnitude components of sound form what is called spectrum analysis.

Physiological acoustics

Knowledge of physiological acoustics can be obtained from selected references,[29–34] whereby most information is drawn from invasive recordings in nonhuman species.

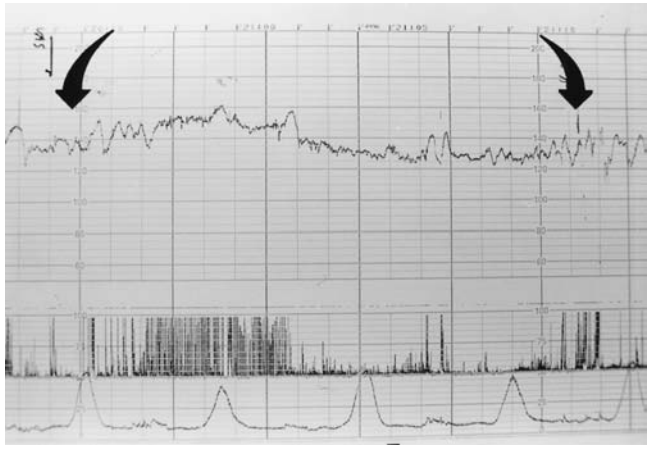

Figure 89.4 Fetal heart rate (FHR, above)/fetal movement (FM, below) tracing after vibroacoustic stimulation in an anencephalic fetus of 34 weeks. There is a long reaction (> 60 s) with increased FM and FHR after the first stimulation (first arrow) and a weaker reaction after the second stimulation (second arrow).

The overall role of the outer ear is to collect sound energy and to shape it by the resonances of the concha and the external auditory canal towards the tympanic membrane. Acoustic energy is transformed into mechanical energy as vibrations of the tympanic membrane and the ossicular chain in the middle ear air, providing an energy gain of around 30 dB due to area differences between the tympanic membrane and the footplate of the stapes. The middle ear also protects the inner ear from high sound pressures.

The role of the cochlea and structures of the inner ear is to couple the vibratory energy delivered to the oval window by the stapes footplate to the hair cells. It was postulated in 1965 by Davis[35] that the binding of the sensory hairs of the organ of Corti depolarizes the hair-cell membrane by altering its resistance. The basis of the frequency-related regional displacement of the entire cochlear partition was revealed by the classic Nobel laureate von Bekesy[36] who described it as 'traveling waves'; this was verified later by sophisticated methods.[37] The links between hair-cell receptors and the auditory system are primary auditory neurons with selective sensitivities for frequencies. With the entry of the acoustic nerve into the brainstem auditory neurons multiply. The frequency-to-place code is equally representative for the organization of central nuclei and the auditory cortex.[38,39] Many auditory abilities are attributable to subcortical processing. Decorticated animals are capable of detecting the intensity and frequency of sounds[40–42]; anencephalic fetuses demonstrate behavioral reactions to external stimuli (Figure 89.4). Central neurons are sensitive to frequency modulation and sound features.[43] An efferent auditory pathway varies the input sensitivity at the level of the hair cells.[44]

Special conditions relating to the fetus

Although perinatologists can occasionally observe gestures familiar from adult life (Figure 89.3), intrauterine hearing conditions are specific for the prenate. Information on fetal hearing has been obtained from invasive experiments on sheep or measurements in pregnancies with ruptured membranes.

Sound conduction

Vibrational direct excitation of skin and tissue is more effective for developing an acoustic field than transmission across the air–skin interface.[45,46] The external auditory canal and the fetal middle ear are filled with amniotic fluid; prenatally, the interface at the stapes footplate is a fluid medium as compared to an air medium postnatally. Sound pressures with the same phase are present at the two windows, which may reduce hair-cell activity. On the other hand, impedance similarities may cause pressure variations to be fairly well transformed.[47]

A bone conduction route is assumed for prenatal hearing based on measurements with round-window electrodes implanted after open fetal surgery in sheep. Cochlear microphonic recordings were registered towards broadband noise delivered by a loudspeaker and compared to input/output functions in the same lamb after delivery.[48] Sound energy is slightly diminished (10–20 dB) for frequencies < 250 Hz, yet significantly reduced for frequencies > 500 Hz (40–50 dB).[48,49] One reason for this 'sound isolation' is the route of sound energy 'underwater', described by bone conduction for adult and fetus.[50,51]

The effectiveness of sound transmission (outer and middle ear versus bone transmission) was tested by sheep experiments, proving that when the fetal head is covered with sound attenuating material, even though the pinna and the ear canal remain uncovered, sound levels must be greater than those necessary to evoke the same response from the bare head.[51] Both cochleae are equally stimulated, so that only one auditory image is likely to be formed.[52,53] This might have implications for lateralization in speech development.[54]

Sound attenuation

A second reason for sound isolation is the sound pressure attenuation described for externally delivered pure tones.[55] A loudspeaker in a rubber annulus was attached to the maternal abdomen, a microphone placed *in utero* near the cervix. Transmission losses ranged from 39 dB at 500 Hz to 85 dB at 5000 Hz,[56] and were 70 dB for frequencies above 2000 Hz.[57] Since an impedance mismatch may bias the results, hydrophones (underwater microphones) were used in humans[58,59] and animals.[46,60–63]

It was shown that the mother's voice in the sheep uterus is louder when picked up by a hydrophone than by a microphone placed by the abdominal wall[62] and that sound attenuation decreases during the last

weeks of gestation.[61,62] Further results were obtained by placing a pregnant ewe in a sound field produced by stereo speakers[46,63] recording simultaneous measurements with a microphone in the air and a hydrophone within the uterine cavity. There was sound enhancement of broadband noises *in utero* for frequencies below 250 Hz; transmission loss increased to an average of 20 dB at 4 kHz. The overall transmission loss was 6.7 dB for broadband noise, and 10–15 dB for pure tone at 1–10 kHz. In humans, exterior sound of at least 65–70 dB was transmitted to the intrauterine cavity with attenuation of 30 dB reduction in sound pressure levels for tones up to 12 kHz; frequencies below 200 Hz were enhanced.[58,59] All in all the results of hydrophone experiments were comparable in sheep and humans.

Sound environment

The sound environment *in utero* might have an 'imprinting' and a masking effect on external sounds as studied in humans[55,57–60,64,65] and in sheep.[61,62] Measurements in sheep have demonstrated that the basal noise is increased during labor.[62] Data in humans, all gathered after rupture of membranes, might underestimate the emergence of external sounds or overestimate background noise described as pulsations of uterine vessels,[66] intervillous injections,[67] or sounds associated with digestion,[68] maternal body movements and with the mother's breath and voice (see below). The intrauterine sound environment is dominated by frequencies below 500 Hz with mean sound pressures of 90 dB at 250 Hz.[58,59]

Sound intelligibility

Intelligibility is based on the ability to distinguish complex sounds and thereby provide speech communication and musical abilities. The auditory sensitivity and prenatal sound attenuation characteristics are similar in sheep and humans.[60,68–70] Language signals are comparable[50] as proven by simultaneous recordings from microphone, fetal cochlear microphone and intrauterine hydrophone recordings in sheep. Music and voices are distinguishable from the basal noise by 8–12 dB for exterior voices and 24 dB for the mother's voice, if all had an intensity of 60 dB. The male voice with an average frequency of 125 Hz is better transmitted, but emerges in the range where internal noise is highest. Female voices with an average frequency of 220 Hz receive a greater attenuation, but emerge in a range where internal noise is low.[58]

The fetus might detect speech and music, ideally low-frequency components below 500 Hz, when the airborne signals exceed 60 dB. Intrauterine sound levels of the mother's voice were enhanced by an average of 5.2 dB. Differences are not dependent on maternal abdominal wall thickness or amniotic fluid volume.[69] Intelligibility of directly transmitted maternal voice compared to airborne maternal, female or male voices did not differ if tapes from intrauterine devices were offered to adult observers.[47] While consonants are indistinguishable, vowel sounds, rhythms and melodic timbre of voices are recognizable. Though attenuation varies with frequency, a variety of music is easily recognized from intrauterine recordings.[64,71]

Prenatal auditory responsiveness under normal conditions

To demonstrate the existence of prenatal sensory perception, one can empirically study electrophysiological, motor and cardiac auditory responsiveness.

Studies of fetal response to sound have chosen a variety of stimuli not always with apparent rationale such as car horns,[3] bicycle bells,[64] electric toothbrushes,[72] or pure tones of 100–2000 Hz, sound pressure levels from 80 to 120 dB measured in air and with various durations.[73] Studies using airborne sounds should be differentiated from studies using vibroacoustic stimuli providing vibration and airborne sound. More recent studies have used the electronic artificial larynx with a vibrating disc attached to the maternal abdomen. It is portable and designed to propagate sound pressure more efficiently, matching impedances between tissue and fluid. The electronic artificial larynx output spectrum was measured by hydrophone fixed near to a lamb's ear *in utero*.[46] Most frequencies were between 0.5 and 1 kHz with multiple harmonics up to 15,000 Hz in air. When the device was placed directly over the hydrophone, sound pressure levels averaged 135 dB, which was greater than predicted in humans.[65,74] In lambs with bilateral cochlear ablation no reactions towards vibroacoustic stimulation could be registered even with high intensities, indicating that in fetal sheep the auditory apparatus is necessary for the FHR and FM responses.[75]

Prenatal responsiveness by means of electrophysiological methods

Recordings of electrical potentials from levels of the auditory system by means of noninvasive techniques are based on compound potentials representing the activity of many cells. Noninvasive methods to investigate the effects of early auditory stimulations are the stimulus-related electroencephalographic (EEG) and magnetoencephographic (MEG) methods. Human EEG responses towards acoustic signals[76–78] have been performed, with one exception,[77] only after ruptured membranes using scalp electrodes.[76,78]

In MEG recordings sensitive magnetic field detectors are used to measure neuromagnetic auditory brainstem responses, which can be performed prenatally with intact membranes.[79,80] Short auditory stimuli like clicks of 1 kHz and a duration of 100 ms up to 100 dB are performed, in a room guaranteeing electrical radiofrequency shielding, to evoke the activity of

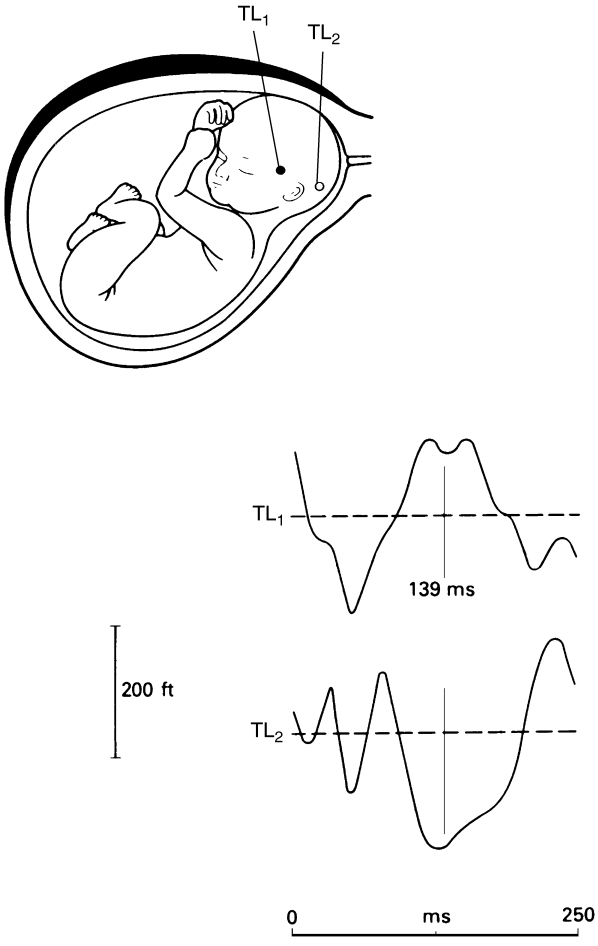

Figure 89.5 Typical waveforms obtained from brainstem after click stimulation at 34 weeks by one-channel magnetoencephalography.[79,80] TL_1, temporal lateral$_1$; TL_2, temporal lateral$_2$; Ft, fentotesla.

electromagnetic sources located in nuclei of the brainstem. In an experimental setting, we succeeded in recording stimulus-related auditory-evoked neuromagnetic fields through the mother's abdomen at 34 weeks by using a one-channel superconducting quantum interference device (SQUID) magnetometer (Figure 89.5).[79,80] The tracings were comparable with postnatal recordings. Latency shifts of brainstem components are proposed to reflect early brain maturation[81] and decrease with advancing age. Although electromagnetic methods are more precise than indirect methods in reflecting the occurrence and latency of reactions, at this moment, the methods are not yet sufficiently developed to allow systematic conclusions to be drawn.

Prenatal behavioral responsiveness

The association of evoked potentials with heartbeat and motor responses implies the reception of the auditory signals up to subcortical levels (Figure 89.4).[82] Due to the present lack of routine technology to record neural activity directly in the womb, fetal sensory abilities are examined by observing behavioral reactions. Appropriate methodology has to be used to ensure that stimulus and response are correlated. Problems arise when the fetus does not react, since we cannot say that the stimulus is not sensed.

Onset of responsiveness

Relating to the onset of immediate fetal responses it was supposed that reactions towards acoustic stimuli do not occur before 24 weeks.[74,83] Using ultrasound, blink responses were first detectable between 24 and 25 weeks, becoming consistent after 28 weeks.[74] Recently, responsiveness to sound was even described at 16 weeks of gestation.[1,84,85] Developmental origins were systematically examined using 80–2000 broadband stimuli between 15 and 25 gestational weeks. When changing the stimulus from a single sound to a series of ten 2-s pulses, an increased number of FM was found after stimulation at 20 weeks. Interpretation refers to hypotheses about the developing neural system prior to the formation of specific receptor cells as described for first reactions towards touch. Ultrasound observations also allow definition of motor responses such as body, head, arm and leg movements.[86] The methodology can be simplified by using Doppler services for the detection of FM which whilst unable to differentiate qualities of responses can differentiate quantities of FM responses with a high sensitivity and specificity.[87] Using this method to record fetal responses and external artificial larynx for stimulation we observed a first fetal reaction (FM) in singletons at 25 weeks[88] and simultaneous reactions of FM of both members of a twin pair at 27 weeks.

Developmental aspects

FM and FHR responses may be classified in immediate reactions such as startles, twinkling, accelerations or decelerations ('reflexes') as well as long-term changes of either FM, FHR baseline or variability ('changes of behavioral patterns'). FHR/FM patterns including breathing movements were studied during 1h after vibroacoustic stimulation.[89,90] Close company changes the development of reactions towards vibroacoustic stimuli in twins compared to singletons. Reactions of longer duration become more frequent in twins compared to singletons (Figure 89.6). With increasing gestational age, an increasing number of FM combined with FHR accelerations is observed in singletons and twins. Among reactions of long duration (> 60 s) FHR baseline changes more dramatically than FHR variability. We also found an increasing number of extreme changes from a very passive to a very active FHR/FM pattern in twin pregnancies. This is in accordance with findings in singletons that after vibroacoustic stimulation unusual changes of state 1F–4F occur, which rarely occur spontaneously.[91] More 'physiologic' state changes from state 1F to 2F were found using a 100-Hz square-wave vibratory stimulus.[92] In any case, vibroacoustic stimulation with the external

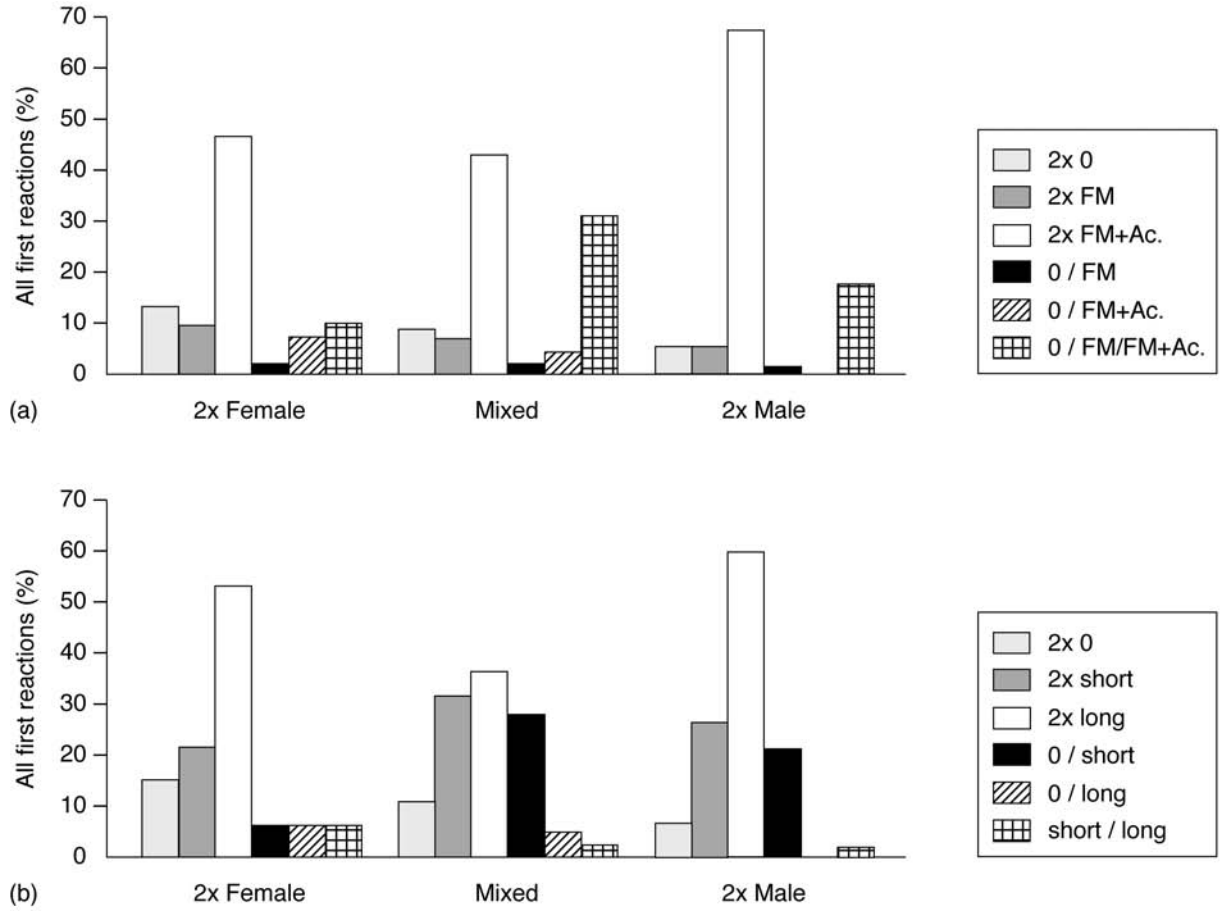

Figure 89.6 Distribution of short (< 60 s) and long (> 60 s) behavioral reactions towards vibroacoustic stimuli in 74 healthy singletons (a) and 64 healthy twins (b) obtained by longitudinal weekly measurements between 26 and 36 weeks. Note that there are significant changes with gestational age, Pearson χ^2 test $p < 0.0005$, and differences between twins and singletons, Pearson χ^2 test $p < 0.0005$.

artificial larynx must have some quite dramatic influence on the fetus, since some gynecologists have even recommended it to induce a change of fetal position to improve visualization of fetal echocardiography[93].

Quality of stimulus

Both the onset and development of auditory responsiveness also depend on qualities of the stimulus. Fetuses from 19 weeks onwards were presented with pure-tone frequencies of 100–3000 Hz. First responsiveness was detected at 23 weeks at 500 Hz, by 27 weeks responsiveness was found to 100, 250 and 500 Hz and only at 31 weeks were responses observed to 1000 and 3000 Hz.[94] It was interpreted that the delayed responsiveness to high frequency is related to the development of phase-locked firing describing a cooperation of nerve fibers to encode high-frequency sound.[95] The sound pressure level required to elicit a response at 35 weeks is 20–30 dB less than at 23 weeks, indicating that the fetal auditory system becomes more sensitive with prenatal age.[94] However, changes in attenuation, maturing behavior and sensomotor neural connections might also have an impact. Even fetal intelligibility has developmental aspects.[95] Using a habituation–dishabituation technique, fetuses aged 35 weeks could discriminate between frequencies of 250 and 500 Hz and between different speech sounds, whereas fetuses of 27 weeks were unable to make this differentiation, although they were able to differentiate between a 250-Hz tone and 80–2000-Hz broadband sound.

Specific or momentary disposition

Additional factors influence fetal acoustic responsiveness such as behavioral state before the stimulus,[96] gender,[72] position *in utero* and individual disposition (own data). Fetal responses to speech stimuli consisting of syllables ('ee' or 'ah') were studied in healthy pregnancies at 26–34 weeks' gestation. During periods of low FHR variability, a decrease in FHR and an increase in the standard deviation of heart rate were found.[97] This is the only demonstration of prenatal responses to speech stimuli whereby the response is dependent on FHR variability which is the primary determinant of fetal state.[98] Female fetuses seem to respond earlier than males.[72] In our experience, twins are ideal models to differentiate further the simultaneous influence of activity state before stimulation, individual disposition (zygosity), position and sex of

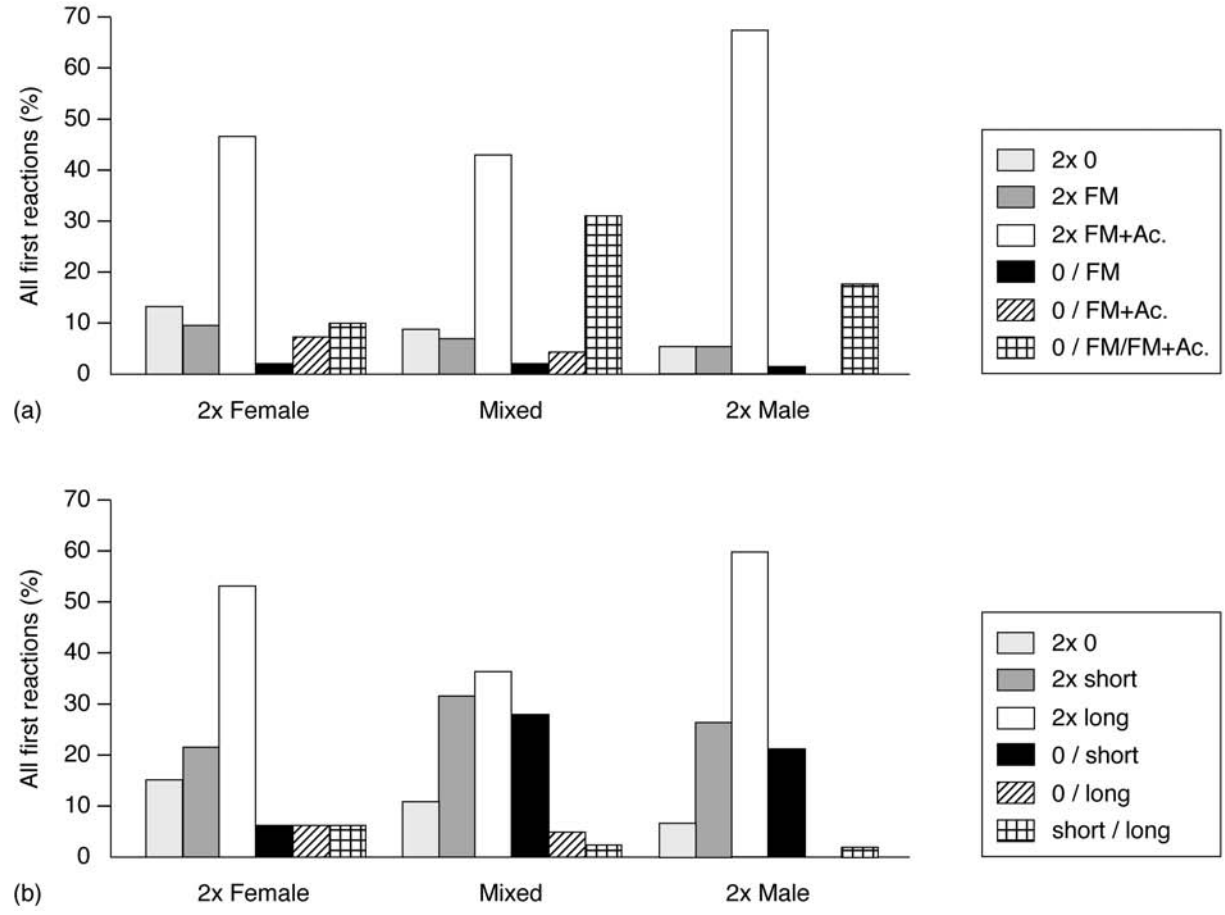

Figure 89.7 Distribution of combinations of 390 fetal heart rate (FHR)/fetal movement (FM) reactions towards vibroacoustic stimuli within 32 twin pairs. (a) Classified relating to first short reactions, (b) classified relating to duration of reactions (0, no reaction; Ac, acceleration; long, > 60 s; short, < 60 s). Note the significantly higher intertwin differences (lighter columns) in twin pairs of different sex, Pearson χ^2 test $p < 0.0001$.

the prenates by analyzing intertwin differences of FHR/FM patterns towards external artificial larynx (Figure 89.7). Similar reactions towards external artificial larynx were significantly increased in twins with the same sex and differences between sex-alike male compared to female groups can be calculated. If all parameters are analyzed by multivariate analysis, age-dependent determinants of fetal responsiveness can be evaluated.

Postnatal auditory responsiveness under normal conditions

After delivery sound conduction and environment change significantly and the newborn is more directly accessible to behavioral[98,99] and electrophysiological examinations.[30–32,99]

Postnatal responsiveness assessed by electrophysiological methods

Auditory-evoked potentials reflect electrical activity from different anatomic levels of the auditory system: the earlier components from peripheral and brainstem levels, the later ones from midbrain and cortical levels. The cochlear (0–4 ms) and early components (4–12 ms) are used for assessing peripheral hearing in children by electrocochleography and auditory brainstem response. Whereas electrocochleography can only be used under anesthesia, auditory brain response has become the method of choice to estimate hearing sensitivity in newborns since it was first described.[100,101] It reflects the integrity of the outer, middle and inner ear and the auditory pathway,[102,103] as described by Davis,[35] and is free from the effects of medication or state. Via headphones click stimuli are performed and short-latency electroencephalographic waveforms are recorded by skull electrodes (Figure 89.8). The detection of cortical potentials and auditory brainstem response as early as 25 weeks indicates functional maturity of the auditory pathway.[104] Electrophysiological responses from the cochlea, the eighth nerve and the auditory brainstem are similar to those in the adult by 32–36 gestational weeks.[103,105] The responses continue to develop in wave components, shape and latency with myelinization[103,106] until the second year. The auditory brainstem response does not necessarily depend

Figure 89.8 Hearing screening in a preterm infant at the NICU with an automatic version (ALGO-1E automated auditory brainstem response infant hearing screener, Natus Medical, Inc.) detecting auditory brainstem responses.

on the same neural events that are essential for perception of auditory capabilities.

Von Bekesy[36] postulated that some sound energy must be emitted from the cochlea back to the external auditory canal ('feedback from the inner ear'). Transiently evoked otoacoustic emissions can be measured, e.g., sounds generated and emitted by the outer hair cells of the cochlea in response to acoustic stimulation.[107] A small probe is placed in the external auditory canal and click stimuli are presented. Otoacoustic emission methods are candidates for application in the newborn permitting the acquisition of frequency-specific information which can be drawn later from audiometry.

Postnatal behavioral responsiveness

Behavioral reactions towards acoustic stimuli are less suitable for preterm neonates, but they are of value to learn about what babies hear and about possible positive or negative influences. Responses and alertness to voices, bells and rattles, or the neonate's ability to shut down aversive reactions due to habituation towards repeated stimuli are used to score infants according to their 'abilities'.[97] Broadband sounds (speech) are more likely than narrowband sounds to elicit responses[108] which also depend on physiological states of hunger and sleep/wakefulness.[98] A newborn infant can differentiate bandwidth, duration, interstimulus interval, frequency and sound pressure level.[109,110] Signals < 4 kHz evoke responses three times more often than signals in the higher range. Lower frequencies generally evoke gross motor activity, high frequencies evoke freezing reactions. The newborn can respond to gross right–left changes, although sound localization is not purely auditory. Even soon after birth a blind infant is less likely to localize sound than a sighted infant. After 2 months infants integrate auditory and visual space (e.g., voice and facial movements).[111]

Some methods have been introduced to objectify behavioral responsiveness. The auditory response cradle compares reactions with and without sound by a pressure sensitive mattress and a monitor for head movements. As in prenatal life high intensities of up to 85 dB are needed to elicit motor responses.[112] The observer-based psychoacoustic procedure controls for observer bias by documenting behavioral changes towards acoustic stimuli while the observer is 'blinded' by earphones for all signals.[113] Using the observer-based psychoacoustic procedure infants of 2–5 weeks showed thresholds at 500 and 4000 Hz of 55- and 60-dB sound pressure levels, respectively.[114]

Effects of prenatal hearing on postnatal development

By correlating morphological and neurofunctional results with perinatal observations, conclusions might be drawn for sensomotory, cognitive and emotional development.

Recognition or 'memorization'

Considerable attention is given by parents to the possibility that the fetus forms memories of speech and music that may influence the abilities postnatally. Habituation has primarily been described by Peiper[3] who reported a decrease in FM after repeated stimulation with a car horn. Since then a number of studies have demonstrated a decrement in response to repeated stimulation while using FHR/FM or ultrasound documentation. Habituation may be distinguished from adaptation or fatigue by several criteria, the most important being the recovery of response on presentation of a new stimulus ('dishabituation') and faster habituation upon re-presentation of the stimulus.[115] The intensity of the stimulus influences habituation time (faster habituation to more intense stimuli).[115]

While habituation reflects short-term memory, there is also proof of long-term memory from pre- to postnatal life. To demonstrate the existence of prenatal sensory perception, one can indirectly study behavioral modifications of a neonate presented with stimuli she or he has been confronted with during prenatal life ('memorization').[47] Prenatal sound experience might have an influence on postnatal sound preference and fine tune the developing auditory system.[116] Neonates have been taught that if they produce a specific sucking pattern they could listen to their mother's voice. Newborn babies showed a strong preference for the voice of their mother over that of other male or female talkers. Using the specially designed baby's dummy connected to a tape recorder, newborns are even able to distinguish between their mother speaking in her native vs. in an unfamiliar language[117] (sucking with higher frequency). Using this 'high-amplitude sucking procedure', 3-day-old newborns prefer a lullaby read twice a day by the mother during the last weeks of pregnancy to a new story.[118] All this suggests the possibility of prenatal acquisitions and antenatal discrimination, however elementary it might be.

Prenatal stimulation has an impact on temperament behavior. Settings of talking, music and meditation were performed during pregnancy and correlated with behavioral outcome.[119] Talking had a 65%, music a 34% and mediation a 31% correlation with all behaviors. For talking only 58% of behavioral variables were identified as positive (e.g., the child being easily comforted, contentment), 16% as ambiguous and 26% as negative (e.g., crying for obscure reasons, needing constant supervision). Music and meditation, however, correlated in 90% and 100%, respectively, with positive attitudes. Talking is known not only to express care, but also irritability, anger or anxiety experienced in pregnancy. It is speculated that not only variations of timbre, but also hormonal or physiological changes associated with the content of speech, may evoke associations in the infant. This hypothesis is supported by a study of infants whose excessive crying was in association with their mothers' depression scores.[120]

Implications for language development and musical expression

Hearing has a close relation to the kinetic system, i.e., 'auditory–vocal–kinetic channel'.[121] From embryology we know that the origins and innervation of hearing and language function are in close proximity, suggesting that there is also 'crying *in utero*' – only we have not yet become sensitive for it. Vocal expression can be heard in fetuses from around 20 weeks onwards. Uterine crying has been proposed following unpleasant maneuvers such as attaching electrodes, versions or catheter insertions.[122–124] The newborn's phonation is based on laryngeal coordination reflecting maturation processes and training. Newborn 'cryprints' are as unique as fingerprints, and characterized by specific features such as fundamental frequency and variation in time ('vibrato') using voice-signal recording.[125]

We suppose influences of nature and nurture on prespeech development. Monozygotic twins have synchronous cry patterns at birth.[126] By listening to the mother's speech the fetus obviously stores her speech features. Early spectrography of the first cries proved that even newborns born at 28 weeks had similar voice performance features to their mothers.[127,128] How far genetic influences or experience of the same sound environment are responsible for first hearing and cry patterns remains to be determined. Babies as young as 12-h-old react to rhythms of human speech.[129] This also might imply that learning of language begins soon after or even before birth. Newborns are able to distinguish between phones in any language and make all sounds of any language.[130] By 6 months linguistic experience has resulted in language-specific phonetic prototypes.[131] Adults can no longer distinguish between phones used in unfamiliar languages. In this context, experience seems paradoxically to diminish auditory skills. Somehow, babies even stimulate adults to speak to them in a stylized way.[132]

Music exists in the passage of time and cross-culturally. It is supposed that musicality is structured by an ensemble of protorhythms of biological inheritance.[133] The hypothesis that music has prenatal origins does not explain the survival value of music,[134] but might clarify its nature with cross-cultural features of rhythm and dancing comparable to rhythmic elements *in utero*, e.g., movements of maternal vessels felt and heard by the prenate. A summary of the up-to-date knowledge on the influence of music during pregnancy is meanwhile published by the main author.[135]

Prenatal acoustical responsiveness as a test for fetal well-being

The understanding of pathophysiology has led to improvements in interpretation of behavioral and hemodynamic mechanisms. Fetal hypoxia is the condition studied most intensively. An arrest of muscular activity to reduce oxygen consumption and a redistribution

of fetal blood flow to maintain oxygen delivery to essential organs were primarily described in sheep experiments[136,137] and later in humans.[138–140] Meanwhile, correlations with antenatal blood gases have been performed.[141,142] Fetal activity and blood-flow redistribution have an impact on FHR patterns. FHR variability and the presence of FHR accelerations with FM are recognized as indicators of fetal health by noninvasive and invasive studies.[142,143] In this context, (vibro)acoustic stimulation was proposed mainly for the assessment of fetal well-being and to discriminate between 'nonreactive' nonstress tests (NSTs) due to hypoxia or just to quiet state.[144,145] Using Medline we found more than 150 studies on vibroacoustic stimulation as a test of fetal well-being from 1980 to date; here we focus only on selected aspects.

Increase of 'efficiency' of non-stress testing and biophysical profile

To compare results, the frequency, duration and intensity of the stimulus as well as gestational age, FHR/FM criteria, habituation time and behavioral states in association with the response have to be analyzed. In general, a 3-s sound stimulus is adequate for a shift to an 'awake' state.[146] In a review of 61 studies, the ability of vibroacoustic stimulation to elicit FHR accelerations has been established, decreasing false-positive rates of nonreactive NSTs.[147] Pregnancies with early-onset intrauterine growth retardation (IUGR) were studied after vibroacoustic stimulation between 26 and 32 weeks' gestation. Accelerations, FHR variability and FM were reduced compared with age-matched normal fetuses.[148] The conclusion that nutritional deprivation is associated with delayed sensory maturation is not necessarily true, since similar FHR and FM patterns are recognizable in early NSTs. The result only proves that there is no reaction, though the stimulus might well be received. Vibroacoustic stimulation was performed in patients with low biophysical profile scores after 15 min. The results of patients whose biophysical profile score improved to normal were compared to normal scores without stimulation. Vibroacoustic stimulation was found to 'improve' an abnormal or equivocal biophysical profile score to normal in 82% of cases without increasing obstetric or neonatal complication rates or the false-negative rate of biophysical profile scores.[149]

Comparative observational studies and clinical trials

Some observational studies compare the vibroacoustic stimulation test concurrently with other tests. In most studies the prediction of poor outcome was comparable with results of the NST.[150,151] In the prediction of an abnormal contraction stress test (CST), a nonreactive vibroacoustic stimulation test had a sensitivity of 100% and a specificity of 91%; therefore vibroacoustic stimulation was slightly better able to diagnose fetal distress compared to the CST in pregnancies with a nonreactive NST at term.[152] After the introduction of Doppler velocimetry of fetal redistribution it has become possible to differentiate ambiguous results of NSTs noninvasively. Thus we compared the clinical value of NST, Doppler ratio of cerebral vs. umbilical blood flow, vibroacoustic stimulation test and CST to predict poor outcome using different cut-off values for all tests separately for IUGR and post-term pregnancies. Doppler velocimetry and NSTs had better prognostic capacities than vibroacoustic stimulation tests and CSTs (Figure 89.9).[153,154] We therefore do not use CST or vibroacoustic stimulation tests in clinical routine, while Doppler studies, computerized FHR analysis, or real-time ultrasound of fetal behavior and amniotic fluid analysis can be performed without 'unnatural stress' for mother and fetus. We admit that in units where skills in ultrasound examinations or sophisticated equipment are not available, vibroacoustic stimulation or CST might be of value. Clinical trials demonstrate that the introduction of vibroacoustic stimulation in combination with the NST[155] or with amniotic fluid assessment[156] has not led to an increased rate of mortality. Since in the Western world all of the currently used forms of antenatal surveillance are combined with low mortality rates, it is unlikely that vibroacoustic stimulation will ever lower perinatal mortality in any randomized or historic trial.[157] In the only controlled clinical trial, where vibroacoustic stimulation test was compared to NST,[145] false-positive tests were slightly lowered and performance reduced from a mean of 27 to 23 min. Although it has been proven that vibroacoustic stimulation does at least not increase catecholamine release[158] or meconium passage in healthy fetuses,[159] the question remains whether 4 min justify frightening – or even awakening – an innocently sleeping fetus (it is recommended that vibroacoustic stimulation is performed during quiet sleep!). In other words: which parents would appreciate this postnatally?

Vibroacoustic stimulation during labor

The same holds true for studies during labor, where vibroacoustic stimulation was primarily applied to test attenuation via hydrophones. Data suggest that an intrauterine threshold of 94-dB sound pressure level is necessary to produce a consistent FHR response during active labor.[160] At the first stage of labor vibroacoustic stimulation was studied possibly to improve interpretation of ominous spontaneous FHR testing. Undoubtedly, nonreactive responders to vibroacoustic stimulation were at significantly greater risk of subsequent abnormal FHR patterns, meconium staining and fetal distress; however, transient FHR decelerations occurred in 25% where fetal outcome was not impaired.[161] Although it was concluded that vibroacoustic stimulation differentiated compromised from non-compromised fetuses, we think that it might also

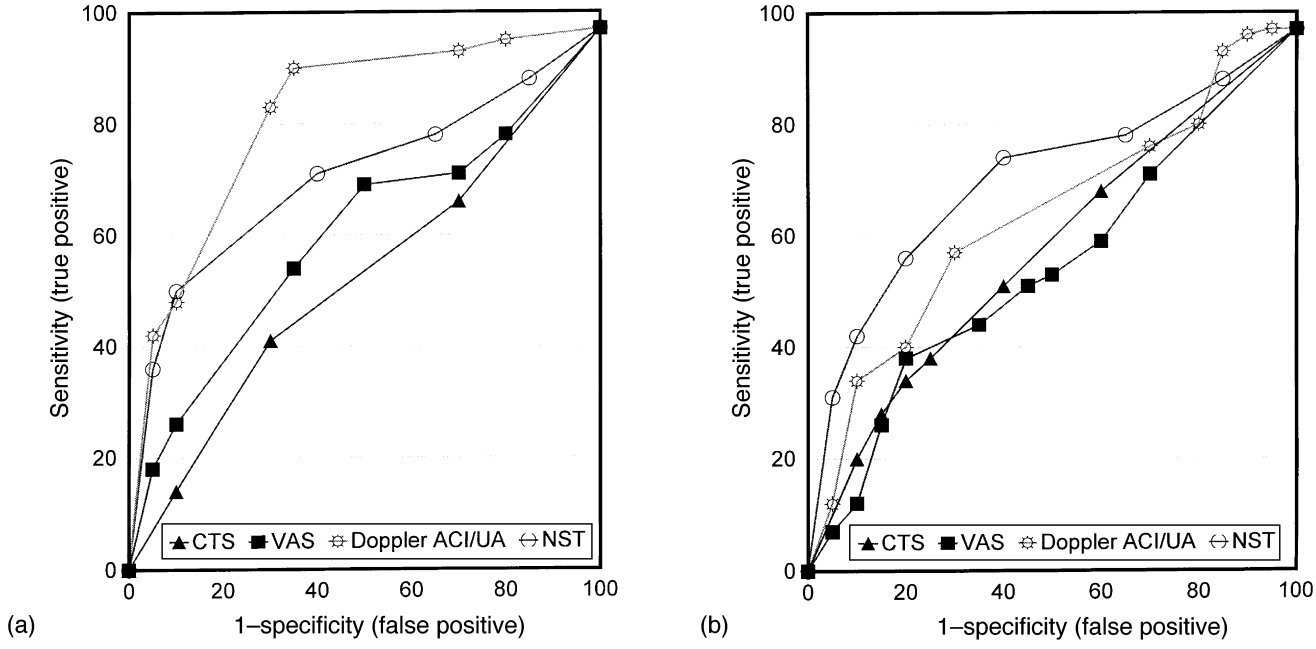

Figure 89.9 Receiver–operator characteristics of antepartum tests to predict fetal distress requiring operative delivery (measurements 1–3 days antepartum; CTS, contraction stress test; VAS, vibroacoustic stimulation; Doppler ACI/UA, resistance index ratio of arteria carotis communis/umbilical artery; NST, nonstress test) in 103 intrauterine growth retarded (IUGR) (a) and 110 post-term (b) pregnancies.[142,143]

confuse inexperienced staff. At the second stage of labor fetal blood sampling (FBS) has been correlated with vibroacoustic stimulation testing: vibroacoustic stimulation had a sensitivity of 100%, a specificity of 59.6% and a positive predictive value of 27.6% for the detection of fetal acidosis.[162] Although it was evident that mean fetal blood pH values obtained within 30 min of vibroacoustic stimulation were higher in reactive compared with decelerative or nonresponders, acidotic pH values were also found in fetuses with reactive FHR patterns after vibroacoustic stimulation.[163] In recent studies it was concluded that the FHR response after vibroacoustic stimulation does not predict neonatal outcome and might not replace FBS.[164,165] There are even warning hints about using vibroacoustic stimulation as a routine procedure, such as an unknown influence on cerebral blood flow in quiet sleep,[166] false-negative results in fetal sepsis,[167] activation of swallowing[168] or micturation[169] and provocation of unnecessary pathological FHR patterns in cases with nuchal cord.[170]

We conclude that many studies do not address the physiological changes of fetal responsiveness or habituation time by gestational age or standardize FHR/FM patterns before or after vibroacoustic stimulation. Appropriate implementation of vibroacoustic stimulation tests requires appropriate questions. In twin studies we have found that prenatal reactiveness – either to touch of the co-twin or to external stimulation – is combined with larger interindividual variations than spontaneous behavior. For the time being, we recommend vibroacoustic stimulation as a challenge test only under controlled conditions, but not for routine use just to simplify antenatal surveillance. This has been proposed by other authors.[171]

Early hearing disturbances

Compared with the vestibular part, the auditory system is phylogenetically young with a greater demand for oxygen and glucose and can therefore be selectively damaged.

Early hearing is prerequisite for speaking and for intellectual, social and emotional development.[172] Even a relatively mild hearing loss of 35–40 dB near hearing level means that a child misses approximately 50% of normal conversation.[173] Severe congenital hearing impairment affects 0.1% of live-born infants[104,174] and 1–4% of graduates of neonatal intensive care units (NICUs).[174,175] The prognosis is improved when the diagnosis is made early.[176] The fitting of hearing aids within the first 6 months improves speech and language development compared with placement at a later age. However, the age at diagnosis of hearing impairment was at least 18–30 months,[177] even in countries with a nationwide behavioral screening program starting at 9 months of age. However, the age of diagnosis is rapidly changing in those countries with a nationwide neonatal screening program. Using high-risk registers 50–75% of infants with hearing loss are identifiable.[178] Both the American Joint Committee on Infant Hearing and the European Consensus Development Conference postulated that universal hearing screening should be implemented within 3 months of life.[179,180] Habilitation should be started before

Table 89.1 Indicators associated with sensorineural and/or conductive hearing loss in the newborn (indications for hearing tests when universal screening is not available)

Indications
Positive family history or hereditary childhood sensoneural hearing loss
Congenital infections (toxoplasmosis, cytomegalovirus, rubella, syphilis, herpes)
Craniofacial anomalies including those with morphological anomalies of pinna and ear canal
Admission for ≥48 h to a neonatal intensive care unit
Stigmata or other findings associated with a syndrome known to include hearing loss

6 months of age. In those countries with limited financial facilities neonatal hearing screening may be limited to high-risk groups for hearing loss (Table 89.1). All infants admitted to neonatal intensive care units should be screened for hearing loss prior to discharge.

Electrophysiological measurements for screening

Auditory brainstem responses

The conventional auditory brainstem response (ABR), e.g., the ability to evoke and record a short-latency electroencephalographic waveform in response to a click stimulus is considered to be the gold standard in detecting the neonatal hearing threshold,[105,181,182] though it is not yet widely used because it is costly and time-consuming. The click-evoked ABR may occur as early as at 25 gestational weeks but typically appears during the 27th week. Development of the infant ABR is usually complete by the end of the second year of life.

Automated ABR infant hearing screeners have been introduced as an alternative.[183] Based on a statistical model for the detection of a response (auditory brainstem response algorithm) and a dual artifact rejection system for environmental noise and myogenic artifacts, the equipment provides a pass/fail outcome. Stimulation via headphones with 35 dB near hearing level clicks with frequencies of 700–5000 Hz can be performed even under NICU conditions (Figure 89.8). No special training is necessary. Clinical trials proved the concordance between an automated version and conventional auditory brainstem response screening,[184] whereby a sensitivity of 100% and a specificity of 98.7%[185] was detected. Follow-up results support the value of automated auditory brainstem response screening.[185] The mean time needed to perform a screening has been reduced to 8 min.[186] To avoid ambiguous results in preterms, screening is advised from a postconceptional age of 30 weeks onwards.[185]

Otoacoustic emissions

In transiently evoked otoacoustic emissions (TEOAE) measurements, 'a pass' has been defined as the presence of emitted energy of at least 3 dB signal/noise ratio between 1.6 and 4 kHz,[187] but until now no objective pass/fail criteria have been established. The response is frequency specific and does not provide an indication of audiometric threshold. Depending on the stimulus, TEOAE can be detected in up to 98% of humans with normal hearing and are absent in hearing impairment of 20–40 dB. TEOAE takes 7–9 min and can be administered by a trained nurse.[187,188] In NICU infants screened with TEOAE at 3 months, there is a sensitivity of 93% and a specificity of 84% to detect absent auditory brainstem response.[189] Hypoxia or infection may result in a reversible reduction of the TEOAE spectrum. Children with hearing loss primarily due to involvement of the auditory pathway or CNS may have normal evoked otoacoustic emissions as a result of a normal functioning cochlea.[190]

Otoacoustic emissions (OAE) screening is less suitable for use on a NICU because of the ambient noise and the difficulty of placing the ear probe in preterms.[191] Besides, children with nonorganic hearing loss or hearing loss primarily due to involvement of the auditory pathway or central nervous system may have completely normal OAEs as a result of a functioning cochlea.[192] Therefore, children at risk for auditory neuropathy should be screened with ABR methods.

Several other types of OAE have been identified. These include spontaneous OAE, clicked evoked OAE, and distortion product OAE. With future research and automated analysis, each of these methods will become increasingly available for hearing screening, especially in term neonates.

Behavioral screening

Behavioral hearing screening methods such as the auditory response cradle and the crib-o-gram have been developed for term infants. Although easy to perform, they are not suitable for screening preterm or sick neonates and detect only severe hearing impairment. The sensitivity (75%) and specificity (71%) are too low compared to neurofunctional methods.[193] Behavioral observations remain the basis of the investigation of the harmful influences of high-intensity noise in neonatal intensive care units; prematures wearing earmuffs spent more time in quiet sleep states and had higher mean oxygen saturation levels compared to controls.[194]

Information about pediatric auditory research projects are available on the Internet.[195]

Possible damage from environmental hazards during pregnancy

Children who have been exposed *in utero* to vibroacoustic stimulation for the assessment of fetal well-being have been evaluated at 4 years of age by

auditory tests of 20–25 dB at frequencies between 500 and 8000 Hz in Sweden ($n=460$)[196] and the United States ($n=465$).[197] No hearing damage or neurodevelopmental abnormalities that could be connected to the vibroacoustic stimulation were found. Fetal noise-induced hearing loss has been a matter of concern regarding the working and living conditions of pregnant women.[198,199] Epidemiological and animal research suggest that noise can adversely change fetal hearing; however, studies in humans still lack control groups. Auditory brainstem response changes were examined in sheep suggesting that noise sources with low-frequency components and high-intensity impulses have temporary effects on auditory brainstem response waves, whereas long-term effects are still unknown.[200] In summary, the Committee on Hearing, Bioacoustics and Biomechanics,[201] attempting to protect fetal hearing, suggested that pregnant women should avoid noise exposures greater than 90 dB.

Direction of future research

The phenomenon of prenatal perception and the implications for future life represent a wealth for ongoing and future research.

Methodological aspects

Prenatal hearing reflects the complex neurological development of the early brain. Evaluation of fetal brain function is one of the most important objectives of basic and clinical research in perinatology. Imaging of the fetal brain only demonstrates a small part of its function and most functional approaches have been indirect. The introduction of magnetoencephalography in perinatal medicine was a pioneer step to evaluate prenatal brain function directly,[79,80] though the single-channel magnetometer did not allow high-quality auditory-evoked signals. By using multichannel MEG[202] or detectors specifically designed for the prenate, the window of observation of early gestational age and various indications might be expected to be extended. The method might be used in newborns[203]; examinations in twins would enhance our knowledge about hereditary or environmental influences. The sophisticated method might have implications for prenatal neuroscience and clinical use. Prenatal training of laryngeal coordination is likely to occur during mouthing or breathing movements. Doppler combined with real-time ultrasound examinations might elucidate how far this is performed at a special rhythm. Correlations with postnatal cry spectroscopy might be of interest.

Aspects of using early sensation for developmental support

Health is understood as the physical, mental and social well-being that goes further than just the absence of illness. As important as it is to teach children abilities at certain times creating integrated stimulations for the unborn might favor development or prevent sensory retardation. This should be a matter of concern in public health projects. In Venezuela, a program was introduced including weekly lectures to pregnant mothers about adequate stimulation and nutrition. Significant improvement was found at the 2nd and 25th days in orientation and autonomic stability of the infants in the experimental compared to the control group.[204] Perinatal auditory stimulation programs need the knowledge of critical developmental phases. Pilot studies have demonstrated an immediate reduction of fetal breathing and an increase of FM when mothers only listen to a preferred type of music via earphones,[205] or a reduction of fetal activity if fetuses only listen to rhythmic music.[64] The first study is proof that integrated programs for mother and fetus may even be regarded as conditioning (e.g., 'music, mother relaxed'). Is the unborn more affected by the mother's preferences of listening – the same holds true for singing and talking to the unborn – than by the sound alone? Postnatal conditioning has a larger scale, e.g., sound stimulations recalling intrauterine noise can not only lull the newborn to sleep,[67] but also serve as a reinforcer during sucking.[206] Similarly, feeding may be enhanced by background music. The perception of music as pleasant might even be a process of conditioning from the parents.[71] Singing lullabies and simultaneously rocking cradles have been used to soothe babies by simultaneous stimulation of the vestibular and acoustic sensory system. The experience of rhythmic stimulations by a 'breathing teddy bear' adapted to the child's individual breathing frequency has proven to facilitate neurobehavioral development.[207] Further studies relating to supportive perinatal conditioning are necessary whereby music stimulation might play an essential part.[135]

Aspects for pathological development

Working groups in Western countries are planning protocols for the evaluation of early hearing screening. Thereby it is a major goal of the Maternal Child Health grant in the United States to establish universal neonatal screening, to identify specific hearing loss by 3 months, to institute intervention by 6 months and to measure the impact of early identification on developmental outcome. Average costs were given as $25 per test,[208] and as $43,785 to identify a child with sensorineural hearing loss.[209] Considering the given incidence of hearing impairment further programs are needed. Future research of the use of acoustic therapy and shelter may provide measures positively to alter the critically ill newborn's environment.

Conclusions

Encouragement and avoidance of sound have to be considered and balanced in future analytical and interventional projects according to critical developmental

phases. Whether we go so far as to found prenatal universities, as in California, is of secondary importance as long as we strive to understand the physiology and pathophysiology of early hearing and to create designs of adequate stimulation suitable to induce a comprehensive expression of our genetic potential, prevent unnecessary illness and to detect hearing loss as early as possible.

90 Fetal responses to placental insufficiency

M. L. Kush and A. A. Baschat

Introduction

The placenta forms the interface for nutrient, fluid and gas exchange between the mother and the fetus. Successful placental development is of critical importance as it is permissive for the normal development of an individual. While the fetal growth potential is genetically predetermined[1] the ultimate neonatal weight, proportions and condition at birth are dependent on placental development, fetal health and maternal health. Normal placentation of a genetically normal fetus in a healthy mother is therefore most likely to end in fulfillment of the growth potential. However, if any of these factors is deficient a number of fetal and maternal adverse outcomes may be the consequence. Of these placental insufficiency is of particular interest because it may lead to fetal growth restriction (IUGR), a condition that is associated with an increased risk for adverse health events that manifest in fetal life and extend all the way into adult life.[2–6] There are several conditions that are associated with fetal growth restriction (Figure 90.1). Of these, placental vascular insufficiency is clinically the most relevant since it is most prevalent and potentially derives a benefit from intervention.

Because of its diverse impacts placental disease has been a constant research focus for decades. However, it is the multidisciplinary approach of multiple medical subspecialties that has elevated our level of understanding to a point where the diverse impacts of placental dysfunction on fetal health are being appreciated. While traditional antenatal surveillance examines a relatively narrow spectrum of fetal responses, utilization of more sophisticated research tools has uncovered responses in almost every organ system. Before expanding on these multiple effects of placental insufficiency an understanding of the normal maturational process of the placenta and fetus is essential.

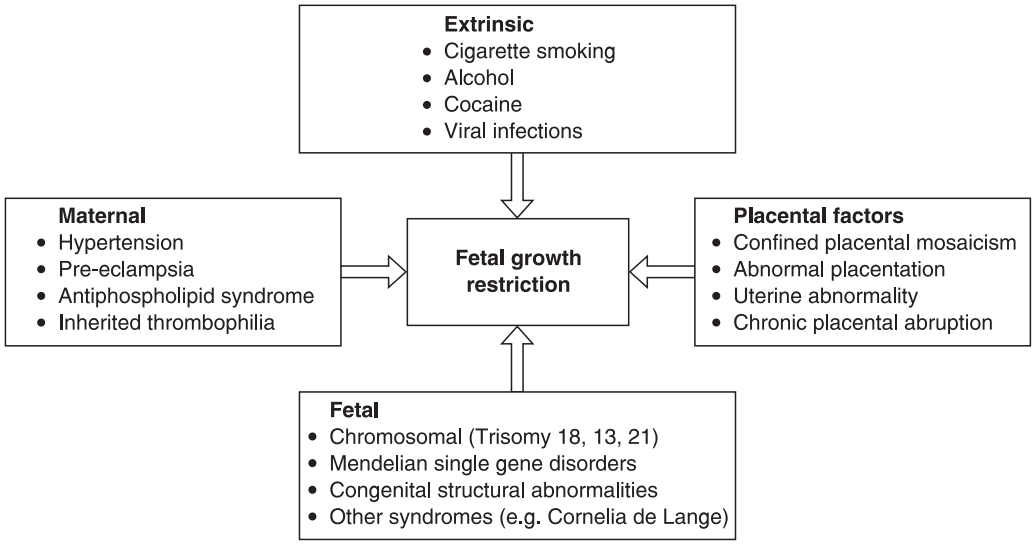

Figure 90.1 The principal causes and most common conditions that are associated with fetal growth restriction.

Placental development

Fetal growth is regulated at multiple levels, and requires successful placentation for the coordination of key components in the maternal, placental and fetal compartments for adequate maternal–fetal exchange throughout gestation. Successful placental adherence in the first trimester initiates a series of important milestones in the three overlapping gestational epochs. First-trimester initiation of placental vascular development permits nutrient and oxygen delivery to the growing trophoblast beyond the capacity of simple diffusion. Maternal adaptations to pregnancy predominate in this epoch. Differentiation of placental transport mechanisms and paracrine and endocrine signaling pathways between the mother, placenta and fetus then continue throughout the second trimester. Successful initiation of these steps allows placental growth and establishment of efficient and coordinated nutrient transfer, waste and gas exchange by the second trimester. This is a prerequisite for exponential fetal growth and differentiation in the third trimester in preparation for extrauterine life.

Following fertilization, the cytotrophoblast migrates to form anchoring sites through controlled breakdown of the extracellular matrix by metalloproteinases and localized expression of adhesion molecules. Placental adherence between the decidua and uterus is established by the formation of these anchoring villi that connect the decidua and uterus. Angiogenesis produces vascular connections to the maternal circulation that establish maternal blood supply to the intervillous space. This high level of nutrient and oxygen supply is required to support the growing embryo and trophoblast.[7,8] With this nutritional and vascular support in place, the villous trophoblast, consisting of a maternal microvillous and fetal basal layer, is formed.[9] Increasing placental synthetic activity is now sufficiently supported and results in the appearance of several secretory substances in the maternal circulation (e.g., human chorionic gonadotrophin and placental lactogen). Some of these substances promote postprandial hyperglycemia, increased fasting levels of free fatty acids, triglycerides and cholesterol, fat deposition, maternal intravascular volume expansion and relative refractoriness to vasoactive agents. These maternal adaptations increase substrate availability and steadiness of nutrient delivery to the placenta and are permissive for ongoing placental development.[10] Several paracrine signaling substances also appear in the placenta (e.g., nitric oxide, endothelin) and active cellular transport systems for major nutrient classes (glucose, aminoacids, and fatty acids) differentiate. Initiation of fetal cardiac activity allows for the active distribution of nutrients between fetus and placenta and completes the functionality of the feto-placental unit.[11] Ongoing development in the maternal and fetal compartments results in the formation of the villous trophoblast that consists of a maternal microvillous and fetal basal layer and is the primary site of exchange. The efficiency of maternal–fetal exchange depends on four principal factors: (1) the thickness that has to be traversed by diffusible substances; (2) the vascular throughput from the maternal and fetal circulations; (3) the surface area available for exchange; and (4) the elaboration of active transport mechanisms.

By the 16th week the villous trophoblast has progressively thinned down to 4 μm providing little resistance to diffusion. Vascular throughput through the placenta increases in both vascular compartments. Extravillous cytotrophoblast infiltration of the maternal spiral arteries results in progressive loss of the musculoelastic media, first in the decidual, then in the myometrial portion of these vessels.[12] This process is paralleled in the fetal compartment by continuous villous vascular branching.[13] Significant reduction in vascular resistance and a rapid increase in the exchange area are achieved by 26 weeks and then continue at a slower rate towards term. Through concurrent increases in fetal cardiac output, villous blood flow increases exponentially through the third trimester.[9,11] Under normal circumstances in the term placenta up to 600 ml/min of maternal cardiac output are delivered to an exchange area of up to 12 m^2. In the fetal compartment this is matched with a blood flow volume of 200–300 ml/Kg/min throughout gestation.[9,14,15] This magnitude of maternal blood flow is necessary since maintenance of placental function is energy intensive and consumes as much as 40% of O_2 and 70% of glucose supplied to the uterus.[16–18] Perfusion matching between the maternal and fetal compartments is further modulated and optimized through placental autoregulation, which is probably mediated through local paracrine factors such as nitric oxide (NO), endothelin, red blood cell (RBC) adenosine or cyclic guanosine monophoshate and fetal atrial natriuretic peptide (ANP). Optimal fetal growth and development is achieved when nutrient and oxygen delivery is sufficient to allow ideal fetal substrate utilization. This is only possible when the magnitude of maternal nutrient and oxygen delivery to the uterus exceeds placental demands leaving sufficient surplus for the fetus and when perfusion matching between the maternal and fetal compartments is optimized through placental autoregulation. While these developments significantly enhance the efficiency of exchange for diffusible substances other substances such as glucose, amino acids, and fatty acids that cannot efficiently pass this bilayer by simple diffusion require additional elaboration of active transport mechanisms.

Transplacental transport systems optimize the transfer of glucose, amino acids, and fatty acids.[19–21] Transmembrane ion pumps such as the Na/H^+ pump also develop, maintaining cellular homeostasis and normal cellular function.[22] Each of the nutrient classes has different roles in the fetus. Glucose is the

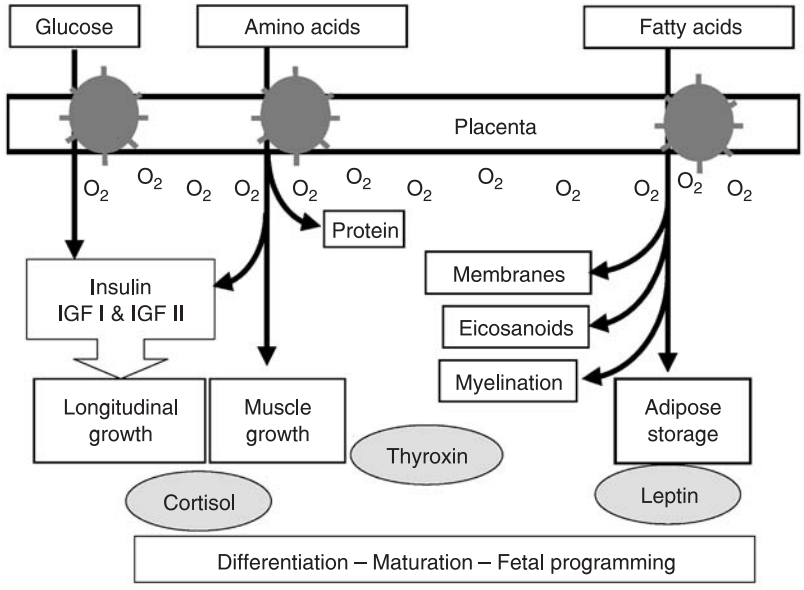

Figure 90.2 In the presence of adequate oxygenation, normal functioning of transplacental transport mechanisms for glucose, amino acids and fatty acids ensure availability of substrate for the fetus. Glucose and amino acids are the main stimulants of the insulin, IGF growth axis and stimulate longitudinal fetal growth. In addition, amino acids are utilized for protein synthesis and contribute to muscle bulk. Fatty acids have roles at many levels serving as precursors for eicosanoids and structural components of cell membranes and myelin sheaths. In the third trimester accumulation of adipose stores provides a reservoir for essential fatty acids. Endocrine axes – including hormones such as cortisol, thyroxin and leptin – modulate fetal maturation and differentiation according to substrate availability and may have significant impacts on adult life through fetal programming.

primary oxidative fuel while amino acids are incorporated into proteins. Fetal glucose and amino acids are the primary stimulants of insulin-like growth factors (IGF) I and II, and therefore stimulate longitudinal growth and differentiation.[23] Amino acids as major contributors to protein synthesis and are also laid down as muscle bulk.[23] Fatty acids are precursors for bioactive compounds including prostaglandins, thromoboxanes, leukotrienes and are also necessary for maintenance of cell membrane fluidity and permeability. In addition, long chain polyunsaturated fatty acids such as arachidionic and docosahexanoic acids are essential for normal brain and retinal development. Leptin coregulates transplacental amino acid and fatty acid transport and thereby modulates fetal body fat content and proportions.[24,25] With advancing gestation the magnitude and efficiency of transfer of these substances increases significantly to provide for placental and fetal growth requirements (Figure 90.2).

Concurrent development of the fetal circulation as a conduit for nutrient and waste delivery is an important cofactor in the fetal growth process. With establishment of a functional circulation, nutrient- and oxygen-rich blood from the primitive villous circulation enters the fetus via the umbilical vein. The arrangement of the fetal circulation allows further preferential streaming of these nutrients. The ductus venosus is the first vascular conduit encountered. Through modulations in shunting through the ductus venosus, 68–82% of umbilical venous blood continues to the liver, while the remainder is distributed to the heart.[26] Differential directionality of blood streams entering the right atrium ensures that nutrient rich blood is distributed to the left ventricle, myocardium, and brain, while low-nutrient venous return is distributed to the placenta for re-oxygenation and nutrient and waste exchange.[27] In addition to this overall distribution of left and right-sided cardiac output, several organs can modify local blood flow to meet oxygen and nutrient demands by autoregulation.[28]

With achievement of these milestones the prerequisites for normal placental and fetal growth are met. The metabolic and vascular status of the mother promotes a steady and enhanced nutrient delivery to the uterus and placental transport mechanisms allow for efficient bidirectional exchange of nutrient and waste. Under these circumstances placental and fetal growth remain closely related throughout gestation.[29] Their growth process across the three trimesters is characterized by sequential cellular hyperplasia, hyperplasia plus hypertrophy, and lastly hypertrophy alone. Placental growth follows a sigmoid curve that plateaus in midgestation preceding exponential third trimester growth of the fetus.[30,31]

During this exponential fetal growth phase of 1.5% per day initial weight gain is due to longitudinal growth and muscle bulk and therefore correlates with glucose and amino acid transport. Throughout gestation essential fatty acids are deposited in the developing brain and retina and account for up to 50% of dry brain weight.[32] After 20 weeks' gestation a notable increase in fatty acid transport and utilization initiate the deposition of significant fetal adipose tissue. From 24 weeks onward exponential fetal growth and

adipose tissue deposition coincide with increasing conversion of glucose into fat, as well as increased utilization of fatty acids.[32,33] From 32 weeks to term fat stores increase from 3.2% of fetal body weight to 16% accounting for the significant reduction in body water content.[34,35] Throughout gestation, relative serum concentrations of free fatty acids remain related to maternal dietary intake. However, enhanced transplacental transport of essential polyunsaturated fatty acids and especially their storage in adipose tissue occurs during the period of exponential fetal growth. Therefore third trimester increase in fetal size is characterized by longitudinal growth accompanied by accumulation of essential body stores in preparation for extrauterine life.

Mechanisms of placental insufficiency

The mechanisms by which various diseases affect placental function are the subject of much inquiry. In maternal hypertensive disorders, increased syncytial knot formation indicates premature placental aging and apoptosis. Occlusive vasculopathy affects both the maternal and fetal circulatory compartments of the placenta, and is most pronounced in antiphospholipid syndromes. Fetal causes may exert their effects on growth at multiple levels. Placental causes may result in decreased placental blood flow and/or altered transport mechanisms with resultant abnormal placental cellular homeostasis.

The majority of IUGR pregnancies are the result of conditions that interfere with placental vascular development.[36] Depending on the gestational age and on the extent of interference with placental development, various clinical scenarios may occur within the maternal, placental, and fetal compartments. If interference with angiogenesis occurs early in the first trimester, successful placental adherence is unlikely to transpire and will likely result in miscarriage. If sufficient supply to the placenta can be established and maintained despite suboptimal vascular development, further placental differentiation is possible. However, suboptimal maternal pregnancy adaptation and deficient nutrient delivery pose limitations to placental metabolic and synthetic activity, which ultimately interfere with the differentiation of endocrine feedback loops and active transport mechanisms. If the trophoblast invasion remains confined to the decidual portion of the myometrium maternal spiral and radial arteries fail to undergo the physiologic transformation into low resistance vessels.[37,38] Altered expression of vasoactive substances may increase vascular reactivity, and if hypoxia-stimulated angiogenesis cannot overcome these challenges, placental autoregulation becomes deficient. Eventually loss of this placental autoregulation promotes vascular occlusion, infarction and permanent structural damage.[39] Maternal placental floor infarcts, fetal villous obliteration and fibrosis both increase placental blood flow resistance, producing maternal–fetal placental perfusion mismatch that decreases the effective exchange area.[39–42] With progressive vascular occlusion feto-placental flow resistance is increased throughout the vascular bed and eventually the metabolically active placental mass is reduced. If adaptive mechanisms permit ongoing fetal survival early onset growth restriction with its many fetal manifestations develops.

The balance of compensatory and decompensatory responses determines the spectrum and degree of fetal manifestations in various organ systems. If compensatory mechanisms are unsuccessful, permanent fetal damage, or stillbirth results. With successful compensation, the consequences of nutrient shortage may remain largely subclinical, only to be unmasked through the restrictive effect on exponential fetal growth in the second to third trimester. In these cases, vascular manifestations may be less pronounced and physical characteristics more apparent. A decrease in adipose tissue or abnormal body proportions at birth may be the only indication that placental insufficiency occurred. In addition, a sizeable proportion of subtle third-trimester IUGR neonates may escape detection, particularly if population based, rather than customized, weight references are used.[43] An appreciation of the multiple manifestations of placental insufficiency provides the basis for the development of a uniform diagnostic approach to fetuses with suspected IUGR.

Fetal metabolic responses

In the setting of mild placental insufficiency, placental glucose and oxygen utilization initially remains unaffected, while fetal demands have to be met by increased fractional extraction. Only when uterine oxygen delivery falls below a critical value (0.6 mmol/min/kg fetal body weight in sheep) is fetal oxygen uptake and glucose transfer reduced.[44] When the levels of glucose transferred to the fetus fall, hypoglycemia ensues which results in a blunting of pancreatic insulin responses and allows gluconeogenesis from hepatic glycogen stores to begin.[45–48] A proportion of fetal glucose and lactate is then redirected to the placenta for nutrition. Since fetal hepatic glycogen stores are minimal, persistent, or progressive nutrient scarcity results in worsening fetal hypoglycemia. Subsequently, the ability to maintain fetal oxidative metabolism and placental nutrition becomes limited.

At this point, the downregulation of active placental transport mechanisms and the fetal need to recruit other energy sources, result in widespread metabolic responses. Limitation of amino acid transfer and breakdown of endogenous muscle protein to obtain gluconeogenic amino acids results in depletion of branched chain and other essential amino acids.[49–51]

Simultaneously, lactate accumulates due to the limited capacity for oxidative metabolism. The placental transfer capacity for fatty acids remains unaltered, unless there is a considerable loss of placental substance. However, despite maintaining the ability to transfer fatty acids, the selectivity of the transport mechanisms, especially for essential fatty acids, may decline. In the fetal circulation, free fatty acid and triglyceride levels increase secondary to reduced fetal utilization, which results in a failure to accumulate adipose stores. In this setting of advanced malnutrition, the liver metabolizes the majority of accumulating lactate. However, the fetal brain and heart can switch their primary nutrient source from glucose to lactate and ketones[52] – cardiac metabolism has the capacity to remove up to 80% of the circulating lactate.[53,54] Acid–base balance can be maintained as long as acid production is met by sufficient buffering capacity of fetal hemoglobin and a matching removal rate by these organs.

These increasing degrees of metabolic compromise have been documented through cordocentesis in human fetuses. Hypoglycemia and hypoxemia with decreased levels of essential amino acids occurs first. As the placental dysfunction worsens, progressive hypoxemia and increasing lactate production are exponentially correlated to the degree of acidemia. Overt hypoaminoacidemia, hypercapnia, hyperlacticemia, and triglyceridemia accompany the development of acidemia.[51,55–57]

Amniotic fluid elevation of the glycine/valine ratio and ammonia levels are additional indicators of this state of protein energy malnutrition (Table 90.1).[58,59] This degree of metabolic deterioration is associated with elevated transaminases as evidence of hepatic dysfunction, and may be precipitated by a significant decline of hepatic blood flow as a result of excessive shunting at the level of the ductus venosus.[60,61] Fetuses that manifest growth restriction early in gestation are more likely to have greater and broader metabolic derangements as compared to fetuses that manifest growth restriction in the third trimester which are more likely to have less severe metabolic and acid–base disturbance and only subtle changes in lipid metabolism.[62]

Fetal endocrine responses

The immediate effect of decreased fetal glucose and amino acid levels is the downregulation of the principal endocrine growth axis involving Insulin, IGF I, IGF II, and transforming factor beta.[63,64] This may be further exacerbated by pancreatic cellular dysfunction that is evident through a decreased insulin/glucose ratio and impaired fetal glucose tolerance.[51,65] Elevations in serum glucagon and stimulation of the fetal adrenal axis promote the mobilization of hepatic glycogen stores and peripheral gluconeogenesis.[66] Corticotropin releasing hormone (CRH), Adreonocorticotrophic hormone (ACTH) and cortisol levels are significantly elevated relating both to the level of hypoglycemia and the degree of placental vascular compromise.[51,67,68] However, elevations of cortisol downregulate IGF I activity and may therefore have additional negative impacts on linear growth as well as the potential to limit the capacity for postpartum catch-up growth.[69,70] In addition to the glucocorticoid axis, significant elevations of adrenaline and noradrenaline levels are also found in IUGR fetuses, while aldosterone levels appear unchanged.[71–73]

Disturbances at all stages of thyroid function have been documented in IUGR fetuses and correlate with the degree of hypoxemia.[74,75] Glandular dysfunction, as denoted by low levels of thyroxine and T3 despite elevated thyroid stimulating hormone (TSH) levels,

Table 90.1 Summary of metabolic responses to placental insufficiency

Substrate	Change
Glucose	Decreased proportional to the degree of fetal hypoxemia
Amino acids	Significant decrease in branched-chain amino acids (valine, leucine, isoleucine) as well as lysine and serine. In contrast hydroxyproline is elevated.The decrease in essential amino acids is proportional to the degree of hypoxemia
	Elevated amniotic fluid glycine to valine ratio
	Elevations in amniotic fluid ammonia with a significant positive correlation to the ponderal index
Fatty acids and triglycerides	Decrease in long-chain polyunsaturated fatty acids (docosahexanoic and arachidionic acid). Decrease in overall fatty acid transfer only with significant loss of placental substance
	Hypertriglyceridemia due to decreased utilization
	Lower cholesterol esters
Oxygen and CO_2	Degree of hypoxemia proportional to villous damage and correlates significantly with hypercapnia, acidemia, hypoglycemia and hyperlacticemia

may develop. In other cases, central production of TSH may be responsible for fetal hypothyroidism.[76] Finally, downregulation of thyroid hormone receptors may limit the biologic activity of circulating thyroid hormones in specific target tissues such as the developing brain.[77]

IUGR fetuses also show evidence of disturbed endocrine regulation of bone formation. Serum levels of active vitamin D and osteocalcin are appreciably decreased and may be responsible for decreased bone mineralization as well as decreased bone growth.[78,79]

Hematologic responses

Erythropoietin release and stimulation of RBC production, through both medullary and extramedullary sites, is triggered by fetal hypoxemia and results in polycythemia.[80–83] Extramedullary hematopoiesis may be physiologic until 28 weeks, but can occur in older fetuses by being induced by prolonged tissue hypoxemia and/or acidosis. Extramedullary sites have larger capillary fenestrations that permit the escape of large nucleated red blood cells (NRBC). Thus, elevated NRBC counts correlate with metabolic and cardiovascular status and are independent markers for poor perinatal outcome.[84–87] With advancing compromise complex hematologic abnormalities suggest dysfunctional erythropoiesis. Fetal anemia despite increased NRBC release in conjunction with an overt decrease in red cell progenitors could reflect downregulation of pro-erythropoietic cytokines, Vitamin B12, and ferritin deficiency or a combination of these.[88–91]

Coinciding with the abnormalities in red cell indices, platelet counts also decrease. Although platelet-activating factor is inhibited,[92] abnormal villous vasculature as indicated by umbilical artery absence or reversal of end-diastolic velocities (AREDV) may pose an overwhelming stimulus for placental platelet activation and aggregation.[93] Under these circumstances the incidence of thrombocytopenia increases 10-fold.[94] As the anemia and hypoxemia progress, they become independent risk factors for declining platelet counts.[95] Elevation of whole blood viscosity,[96,97] decrease in RBC membrane fluidity,[98] and platelet aggregation may be important cofactors for accelerating placental vascular occlusion and progressive dysfunction.

IUGR fetuses also show evidence of immune dysfunction at the cellular and humoral level. Decreases in immunoglobulin and absolute B-cell counts have long been recognized.[99] Reduction in total white blood cell counts and neutrophil, monocyte, and lymphocyte subpopulations occur.[100] Selective suppression of T-helper and cytotoxic T-cells has been observed.[101] The extent of these abnormalities is related to the degree of acidemia and can explain the greater susceptibility to infection these fetuses experience as neonates.

Fetal vascular responses

Doppler ultrasound allows the assessment of vascular effects of placental dysfunction in the maternal (uterine arteries) and fetal (umbilical arteries) compartments. The presence of an early diastolic notch in the uterine arteries at 12–14 weeks is the earliest evidence of delayed trophoblast invasion of the maternal spiral arteries.[102] When the 'notching' persists beyond 24 weeks of gestation, poor trophoblast invasion is almost certain.[38] These findings represent persistent elevated blood flow resistance in the maternal compartment, thus jeopardizing uterine perfusion. In the fetal circulation changes in blood flow are related to placental blood flow resistance, fetal oxygenation, organ autoregulation, and vascular reactivity. A reduction of umbilical venous blood flow volume may be the earliest Doppler sign of subtle decreases in fetal villous perfusion.[103] Abnormal villous branching or progressive villous vascular occlusion results in elevated blood flow resistance that is reflected in the umbilical artery waveform. A decrease of the umbilical artery end-diastolic velocity becomes apparent when approximately 30% of the fetal villous vasculature is abnormal.[104] AREDV can occur after 60–70% of the villous vascular tree is damaged.[105] Progression of Doppler abnormalities in the maternal compartment identifies patients at risk for pre-eclampsia, abruption and IUGR,[106] while abnormal umbilical flow indicate increased risk for hypoxemia and acidemia proportional to the severity of Doppler abnormality (Figures 90.3 and 90.4).[107,108]

Fetal circulatory responses to placental insufficiency can be subdivided into early and late responses corresponding to the degree of fetal compromise.[109,110] These circulatory responses are in part passive and due to the effects of placental afterload on the distribution of cardiac output and in part due to active organ autoregulation. Through modulations in ductus venosus shunting, umbilical venous blood increasingly bypasses the liver and is preferentially directed toward the heart. At the same time, elevated placental blood flow resistance increases right ventricular afterload. Because of the parallel arrangement of the fetal circulation, changes in cardiac afterload determine how this increased blood volume is distributed in the downstream circulation.[111–113] The result is a relative increase in left-sided cardiac output.[112,113] Consequently, blood (and nutrient) supply to the coronary circulation and brain increase. This redistribution of cardiac output can be documented by a decrease in the ratio of Doppler indices in cerebral and umbilical arteries (cerebroplacental Doppler ratio).[114] This redistribution is achieved in two principal ways. First of all, peripheral arterial vasoconstriction in the fetal trunk in conjunction with elevated placental blood flow resistance lead to elevations in thoracic and descending aortic Doppler resistance indices ('hind limb reflex') and therefore increased

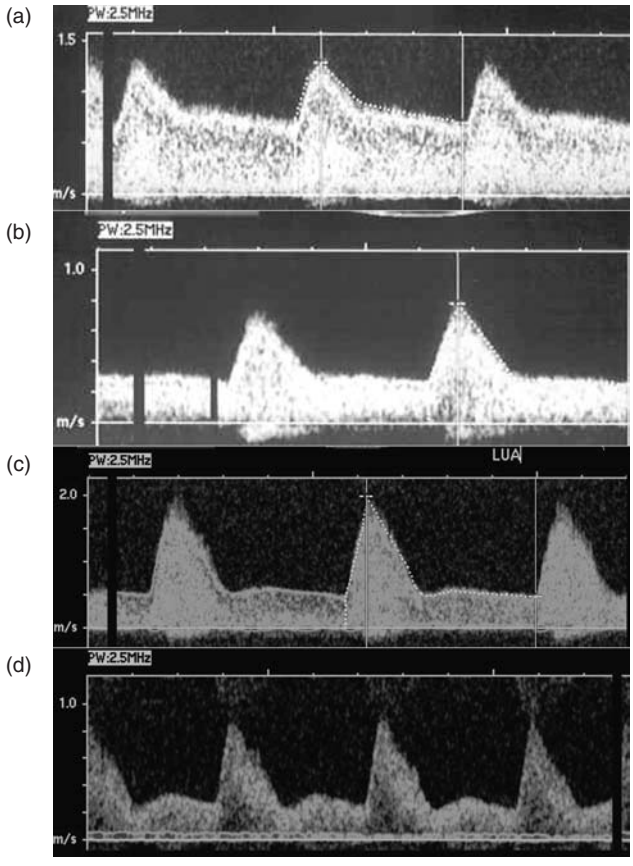

Figure 90.3 Flow velocity waveforms obtained from the uterine artery beyond 24 weeks gestation. In the first patient (a) high volume diastolic flow is established indicating successful trophoblast invasion. Elevated placental vascular resistance is associated with a decline in diastolic velocities and a subsequent rise in the Doppler index (b). Persistence of an early diastolic notch in the uterine artery flow velocity waveform is evidence of increased spiral artery blood flow resistance. Frequently, 'notching' is more subtle beyond 32 weeks (c) than in the late second or early third trimesters (d).

right ventricular afterload.[115,116] Next, cerebral blood flow may be actively enhanced during periods of perceived hypoxemia by a decrease in cerebral blood flow resistance with a subsequent decline in left ventricular afterload. This results in a decrease of the Doppler index in one of the cerebral vessels ('brain sparing) (Figure 90.5).[117,118] Fetuses that show these early Doppler changes are at increased risk for hypoxemia, while the pH is usually maintained in the normal range.[116,118,119] The shifting balance between right and left ventricular afterload accounts for the decline of the cerebroplacental Doppler index ratio and the measurable decline in end-diastolic velocities in the aortic isthmus.[120,121] At the same time, blood flow resistance in the peripheral pulmonary arteries,[122] celiac axis,[123] mesenteric vessels,[124,125] renal,[126,127] femoral and iliac arteries[128] may become elevated. Individual vital organs such as the adrenal glands[129] and spleen[130] may show evidence of enhanced blood flow. The overall impact of these changes is an improved distribution of well-oxygenated blood to the heart and brain with preferential streaming of descending aortic blood flow to the placenta for re-oxygenation (Table 90.2). These circulatory derangements are associated with elevations of endothelin, vasoactive intestinal peptide, vasopressin and renin–angiotensin levels.[131–133] A decrease of the thromboxane to prostacyclin ratio provides evidence of endothelial dysfunction, while elevations in NO production indicate a compensatory response.[134,135] It is likely that the degree of vascular reactivity is not only responsible for the high complication rate following invasive procedures, but also contributes to the clinical progression by impacting on blood flow resistance in many vascular beds.[136–139]

Late Doppler changes appear with further metabolic deterioration. Under these circumstances declining forward cardiac function, abnormal organ autoregulation, and ductus venosus shunting away from the liver occur. The shunting of flow away from the liver may compromise hepatic perfusion to a degree that interferes with organ function. In this condition, steep elevation in blood lactate and transaminases, as well as sudden compensatory hepatic artery vasodilatation have been reported.[60,61,140] When the increased metabolic demands of cardiac function cannot be met, myocardial dysfunction occurs. Declining cardiac function results in a failure to accommodate venous return and leads to increased venous Doppler indices indicating evidence of increased central venous pressure.[141] The venous flow velocity waveform is triphasic, and therefore more complex than the arterial waveform. It consists of systolic and diastolic peaks (the S- and D-waves) that are generated by the descent of the AV-ring during ventricular systole and passive diastolic ventricular filling, respectively. The sudden increase in right atrial pressure with atrial contraction in late diastole causes a variable amount of reverse flow producing a second trough after the D-wave (the a-wave) (Figure 90.6). In extreme cases, atrial pressure waves may be transmitted all the way back into the free umbilical vein resulting in pulsatile flow.

When venous Doppler indices become elevated, a significant rise in ANP occurs, probably as a compensatory mechanism to regulate blood volume.[142,143] When forward cardiac function declines significantly, coronary vasodilatation becomes exaggerated to recruit all the available coronary blood flow reserve.[144] If these adaptations fail to support myocardial nutrition sufficiently, the amount of cardiac dysfunction may become critical. Cardiac dilatation with holosystolic tricuspid regurgitation and loss of cerebral autoregulation (normalizing cerebral Doppler indices) are observed at this level of compromise and indicate loss of cardiovascular homeostasis.[145] Elevations of troponin I, S100B protein levels and transaminases provide evidence of cellular damage in the myocardium, brain, and liver.[146–148] An increased risk for necrotizing enterocolitis in survivors has been attributed to bowel injury secondary to chronic underperfusion.[149] If the

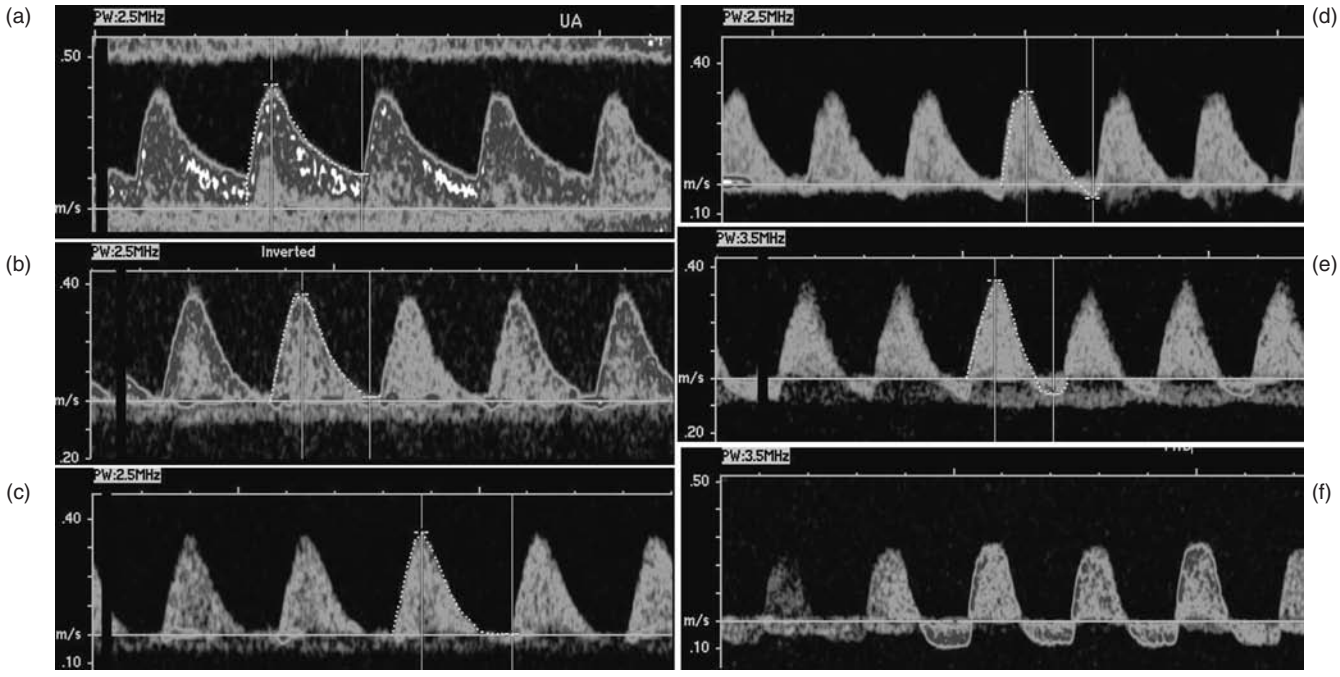

Figure 90.4 The normal umbilical artery flow velocity waveform has marked positive end-diastolic velocity that increases in proportion to systole towards term (a). Moderate abnormalities in the villous vascular structure raise the blood flow resistance and are associated with a decline in end-diastolic velocities (b). When a significant proportion of the villous vascular tree is abnormal (50–70%), end-diastolic velocities may be absent (c) or even reversed (d). Depending on the magnitude of placental blood flow resistance and the fetal cardiac function reversal of end-diastolic velocities may be minimal (d), moderate (e) or severe (f). In the latter case precordial venous flows were universally abnormal.

Table 90.2 Summary of fetal vascular responses to placental insufficiency

Response	Features	Doppler evidence
Hind limb reflex	Diversion of blood flow away from the carcass at the expense of the lower body. Achieved through increase in right ventricular afterload proximal to the umbilical arteries as well as increased blood flow resistance distally. In addition to centralization (see below) descending aortic blood flow is also preferentially distributed to the placenta	Elevation of blood flow resistance in the thoracic aorta and iliac artery
Centralization	A measurable shift in the relationship between right and left ventricular afterload, which results in redistribution of cardiac output in favor of the left ventricle (i.e., the heart and brain)	Decrease in the cerebroplacental Doppler ratio. Direct measurement of cardiac output. Reversal of end-diastolic velocity in the aortic isthmus. Inferred through absence or reversal of umbilical artery end-diastolic velocity
Brain sparing	Cerebral vasodilatation in response to perceived hypoxemia	Decrease in the carotid-, or middle cerebral artery Doppler index
Liver sparing	Preferential arterial blood supply to the fetal liver invoked when increased diversion of umbilical venous blood through the ductus venosus jeopardizes hepatic perfusion	Measured dilation of the ductus venosus with elevated Doppler index accompanied by a decreased hepatic artery Doppler index
Adrenal sparing	Enhanced adrenal perfusion is triggered as part of the fetal stress response to chronic or acute-on-chronic malnutrition	Decreased Doppler index in the adrenal artery flow velocity waveforms
Heart sparing	Marked augmentation of coronary blood flow in situations of acute on chronic hypoxemia that is achieved through upregulation of coronary vascular reserve and vasodilatation	Sudden ability to visualize and measure coronary blood flow in a setting of deteriorating venous Doppler indices in a premature IUGR fetus

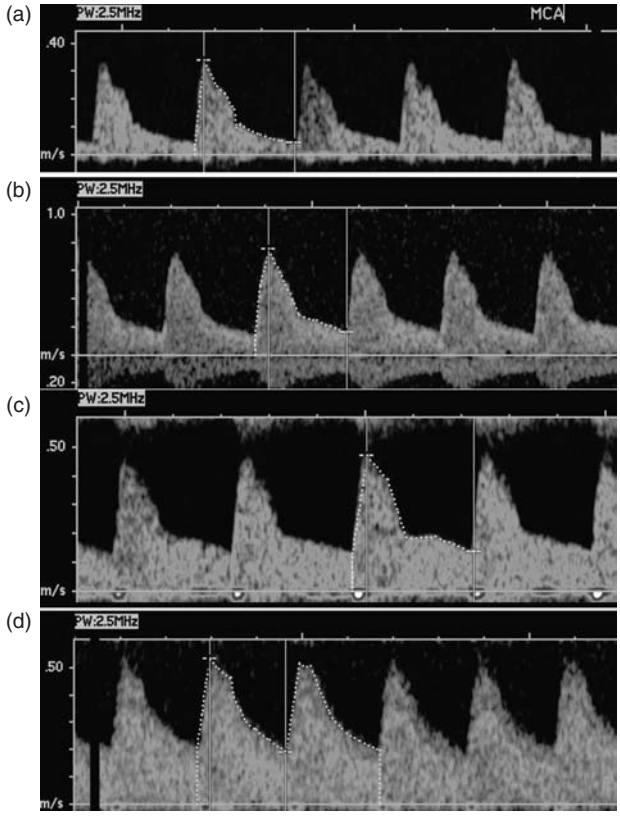

Figure 90.5 The normal middle cerebral artery flow pattern has relatively little diastolic flow (a). With elevation of placental blood flow resistance the changes in the middle cerebral artery waveform may be subtle, although the cerebroplacental ratio may become abnormal (b). With progressive placental dysfunction there may be increase in the diastolic velocity resulting in a decrease in the Doppler index (brain sparing, c). With marked brain sparing the systolic down slope of the waveform becomes smoother so that the waveform almost resembles that of the umbilical artery (d). The associated rise in the mean velocity results in a marked decline in the Doppler index.

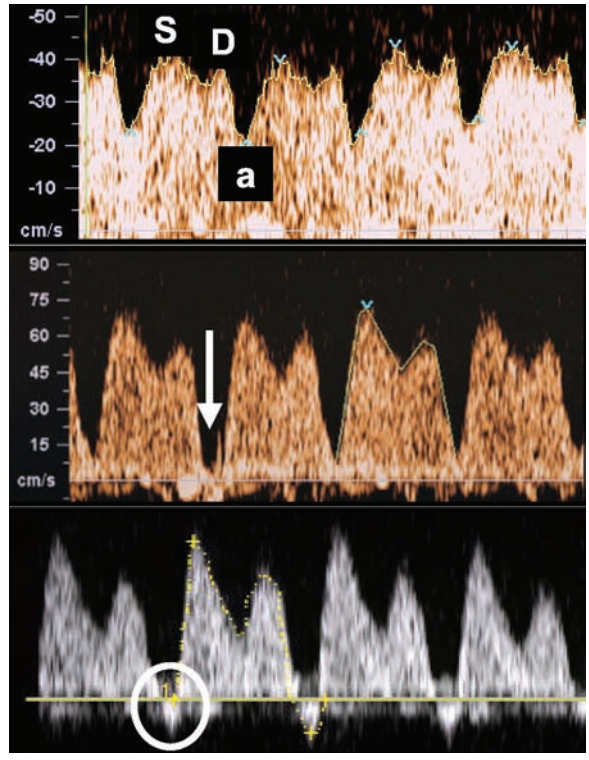

Figure 90.6 (Top panel) In the venous Doppler waveform systolic and diastolic peaks (the S- and D-waves) are generated by the descent of the AV-ring during ventricular systole and passive diastolic ventricular filling, respectively. A second late diastolic trough after the D-wave is the consequence of sharply increasing right atrial pressures during atrial systole (the a-wave). (Middle panel) With declining forward cardiac function forward velocity during atrial systole (arrow) and to a lesser degree during diastole decreased. This is associated with an increase in venous Doppler indices. (Bottom panel) When ductus venosus Doppler indices escalate, absence or reversal of forward flow during atrial systole (circle) may be observed as the most marked Doppler abnormality.

fetus remains undelivered, spontaneous late decelerations of the fetal heart rate and stillbirth ensue.[150,151]

Fetal biophysical responses

Normal fetal behavioral development proceeds sequentially with the appearance of movement, coupling, cycling of behavior, and finally the integration of movement patterns into stable behavioral states. Autonomic reflexes originating from the brainstem are superimposed on intrinsic cardiac activity and determine fetal heart rate characteristics. As gestation advances, the interaction between the nervous system and the heart becomes more refined and is modulated by ambient oxygen tension, signals from higher brain centers and the reticular activating system as well as peripheral sensory inputs. Successful maturation of these connections is reflected by decreasing baseline heart rate, increasing heart rate variability and variation, coupling of episodic accelerations with fetal movement and the superimposed impact of behavioral states. This level of central integration of fetal heart rate characteristics with fetal behavior is normally accomplished by 28 weeks of gestation.[152]

IUGR fetuses with chronic hypoxemia exhibit a delay in all aspects of central nervous system (CNS) maturation which probably relates to altered myelination as well as changes in central neurotransmitter availability.[153–157] The delayed development of behavioral milestones and their central integration with the fetal heart rate are primary determinants of lower short- and long-term variation (on computerized analysis), delayed decline in heart rate baseline and delayed development of heart rate reactivity in IUGR fetuses.[158–162] Despite the maturational delay of some aspects of CNS function, several centrally regulated responses to acid-base status are preserved.

Once fetal hypoxemia is perceived, a decline in global fetal activity precedes the loss of individual biophysical variables and is often also accompanied by a gradual decline in amniotic fluid volume.[163,164]

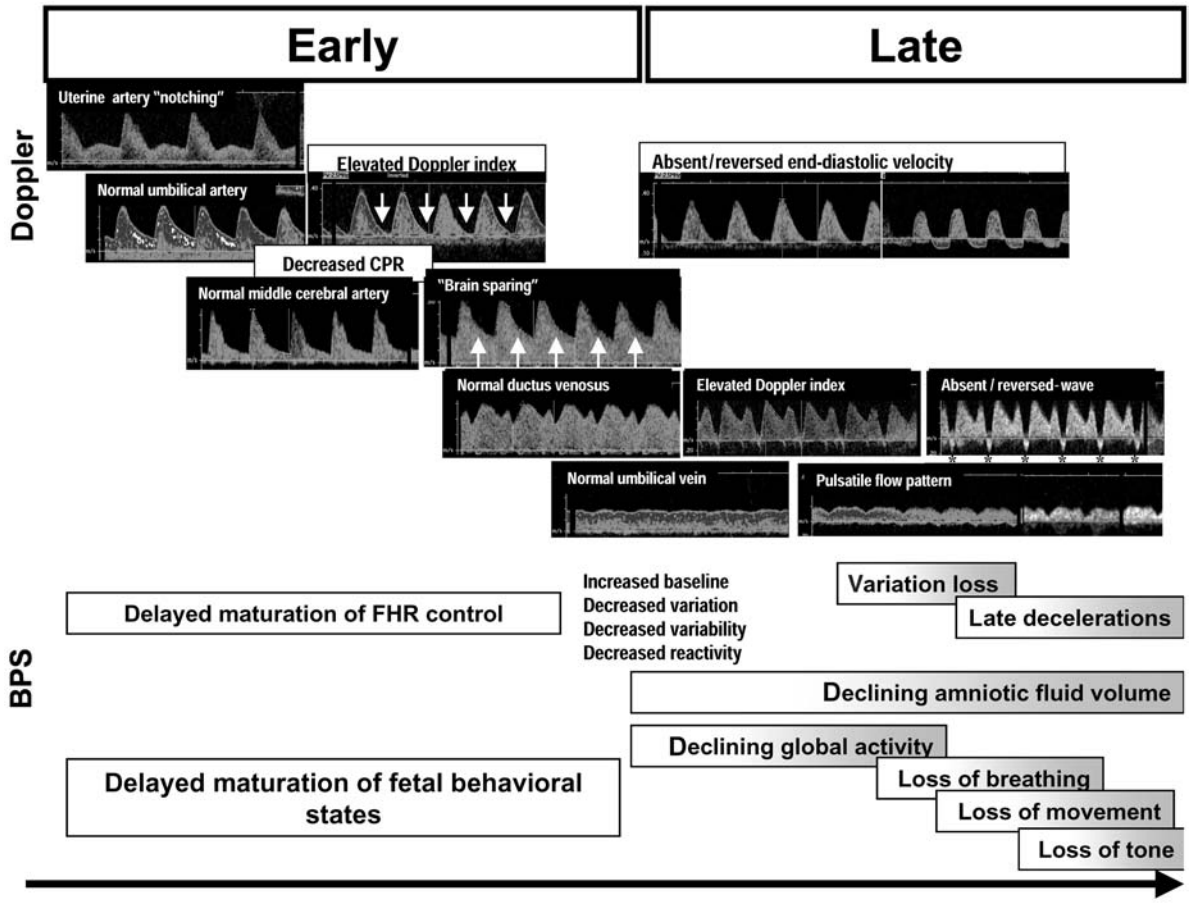

Figure 90.7 This figure summarizes the early and late responses to placental insufficiency. Doppler variables in the placental circulation precede abnormality in the cerebral circulation. Biophysical parameters (BPS) are still normal at this time and computerized analysis of fetal behavioral patterns is necessary to document a developmental delay. With progression to late responses venous Doppler abnormality in the fetal circulation is characteristic often preceding the sequential loss of fetal dynamic variables and frequently accompanying the decline in amniotic fluid volume. The * in the ductus venosus flow velocity waveform marks reversal of blood flow during atrial systole (a-wave). The decline in biophysical variables shows a reproducible relationship with acid base status. If adaptation mechanisms fail stillbirth ensues.

With increasing hypoxemia, fetal breathing movement ceases. Gross body movements and tone decrease further and are lost as acidemia deepens.[165] Abnormal fetal heart rate patterns are generally also observed at this time (Figure 90.7).[166,167] The effects of hypoxemia and vascular status on renal perfusion and fetal urine production affect amniotic fluid volume. As progressive deterioration of acid–base and vascular status occurs; a progressive decline in amniotic fluid volume is observed. The decline of these biophysical variables is determined by the central effects of hypoxemia/acidemia independent of the cardiovascular status.[168–171]

The biophysical profile score (BPS) as a composite score applies categorical cut-offs for fetal tone, breathing movement, gross body movement, amniotic fluid volume as well as traditional fetal heart rate analysis. Although a gradual decline in all of these parameters precedes an overtly abnormal BPS, analysis of the percentage change in these variables offers no advantage in the prediction of academia.[163] The five-component BPS shows a reliable and reproducible relationship with the fetal pH irrespective of the underlying pathology and gestational age.[166,172] Concurrent evaluation of fetal cardiovascular and biophysical variables indicates that Doppler deterioration precedes an abnormal BPS in the majority of IUGR fetuses.[164] When the relationship between the various testing modalities and fetal acid–base status is compared, biophysical parameters show a closer relationship with the pH while Doppler parameters have a wider variance (Figure 90.8).

An integrated approach to diagnosis and management of fetal growth restriction

The many etiologies and presentations of fetal growth restriction require a diagnostic approach that integrates information from several diagnostic modalities. Only a complete evaluation of the maternal history and the fetal, placental, and amniotic fluid characteristics can

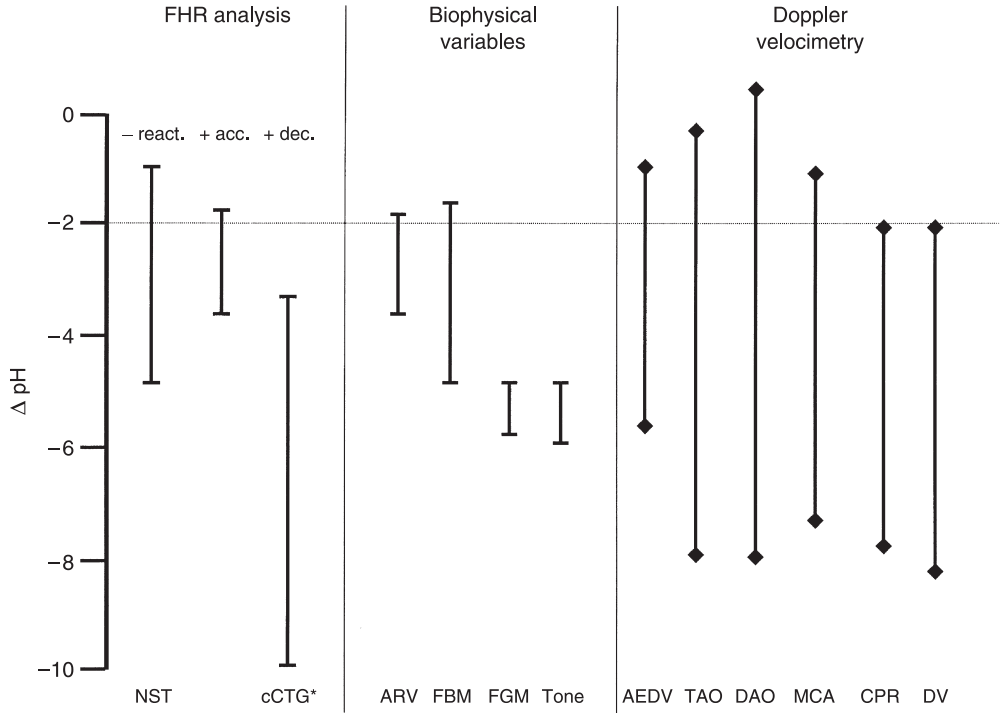

Figure 90.8 This figure displays a diagrammatic representation of pH deviation from the gestational age mean (ΔpH) with abnormal test results in various antenatal tests. These include fetal heart rate (FHR) analysis using traditional nonstress testing (NST, – react = nonreactive) and the computerized cardiotocogram (cCTG, +acc = accelerations present, +dec = obvious decelerations present). Biophysical variables (AFV, amniotic fluid volume; FBM, fetal body movement; FGM, fetal gross movement). The same relationships are expressed for umbilical artery absent end-diastolic velocity (AEDV) and deviation of the arterial or venous Doppler index > 2SD from the gestational age mean for the thoracic aorta (TAO), descending aorta (DAO) the middle cerebral artery (MCA), cerebroplacental ratio (CPR) and the ductus venosus (DV). Reproduced from Baschat[120] with permission.

direct an appropriate diagnostic workup and perinatal management. The accurate identification of fetuses that are truly at risk for adverse outcome requires exclusion of small fetuses that are normally grown and those in whom IUGR is due to an underlying condition not amenable to intervention. Conditions such as aneuploidy (especially trisomy 18, 13, and 21), skeletal dysplasia, nonaneuploid syndromes and viral infections should always be placed high on the list of differential diagnoses. Gray-scale ultrasound is the primary diagnostic tool allowing for a detailed fetal anatomic survey, biometric assessment of fetal growth, assessment of amniotic fluid volume and placental appearance. Although ultrasound provides important clues to the presence of IUGR the liability of preterm delivery and iatrogenic complications is large if the diagnosis and management is based only on biometry.[173] It is the complementary use of fetal biometry and Doppler assessment which creates the best available tool for the identification of small fetuses who are at risk for adverse outcome due to placental insufficiency.[174–177]

A detailed anatomic survey is mandatory in any fetus with suspected IUGR. Critical evaluation for aneuploidy markers such as echogenic bowel, nuchal thickening, abnormal hand positioning is necessary. Important anomalies that are associated with IUGR include gastroschisis, omphalocele, diaphragmatic hernia, and congenital heart defects. Assessment of the thoracic shape may suggest the presence of a skeletal dysplasia. Markers for viral infection are nonspecific, but may include echogenicity and calcification in organs such as the brain and liver. Occasionally, hydrops may be present.[178] The amniotic fluid volume should be assessed at the same time as the fetal anatomic survey. The regulation of amniotic fluid volume is complex, but by the third trimester primarily dependent on fetal urine production. Placental dysfunction and fetal hypoxemia both may cause fetal oliguria and consequently oligohydramnios. However, the accuracy of ultrasound in the assessment of amniotic fluid volume is poor[179] and serves as a poor screening tool for the prediction of IUGR and fetal acidosis.[180,181] Nonetheless, assessment of amniotic fluid volume by any method such as the four quadrant amniotic fluid index (AFI) and maximum vertical pocket), especially if performed serially, provides an important diagnostic as well as prognostic tool. In the setting of small fetal size, abundant amniotic fluid volume is an indicator of aneuploidy or fetal infection while normal or decreased amniotic fluid is more compatible with placental insufficiency.

The actual quantification of growth is based on fetal biometry. Since almost all fetal measurements change with gestation, an accurate assessment of gestational age is a prerequisite for the calculation of percentile

ranks of absolute measurements. An estimated date of confinement (EDC) is ideally based on a sure last menstrual period when the sonographic estimate of gestational age is within the predictive error (7 days in the first and 14 days in the second trimester, and 21 days in the third trimester). Once the EDC is set by this method or a first-trimester ultrasound, it should not be changed. Later adjustments to the EDC will interfere with the ability to diagnose fetal growth abnormalities. Once the EDC has been assigned, selection of appropriate reference ranges that are based on uncomplicated pregnancies delivered at term is of importance. Individualized reference ranges of growth potential that account for maternal, ethnic, and fetal variables provide the most accurate reference.[1,182] Once gestational age is assigned, the interpretation of the ultrasound examination is based on the fetal anatomic survey, amniotic fluid volume, percentile rank of fetal size measurements, the interval growth since the last study, and a functional assessment of the feto-placental unit with Doppler ultrasound.

Of all fetal biometric measurements the abdominal circumference (AC) is related to the liver size as a major indicator of fetal glycogen storage and therefore the single best measurement with the highest sensitivity and negative predictive value for the detection of IUGR.[183–185] Its sensitivity is further enhanced by serial measurements at least 14 days apart.[186] The most accurate AC is the smallest directly measured circumference obtained at the level of the hepatic vein between fetal respirations.[187] Using a reference range based on healthy women delivering appropriately nourished neonates at term, an AC <10th percentile for gestational age is consistent with IUGR. If cross-sectional population references including small, appropriately grown, preterm and term newborns are used the 2.5th percentile is more appropriate.[188] Compared to the AC, the biparietal diameter, head circumference (HC) and transverse cerebellar diameters are poor tools for the detection of IUGR. This is in part due to the inherent physiologic variation in skull shape[189] and the relative sparing of the head growth and therefore delayed manifestation of placental insufficiency.[190] Ratios of fetal measurements do not improve the detection of growth delay, but may be helpful pointers towards underlying aneuploidy.[191–193] Concurrent measurement of the HC, AC, and femur length allows calculation of the sonographically estimated fetal weight (SEFW). An SEFW below the 10th percentile for gestational age has a lower sensitivity than the AC (85% vs. 98%) but a higher positive predictive value (51% vs. 36%).[185]

The next step in the diagnostic assessment of the suspected IUGR fetus is the evaluation of feto-placental vascular function. Randomized trials and meta-analyses confirm that the use of umbilical artery Doppler in suspected IUGR results in a significant reduction in perinatal mortality and iatrogenic intervention since documentation of placental vascular insufficiency effectively separates constitutionally small fetuses from those in need for surveillance and possible intervention.[194–196] A more complete assessment of feto-placental vascular status can be achieved if the uterine and middle cerebral arteries are examined in addition to the umbilical artery. For qualitative waveform analysis presence of uterine artery notching and umbilical artery end-diastolic velocity (positive, absent, or reversed) should be noted. For clinical Doppler waveform analysis angle independent indices are used. Of these, the pulsatility index offers the advantage of a smaller measurement error, narrower reference limits and the possibility for ongoing numerical analysis even when end-diastolic velocity is absent.[197,198] In fetuses presenting with IUGR due to placental insufficiency before 34 weeks' gestation the umbilical artery Doppler waveform is frequently abnormal. Beyond this gestational age the umbilical artery Doppler waveform may be normal. At the same time cerebral artery Doppler responses to placental insufficiency still occur.[176,199] Therefore the middle cerebral–umbilical artery Doppler ratio (cerebroplacental ratio) may be abnormal in fetuses with mild placental disease.[174,200] Beyond 34 weeks' gestation a decrease in the middle cerebral artery Doppler index or the cerebroplacental ratio should therefore heighten suspicion for IUGR even if the umbilical artery blood flow is normal (Figure 90.9).

Once the suspicion of IUGR is confirmed, fetal karyotyping should be offered and further specialized tests such as maternal serology (TORCH), thrombophilia studies, or amniotic fluid viral DNA testing, may be indicated. Once nontreatable underlying fetal conditions and chromosome abnormalities have been ruled out further antenatal surveillance should be instituted based on the severity of the maternal and/or fetal condition.

An integrated approach to surveillance in fetal growth restriction

Antenatal surveillance in IUGR gestations aims to provide longitudinal assessment that is tailored to the severity of the fetal condition and is predictive of critical outcomes. Since there are no effective therapies for *in utero* treatment of IUGR, management options include increasing the frequency of monitoring and delivery when fetal testing suggests that the intrauterine risks exceed neonatal risks of adverse outcomes. It is increasingly becoming apparent that IUGR fetuses are at particularly high risk for prematurity related complications and adverse outcomes, especially below 32 weeks' gestation.[4,201] Therefore the delivery threshold is highest between viability and 32 weeks, placing the greatest demands on the precision of fetal assessment. This requirement for detailed assessment

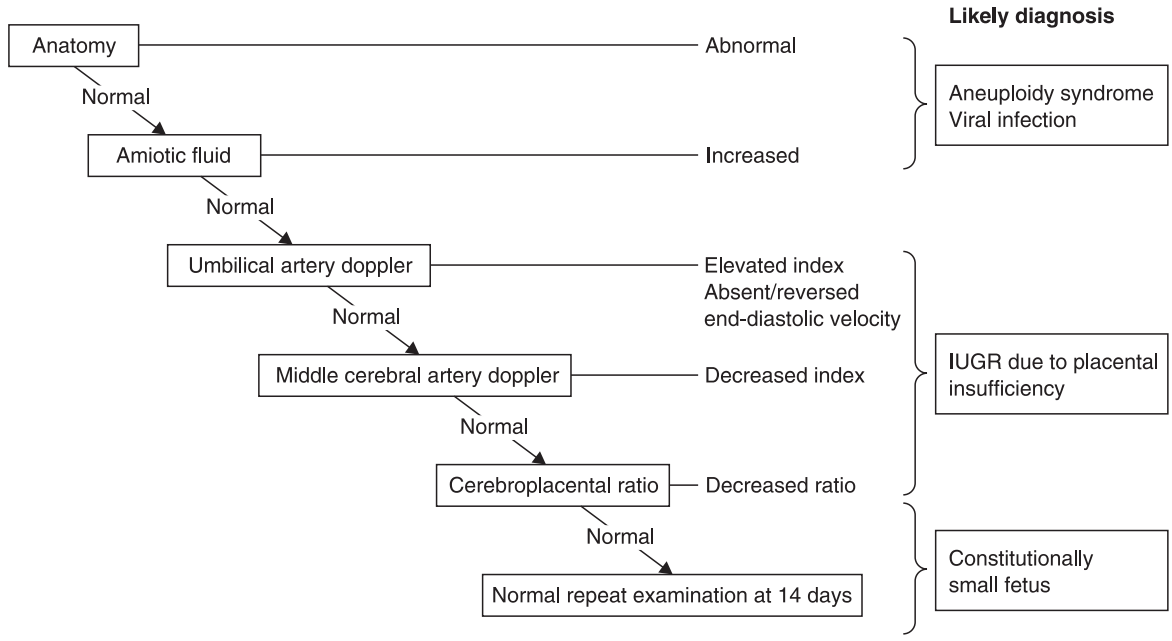

Figure 90.9 This figure displays a decision tree following the evaluation of fetal anatomy, amniotic fluid volume, umbilical and middle cerebral artery Doppler. The most likely clinical diagnosis is presented on the right hand side. A high index of suspicion for aneuploidy, viral and nonaneuploid syndrome needs to be maintained. IUGR, intrauterine growth restriction.

is offset by the need for practicability in order to facilitate generalized application. Utilizing knowledge about the fetal responses to placental insufficiency and the limitations of antenatal testing modalities helps formulate an appropriate monitoring approach to IUGR fetuses at highest risk. In this context several principles are important.

In pregnancies that present with IUGR prior to 34 weeks' gestation, umbilical artery blood flow changes usually precede other cardiovascular responses.[200,202] Once the diagnosis of IUGR has been made by biometry and Doppler evaluation, continuing surveillance for deterioration of fetal cardiovascular status requires examination of the cerebral circulation and the precordial veins. When brain sparing develops, venous Doppler indices are frequently normal and biophysical abnormalities are generally not clinically observed. Development of abnormal venous Doppler indices indicates an acceleration of the deterioration.[203,204] At this time, abnormalities in biophysical parameters become clinically apparent. However, since the BPS is a composite of five variables the overall result may deteriorate relatively late in the disease process.[164] When Doppler and biophysical parameters show abnormalities, the information gained through their concurrent evaluation is complementary and offers the best prediction of fetal status and outcome.[119]

Taking these principles into account, a surveillance approach to pregnancies with IUGR due to placental disease that combines Doppler ultrasound and biophysical profile scoring (integrated fetal testing) has been devised. The testing is always supplemented with maternal assessment of fetal movement ('kick counts'). Doppler examination includes evaluation of the umbilical artery, middle cerebral artery, ductus venosus, and free umbilical vein flow velocity waveform. The traditional nonstress test component of the BPS is supplemented by computerized fetal heart rate analysis. Monitoring frequencies are adjusted to the fetal condition. Before 28 weeks, fetuses with isolated elevation of the umbilical artery Doppler index are followed with weekly biophysical profile scoring and repeat Doppler every fortnight. If umbilical artery end-diastolic velocity disappears, MCA Doppler meets criteria for centralization or amniotic fluid volume declines all testing (Doppler and biophysical profile score) are repeated every 3–4 days. In patients with elevated ductus venous Doppler index with umbilical venous pulsations complete testing is repeated every 24 h (Figure 90.10).

The issue of optimal delivery timing for IUGR fetuses remains unresolved. In principle the decision for delivery always weighs fetal vs. neonatal intensive care unit (NICU) risks. Typically, decline in neonatal mortality is greatest between 24 and 28 weeks while morbidity declines progressively thereafter towards 32 weeks.[201] Perinatal mortality and morbidity is greatest among IUGR fetuses with abnormal venous Doppler indices irrespective of the umbilical artery Doppler waveform.[201,203] Therefore, basing delivery decision on the umbilical artery waveform alone appears no longer appropriate.[205] In preterm IUGR fetuses, we consider abnormal venous Doppler indices and/or and abnormal BPS as indicators for delivery. Beyond 34 weeks where the frequency of dramatically abnormal Doppler is lower reliance on BPS and obstetrical factors should guide delivery.

IUGR unlikely		
Normal AC, AC growth rate and HC/AC ratio UA, MCA Doppler, BPS and AFV normal	Asphyxia extremely rare Low risk for intrapartum distress	Deliver for obstetric, or maternal factors only, follow growth

IUGR		
AC<5th, low AC growth rate, high HC/AC ratio abnormal UA +/ or CPR; normal MCA and venous Doppler, BPS ≥ 8/10, AFV normal	Asphyxia extremely rare Increased risk for intrapartum distress	Deliver for obstetric, or maternal factors only, fortnightly Doppler Weekly BPS
With blood flow redistribution		
IUGR diagnosed based on above criteria, low MCA, normal venous Doppler, BPS ≥ 8/10, AFV normal	Hypoxemia possible, asphyxia rare Increased risk for intrapartum distress	Deliver for obstetric, or maternal factors only, weekly Doppler BPS 2 times per week
With significant blood flow redistribution		
UA A/REDV, normal venous Doppler, BPS ≥ 6/10, oligohydramnios	Hypoxemia common, acidemia or asphyxia possible Onset of fetal compromise	>34 weeks: deliver 32-34 weeks: consider delivery <32 weeks: antenatal steroids repeat all testing daily
With proven fetal compromise		
Significant redistribution present Increased DV pulsatility BPS ≥ 6/10, oligohydramnios	Hypoxemia common, acidemia or asphyxia likely	>32 weeks: deliver <32 weeks: admit, steroids, individualize testing daily vs. tid.
With fetal decompensation		
Compromise by above criteria Absent or reversed DV a-wave, pulsatile UV BPS < 6/10, oligohydramnios	Cardiovascular instability, metabolic compromise, stillbirth imminent, high perinatal mortality irrespective of intervention	Deliver at tertiary care center with the highest level of NICU care

Figure 90.10 The management algorithm for pregnancies complicated by fetal growth restriction is based on the ability to perform arterial and venous Doppler as well as a full five component biophysical profile score. AC, abdominal circumference; AFV, amniotic fluid volume; A/REDV, absent/reversed end-diastolic velocity; BPS, biophysical profile score; CPR, cerebroplacental ratio; DV, ductus venosus; HC, head circumference; MCA, middle cerebral artery; NST, nonstress test; NICU, neonatal intensive care unit; tid, three times daily, UA, umbilical artery.

Since the outlined surveillance approach requires multivessel Doppler as well as biophysical profile scoring it can only be performed at centers that are familiar with both techniques. Modifications of this surveillance protocol should address the limitations of such an approach. For example, the BPS alone offers little in the prediction of longitudinal progression. Thus, if biophysical profile scoring is the only surveillance tool, daily testing may be required to assure a good outcome.[206]

Further investigation and evaluation of nutritional, metabolic, endocrine, and hematologic responses at birth in growth restricted neonates and their relationship to fetal proportions, Doppler and behavioral parameters will refine our understanding of this condition. Neonatal management will become optimal when knowledge of the fetal status and an appreciation of the spectrum of fetal consequences of placental insufficiency are integrated to guide their evaluation and management. A uniform prenatal diagnostic standard and a comprehensive integrated management approach that bridges fetal and neonatal periods is most likely to impact on adult health focusing on the small fetus at risk and sparing normally developed babies from iatrogenic interventions.

91 The role of essential fatty acids and antioxidants in neurovascular development and complications of prematurity

K. Ghebremeskel, Y. Min, B. Thomas and M. A. Crawford

Introduction

Membrane integrity and function are dependent on the incorporation of appropriate amounts of arachidonic (20:4n-6, AA) and docosahexaenoic (22:6n-3, DHA) acids, and antioxidant protection. AA and DHA are highly unsaturated and therefore must be protected from peroxidative damage. There is an interdependence between membrane AA and DHA, and membrane-bound antioxidant enzymes. Optimum activity of the enzymes is dependent on the physical integrity of the membranes. At the same time, the membrane fatty acids require the antioxidant enzymes for protection. Paradoxically, it has also been shown that n-3 polyunsaturated fatty acids exert protective effects against injury caused by oxidative stress. In the very low birth weight baby, tissue maturation, structural integrity, function and protection are closely intertwined; hence, there is a need to consider both polyunsaturated fatty acids and antioxidants together.

Our proposition is that low AA and DHA, suboptimal antioxidant protection and the immature anatomy in an alien oxygen radical-generating environment predispose the very low birth weight babies to serious disorders often described as the complications of prematurity. This hypothesis of *synergistic insufficiency* brings together the concepts of free-radical damage and structural integrity, consistent with the proposition of Saugstad[1] that the various complications of prematurity are 'facets of one disease'.

Essential fatty acids

The term *essential fatty acids* originated from the discovery that absence of certain fatty acids, which are not synthesized *de novo* by animals, in the diet leads to clinical abnormalities. They are vital for reproduction, normal growth, development and function of all tissues. There are two families of essential fatty acids, namely, the n-3 and n-6 families. Linoleic (18:2n-6, LA) and α-linolenic (18:3n-3, ALA) acids are the parent compounds of the n-6 and n-3 families, respectively. By convention the formula for fatty acids is abbreviated as *X*:*Y*n-*M*. *X* refers to the number of carbon atoms, *Y* to the number of double bonds, and *M* the position of the first double bond counting from the terminal methyl (CH_3) group (Figure 91.1).

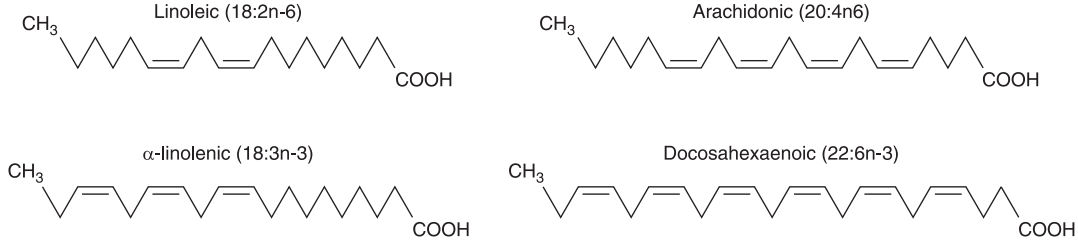

Figure 91.1 Structural formula of linoleic, α-linolenic, arachidonic and docosahexaenoic acids.

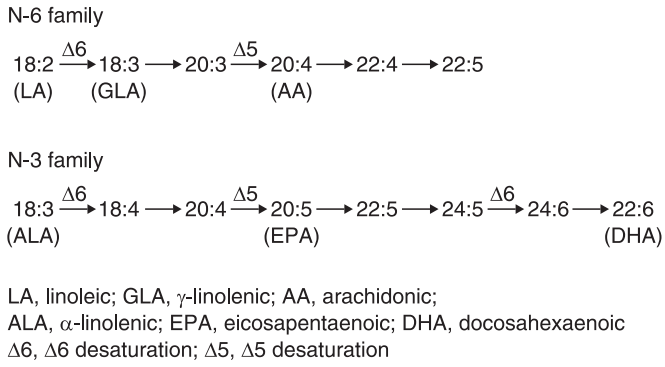

Figure 91.2 Metabolic pathway of the synthesis of n-6 and n-3 polyunsaturated fatty acids.

Animals cannot synthesize either LA or ALA. However, they can add double bonds and carbon atoms to LA and ALA. This metabolic process produces long-chain derivatives with 20 and 22 carbon atoms, and 3, 4, 5 and 6 double bonds (Figure 91.2). The two most important members of the n-6 and n-3 families in cell membrane, which are often regarded as essential, are AA and DHA.

Dietary sources of essential fatty acids

Fruits, seeds and vegetable oils such as sunflower, safflower, soybean, cottonseed and corn are the predominant source of LA.[2] ALA is a minor constituent of most vegetable oils except in linseed, soybean and rapeseed oil; it is a major fatty acid in green leafy vegetables.[3,4] Gamma-linolenic acid (18:3n-6, GLA) is found in evening primrose, borage and blackcurrant seed oils. AA is found in eggs, lean meat and offal such as liver, brain and entrails. It is also found in substantial proportions in tropical fish and shellfish.[5–7] Fish, shellfish and fish oils are the main source of eicosapentaenoic acid (20:5n-3, EPA) and DHA. Fish caught in Northern latitudes (> 30°N) have, on average, seven times as much n-3 fatty acids as n-6 fatty acids.[5,7]

Distribution in tissues and the brain

Long-chain fatty acids, both of the n-3 and n-6 families, are vital components of cell membrane lipids (Figure 91.3). AA is present in all biological membranes and represents up to 15% of the total fatty acids in polar phospholipids. DHA is more specifically present at very high levels in the retina, brain, testis and sperm.[3] In the cerebral gray matter, DHA makes up to one-third of the total fatty acid content of ethanolamine and serine phosphoglycerides.[8,9] Among subcellular fractions of brain tissue, the highest levels of DHA are found in synapotosomes, synaptic vesicles, mitochondria and microsomes where there is evidence of selective incorporation.[10] In the photoreceptor outer segments, the level of DHA is as high as 60% of total fatty acids.[11] White matter and its myelin fractions contain low levels of AA and DHA and high levels of saturated and monounsaturated fatty acids.[12]

Essentiality of n-3 and n-6 fatty acids

Essential fatty acids are required for the structure and function of membranes.[13–15] They are also converted to eicosanoids, which are regulators and coordinators of local multicellular function. n-6 fatty acids were recognized as essential over 60 years ago.[16,17] However, it is only in the last two decades that the essentiality of the n-3 fatty acid has been conclusively established. Although AA and DHA can be formed from LA and ALA as described above, △6 desaturase, the enzyme required for the first and last metabolic steps, is rate limiting. In some species such as the cat, the activity of this enzyme is too low to measure hence AA and DHA are essential fatty acids and must be provided in the diet.[18] Fat-free diets or those deficient in n-6 and n-3 polyunsaturated fatty acids produce reproductive failure, retarded growth and abnormal changes in many organs such as the skin, liver and kidney in many species including the human infant.[16,17,19,20]

In experimental animals, membrane structural alterations resulting from changes in the AA and DHA composition leads to loss of cellular integrity and functions.[21–23] Deficits of the essential n-3 fatty acids cause cerebral hemorrhage in chicks,[24] and learning and visual impairment in rats.[25–27] Polydipsia, visual impairment and abnormal electroretinogram are manifested in non-human primates deficient in n-3 fatty acids.[20,28]

In addition to their structural and functional properties, some fatty acids, namely, dihommo-γ-linolenic acid (20:3n-6, DHGLA), EPA and AA are precursors of hormone-like compounds known as eicosanoids. These are a complex group of highly biologically active compounds, which are involved in the control and regulation of blood flow, intraocular pressure, cell-mediated immunity and inflammation, renal function, insulin release and reproduction.[29] Recently, it has been demonstrated that DHA is the precursor of a novel brain protective messenger, 10,17S-docosatriene, which inhibits ischemia–reperfusion-mediated leukocyte infiltration and pro-inflammatory gene expression.[30]

Essential fatty acids and pregnancy

During pregnancy, there is a high demand for AA and DHA for the development of fetal brain and other vital tissues. Consequently, in the third trimester the accretion of total n-6 and n-3 fatty acids by the fetal brain increases progressively.[31,32] It is estimated that the fetus accumulates about 70 mg/day of long-chain n-3 fatty acids, primarily DHA, during the third trimester.[32,33] The fetus has the ability to synthesize AA and DHA

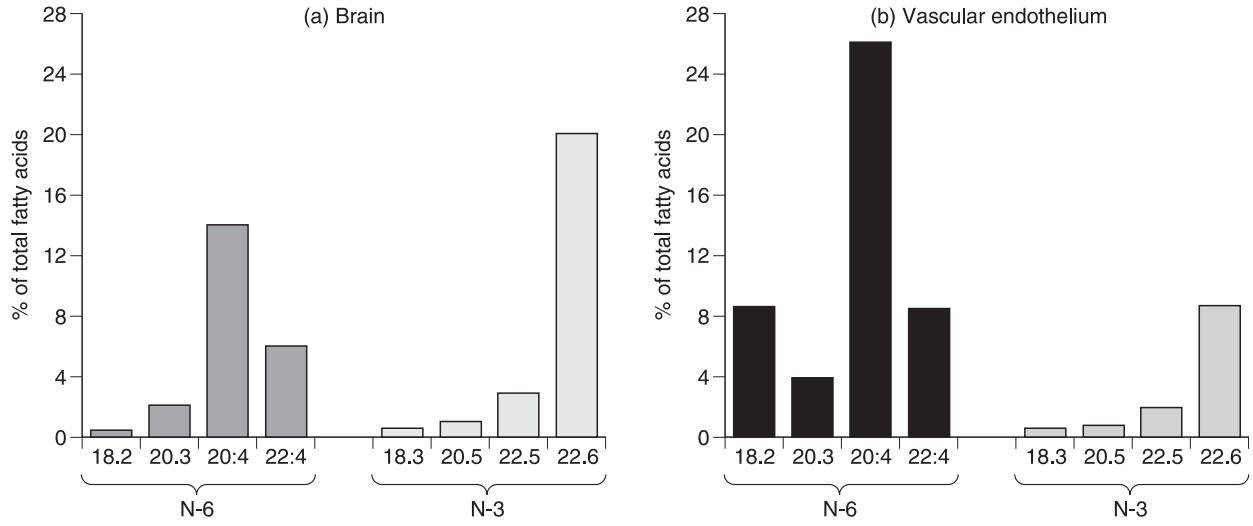

Figure 91.3 n-6 and n-3 fatty acid composition of the inner cell membrane phospholipid (ethanolamine phosphoglycerides) of the brain and vascular endothelium.

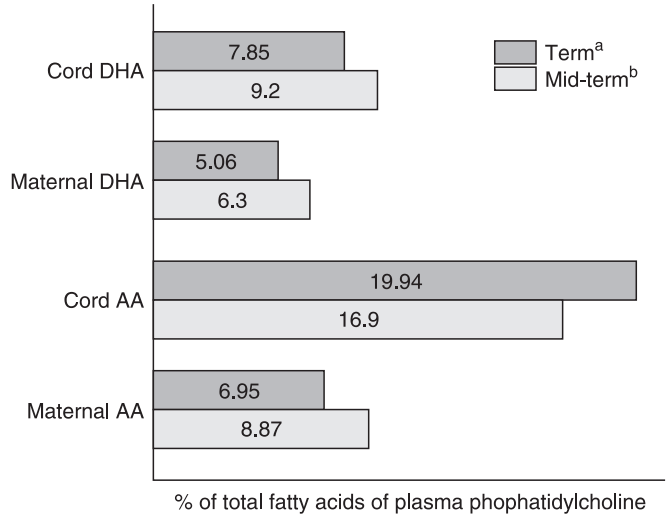
from their respective parent compounds LA and ALA.[34] However, the rate of synthesis is not fast enough to meet requirements and hence, these fatty acids are obtained from maternal circulation by placental selection and extraction. This selective transfer is reflected in a significant decrease in the blood level of AA and DHA in healthy pregnant women[35,36] and a concomitant increase in the fetus (Figure 91.4). Fish-eating populations with a raised intake of long-chain n-3 fatty acids have prolonged pregnancies and reduced incidence of both pregnancy-induced hypertension and preterm deliveries.[37] Maternal supplementation with n-3 fatty acids during pregnancy, and pregnancy and lactation are associated with cerebral maturation of the newborn[38] and mental development at 4 years of age,[39] respectively.



[a] Term data are from normal deliveries at 39–42 gestation weeks and birth weight >3.0 kg.
[b] Mid-term data are derived from mid-term elective abortion.

Figure 91.4 Maternal and fetal (cord blood) arachidonic (AA) and docosahexaenoic (DHA) acids in plasma choline phosphoglycerides at mid-term and term.

Essential fatty acids in the human neonates

Appropriately grown term babies of healthy mothers are born with high levels of AA and DHA due to placental enrichment. This selective placental transfer of AA and DHA from the mother to fetus would be reduced if the mothers have chronic disease such as diabetes[40–42] (Figure 91.5), impaired fatty acid metabolism or placental infarction. Babies born to mothers with marginal or low AA and DHA status because of insufficient intake prior to, and during, pregnancy will also be expected to have depressed levels of these essential fatty acids at birth.

Preterm and low birth weight babies are born with depressed levels of AA and DHA.[43–45] Our study on maternal and cord blood phosphoglycerides showed that low concentrations of AA and DHA were associated with low birth weight and gestational age, respectively, and low levels of AA and DHA, independently and together, were associated with reduced head circumference.[46,47] A parallel investigation of umbilical arteries over a wide birth weight range demonstrated that the triene/tetraene ratio (20:3n-9/20:4n-6), an index of essential fatty acid deficiency, and the 22:4n-6/22:5n-6 ratio, an index of DHA insufficiency, were abnormal in low birth weight babies.[43] In addition, it has been shown that intrauterine growth restriction is associated with changes in fetal–maternal polyunsaturated fatty acid relationship[48] and reduced levels of AA and DHA at birth.[49] Moreover, Zhang[50] has demonstrated that treatment with LA and ALA increases bi-parietal diameter and weight in the intrauterine-restricted fetus.

Subsequent to birth, in the human preterm infant, the plasma levels of AA decrease substantially, despite a threefold increase in its precursor LA

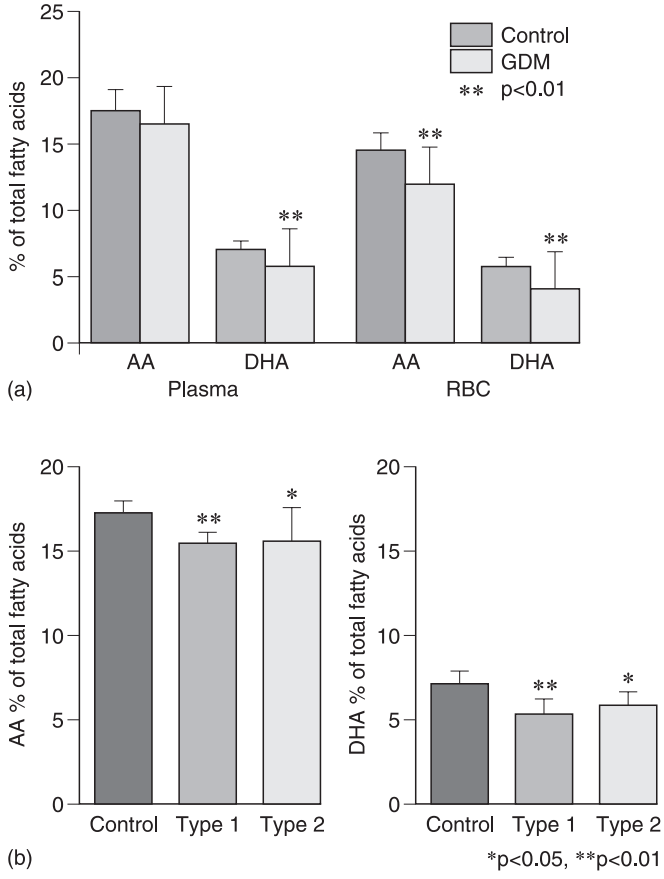


Figure 91.5 Neonates of diabetic mothers have reduced blood levels of arachidonic (AA) and docosahexaenoic (DHA) acids.

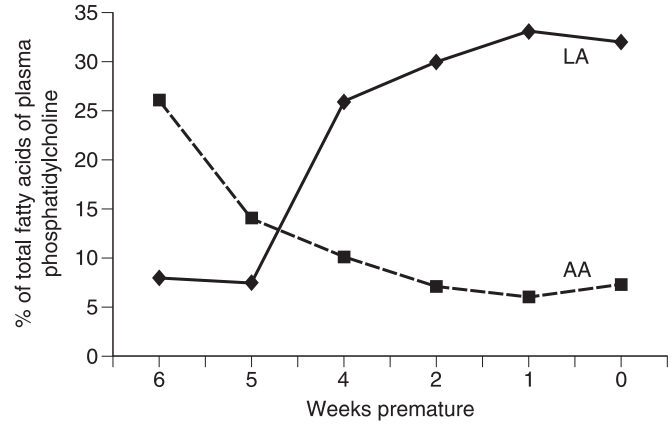

Figure 91.6 The diagram illustrates the scale and speed of loss of arachidonic acid (AA) from plasma choline phosphoglycerides of preterm babies between birth and the expected date of delivery (LA is the precursor of AA).

(Figure 91.6). A similar fall in DHA is also reported.[45,47] In preterm babies fed formula milk containing LA and ALA but devoid of AA and DHA, the plasma levels of AA and DHA decline by 47% and 23%, respectively, between birth and postnatal day 15.[51] This indicates that the rate of neonatal synthesis[52,53] is unable to meet the AA and DHA demand for growth and development.[54] Koletzko *et al.*[55] estimated that endogenous synthesis contributed only about 23% of total plasma AA by day 4 in term infants.

Postnatally, suboptimal nutritional management compounds the prenatal nutrient deficit of AA and DHA when infants are fed on artificial milks devoid of these two nutrients. Predictably, this is reflected in alterations in membrane composition. Term and preterm babies fed on conventional infant formula without AA and DHA have depressed levels of DHA in the blood[51,56,57] and in brain tissue compared with babies fed on breast milk which does contain AA and DHA.[58,59]

An insufficiency of polyunsaturated fatty acids has a profound impact on neurovisual development in term and preterm infants[60–66] that is shown to be long lasting. Infants fed on formula milk devoid of DHA had lower visual acuity and cognitive scores compared with those fed breast milk. Supplementation of formula with DHA is related to enhanced visual acuity[60–64] and discriminative learning.[67] Bjerve *et al.*[68] have reported lower psychomotor performance scores associated with low levels of plasma DHA at 1 year of age. At 3 years of age term babies who have been fed on formula milk without DHA, had significantly lowered visual and stereo acuity and letter matching compared with babies fed on breast milk.[61,66] Eight-year-old children previously fed on formula milk as preterm babies had an eight point lower IQ score compared with those fed on breast milk.[69] Lanting *et al.*[70] reported a neurodevelopmental disadvantage in a 9-year-old children who had been fed breast milk compared with those fed on formula milks.

Some reports on term infants have demonstrated improved visual acuity with formula milk containing DHA[71] while others have not.[72] In the latter study, the range of DHA in human milk is quoted as 0.1–0.9% of the fatty acids and yet the amount of DHA used was 0.02% above the lowest level. Bearing in mind that maternal diet and health will influence milk DHA,[73] one wonders as to the validity of choosing such low levels, which reflect the lowest nutritional status in the range, reported. Unfortunately, few workers select mothers for the study of human milk based on sound evidence of good health and nutritional status.

Human milk, lipid and fatty acids

In human milk, the lipid fraction provides about 60% of the energy for the infant. It mainly consists of triglycerides, which account for about 96% and phosphoglycerides for about 2–3%. The concentration of lipid in human milk is variable and is influenced by length of gestation (term or preterm), length of lactation, time of day, duration of individual feeds (low in fore and high in hind milk) and most of all maternal diet.[74,75] In contrast to lipid concentration, the fatty acid composition of mature human milk changes little

with the duration of the feed, the time of the day and length of lactation.[73,76] Colostrum contains higher levels of AA and DHA than mature milk.[76,77] Similarly, very preterm and preterm human milk contain higher levels of the two fatty acids compared with term milk.[78]

Although it seems that milk AA and DHA are resistant to dietary change, they do respond to maternal diet, which is the most important determinant of fatty acid composition of human milk. Comparisons of vegetarian and non-vegetarian women show that the milk essential fatty acids reflect the diet.[79] Greenland Eskimos, North Canadian Inuit and Japanese islanders have high intakes of seals, fish and other seafoods. Consequently, breast milk from these communities is high in the n-3 fatty acids, namely, EPA and DHA.[80,81] Mothers from countries where fat provides greater than 35% of the daily energy (high fat intakes) have lower short-chain and higher long-chain fatty acid concentrations. Conversely, those from countries where the habitual diet is relatively low in fat (less than 15% of the energy) have high proportions of short-chain and AA and DHA.[73,82] It is intriguing why breast milk DHA of western (European and American) women, who are supposed to be 'well nourished', is invariably very low (< 0.2%) in contrast to milk of inadequately nourished women from Africa and Asia (> 0.4%). Since plant-based foods are the major sources of dietary lipids of the latter group, their intake of saturated fat would be less than 5%, which is well below the amount consumed by Western women (range: 15–25%). Hence, it is plausible that high total and saturated fat intakes reduce the relative proportions of DHA in breast milk of Western women. This proposition is consistent with our recent experimental study[83] that showed suckling pups born to dams fed high total and saturated fat diet, akin to western foods, during pregnancy and lactation had about 25% lower DHA in liver choline and ethanolamine phosphoglycerides compared with the controls indicating that the metabolism of DHA is adversely influence by saturated fat.

Breast milk and artificial formulations, which simulate breast milk, with respect to DHA, appear to enhance DHA status, cognitive development and visual functions of the preterm baby. Nevertheless, it is questionable whether these feeds meet the AA and DHA requirement for optimum development of preterm babies. The current AA and DHA recommendation for infants, and the consequential formulation, which is modeled on milk of Western women, is also questionable. It is legitimate to argue that breast milk evolved to support the postnatal development of the term neonate born with appropriately developed and functional systems. The preterm baby, who is born with immature anatomy and metabolic systems, will have to continue its interrupted prenatal development under neonatal conditions. This can only be done if the infant is provided with the appropriate nutrients in the right amounts. What the preterm baby requires in the immediate neonatal period is a surrogate placenta that provides enriched AA, DHA and other essential nutrients rather than mammary glands, which generate breast milk for the normal birth weight term baby.

Antioxidants

Membrane integrity and function are dependent on the incorporation of appropriate amounts of the highly unsaturated fatty acids, AA and DHA, which are susceptible to peroxidation unless protected by antioxidants. There is an interdependence between membrane AA and DHA and membrane-bound antioxidant enzymes. Optimum activity of the enzymes is dependent on the physical integrity of the membrane. At the same time, the membrane fatty acids require the antioxidant enzymes for protection. It has been shown that the activity of mitochondrial manganese-superoxide dismutase (Mn-SOD) is influenced by dietary essential fatty acids, while the activity of cystosolic Cu/Zn-SOD remains unaffected.[84]

Reduced competence of the antioxidant defense may lead to damage to the structural membrane of the brain, retina, lungs and other tissues, particularly in a hyperoxic environment. Indeed Saugstad[85] and Sullivan[86] postulated that oxygen radical injury may be a common pathogenic mechanism in the neonatal diseases bronchopulmonary dysplasia, hemolytic anemia, intraventricular hemorrhage and retinopathy of prematurity.

In the chicken model of intraventricular hemorrhage, we have been able to induce hemorrhage in the cerebellum between 10 and 28 days after hatching. The window of susceptibility corresponds to the time of rapid growth of the cerebellum and acquisition of long-chain polyunsaturated fatty acids. Provision of vitamin E, or ALA without vitamin E arrests the disease.[24,87] This model illustrates the importance of considering both the membrane structure and its protection together.

Research into the role of antioxidant vitamins and fatty acids in non-human primates demonstrates that these nutrients provide protection against oxidative stress. Laboratory-bred marmosets had a high hydrogen peroxide-induced erythrocyte hemolysis *in vitro*,[88] which correlated negatively with levels of vitamin E and LA.[88,89] The high erythrocyte hemolysis skin lesions and alopecia manifested in these animals were ameliorated by an increased intake of vitamin E and the correction of membrane n-6/n-3 balance.[90] Similarly, other studies[91–94] have reported that dietary n-3 fatty acids exert a protective effect against injury caused by oxidative stress.

Animal studies show reduced activities of the antioxidant enzymes in the lung and kidney of those delivered before term. These studies indicate that

functionally protective enzymes are being put in place towards the end of gestation in preparation for a normal term delivery.[95,96] Similarly, the activities of superoxide dismutase, glutathione peroxidase and catalase are low in preterm and low birth weight babies.[97–99]

Preterm and low birth weight infants are born with low circulating and hepatic levels of vitamins A and E.[100–102] Reports suggest a protective effect of vitamin A against bronchopulmonary dysplasia,[103] and of vitamin E against retinopathy of prematurity[104,105] and intra/periventricular hemorrhage.[106–108]

Conclusion

All these data show that the preterm baby is born disadvantaged because of the loss of the placental input of structural fatty acids and immature endogenous peroxidative defense systems. Moreover, these premature-birth-induced disadvantages persist postnatally. Blood antioxidant protection remains depressed and the proportions of plasma structural fatty acids fall precipitously. These babies are indeed a mirror of the chicken model of brain hemorrhage caused by a combined deficit of antioxidants and structural fatty acids.

92 Maternal inherited metabolic disease

R. Floyd, F. Cockburn and B. J. Clark

Introduction

Recombinant DNA technology with the mapping of the human genome has made possible the localization, identification and isolation of disease-related genes which, in turn, have improved disease diagnosis and prediction and identified inherited defects underlying many common metabolic disorders affecting adults. Inherited metabolic disease may be diagnosed prenatally, in infancy, or may present as an adult-onset disease, particularly in diseases not generally associated with a detectable chromosome aberration or a clear Mendelian pattern of inheritance. Many of these metabolic disorders have been called polygenic or multifactorial even though it is not usually known how many genetic loci are involved or how they interact with environmental factors. Diabetes mellitus and essential hypertension are examples though the genetics of both of these disease processes are currently being illuminated. There are many perturbations of maternal metabolism which can adversely affect growth and development of the human embryo and fetus. The purpose of this chapter will be to review those maternal inherited metabolic disorders which can result in failure of implantation, early loss of implanted ova and congenital malformations or metabolic disorder in the newborn infant.

The number of autosomal and X-linked chromosomal disorders identified continues to grow daily, many of which result in metabolic diseases or disorders. The development of management strategies to alleviate or correct these inherited disease processes has encouraged early detection with screening programs. Table 92.1 gives the frequency of some inborn errors of metabolism for which screening tests are available.[1] Although we now have considerable information about phenylketonuria in relation to pregnancy management and outcome there are many other inherited metabolic disorders affecting young women which carry a risk to the developing embryo and fetus.

Table 92.1 Frequency of some inborn errors of metabolism for which neonatal screening tests are available

Disorder	Average frequency in liveborn infants*
Cystic fibrosis	1 in 2500
Cystinuria	1 in 6000
Phenylketonuria	1 in 10,000
α_1 Antitrypsin deficiency	1 in 8,000
Histidinemia	1 in 10,000
Hartnup disorder	1 in 26,000
Galactosemia	1 in 60,000
Biotinidase deficiency	1 in 60,000
Maple syrup urine disease	1 in 200,000
Homocystinuria	1 in 200,000

*These frequencies vary widely between ethnic groups, e.g. phenylketonuria 1 in 7000 in Scotland and 1 in 200 000 in Japan.

Maternal metabolic disorders and pregnancy

Diabetes mellitus

It has long been known that the infant of the poorly controlled diabetic mother is at increased risk of congenital malformation, fetal overgrowth and neonatal hypoglycemia.[2] With improved care of pregnant diabetic women, these complications and perinatal mortality for the infant have been reduced.[3–7] There is a recognized higher prevalence of diabetes mellitus in children born to diabetic parents. A higher incidence of non-insulin-dependent diabetes or gestational diabetes is found in children born to diabetic mothers than when the father is diabetic.[8] There is also a higher incidence of diabetes in offspring from diabetic maternal great-grandmothers but not paternal ones.[9] Genomic imprinting is a possible explanation for

these findings.[10–12] In HLA-DR4-positive diabetics, there is evidence of a gene or genes affecting the HLA region on chromosome 6p21 and the region of 11p15 where the genes for insulin and insulin-like growth factor-2 are located.[13]

A further interesting observation has been that systematic treatment of diabetic mothers during pregnancy, results in a decreased incidence of diabetes in their children.[14,15] This implies that the abnormal intrauterine environment may have as much if not more effect in determining susceptibility to subsequent diabetes in later childhood than do the genetic predisposing factors. Mechanisms for the predisposition to diabetes in the infant of a diabetic mother may be related to an intrauterine influence on the effective development of islet β-cells in the fetal pancreas or to an alteration in the numbers or sensitivity of insulin receptors in muscle, liver and other body tissues.

Cystic fibrosis

This is an autosomal recessive condition in which there is an abnormality of transmembrane protein function rather than a defect or deficiency of an enzyme which characterizes the majority of inherited metabolic disorders. Although there are problems of infertility in both females and males there is no evidence of embryopathy or fetal disorder given an adequate maternal nutritional status during pregnancy.[16]

Histidinemia

Maternal histidinemia is probably benign to the fetus. At least 61 children from 23 histidinemic mothers, most of whom were normal, have been reported.[17] No adverse outcomes secondary to this disorder have been noted.[17–21]

Hartnup disorder

Hartnup disease, a disorder of neutral amino acid transport in the intestinal epithelium, is inherited in an autosomal recessive manner. Maternal Hartnup disorder is also probably benign to the fetus. At least 14 children of women with the condition are known and almost all are normal. Therapy requires nicotinamide replacement and a high protein diet. Pregnancy does not appear to have any clinical impact on these families.[22]

Homocystinuria

Homocystinuria is an autosomal recessive disorder that is characterized by increased concentrations of homocystine and methionine in blood and urine and physical features such as mental retardation, epilepsy, ectopia lentis, osteoporosis, skeletal anomalies, fatty liver and thrombotic vascular disease. These findings are secondary to a deficiency of the enzyme cystathionine β-synthase. The disorder is responsive to B6 cofactor and a low methionine diet in about 50% of patients.[23] Pregnancies have been reported in both pyridoxine responsive and non-responsive mothers with a normal outcome.[24–26] An adequate intake of pyridoxine should be ensured as treatment with pyridoxine appears to significantly lower the risk of fetal loss.

Heterozygotes are at an increased risk for multiple thromboses, coronary artery disease and other vascular disease.[27] Third-trimester complications similar to those with other inherited coagulopathies and postpartum thrombotic deaths have been reported which suggest the use of anticoagulation therapy may be indicated.[28–30]

Folate metabolism disorders

A genetic defect in 5,10-methylenetetrahydrofolate reductase in young women has been shown to be a risk factor for neural tube defect.[31–33] This enzyme is involved in the conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate which is involved in the conversion of homocysteine to methionine (Figure 92.1). The common mutation of 677CT defect is found in 5–7% of the European population and homozygosity for this mutation results in elevated homocysteine levels, elevated red cell folate and lowered plasma folate concentrations. Periconceptual folate administration reduces neural tube birth prevalence by over 60%.[33–36] Altered folate and vitamin B_{12} metabolism has been found in families with infants with spina bifida.[37] This study did not support a major involvement of methionine synthase in the etiology of neural tube defect but favored the involvement of genetic variation at loci coding for the formation of 5-methyltetrahydrofolate. A relatively mild biochemical defect in folate metabolism, requiring a higher nutritional folate intake, may become of major importance during pregnancy. Whether there would be value in detecting those individuals heterozygous for the known defects is questionable as universal prenatal folate supplementation is so effective. These patients have also been noted to have an increase in complications in the third trimester consistent with those seen in patients with an inherited coagulopathy and the use of anticoagulation should be considered in those patients with a history of thrombosis or poor pregnancy outcome.

Isovaleric acidemia

Maternal isolaveric acidemia has minimal impact on pregnancy and vice versa and has no ill effect on the offspring.[38] Treatment of the mother should be instituted prior to conception with protein restriction and additional glycine 0.5 g/day and L-carnitine 1 g/day to reduce the risk of metabolic acidosis in the mother and thus reduce potential hazards to the embryo and fetus. Vomiting in early pregnancy must be actively managed with a high carbohydrate intake, if necessary by nasogastric tube or parenterally, to avoid a catabolic state.

Urea cycle defects

The urea cycle defects include citrullinemia, argininosuccinic aciduria (ASLD), ornithine trancarbamylase deficiency (OTC), carbamoylphosphate synthetase

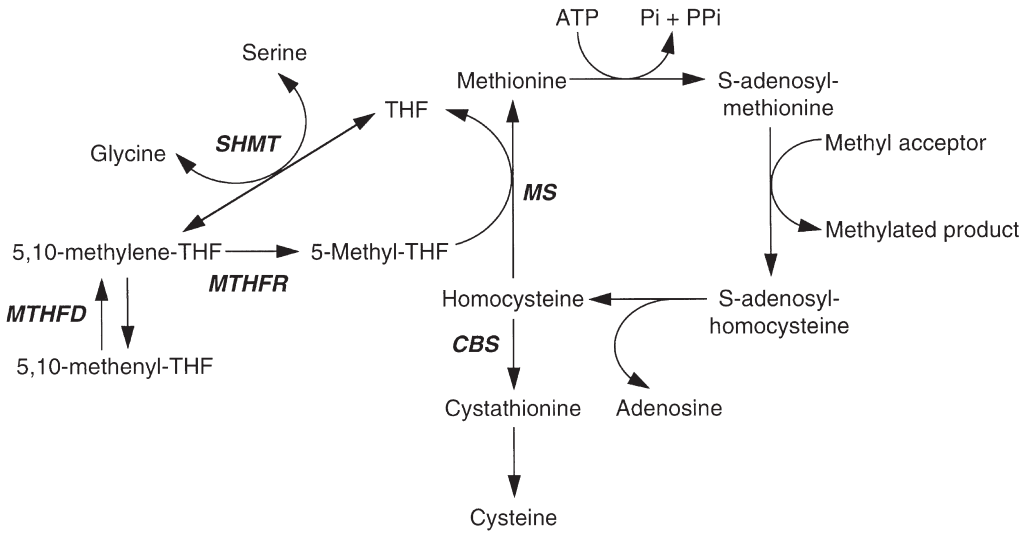

Figure 92.1

deficiency and N-acetyl glutamate synthase deficiency.[39] There are very few reports in the literature as to the effects of these disorders on pregnancy and infants. Heterozygotes for OTC deficiency, the only X-linked disorder of the urea cycle, are known to be at risk for the development of hyperammonemic coma in the peripartum period, possibly due to increased tissue catabolism.[40] It has been reported that a woman with carbamoyl phosphate synthetase I deficiency developed hyperammonemic coma and died in the postpartum period.[41]

ASLD due to argininosuccinate lyase deficiency usually presents at birth with poor feeding, lethargy, hypotonia, irritability, apnea and occasionally death in the neonatal period.[42] More often there is a chronic presentation which involves mental retardation, with or without intermittent episodes of vomiting, lethargy and irritability. Trichorrhexis nodosa is a frequent occurrence, probably because of a relative deficiency of arginine.[39] Early treatment of patients with partial ASLD can result in normal intellectual and psychomotor development and as a result some patients are now surviving into adulthood and considering pregnancy. In females affected with argininosuccinate lyase deficiency, careful clinical and biochemical monitoring of pregnancy will minimize the risk of metabolic decompensation in the perinatal period. There is one report of a 'successful' pregnancy with no evidence that the argininosuccinate was teratogenic. The mother had been treated with a low protein diet and arginine supplements but her compliance with the arginine supplementation was suboptimal. When reviewed at 3 months of age, the baby was mildly dysmorphic with hypertelorism, a broad nasal bridge and down-slanting palpebral fissures but was developing normally.[43]

In all the urea cycle defects it is essential to ensure an adequate energy intake throughout pregnancy and if vomiting occurs enteral and/or parenteral therapy with carbohydrate should be given immediately.

Glycogen storage disorders

The glycogen storage disorders result from an inborn error of glycogen metabolism secondary to mutations in the genes coding for the enzymes involved in glycogen storage. These disorders have a variable age of onset from birth to adulthood and are categorized by number based upon the chronology of recognition of the responsible enzyme defect. Only those with a reasonable likelihood of presence during and potential impact upon pregnancy are discussed.

Glucose-6-phosphate deficiency (type I glycogen storage disease) is an autosomal recessive disorder involving mutations in the genes for glucose-6-phosphate hydrolase located at 17q21 (type 1a) and glucose-6-phosphate translocase located at 11q23 (type 1b,c,d). The incidence of specific mutations varies with ethnicity.[44,45] Affected patients typically present in early infancy with hepatomegaly, hypoglycemia and lactic acidosis.[46] The majority of patients will also have hyperuricemia and marked hyperlipidemia.[46] Platelet dysfunction is common and liver adenomas often develop in older children and adults with malignant transformation in approximately 10%.[47] Patients with type 1b also have chronic or intermittent neutropenia and neutrophil dysfunction.

Maintenance of physiologic levels of glucose is the mainstay of therapy. This becomes markedly more difficult during pregnancy and provision of frequent meals high in carbohydrate content and supplementation with uncooked cornstarch during the day and prior to bedtime can usually accomplish this goal. In some cases, the use of continuous infusion of glucose solution via nasogastric tube or additional doses of cornstarch in the early morning hours may be necessary.

Multivitamins and calcium should supplement the diet and fructose and galactose restricted. Intravenous glucose and platelet transfusion may be used for abnormal bleeding; the use of allopurinol and vasopressin during pregnancy are currently proscribed.[48]

Pregnancy outcomes with adequate glucose supplementation appear to be good in most cases. The incidence of growth restriction may be increased and monitoring the fetus with serial ultrasound measurements in the third trimester should be considered. Patients with type 1b should be monitored for evidence of subclinical infection (upper respiratory, urinary tract) due to the potential for neutrophil dysfunction. Delivery at or near term should be anticipated. The intrapartum glucose levels should be closely monitored and appropriate supplementation provided.[49,50]

Type III glycogen storage disease is inherited as an autosomal recessive trait and is specifically a mutation in the gene that encodes for the debrancher enzyme amyloglucosidase. This gene is located at 1p21 and again, specific mutations vary with ethnic background.[51,52] Clinical features of the disease include liver and muscle involvement with hepatomegaly, hypotonia, weakness and muscle wasting as well as cardiac involvement. Hepatomegaly and liver function typically improve with age and muscle weakness is the primary finding in adults. Involvement of the liver alone occurs in approximately 15% of patients.[53–55]

Case reports of maternal type III glycogen storage disease relate the potential for life-threatening complications, specifically cardiac decompensation.[56] Evaluation of cardiac anatomy prior to and during pregnancy (at 28 weeks) and postpartum should be obtained. Management includes supplementation of glucose as described for type I glycogen storage disease.

Type V glycogen storage disease (McArdle's disease) is a disorder caused by mutations in the single gene encoding the muscle isoform of phosphorylase.[57] This gene is located at 11q13.[58] Phosphorylase catalyzes the removal of 1,4-glucosyl residues from the outer branches of the glycogen molecule liberating glucose-1-phosphate. This myophosphorylase deficiency results in accumulation of glycogen in skeletal muscle and reduction in ATP generation. Clinically, this manifests as muscle fatigue and cramping with strenuous exercise. There is no heart or liver involvement. Case reports of pregnancy outcomes relate no deterioration or exacerbation of symptoms.[59] Limiting activity during pregnancy will control the symptoms associated with the disorder and the only complication of labor reported is that of forearm cramping secondary to the use of an automatic blood pressure cuff.

Hyperglycinemia

Hyperglycinemia is a non-specific feature of several organic acidurias and is usually associated with intermittent ketosis. Non-ketotic hyperglycinemia is a specific disorder of glycine catabolism caused by a defect in the glycine cleavage system.[60] The disorder usually presents in the first week of life with somnolence, lethargy and lack of spontaneous movement and apneic episodes. There may be seizures and exaggerated reflexes. Milder forms of the disorder are found with non-specific mental retardation in adult life. The diagnosis is made on the basis of finding hyperglycinemia and hyperglycinuria in the absence of a disorder of organic acid metabolism. The diagnosis is usually confirmed by the finding of high cerebrospinal fluid concentrations of glycine. In the milder forms of the disorder administration of large doses of sodium benzoate has been shown to reduce CSF glycine and the frequency of seizures. The authors have experience of three pregnancies in one non-ketotic hyperglycinemic mother managed with oral sodium benzoate. The control of plasma glycine levels in the mother was relatively easy during the pregnancy and indeed was less troublesome than during the non-pregnancy phase. The three infants were normally grown and have thrived with normal subsequent development.

Galactosemia

Galactosemia is the term used to describe disorders of galactose metabolism. The disorder is actually three distinct disorders caused by defects in galactose-1-phosphate uridyl transferase, galactokinase and uridine diphosphate galactose-4-epimerase.[61] The only form discussed here is that caused by defective galactose-1-phosphate uridyl transferase in which conversion of galactose to glucose is impaired. Accumulation of galactose-1-phosphate, galactitol, galactonate and uridine diphosphate (UDP) galactose is thought to be the cause of the complications of galactose ingestion. In the newborn period, ingestion of galactose leads to vomiting and diarrhea with progression to hyperbilirubinemia, hepatomegaly, liver dysfunction and cirrhosis, hemolysis, and sepsis. Cataracts rapidly develop in the first week of life. Despite early therapy these patients still manifest developmental delay, poor growth, mental deficiency and premature ovarian failure. Up to 75% of affected females over 14 years of age will experience ovarian dysfunction. Pregnancies in affected females appear to proceed normally without adverse fetal affects.[62,63] Breast feeding is contraindicated due to effects on the mother. The production of galactose-1-phosphate from the breakdown of endogenous lactose produced in the mammary glands is problematic, leading to accumulation of galactose-1-phosphate, galactitol, galactonate and UDP-galactose.[64]

Phenylketonuria

Early treatment of phenylketonuria has resulted in a markedly improved outlook for survival with good intellect. In recent years there has been some concern that the withdrawal of dietary therapy in later life may be associated with neurological disorder and

gross cerebral changes shown by magnetic resonance imaging.[65]

Charles Dent was probably the first investigator who noted the association of fetal abnormality and maternal phenylketonuria in 1956.[66] Since that time there have been many reports of fetal abnormalities associated with uncontrolled or poorly controlled maternal phenylketonuria.[67–72] Abnormalities reported in untreated phenylketonuria, when the intrapartum maternal plasma phenylalanine concentration exceeded 1.5 mmol/l, include mental retardation in 92%, microcephaly in 72%, intrauterine growth delay in 40% and congenital heart malformation in 12% of the offspring.[69] Phenylalanine is transported across the placenta by an active transport process which results in higher plasma concentrations of phenylalanine in the fetus than in the mother. The ratio of fetal to maternal plasma concentrations of phenylalanine varies throughout pregnancy with a higher ratio in the earlier months. The observed average ratio of fetal to maternal plasma phenylalanine is 1.48 with a range of 1.13–2.91.[73] Any increase in maternal plasma phenylalanine is therefore magnified within the embryonic and fetal tissues. The embryopathy affects the cardiovascular and central nervous systems causing the clinical features described.

Fortunately, fetal defects can be prevented by appropriate maternal dietary management to ensure reasonable plasma concentrations of phenylalanine from before the time of conception.[69–72,74] Two Medical Research Council Working Party reports have summarized the present recommendations for the dietary management of phenylketonuria and expressed the hope that there will be a molecular genetic treatment and prevention program for phenylketonuria.[75,76] Good management of maternal phenylketonuria prevents a variety of dangers and dilemmas for the mother and her medical advisers.[77] Dietary problems are related to the palatability, bulk and osmolality of available amino acid mixtures and the palatability and nutrient value of the permissible low-protein foods. In spite of the dangers to the developing embryo and fetus there is enormous reward for the families and health care providers for having a healthy baby by achieving good maternal dietary control. Until there is a safe effective method for the substitution of the defective gene or phenylalanine hydroxylase or both in the affected individuals, there continues to be a need to achieve prenatal and perinatal control of phenylalanine and tyrosine concentrations in mothers with phenylketonuria.

Conclusions

Perhaps the most important aspect of maternal inherited metabolic disorders is the need to have clinicians informed and aware of the wide range of maternal disorders which can predispose to embryonic, fetal and neonatal problems. For optimal pregnancy outcome, most of these conditions must be identified and metabolic control achieved preconceptually. This review does not address the effect of abnormal pharmacogenetics on maternal drug metabolism and the potential consequence to the fetus. An inherited predisposition to folate disorder will certainly alter the response to drugs that interfere with folate metabolism and maternal alcoholism is influenced by defects in alcohol dehydrogenases.[78,79] A high degree of clinical awareness and effective management would improve the outcome of infants born to mothers with metabolic disorders.

93 Fetal and neonatal nutrition – lipid and carbohydrate requirements and adaptations to altered supply at birth

H. Budge and M. E. Symonds

Introduction

The maintenance of a balanced and continuous supply of nutrients from the mother to the conceptus is critical in maintaining both a healthy and viable embryo as well as ensuring fetal growth and development is optimal throughout gestation. In this respect, a deficit in nutrient intake by the mother not only has a detrimental effect on the reproductive process itself but can also contribute to long-term ill health in the resulting offspring.[1,2] Even prior to conception, it is important that maternal dietary intake is adequate to ensure normal development of the egg.[3] Inadequate maternal nutrition before ovulation can potentially contribute to a range of clinical conditions including neural tube defects[4] in the fetus and even result in premature labour.[5,6]

There are seven distinct, but inter-related, stages between ovulation and weaning in which inadequate, or an imbalanced, supply of nutrition can have deleterious effects on the conceptus. These can be summarized as follows:

(1) Periconceptionally during the time of egg development
(2) Fertilization and subsequent period of embryogenesis and elongation
(3) Implantation and placental establishment
(4) Period of rapid placental growth
(5) Period of rapid fetal growth and mammary development
(6) Birth and separation of the fetus from the placenta
(7) Lactation and the period of postnatal growth.

In order to enable the newborn to establish independent life it undergoes a range of pronounced metabolic, endocrine and functional adaptations at birth.[7,8] These are vital in enabling the infant to commence independent breathing, thermoregulation and nutrient intake. Nutrient supply to the fetus is primarily regulated at the level of the placenta which effectively acts as the fetal gut. Then, after birth and the onset of breast feeding, the neonatal bowel takes on this role. There are some similarities between the function of the placenta before birth and the neonatal gut which acts to ensure that nutrient supply is maintained and then increased to meet the much higher postnatal metabolic requirements as growth accelerates.[9]

The fetus grows in a hypoxic environment in which a reduction in supply of both macronutrients, which include oxygen and micronutrients, can have adverse consequences.[10] Fetal arterial blood has a PaO_2 of around 2.8 kPa (21 mmHg) compared with ~12 kPa (90 mmHg) in the adult. The fetus adapts to this lower PaO_2 by maintaining a minimal metabolic rate,[11] ensuring available nutrients can be utilized to promote tissue growth rather than be partitioned toward metabolism. Nevertheless, even when fetal growth rate is maximal, it is usually slower than after birth.[12,13] In conjunction with this relatively low growth rate, cell division, rather than an increase in cell size, primarily contributes to fetal tissue growth. Thereafter, following birth, there is pronounced hypertrophy as nutrient supply is no longer constrained by placental exchange capacity, maternal intake and body stores. One tissue in which this adaptation is most apparent is adipose tissue.[14] Lipid synthesis has a much higher energetic requirement (i.e. 39 MJ/kg) compared with carbohydrate or protein (15–25 MJ/kg), so it is not surprising that fat deposition is normally low in the fetus and is highly dependent on fetal nutrition.[15]

Fetal fat deposition principally occurs over the final third of gestation[16] but, in contrast with all other organs, fat cells can continue increasing in size for the

remainder of an individual's life. It is, therefore, not unexpected that in nutritional and environmental conditions of excess feed availability, reduced physical and metabolic activity and raised ambient temperatures, there is an increasing propensity for obesity to occur earlier and in more people.[17] The extent to which predisposition to later obesity is determined by the *in utero* environment remains an area of significant scientific interest.[18]

In this chapter, we will focus on the acquisition of fat and fatty acids by the fetus and neonate and consider their roles in brain and adipose tissue development. For the fetus, as in the adult, fat represents a storage site in which excess energy intake is stored to be mobilized in times of later nutrient deficiency.[18] The other major energy storage is glycogen which is deposited in the fetal liver and skeletal muscle.[19] We will, therefore, consider the regulation of carbohydrate metabolism within the fetus as this is the precursor for both stored glycogen and the primary metabolic substrate for fetal lipid synthesis.

Comparative requirements between humans and other mammalian species

The use of other animals has greatly added to our understanding of fetal and neonatal lipid and carbohydrate metabolism and its impact on brain and fat development. It is, therefore, important to appreciate both the differences and similarities between respective animal models which have enabled us to make substantial advances in our knowledge of fetal nutrition and physiology that would not be possible within the pronounced limitations of human studies. As a consequence of the substantial differences in length of gestation in various animal species, together with the degree of maturity of the newborn at birth, the impact of compromised placental function, as opposed to poor lactational performance, can have very different outcomes on the resulting offspring.

The most notable difference between human newborn infants and nearly all other mammals is their much higher total fat content (150 g/kg body tissue) compared with most domestic species and laboratory mammals (< 10 g/kg body tissue)[20] except the newborn guinea pig (70 g/kg body tissue). The high fat content of the human fetus reflects the dramatic increase in subcutaneous fat deposition that occurs over the final 10 weeks of gestation. This is largely white fat which has an important insulatory role in the newborn as well as providing a large energy store that can be mobilized over the first few days of neonatal life before lactation is fully established. In the latter respect, the human differs from many other mammalian species in which lactation rapidly commences at birth to ensure survival. For example, in sheep, failure to rapidly establish lactation leads to starvation, hypothermia and death within a few hours of birth.[21]

Newborn sheep, like humans,[22] also possess brown adipose tissue which is characterized as possessing a unique uncoupling protein that when maximally activated is able to produce up to 300 W/kg tissue of heat compared with 1–2 W/kg tissue by most other tissues.[23] The amount of brown fat, located around the internal organs, in newborn sheep and humans is comparable at about 2% of birth weight.[24,25] This contrasts with rats and mice in which minimal fat is present at birth and in whom brown fat is located in the interscapular region and is recruited postnatally.[26] In contrast, pigs are born with some subcutaneous fat but do not possess any brown fat.[27]

Fetal brain growth relative to adult brain weight is appreciably greater in the human than all other species for which comparable data are available (Figure 93.1). In addition, its growth rate is normally maintained for the whole of pregnancy so that the weight of the brain in the newborn is ~13% of birth weight.[28] Subsequently, as growth of all other tissues accelerates after birth, brain weight, as a fraction of total body weight, gradually declines to the adult value of ~2%, which is the typical value found in most other large animal species at birth.[29]

These pronounced differences in fetal brain growth are reflected in the ability of non-esterified free fatty acids (NEFAs) to cross the placenta. In the chorioallantoic (hemochorial) placenta of humans, although the fetal endothelium and chorionic epithelium separate the maternal and fetal circulations, NEFA can pass relatively freely from mother to fetus.[30] This contrasts with the placentae of species that have a distinct maternal layer (such as the pig and sheep) and are impermeable to NEFA.[31] Small laboratory mammals which

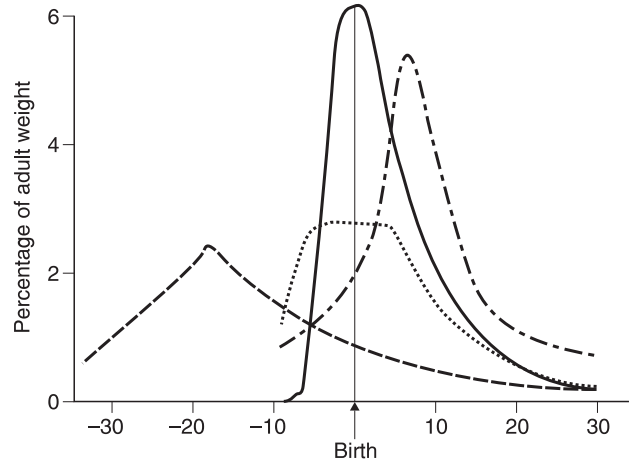

Figure 93.1 Diagrammatic summary of the rate of fetal and postnatal brain growth (wet weight) in the human compared with other species. Developmental age for each species is represented as follows: human (continuous line) in months; guinea pigs (dotted line) in days; pig (dashed line) in weeks and rat (dotted and dashed line) in days. Adapted from Dickerson[29] with permission.

have a very short gestation further differ from humans in that the offspring have an immature hypothalamic–pituitary axis at birth with brain and fat growth occurring primarily after birth.[32] This has several major functional consequences, both for organ development and nutritional requirements. The major source of energy in rat milk is lipid and the mother devotes up to 80% of her time suckling the young whose weight doubles in a week.[33] By the time of weaning, brain growth is complete and the neonate has maximized glucose production necessary to maintain the brain's high metabolic requirements compared with the rest of the body.[34] It is not until weaning that glycogen is laid down as an energy reserve for possible later food deprivation. This process of events is in marked contrast to long gestation species in which these developments all occur *in utero*. Not surprisingly, appreciable differences in milk composition between species, likely to reflect the degree of maturity of the offspring at birth, are also apparent. Humans and large mammals, such as the sheep and cow, produce milk with a lower relative fat and protein content compared with that of small mammals, such as rats and mice, that have a lower relative carbohydrate content.[33]

Lipid and carbohydrate requirements for placental and fetal growth

Dietary availability, in conjunction with the ability to mobilize maternal body tissue stores, determines nutrient supply to the conceptus and, therefore, both placental and fetal growth.[35] A reduction in maternal energy stores either before, or during gestation, can have substantial effects on fetal energy deposition[15] and these can be exaggerated in the term human infant because it possesses large stores of both lipid and carbohydrate in comparison with most other mammals.[36] Such effects are amplified because the fetus has limited ability to synthesize glucose[37] or essential fatty acids including long-chain polyunsaturated fatty acids (LCPUFAs).[38] It is, therefore, not surprising that infants with poor energy reserves at birth can have long-term deficits in their metabolic control mechanisms.[39] Indeed, such effects may be compounded by the need to mobilize energy supplies during the sometimes lengthy period of parturition[40] up to the time of full establishment of lactation.[41]

The placenta – development and function as the site of nutrient supply

The human hemochorial placenta is a fetal organ and is regulated by fetal genes. It separates the fetal and maternal circulations by a barrier composed of fetal endothelium and chorionic epithelium. The primary site of nutrient exchange is the chorionic villi which are supported by the syncytiotrophoblast and are surrounded by maternal blood.[42] They act as a lipoidal membrane across which nutrients, dissolved gases, waste products and other substances occur. Like the adult gut, this site of the placenta has a very large surface area which increases from 0.83 m^2 in week 3 of gestation to peak at ~12.5 m^2 at term.[42] At the same time, the maternal–fetal diffusion distance decreases from 55 to 4.8 mm, thereby facilitating nutrient exchange. The syncytiotrophoblast is also being continuously renewed from the underlying villous cytotrophoblast.

The placenta has a range of transport mechanisms and/or transporters which can limit or promote uptake of specific nutrients including fatty acids,[38] glucose[43] and amino acids.[44] Their abundances can be developmentally regulated and are normally reduced in the placentae of growth-retarded infants. In addition to its role in nutrient transfer, the placenta acts as an important endocrine organ secreting hormones into both the maternal and fetal circulations and, thereby, exerting direct effects on maternal metabolism and nutrient supply to the fetus.[45]

Placental requirements for growth and metabolism

Normal growth and development of the placenta is critical in ensuring that a healthy, appropriately sized fetus is born at term. The placenta grows exponentially during gestation, weighing ~6 g at week 3 of gestation and ~470 g at term. Maximal growth of the placenta precedes that of the fetus[46] but nutritional exchange capacity increases with gestational age in conjunction with structural maturation of the placenta[47] as the fetus grows and its overall metabolic rate rises.[48] At term, placental and fetal weights are positively correlated with placental weight, normally being between 10% and 15% of newborn body weight.[49]

Not surprisingly, given the diverse functions of the placenta and its rapid growth, a constant and plentiful source of energy is required. The human placenta derives energy from both glucose[43] and NEFA by glycolysis and β-oxidation,[50] respectively. It utilizes glucose as its major energy source and there are multiple glucose transporters present in the placenta.[43] Enzymes involved in glycolysis and the citric acid cycle are also active within the placenta. Indeed, it has been suggested that adequate glucose supply can prevent NEFA uptake and oxidation within the placenta by inhibiting the enzymes (e.g. carnitine palmitoyltransferase type 1) involved in this process.[51] This is not always the case, as appreciable activities of a number of enzymes involved in β-oxidation (e.g. acyl and hydroxyacyl-CoA dehydrogenases) have been detected although activity decreases with gestational age.[50] The utilization of fatty acids as a metabolic fuel may, therefore, decline as gestation progresses with glucose becoming more important.[52]

As the placenta utilizes both glucose and NEFA, abnormalities in the metabolism of either can be associated with adverse outcomes in pregnancy.[50] Diabetes during pregnancy, in which both the transfer of

glucose and NEFA across the placenta are increased, causes placental and fetal macrosomia.[53] Maternal liver diseases of pregnancy may also be the result of a placental defect in NEFA oxidation,[54] with maternal symptoms worsening in late gestation when the higher metabolic demands of the fetus[55] result in increased fat mobilization and a concomitant rise in lipoprotein lipase activity.[54] Defective fatty acid oxidation in the placenta results in placental accumulation of abnormal metabolic precursors (e.g. hydroxyacylcarnitines and dicarboxylic acids)[56] that may further contribute to the intra-uterine growth retardation seen in such clinical conditions as pre-eclampsia.[57]

Fetal requirements for brain growth and neural development

As with all fetal organs, the most rapid period of brain cell division is during the period of embryonic growth. Normally, by the end of the second month of gestation, the majority of neurons have migrated within the cerebral cortex forming the gray matter.[58] At this stage of development, approximately 50% of the embryo is made up of the fetal head, with the brain utilizing up to 70% of available energy provided by the placenta. The brain has a very high lipid requirement and content, of which 60% is structural. The majority (85%) of this is present in the cerebrum. Of the latter, 65% of total lipids are phospholipids with cerebral cortical neuronal membranes being made up of phosphatidylcholine, ethanolamine, serine and inositol.[58]

The structural and metabolic functions of fatty acids in the fetus and placenta are primarily undertaken by PUFA.[59] These fatty acids with double bonds plus three (n-3) or six (n-6) carbons from the n terminus cannot be synthesized in the human body. They must, therefore, be obtained from dietary sources primarily in the form of linoleic, a n-6 fatty acid, or α-linolenic, a n-3 fatty acid.[38] LCPUFAs are also essential for neural, brain and retinal development as they are not only integral components of the membrane but also act as intracellular signals and contribute to triacylglycerol stores. The primary LCPUFAs are arachidonic acid (20 carbons:4n-6) and docosahexaenoic acid (22 carbons:6n-3) which are amongst the most metabolically active in the cell. They are not normally limited in the diet but, because of the increased demands by the fetus, their supply may become limited during pregnancy.[60] Interestingly, although the fetal brain has relatively high concentrations of docosahexaenoic acid, the absolute rate of accretion is low (e.g. 50-fold lower than in adipose tissue[38]). Although it is only during late gestation that fetal requirements appear to exceed maternal dietary intake,[38] the amount of fatty acids in the diet may have a significant effect on outcome as a reduced dietary intake has been associated with both intrauterine growth retardation and premature birth.[61]

The precise trigger for parturition remains a matter of debate. In humans, it is determined in part by the size constraints and metabolic demands of the fetal brain.[29] As the greatest period of brain growth occurs *in utero*, there is a definite maternal limitation determined by the dimensions of the pelvic outlet. At the same time, a mismatch between fetal nutrient requirements and placental supply capacity may trigger a centrally coordinated cascade of endocrine signals that initiates parturition.[62]

Fetal requirements for adipose tissue deposition

Adipose tissue is primarily laid down during the final third of gestation with the majority (~80%) being deposited as subcutaneous fat that can constitute as much as 16% of birth weight in a normally grown term infant.[63] Its major component is lipid which is primarily found in unilocular cells, although internal fat depots which have a high mitochondrial content also possess a large number of multilocular cells[64] in which the brown adipose tissue-specific uncoupling protein 1[26] is located. The combination of brown fat plus large lipid stores means that heat production within fat is sufficient to provide up to three quarters of total energy requirements at birth.[19]

Fat is not only transferred directly from the mother to the fetus but is also synthesized *in utero* primarily from glucose and also from lactate and short-chain volatile fatty acids.[65] An increase in both glucose and fatty acid supply from the mother to the fetus such as during pregnancies complicated with diabetes results in substantially more fetal fat deposition.[66] Conversely, preterm infants, as well as those with intrauterine growth retardation, are born with depleted fat stores. These individuals may, however, have an increased propensity to lay down more fat in later life.[67]

Fetal deposition of carbohydrate in the liver

Glucose is the primary nutrient utilized by the fetus for oxidative metabolism with up to two-thirds of fetal glucose being oxidized to carbon dioxide and the remaining third stored as glycogen.[68] As in the adult, glucose utilization is largely regulated by the pancreatic hormones insulin and glucagon with the adaptation that, because of the higher insulin to glucagon ratio, glycogen synthesis is stimulated whereas glycogenolysis inhibited.[69] Indeed, except under conditions of extreme nutrient deficiency, the fetal liver has minimal capacity to synthesize glucose.[37] At the same time, other counter metabolic hormones such as growth hormone do not appear to have a role in glucose homeostasis, as the fetus is normally growth hormone insensitive.[70] The fetus is usually exposed to very high circulating growth hormone concentrations[71] and its growth hormone insensitivity is most likely due to the lack of adult growth hormone receptors in the liver.[72]

Glycogen is stored primarily not only in the fetal liver, but also in skeletal muscle, and can be utilized to maintain plasma glucose concentrations during periods of reduced nutrient availability.[34] The main factor determining the content of glycogen in fetal

tissues is the rate of glucose supply from the mother to the fetus which, in turn, is dependent on the maternal blood concentration.[68] Maternal and fetal blood glucose are usually very closely correlated along a glucose gradient to the fetus with fetal blood glucose being 30% lower than that of the mother.[73] Glycogen accumulation commences from 9 weeks gestation but, as for adipose tissue, it is primarily synthesized in the last third of gestation.[40]

Nutrient supply to the fetus: maintenance of a continuous supply

Lipid supply from the mother to the fetus

As a consequence of their large size and high molecular weight, lipids do not directly cross the placenta.[38] Lipids, carried in the maternal circulation by the carrier protein albumin,[74] must first be hydrolyzed to NEFAs before they can be transferred across the placenta. This hydrolysis to NEFAs is performed by the enzyme lipoprotein lipase which is abundant in the human placenta.[75] In addition, intact triacylglycerols and phospholipids can also not be transferred across the placenta.[76] Consequently, as fetal requirements increase with gestation, there is a linear rise in the plasma concentration of triglycerides in maternal blood,[77] whereas plasma NEFAs only rise in late gestation coincident with the mobilization of maternal fat stores.[78]

NEFA transfer across the placenta

The placenta has the capacity to transfer NEFAs both to, or from, the fetus with the net rate of transfer determined by the relative concentrations of NEFAs and their carrier protein, albumin, in the maternal and fetal circulations.[79] Normally, it is the concentration of albumin, which is ~20% higher in fetal than maternal blood, which determines the rate of exchange whereas plasma NEFAs can be up to three times higher in the maternal compared with fetal circulation.[80] Consequently, the plasma NEFA to albumin ratio is 30% lower in the fetus than mother and this gradient promotes fetal uptake of NEFAs. Conditions which result in an increase in maternal plasma NEFAs, such as food deprivation,[81] will result in an enhanced transfer of NEFAs to the fetus.

When NEFAs have permeated the microvillous membrane they cross the two lipid bilayers within the syncytiotrophoblast either by simple diffusion[82] or via fatty acid-binding proteins.[83] A number of these plasma membrane-associated proteins have been identified including:

(1) The plasma membrane fatty acid-binding protein which functions as an extracellular fatty acid acceptor.
(2) Fatty acid transfer proteins that span the lipid bilayer and function as such.[84]

Interestingly, the plasma membrane fatty acid-binding protein exhibits a hierarchy of binding affinities for the range of LCPUFAs that make up NEFAs in the order of docosahexaenoic acid $\geq$ arachidonic acid $\gg$ linoleic $>\alpha$-linolenic $\gg$ oleic acid.[85] Furthermore, the finding that this hierarchy is only found on the maternal side of the placenta may have the effect of selectively promoting the enrichment of LCPUFAs within the NEFAs that are subsequently taken up into the placental syncytiotrophoblast[86] and then transported across to the placenta.

Glucose supply from the mother to the fetus

As stated earlier, maternal blood glucose concentration is the main determinant of fetal glucose supply.[68] Glucose crosses the placenta by facilitative diffusion across specific glucose transporters (GLUT) with the fetal glucose concentration gradient from the mother increasing in late gestation as fetal demands become maximal.[52] Glucose transporters ensure that the rate of glucose transfer occurs at a greater rate than if its transfer was only dependent on simple diffusion. Two glucose transporters are present in the human placenta, GLUT1 and GLUT3,[87] and their relative abundance can change with gestational age.[43] The peak in GLUT3 abundance in late gestation, in conjunction with its higher affinity for glucose compared with GLUT1, indicates its greater contribution in facilitating placental glucose in late gestation[88] than GLUT1.

Cessation of nutrient supply: the environmental challenge to the newborn at birth

At birth, in conjunction with separation of the infant from the placenta, there is a rapid transition in metabolic homeostasis. The newborn must rapidly establish independent respiration, thermoregulation and nutrition. At the same time, there is a profound change in the composition of feed supplied to the infant. During fetal life, the primary metabolic nutrient supplied is glucose.[68] In contrast, once the infant commences suckling, it no longer receives a diet in which the main energy source is carbohydrate. Instead, the newborn consumes a diet that is rich in both lipids and carbohydrates, with half of the required energy coming from triacylglycerols and the other half from lactose.[89] As lactation is established, both the concentration and volume of lipid and lactose produced in milk increases in line with the greater demands of the infant. The change in nutrient supply and availability is accompanied by the onset of gluconeogenesis within the liver and glucose absorption across the gut.[90] This means that, in addition to the substantial changes in lung function and metabolism[91] around the time of birth, there is also a dramatic change in function of the gut and liver[7]

Table 93.1 Summary of the major adaptations at birth within the liver and gut which are necessary to enable the newborn to adapt to separation from the placenta and successfully commence suckling.

Tissue	Nutritional influences	Function
Liver	Glycogen synthesis	Energy storage depot that can be mobilized at birth
	Induction of gluconeogenic enzymes	Initiation of gluconeogenesis at birth
	Protein synthesis	Hormone receptors and binding proteins that promote tissue sensitivity to the postpartum hormones surges at birth
Gut	Maturation of gut morphology	Enables the gut to have maximal digestive capacity after birth
	Induction of digestive enzyme activity	Necessary for the breakdown and absorption of milk after birth
	Onset of digestive capacity	Facilitates the digestion of milk

(Table 93.1) in conjunction with the mobilization and activation of brown and white adipose tissue.[92]

Preparation and adaptation for life after birth

Over the final weeks and days of gestation, there is a gradual process of maturation of the majority of organ systems within the fetus that mean it can rapidly and effectively adapt to the extrauterine environment. The gradual increase in fetal plasma cortisol has a primary role in this process and is important in promoting growth of the gut mucosa,[7] promoting acid secretion, the induction of digestive enzyme activity and hormone secretion by the gut.[93] In the liver, cortisol promotes glycogen deposition, induces the expression of gluconeogenic enzymes,[7] and stimulates hormone and receptor gene expression.[94]

The occurrence of both structural and functional changes within the proximal areas of the gut ensures that ingested nutrients become digested and absorbed soon after birth. It is not uncommon for the intake of milk to be less than requirements for several days after birth.[95] Over this period, energy is largely provided by the mobilization of both fat and glycogen stores which can become greatly depleted. For example, 90% of hepatic and 60% of muscle glycogen stores can be utilized within 24 h of birth.[96] In order to promote these responses, the enzymes essential for glycogenolysis, gluconeogenesis and lipolysis are greatly stimulated. All these processes may be delayed or reduced in preterm infants in which both lipid and glycogen stores are much lower than in term infants. Not unexpectedly, such infants are at much greater risk of hypoglycemia and hypothermia.[97]

The primary role of fat in the newborn relates to protection and maintenance of a normal body temperature.[92] In the infant, this function is achieved both as a result of the production of very large amounts of heat following rapid activation of the brown adipocyte-specific uncoupling protein 1 in central fat depots,[98] or by the insulatory properties provided by subcutaneous fat.[99] It is also the main source of a rapidly mobilized energy-rich substrate in the form of lipid from which NEFAs are released.[100] The instantaneous activation of thermogenesis at birth, coincident with a near maximal metabolic rate that is seldom matched throughout the rest of the life cycle, is an important example of the very different function of fat in fetal compared with adult life. This adaptation is mediated by the rapid increase in the plasma concentrations of a number of metabolic hormones at birth, including glucocorticoids, thyroid hormones, leptin, catecholamines, insulin, glucagon and growth hormone.[92] These are also important in the range of changes in the lung, gut and liver that are critical for ensuring life after birth (see Table 93.1).

Nutrient supply to the neonate: establishment of lactation and adaptation to increased supply

Following birth, the rapid and continuous maintenance of lactation is essential in ensuring that nutrient supply to the newborn does not become limited. Over this period, as nutrient supply increases with requirements, the infant has a greater capacity to meet its full growth potential. The composition of milk and its rate of digestion is very different between breast- and bottle-fed infants.[101] Type of feeding adopted also leads to substantial differences in waking and sleeping activity cycles that will further impact on growth and metabolic requirements.[9] When the infant is fed *ad libitum* and on demand, sleep–wake activity cycles may be limited to 3–4 h at most. Ideally, feeding should be on demand which results in a feeding frequency in the neonate being every 1–2 h compared with longer gaps between feeds in older infants.[102] An environment in which such a pattern of maternal–infant interaction is permitted could be considered to have the greatest beneficial outcome for infant health, growth and mental development.[103] Indeed, human breast milk is sufficient as the sole source of energy and nutrients for the infant until around 6 months after birth.[102]

Structure and function of the neonatal gut

As in the adult, the neonatal gut has a range of functions that are all necessary in maintaining metabolic homeostasis as well as regulating appetite. It, therefore, promotes digestion and absorption of nutrients in conjunction with secretory, motility and immunological functions. The neonatal gut is, however, specifically adapted to utilizing a milk diet, the composition of which varies through lactation, over the course of a feed[95] and with maternal diet and health.

As a consequence of the pronounced growth and maturation of the fetal gut during the final third of gestation, it is normally well adapted to absorb the nutrients it receives in milk after birth.[104] Glucose and NEFA are absorbed across the small intestine, whose surface area is substantially increased compared with the remainder of the gut, as a result of substantial number of valvulae connivantes, villi and crypts, together with the microvilli that form the luminal surface of enterocytes.

Gut function in the infant is not only coordinated by counterregulatory hormones secreted by the central and peripheral endocrine glands but possibly by hormones present in milk.[105] In addition, milk contains a range of trophic factors, anti-inflammatory and anti-infective agents, plus digestive enzymes which will enhance gut development and nutrient exchange. One important difference between the transfer of nutrients across the placenta and their transfer across the mammary gland in milk production is the necessity for the nutritional components of milk to be concentrated and packaged so as to survive transfer across the alveoli of the breast and subsequent exposure to the acidic environment of the small intestine.[106]

Fatty acid supply and utilization

The fat content of the milk does not appear to be greatly influenced by maternal diet or fat stores. Fat constitutes 3.9–4.4 g per 100 ml of milk.[33] Digestion and absorption of fat in the neonatal gut is similar to adults involving four phases: emulsification, hydrolysis, solubilization and mucosal transfer. The enzymes which digest fat are termed lipases of which three are abundant in the neonatal digestive tract, namely lingual, gastric and pancreatic lipase.[89] Of these, lingual lipase secreted from von Ebner's glands in the tongue is the most important in promoting fat digestion, and its activity decreases with age.[107] In contrast, because of the low concentrations of bile salts in the neonatal duodenum, pancreatic lipase is much less important in fat digestion than in later life.[108] The low activity of pancreatic lipases is partially overcome by the presence of bile-salt stimulated lipase (BSSL) found in milk. This is activated by primary bile salts (cholate and chenodeoxycholate) and amino acids (taurine and glycine) that are present in the small intestine.[109] BSSL completely hydrolyses triacylglycerols to glycerol and NEFAs into micellar forms.[110] These combine with the aggregated bile acids or micelles to form mixed micelles which, subsequently, transport the solubilized lipids to the brush border of the gut lining for uptake into the circulation and, thereafter, uptake and utilization by the liver. This process utilizes a fatty acid-binding protein, with triacylglycerol being resynthesized in the endoplasmic reticulum and the formation of chylomicrons.[111]

Not surprisingly, preterm infants in which gut development is immature have a lower rate of fat absorption than term infants.[112] Interestingly, the commercial addition of LCPUFAs to preterm milk formulas can have beneficial effects on long-term IQ, suggesting a direct effect on brain development.[113]

Carbohydrate supply and utilization

As in the fetus, glucose is a major oxidative fuel for many organs in the infant with the brain having an obligatory requirement. The main sugar in milk is lactose which is hydrolyzed to glucose and galactose by the enzyme lactase that is secreted from the apical membrane of the small intestine.[114] Both of these sugar products are then actively transported across the small intestinal epithelium by glucose transport systems that are similar to those present in the placenta with the principal GLUTs present in the gut being GLUT1, 2, 5 and 12.[115] These transporters are all sodium independent and only GLUT 12 has been shown to be insulin responsive.[116] In contrast, another type of GLUT found in the small intestine forms part of the Na^+-dependent family of transporters.[115] The latter transport sugars by a secondary active transport mechanism rather than by facilitative diffusion. This ensures glucose can be transported into cells across its concentration gradient via the Na^+-electrochemical gradient provided by Na^+,K^+-ATPase pump.[117]

The primary factor which determines glucose supply to the infant is the quality and quantity of milk consumed, which is, in turn, dependent on the nutrient intake and health of the mother.[102] It is not, therefore, surprising that many of the adverse effects of inadequate nutrition *in utero* can be overcome after birth. These may, however, have much longer-term consequences. Infants who have developed a 'thrifty phenotype'[118] as an adaptation to an adverse *in utero* environment may suffer later adverse health effects when exposed to the mismatch of a comparatively plentiful nutrient supply after birth. It must be noted that such adaptations will be in response to a very different nutrient intake from the diet than that to which the fetus is exposed *in utero*. In this respect, inappropriate accelerated postnatal growth appears to be deleterious with substantial adverse long-term outcomes. By promoting adiposity,[67] inappropriate accelerated postnatal growth compounds cardiovascular risk[119–122] and obesity.[123,124]

94 Contributions of 3D ultrasonography to the study of embryonic development

R. M. Sabatel López, L. Martínez-Cortés, J. C. Prados Salazar and J. L. Cuadros López

The massive changes a fertilized oocyte undergoes from the time of fertilization up to its transformation into a fetus were hidden from the human eye *in vivo* for many centuries. Thus, most of our knowledge is derived from the microscopic study of anatomical and pathological samples taken from gestating uteruses or aborted specimens.[1–3]

The evolution of ultrasound imaging and the advent of the transvaginal probe enabled the development of sonembryology, thus making available to us the development of the embryo *in vivo*.[4] From the embryological standpoint, this period includes the first 56 days of development.

We have learnt a great deal with conventional diagnostic ultrasound scans, Doppler techniques, and the use of color and power Doppler, but the advent of 3D diagnostic ultrasound techniques is changing our understanding tremendously. The opportunity to observe the volumetric morphology of the embryo and its annexa from the very beginning of gestation is clearly of immense importance in understanding the events taking place in this key period of human development.

First to third week of embryonic development

Conventional diagnostic ultrasound can detect the gestational sac in the endometrium as a round structure with a non-echogenic central area surrounded by a more refringent 2-mm ring (4 weeks and 3 days). 3D diagnostic ultrasound makes it possible to obtain images much earlier: on the 27th day of the cycle (13 days after fertilization) we can already see the outline of an eccentric structure proximal to the bottom of the endometrium, which corresponds to the gestational sac. Four days later we can easily see the yolk sac,[5] which is barely 1 mm in size. In a 2D ultrasound scan, this can hardly be identified (Figure 94.1).

Placental organogenesis begins on the ninth day postfertilization; villi formation begins on day 13, and on day 21 the intervillous circulation appears.[6] Whereas in 2D diagnostic ultrasound, trophoblastic proliferation is identified by the increase in thickness; in 3D ultrasound imaging we can even see the irregularities trophoblastic development confers on the surface of the gestational sac (Figure 94.2).

In the third week of development, the embryo attains a size of 2 mm and appears sonographically as a hyper-refringent area located on the yolk sac.[7] From an embryological point of view it is a highly complex structure: by the 21st day postfertilization the development of the notochordal process changes from 'disk shaped' to 'sandal shaped'. This process, which cannot be visualized with 2D ultrasound scanning, can be seen with 3D ultrasound imaging (Figure 94.3).

Toward days 21–22, the cardiac tube begins to beat. At this stage, the embryo is actually located between the amniotic cavity and the yolk sac, fixed to the trophoblast by a connecting stalk, which can only be verified with 3D sonography (Figure 94.4).

Folding of the embryo

The rapid growth of the nervous system induces and conditions the longitudinal folding of the embryo. At the same time, cross-embryonic growth conditions ventral folding, so that by day 28 the cephalic pole has completely bypassed the cardiac area and by day 35 the embryo has adopted a totally incurved shape.[8–12]

Embryonic folding is another process that can only be observed in three dimensions; initially, this shows the embryo and the yolk sac in different planes. Subsequently, we can identify the embryonic head and tail, not only in different planes, but also joined by a curved nervous system (Figure 94.5).

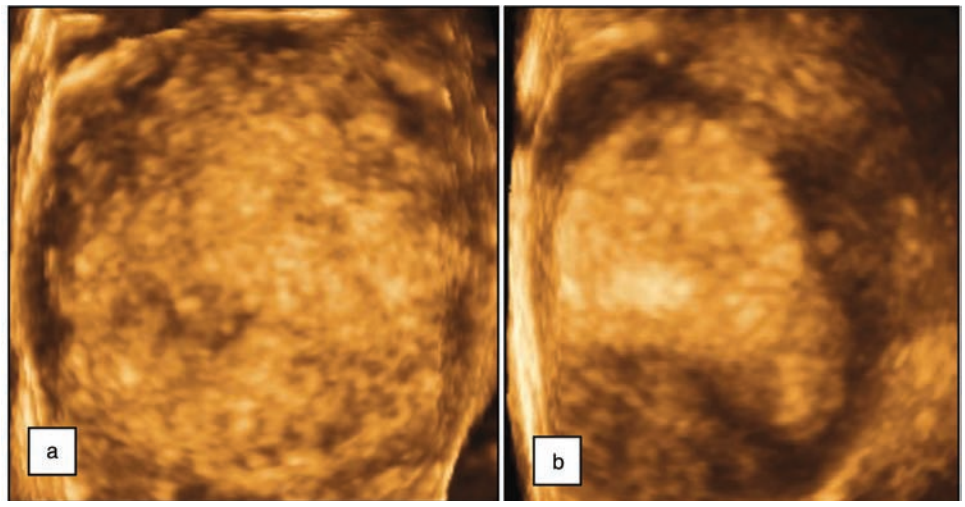

Figure 94.1 (a) Gestational sac on day 13 postfertilization. (b) Gestational sac with yolk sac in the fourth week and third day.

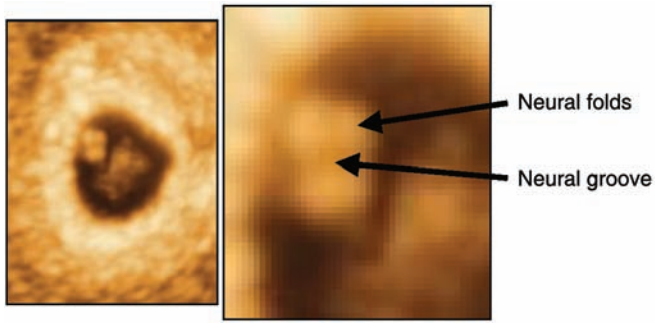

Figure 94.3 Changes in the shape of the embryo as a consequence of the notochordal process.

Figure 94.4 Embryo between amniotic cavity and yolk sac, with visible connecting stalk.

Development of the limbs

The development of limbs is another process unavailable to conventional diagnostic ultrasound techniques, but is visible with 3D sonography. Toward days 26–27 postfertilization we see the buds from which the arms will eventually develop, and then later the buds of the lower limbs appear. During the fourth week of development, the upper limbs adopt the form of a paddle, due to the appearance of the hand plates, whereas the lower limbs look like flippers. By the end of the fifth week the feet plates appear, and in the sixth week the flexure of the elbows. In the seventh week of embryonic development the hand and footplates face each other, and the ridges of the fingers will begin to differentiate, so that by the end of the embryonic phase, the fingers of the hand are visible (Figures 94.6 and 94.7).

Development of facial structures

Due to the curvature of the ventral area, the changes in facial morphology are not appreciable via 3D diagnostic ultrasound until the sixth week of embryonic

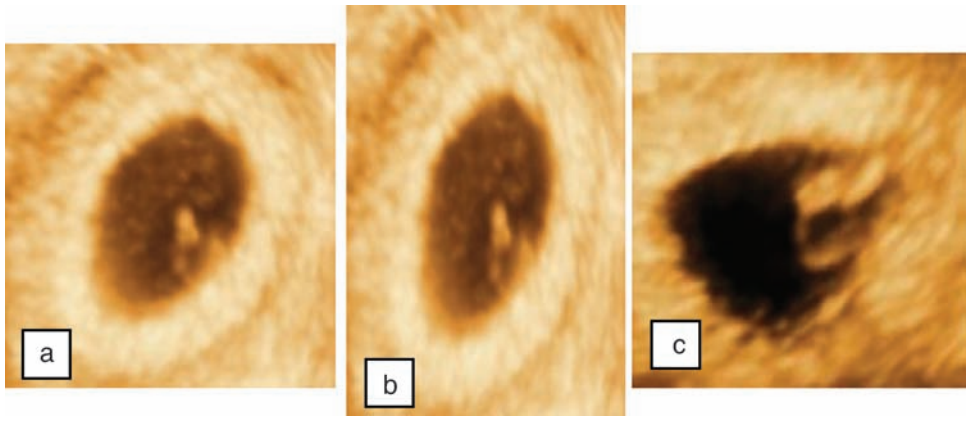

Figure 94.5 Folding of the embryo: (a, c) longitudinal folding and (b) ventral folding.

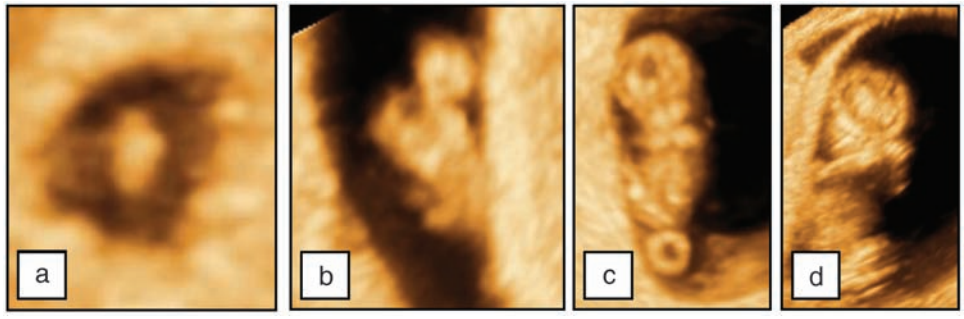

Figure 94.6 Upper limb development. (a) Bud of the arms. (b) Paddle-like arms. (c) The flexure at the elbows permits the placement of the forearm over the thorax. (d) Fingers of the hand at the eighth week of development.

development. By looking at the cephalic pole laterally, we can see the lens placode, the prominences made by the pharyngeal arches, and the auricular hillocks in whose center we see the exit for the auditory channel. A frontal view shows the mandibular and maxillary prominences of the first pharyngeal arch, the nasal pits, and the wide mouth of the embryo. At the eighth week, the frontal view makes it possible to visualize a completely closed palate and the internal configuration of the nose (Figure 94.8).

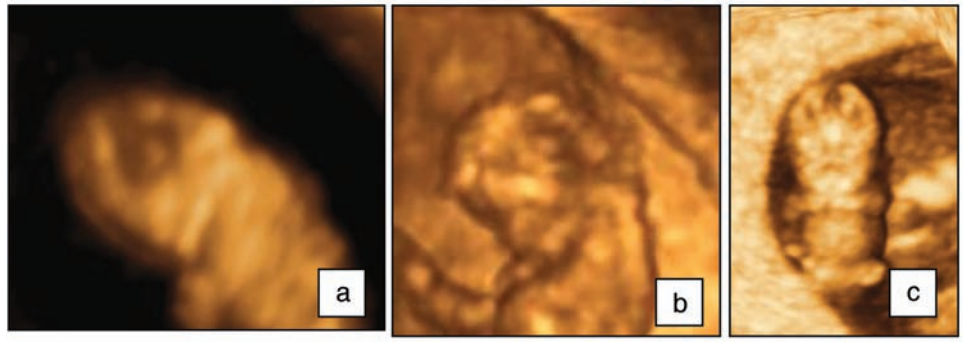

Figure 94.8 Facial structures observed with 3D ultrasound imaging. (a) Lateral view of the face at the sixth week. We can see the lens pits and the prominences of the pharyngeal arches. (b) Frontal view of the face at the sixth week. We can see the mandibular and maxillary prominences as well as the nose pits and the mouth. (c) The frontal view at the eighth week shows the nasal septum, nares, and palate.

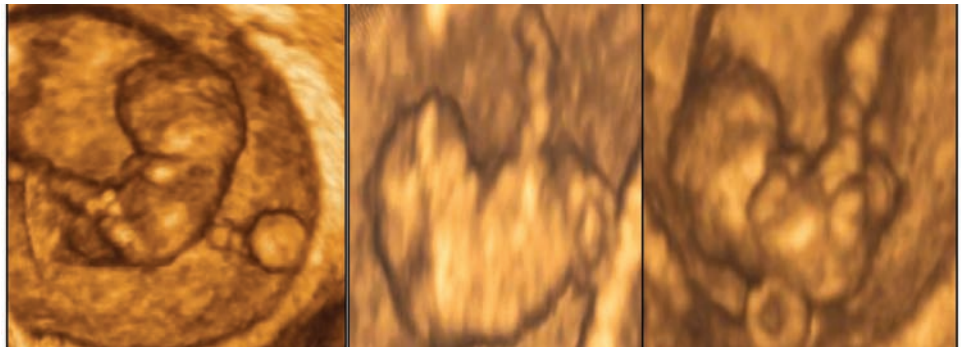

Figure 94.9 Physiological umbilical hernia with 3D sonography.

Abdominal wall

The ventral folding of the embryo makes the yolk sac independent and contributes to the progressive closing of the abdominal wall. By the seventh week, the wall is almost closed except for the area corresponding to where the umbilical will attach. This, together with the rapid intestinal development, influences two sonographically visible facts. First, communication between the primitive intestine and yolk sac becomes reduced to a very fine cord, which allows greater separation between the sac and the embryo. Second, part of the intestine remains in the proximal side of the umbilical cord and, therefore, is outside the abdominal cavity. This is called the 'physiological umbilical hernia', which is visible until the 12th to 13th week of gestation (Figure 94.9).

The spine

In the fifth week of development, the spine presents chondrification centers, visible in 3D at the sixth week of development. Between days 50 and 56 we find three ossification centers in the spine – two lateral centers corresponding to vertebral processes and a central one corresponding to the vertebral body. With 3D ultrasound imaging it is possible to locate the body of the vertebra (greater size) and even the ossification of the vertebral processes of the ribs, which have also begun to evolve during this week (Figure 94.10).

Development of the heart

Toward days 20–21, once the two cardiac tubes fuse into one, the heart begins to beat. At the end of the third week, this single tube bends giving rise to the appearance of the primitive atrium and ventricle, separated by a constriction area: the atrioventricular canal. With 3D PW, we cannot only identify the heart in the fourth week of development, but also identify its external morphology (Figure 94.11).

The complex embryology of the heart develops between the fourth and the fifth weeks. By the end of this stage the septa begin to grow, thus separating the atrioventricular canal. Some of the atrioventricular valves also begin to develop. In the heart of an 11-mm embryo it is possible to differentiate the atria from the ventricles. The former are separated by the primum septum and the ventricles are partially separated by the interventricular septum, which still has an orifice for communication between them. In tandem with

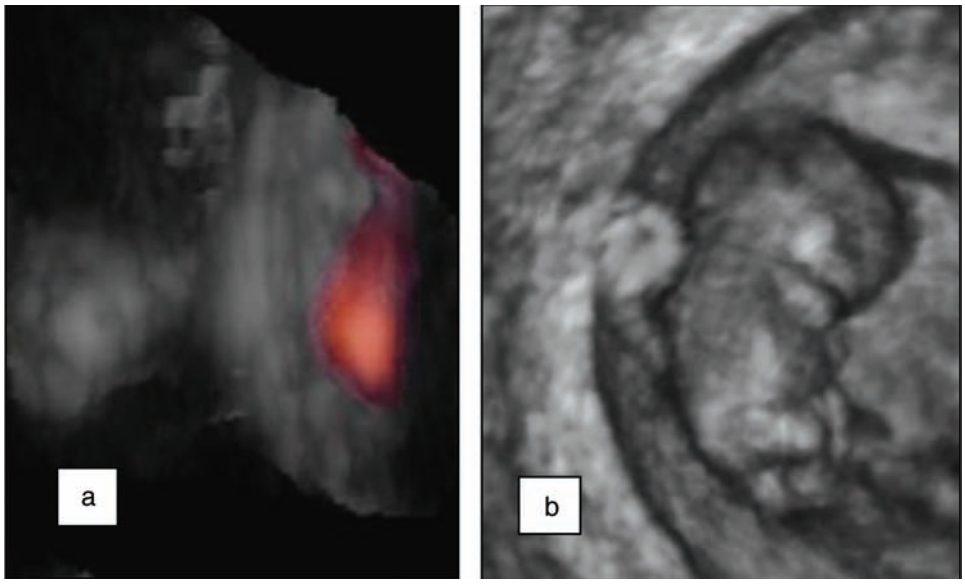

Figure 94.10 The spine (a) in the chondrification phase, sixth week of development, and (b) in the ossification phase, eighth week of development.

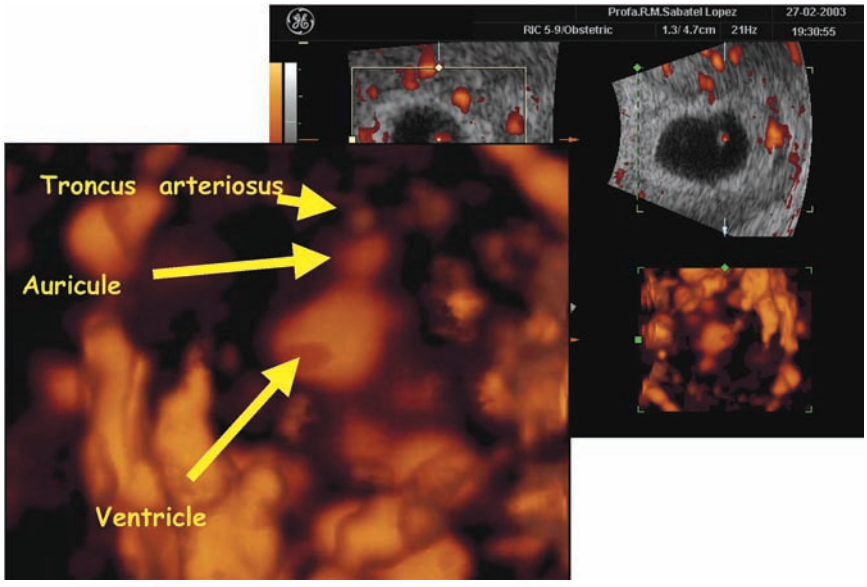

Figure 94.11 Morphology of the heart at the fourth week of development with 3D PW Doppler.

the process of separation of the four cavities, the aorto-pulmonary partition undergoes spiral rotation. With 3D color Doppler sonography we can see the four cavities, and with body capture imaging how they rotate (Figure 94.12).

In the seventh week, the ventricles are totally separated because the orifice existing in the previous week is now closed. Using 3D PW Doppler, it can be seen that the external morphology is very similar to that of the fetal heart (Figure 94.13).

We cannot state that the closing of the interventricular partition – and what this implies for the evolution of the heart conduction system – is the cause of a functional change also observed at this time: the peak embryonic heart rate, which takes place at this time. In the ninth week of amenorrhea, seventh week of development, the heart rate curve reaches its highest peak, with an average of 170 beats/min, which in some cases can reach nearly 190 beats/min. From this point onward, the heart rate decreases until it reaches a plateau by the 14th or 15th week of amenorrhea. These values are maintained during the whole gestation period. This heart rate curve is constant, independent of the number of cases investigated.[13,14]

Development of the nervous system

During the fourth week, the closing of the neural tube has occurred and its differentiation into brain and

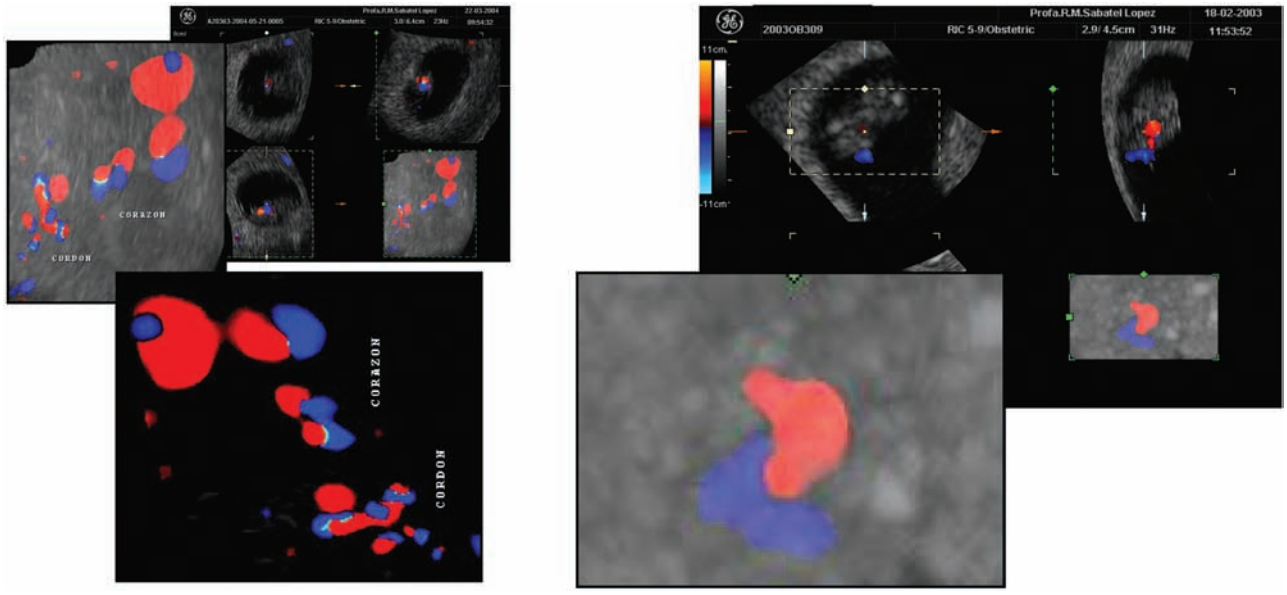

Figure 94.12 Embryonic heart at the sixth week of development.

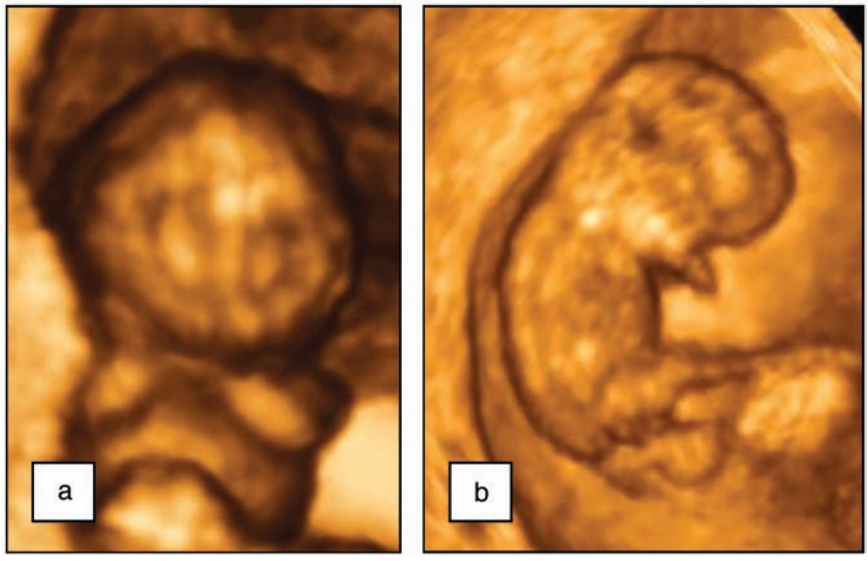

Figure 94.15 Cerebral ventricles at the eighth week of development: (a) lateral ventricles with chorioid plexuses and (b) lateral ventricle, third and fourth ventricles.

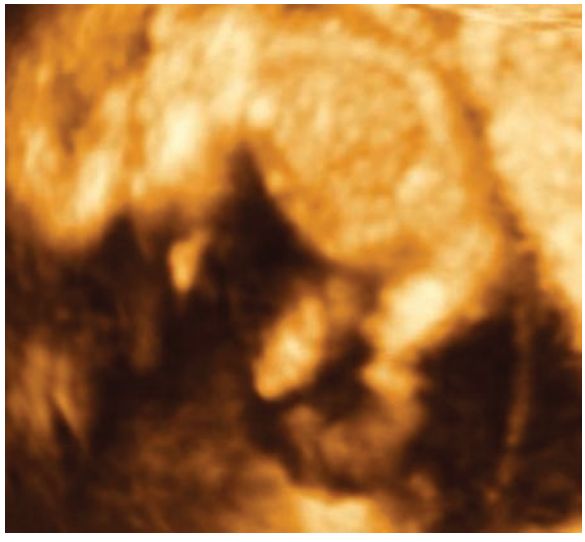

Figure 94.16 Eighth week of development: right lung views with 3D sonography.

spinal cord has begun. By the beginning of the fifth week, the three primary vesicles appear, anterior or prosencephalon, middle or mesencephalon, and posterior or rhombencephalon, and two flexures: one folding the anterior and middle vesicles, and the cervical flexure. By the end of the week, there are five cerebral vesicles: telencephalon, diencephalon, mesencephalon, telencephalon, and myelencephalon. The pontine flexure also appears. The increase in size during the fifth week permits their identification with 3D sonography (Figure 94.14).

These structures are hollow and each of them bulges to give rise to different ventricles, which by the seventh week are in clear development. By the end of this week, the chorioid plexuses begin to develop inside the lateral ventricles (Figure 94.15).

Lung development

In such small embryos, it is practically impossible to follow the development of viscera sonographically due to their small size and the density of the different tissue layers. However, the lungs are different. By the eighth week of development, the bronchial tree is made up of two main bronchi buds (the left and the right, the latter being larger), secondary bronchi and segmentary or tertiary bronchi. From a histological standpoint, the lung is at the pseudoglandular stage. With 3D diagnostic ultrasound, we can identify the embryonic lung, the lobes, and even a section of the bronchi (Figure 94.16).

This review of the first 56 days of development with a 3D ultrasound scanner reveals the real potential of the technique: understanding normal embryological processes that are not visible with 2D sonography and that are clearly necessary to detect early morphological alterations.

95 Two- and three-dimensional power Doppler ultrasound: from ovulation to implantation

L. T. Mercé, M. J. Barco, S. Kupesic and A. Kurjak

Introduction

The ovarian cycle has two main purposes: first, the liberation of a mature oocyte through the ovulatory process; second, the production of a proper hormonal secretion to prepare the endometrium for the embryo implantation. All these processes require and involve great changes affecting the ovarian and uterine blood flows. The follicular growth, the corpus luteum formation and the endometrial development are physiological processes in which angiogenesis takes place in a natural way, thus providing the blood flow supply.

The uterine and ovarian blood flow changes taking place along the menstrual cycle were known basically from invasive experimental results out of different animal species. Doppler ultrasound examination, especially transvaginal color Doppler, has allowed the noninvasive approach to the importance of the blood flow in natural and artificial human reproduction. Recently, three-dimensional (3D) power Doppler and one sophisticated measurement software makes it possible to calculate the number of vessels and the blood flowing through them. This technique has greatly increased our knowledge about the uterine and ovarian vascularity.

In the present chapter, the blood flow changes taking place in the ovary and endometrium are analyzed from ovulation to implantation through the different examination techniques previously named. Currently, some of the parameters evaluated are those used in daily practice as oocyte quality and endometrial receptivity markers. Therefore, the different Doppler modalities become an essential technique to investigate the menstrual cycle physiology and a source of diagnostic and prognostic parameters about the outcome of assisted reproductive technologies.

From ovulation

The ovarian and uterine blood flow changes have different physiological and clinical implications during the menstrual cycle, so from a practical point of view, we will separate their study.

Ovarian blood flow

Doppler studies have demonstrated the ovarian blood flow participation in the recruitment and selection of the dominant follicle during the *early follicular phase* of the ovarian cycle.[1,2] Our investigations confirm that in the beginning, the intraovarian vascular resistance is correlated with the number of recruited follicles. On the contrary, when a follicle reaches 10 mm of diameter it becomes 'dominant' and the intraovarian vascular resistance decreases despite the disappearance of the follicles cohort.[3,4] This relationship between the number of follicles and the intraovarian blood flow supports the utility of these parameters as indicators of the ovarian response to the gonadotrophin stimulation treatment (Figure 95.1).

The number of follicles after pituitary suppression is a better *marker of the ovarian response* than the age of the patient and the ovarian volume.[5] This parameter predicts the number of retrieved oocytes irrespective of age and serum follicle stimulating hormone (FSH) levels.[6] The total number of antral follicles is the best predictor of the ovarian response followed by basal FSH, body mass index and the age of the woman.[7]

The blood flow of the ovarian stroma also predicts the ovarian response. The stromal peak systolic velocity during the early follicular phase is better related to the number of retrieved oocytes than the age of the

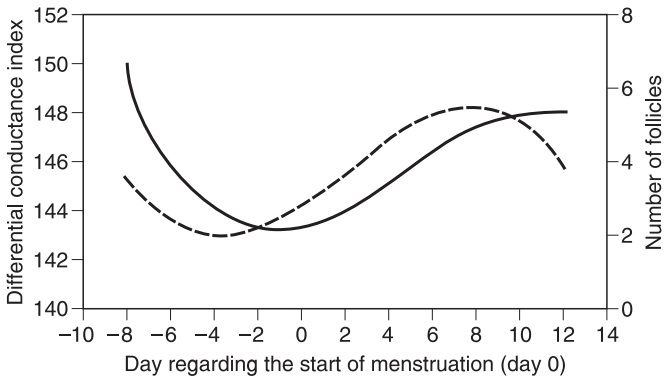

Figure 95.1 Relationship between the number of recruited follicles (red line) and stromal flow, as assessed by its differential conductance index (blue line), during the transitional luteal–follicular period in 22 normal ovulatory cycles.

patient, the basal levels of FSH and estradiol.[8] A diminished stromal blood flow is responsible for a low ovarian response whereas when it rises over 10 cm/s a high number of oocytes and a better pregnancy rate are achieved (Figure 95.2a).[9]

Three-dimensional ultrasound and power Doppler angiography make the estimation of the number of antral follicles and the stromal blood flow much easier without disturbing the patients.[10] Kupesic and Kurjak proved that the number of antral follicles and the index of stromal flow are the best predictors of a favorable outcome in *in vitro* fertilization (IVF).[10] An increased or decreased stromal blood flow can explain a high or low response in IVF cycles.[11,12] Nevertheless, some authors believe that 3D Doppler indices do not offer additional information to predict the ovarian response to gonadotrophin stimulation during IVF cycles (Figure 95.2b).[13]

Our experience in the assessment of 3D power Doppler ultrasound as a marker of the ovarian response comes from a study of 60 patients undergoing their first IVF cycle. A total of 119 ovaries have been separately evaluated because hypothetically the ovarian response could be mediated by the local vascular factors. The number of follicles ≥ 10 mm the day of human chorionic gonadotrophin (hCG) injection and the number of oocytes retrieved are considered as indicators of the ovarian response. A significant correlation ($P < 0.01$) has been observed between the ovarian volume, the number of antral follicles greater than 2 mm, ovarian vascularization index (VI), ovarian flow index (FI) and ovarian vascularization-flow index (VFI) to the number of recruited follicles and the number of retrieved oocytes (Table 95.1). Nevertheless, when a multiple regression is applied, only the number of follicles and the ovarian volume reach a statistical significance.

During the follicular phase the arterial and venous blood flow increase in the active or dominant ovary.[14–18] The color signal at the wall of the dominant follicle increases progressively to almost encircling it. This is due to the intense angiogenesis produced along with the follicular development. The blood flow also increases progressively at the vessels of the ovarian stroma, the ovarian hilum arteries,[16,17] and the venous circulation.[18] On approaching ovulation, the blood flow increases significantly compared to the contralateral or inactive ovary (Figure 95.3).

Several studies of animal experimentation deduce that blood flow increase during the follicular phase is basically due to the growth of the dominant follicle.[5] Our study, along with those of other authors,[19,20] proves this assumption by confirming a significant correlation between the diameter of the dominant follicle and the venous and arterial perifollicular maximum systolic velocity.[21] A high correlation between the dominant follicle size and the serum estradiol is classically acknowledged;[22] nevertheless a significant correlation between the follicular blood flow and the estradiol blood levels has not been proven until now.

The blood flow reaches its maximum values in the *preovulatory follicle* just prior to the follicular rupture. The maximum blood flow velocity increases from 29 h before the follicular rupture, maintaining a peak until at least 72 h after the corpus luteum appearance (Figure 95.4a).[23] The blood flow is similar in every part of the preovulatory follicle before the luteinizing hormone (LH) peak. After the LH peak the maximum systolic velocity increases at the base of the follicle and decreases significantly, almost disappearing, at the apical zone.[24] Three-dimensional power Doppler shows the preovulatory follicular wall has a number of vessels (VI) and an amount of blood flowing through them (FI) significantly increased as compared with the same ovary (Figure 95.4b).[25]

Electronic microscopy has shown the preovulatory follicular walls as having a great amount of sinusoidal dilated vessels and avascular zones due to ischemia and arteriovenous shunts.[26] These findings support the vascular mechanism of ovulation and would explain the blood flow velocity increase by the presence of shunts and the apical disappearance of Doppler signals caused by thrombosis and ischemia phenomena.

The process of angiogenesis, development and vasodilatation of the perifollicular vascular network culminates at the *ovulation*. From the follicular rupture onward, the theca vessels begin the invasion of the granulosa cells showing an intense angiogenesis and wide arteriovenous shunts. Moreover, the growth in size of the ovary leads to a straightening of the spiral arteries which compromise the hemodynamic stability of the whole system producing an increase in the turbulence of the blood flow.[3,4] This flow increase associated with changes in the spectral Doppler signal is named 'luteal conversion' and is of great help to the diagnosis of ovulation (Table 95.2). The luteal conversion is independent of the sonographic visualization or appearance of the corpus luteum. In the luteinized unruptured follicle (LUF) syndrome the follicular

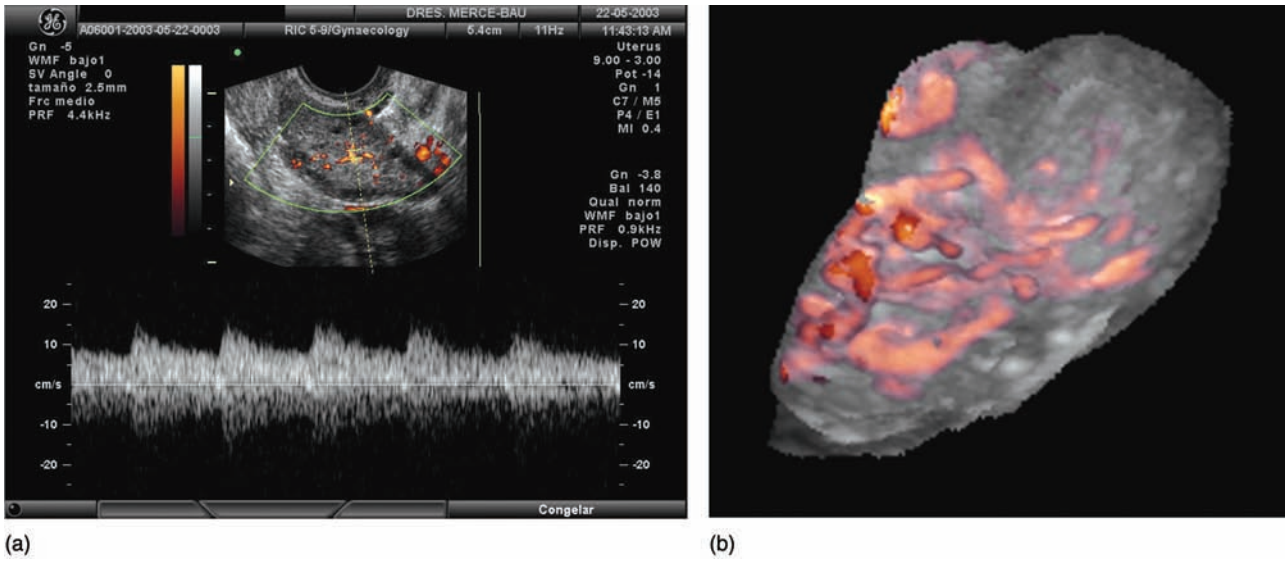

Figure 95.2 Sonographic markers of the ovarian response. (a) Recording of the ovarian stromal flow velocity wave (FVW) after pituitary suppression by GnRh analogs. The peak systolic velocity is a good predictor of the number of follicles to grow. (b) Three-dimensional ultrasonography and power Doppler angiography allow the assessment of all the sonographic and Doppler parameters involved in the prediction of the ovarian response.

Table 95.1 Correlation coefficients of the sonographic parameters and power Doppler indices after pituitary supression, with the number of recruited follicles and the number of retrieved oocytes in 65 IVF cycles

	No. of follicles on hCG day	No. of retrieved oocytes
Ovarian volume	0.46	0.41

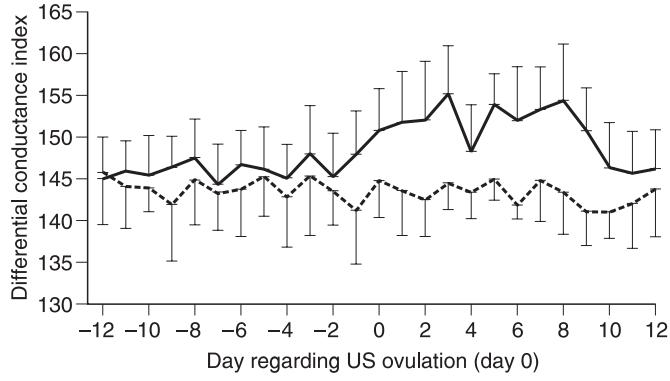

Figure 95.3 Differential conductance index of the dominant or active ovary (blue line) and the contralateral or inactive ovary (red line) during the ovarian cycle. Luteal values of the dominant ovary are significantly increased compared to those of the follicular phase or those from the luteal phase of the inactive ovary.

rupture does not take place so the luteal conversion is not present.[15] Therefore, the luteal conversion is a very reliable parameter of ovulation.

The corpus luteum has a greater arterial and venous blood flow than the preovulatory follicle.[3,4,14–18] The helical arteriole of the corpus luteum presents the highest systolic velocities with a small variability.[27] The luteal vascularity can be depicted with a great accuracy by 3D power Doppler (Figure 95.5). The luteal vascularization, flow and vascularization flow indices calculated from 3D angiography are significantly superior to the follicular ones (Table 95.3). During the luteal phase the blood flow increases in the stromal and hilum arteries of the active ovary[16,17] and also in the utero-ovarian and ovarian ipsilateral arteries.[3]

This increase in the amount of blood flow is essentially caused by the development of new vessels in the ovary carrying the corpus luteum but it should be controlled by local and systemic mediators. An inverse and significant relationship has been proven between the vascular density of the corpus luteum and its pulsatility index.[28] Color Doppler studies confirm that the arterial[17,29,30] and venous[18] blood flow of the corpus luteum is correlated with progesterone secretion. The cycles with luteal or secretory deficiency show an increase in the luteal vascular resistance[29,30] and a decrease in the venous flow velocity[18] In the LUF syndrome the blood flow remains unchanged after the LH peak. During the 'false' luteal phase, the vascular resistance is similar to that of the

follicular phase without detectable differences between them (Figure 95.6).[15,18,31]

Uterine and endometrial blood flow

The blood flow of the uterine arteries and their radial branches does not experience significant changes during the early and middle follicular phase.[16,30] The findings on blood flow during the periovulatory period are contradictory. Whereas some authors[32,33] find an increasing uterine and endometrial (uterine, radial and spiral arteries) blood flow from the LH peak onward, others[16,34,35] find a decreasing blood flow until past ovulation. By means of 3D power Doppler it has been recently proven that the endometrial and subendometrial blood flow and vascularity indices increase from the middle follicular phase to attain their maximum values three days prior to ovulation. After that, these indices decrease until reaching their nadir 5 days after ovulation to increase progressively again during the middle and late luteal phases (Figure 95.7).[36]

During the luteal phase the blood flow in the whole uterine vascular tree, from the uterine arteries to the endometrial spiral arteries, increases significantly compared to that of the follicular phase.[16,32,33] As the menstrual cycle advances but especially during the luteal phase, the color signals from the intramyometrial and endometrial vessels grow in number and intensity.

When no pregnancy is achieved, the blood flow in all the utero-ovarian vascular network decreases and menstruation begins a new cycle.

To implantation

Implantation is a dynamic process requiring a true dialog between mother and embryo. The assisted reproductive technologies (ARTs) have demonstrated that success in achieving implantation and a normal ongoing pregnancy depends essentially upon the embryo quality and endometrial receptivity. Since many years, sonographic and Doppler parameters have been sought to be used as 'implantation markers'.[37,38]

The follicular size and perifollicular vascularization have been proposed as ultrasound markers of

oocyte quality and competence. The endometrial pattern and thickness have been also evaluated as indicators of endometrial receptivity.

Follicular blood flow

The intrafollicular oxygen concentration determines a normal embryo development. Oocytes with cytoplasmatic defects and embryos with multinucleated blastomeres come mainly from follicles with severe hypoxia causing an abnormal arrangement of chromosomes.[39] On the other hand, a defective development of the perifollicular vascular network has been implicated in the origin of intrafollicular hypoxia.[40] The embryonic triploidies rate is significantly raised in the poorly vascularized follicles.[41] On the contrary, the best vascularized follicles are those showing the highest oxygen concentrations.[39] Given that similar size follicles can contain different oxygen concentrations, perifollicular vascularity is an independent marker of the follicular diameter.[42]

The follicular blood flow can be assessed by the maximum systolic velocity in the perifollicular arteries.[43,44] This technique assumes that the blood flow in a single artery represents all the follicular blood flow. The perifollicular color mapping with power Doppler is an easier and reliable technique to assess the follicular blood flow.[41,42,45,46] This procedure assumes that the color signal coming from a single perifollicular vascular plane represents all the follicular blood flow. Three-dimensional power Doppler evaluates all the perifollicular vessels and determines the vascularization index (number of vessels) and flow (flow intensity) from the whole follicular volume. Therefore it is the only method directly assessing the entire follicular blood flow (Figure 95.8).

In accordance with the percentage of color area from the perifollicular power Doppler mapping, follicles have been classified as: grade 0, when no color can be depicted[45]; grade I, less than 25% of the follicular circumference; grade II, between 26% and 50%; grade III, between 51% and 75%; and grade IV, between 76% and 100% (Figure 95.9).[41,42,46] The number of retrieved oocytes, mature and fertilized is significantly higher from the well vascularized follicles (grades III and IV) than from those showing poor vascularization (grades I and II.[41] According to our results, perifollicular vascularization determines specially the maturity and fertilization indices in follicles < 15 mm, being significantly higher in those well vascularized. The recovery rate is independent from vascularization and shows rates higher than 50% (Table 95.4).

We have evaluated a single IVF/ICSI cycle in 80 infertile women by 3D power Doppler ultrasonography. We studied the relationship between the sonographic parameters (ovarian volume, number of follicles > 10 mm and total follicular volume) and 3D power Doppler indices (vascularization index, flow index and vascularization-flow index) on the day of hCG administration with the laboratory biological parameters (number of retrieved oocytes, number of mature oocytes, number of fertilized oocytes, number of embryos on transfer day, number of Grade 1 embryos on transfer day and cumulative embryo score of all the embryos on transfer day). As you can see in Table 95.5, all the sonographic and vascularity

parameters are significantly correlated with the laboratory data. Nevertheless, a multiple regression analysis has demonstrated that the vascularization index and the number of follicles are the only independent predictors of the number of Grade I embryos developed on the embryo transfer day. Therefore, the embryo quality depends not only of the number of follicles but of the ovarian vascularization index as well.

The transfer of an embryo from a well-vascularized follicle implies a significantly high pregnancy rate, whereas the pregnancy loss rate is increased when the embryos transferred come from low vascularized follicles.[41,46] The probability of pregnancy has been observed to be higher if at least one follicle shows a peak systolic velocity ≥10 cm/s.[45] According to our results,[38] the transfer of at least one embryo from one follicle with a vascularity ≥75% or with a peak systolic velocity ≥10 cm/s has a positive predictive value of pregnancy greater than 55%. That means that the application of this marker could improve results significantly, almost doubling the pregnancy rate (32% in this series).

Kupesic and Kurjak[10] studied 56 patients with 3D power Doppler after pituitary suppression. When the average stromal flow index from both ovaries was greater than 11, they observed a fertilization rate of 89% and a pregnancy rate of 50%. When this index was between 11 and 13 the fertilization and pregnancy rates were 75.2% and 47.2%, respectively. However, if the average flow index from both ovaries was below 11 the fertilization rate fell to 64.3% and no pregnancy was achieved. Our results are shown in Table 95.6, where significant differences between pregnant and non-pregnant patients for the majority of IVF evaluated parameters can be appreciated. Although the number of transferred embryos was similar, the biological quality was greater in the pregnant group. Three-dimensional power Doppler indices are significantly increased in the pregnant group. Ovarian flow index lower than 60 is significantly associated with a lower pregnancy rate and to a greater number of miscarriages (14.3% and 50% respectively). On the contrary, a flow index higher than 70 is significantly related to a higher pregnancy rate and to a lower rate of pregnancy loss (74.1% and 5% respectively). When the flow index was between 60 and 70 the pregnancy rate was 41% and the miscarriage rate was 37.5%.

Uterine and endometrial blood flow

Goswany *et al.*[47] demonstrated that the uterine receptivity improved after increasing the uterine arteries blood flow under hormonal replacement therapy. The optimal uterine receptivity seems to appear when the average pulsatility index from both uterine arteries ranges from 2 to 3.[48–50] The implantation and pregnancy rates decrease significantly when the pulsatility index is greater than 3 or 4[48–56] or when no diastolic flow is registered in the Doppler signal (Table 95.7).[55,56]

According to these limits, a diminished blood flow in the uterine arteries would prevent implantation (NPV = 88–100%) but a good uterine perfusion will not always guarantee a pregnancy (PPV = 44–56%).

Table 95.8 Pregnancy rate according to endometrial blood flow mapping on the hCG administration day in 40 IVF cycles

Endometrial blood flow	No. of cases, *n* (%)	Pregnancy rate, *n* (%)
Type 0	5 (12.5%)	1(20%)
Type I	17 (42.5%)	6 (35%)
Type II	12 (30%)	5 (42%)
Type III	6 (15%)	4 (67%)

The endometrial blood flow should reflect more properly the uterine receptivity given that the endometrium is the place for the embryo implantation.[38] In accordance with the color mapping four types of endometrial blood flow can be distinguished[38,57–59]: Type 0 or negative endometrial blood flow, when only vessels from the surrounding myometrium without reaching the endometrium can be depicted; Type I or peripheral endometrial blood flow, if the color signal reaches the hyperecogenic endometrial border; Type II or intermediate endometrial blood flow, when the color map occupies the external half of the endometrial thickness; and Type III or central endometrial blood flow when vessels come to the endometrial cavity invading the entire endometrial thickness (Figure 95.9). It is more convenient to apply power Doppler to detect the signal from vessels showing low velocity blood flow, thus avoiding the loss of signal due to a perpendicular incidence of the beam, as it occurs with conventional color Doppler.[38]

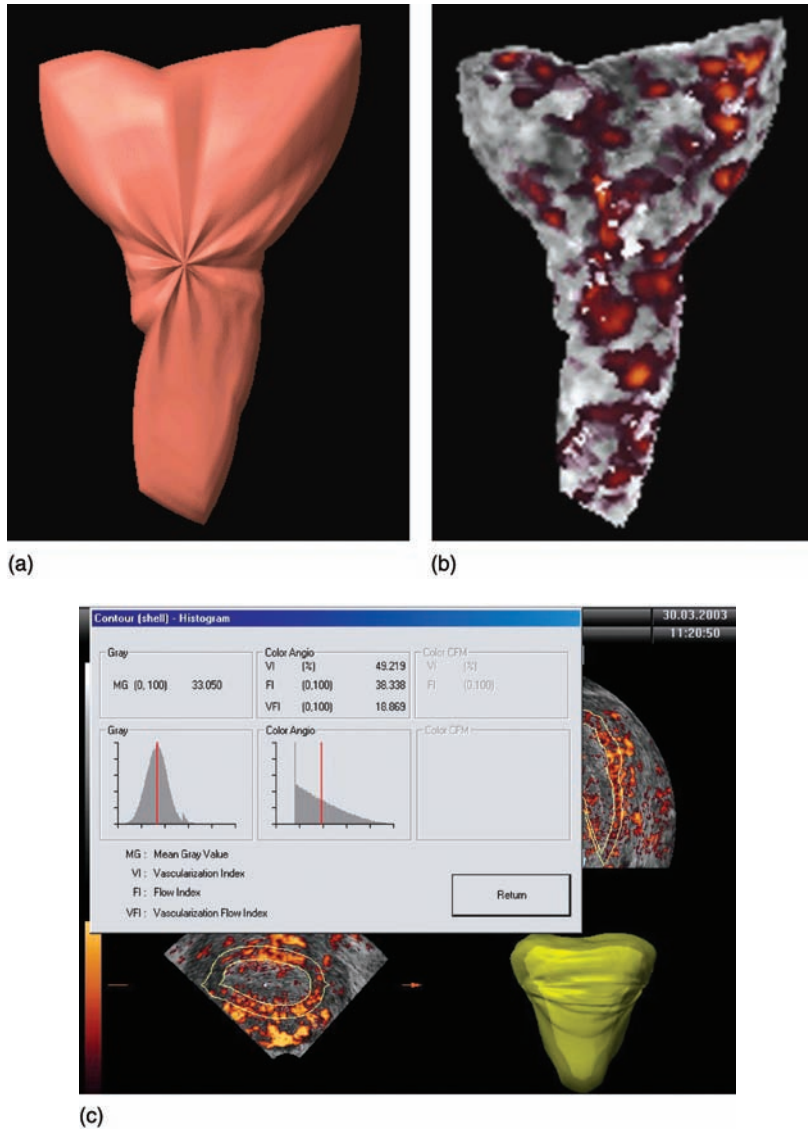

Figure 95.10 Three-dimensional ultrasound and power Doppler angiography of the endometrium and its vascularity on the day of hCG administration. (a) Endometrial volume by 'skin' rendering. (b) Three-dimensional power Doppler mapping of the endometrial vasculature. (c) Technique of 'shell' to calculate subendometrial 3D power Doppler vascularity indices.

The absence of a color map at the endometrial and myometrial subendometrial levels implies a complete failure[57] or significant decrease[60,61] of implantation, whereas the pregnancy rate increases when vessels reach the subendometrial halo and the endometrium.[57,60] In a study of about more than 600 cycles with color Doppler, the day of embryo transfer, the implantation and pregnancy rates were 24.2% and 47.8%, respectively when endometrial and subendometrial blood flow was detected; 15.8% and 29.7% if there was only subendometrial flow; and 3.5% and 7.5% when no flow was present.[60] Women showing a large endometrial blood flow area by power Doppler have a greater pregnancy rate, whereas a value below 5 mm^2 means that it is very difficult to achieve implantation despite a proper endometrial thickness.[62] Our results from 40 IVF cycles show that the pregnancy rate increases along with vascularity improvement, reaching a 67% when the color signal arrives at the endometrial cavity (Table 95.8).

Ultrasonography and 3D power Doppler have the advantage to assess the endometrial volume and the endometrial and sub-endometrial blood flow at the same time (Figure 95.10). The subendometrial flow index the day of embryo transfer is greater in the group of patients achieving pregnancy.[63] A subendometrial vascularization-flow index above 0.24 showed a 83.3% sensitivity, a specificity of 88.9%, PPV of 93.8% and NPV of 72.3% to predict gestation when it is evaluated the day of hCG administration in IVF cycles.[64]

Table 95.9 Pregnancy rate according to subendometrial 3D power Doppler indices on the hCG administration day in 40 IVF cycles

Doppler indices		No. of cases, n (%)	Pregnancy rate, n (%)
Vascularization	<10	5 (12.5%)	0 (0%)
	10–35	18 (45%)	11 (61.1%)
	>35	17 (42.5%)	5 (29.4%)
Flow	<28	12 (30%)	1 (8.3%)
	28–34	20 (50%)	12 (60%)
	>34	8 (20%)	3 (37.5%)
Vascularization-flow	<6	10 (25%)	1 (10%)
	6–12	17 (42.5%)	10 (58.8%)
	>12	13 (32.5%)	5 (38.5%)

According to our results, an intermediate vascularization, flow and vascularization-flow indices are associated to a high pregnancy rate. On the contrary, when the vascularization index is below 10 no pregnancy is achieved. When the blood flow is very high, the pregnancy rate decreases without significant differences (Table 95.9).

96 Implantation and the yolk sac

S. Kupesic and A. Kurjak

Introduction

Recent advances in perinatal technology have increased tremendously our understanding of early human development. This, in turn, has led investigators to ask numerous searching questions about both maternal and fetal placental hemodynamics.

The early beginning of embryonic life is a gestational period of important hemodynamic changes, mainly characterized by establishment of a continuous maternal blood flow in the intervillous space. In this development process, the maternal vascular bed and spiral arterioles form the basis for perfusion of the placenta. Current anatomical knowledge has largely been based on the classical studies of earlier investigators. In many instances, their theories have been confirmed by new information, but, in others, initial errors in observation or conclusion have been brought to light necessitating revision or replacement of the original concepts.

Many questions are presently directed to the intervillous space, probing in particular its size and form, its source of blood supply and the mechanism of circulation within it. In 1962, in an excellent review article[1] on circulation in the intervillous space Ramsey wrote: 'Old ideas die hard, however, even when their validity has been challenged, and it is well known that they frequently maintain their position in textbooks for some time after they have been discarded by workers in the forefront of the field. Old ideas also have a tendency to leave fragments of themselves, as a complicating legacies, incorporated in the theories which finally replace them'.

How little has changed in a period of more than 34 years! We are still searching for satisfactory answers to many of the queries on the intervillous circulation. However, a good deal of data are already available, especially as a result of recent research on Doppler proofs of the continuous blood flow in intervillous space. In our effort to facilitate a better understanding of the present concepts on intervillous circulation, a brief recapitulation of anatomy and embryology will be included in the subsequent sections of this chapter. It is our intention to synthesize and clear out the chronology and factography of the controversial data and theories about the establishment of intervillous circulation and yolk sac morphology and function.

The 'classic' embryological concept of the early uteroplacental circulation

The labyrinthine series of cavities, which together constitute the intervillous space in the placenta, was first identified by William and John Hunter in the 18th century. However, there is still uncertainty regarding many of its features.[2]

The first week of embryonal development is the preimplantation stage. By the end of day 5, blastocyst is formed consisting of the trophoblast and embryoblast (inner cell mass).[3]

After this period begins the implantation period, the process whereby the blastocyst attaches to and erodes through the endometrial epithelium. One of the earliest modifications of the endometrium after fertilization is an increase in vascular permeability. The other changes of the endometrium include increased vascularity, edema and thickening (i.e. decidual reaction). Trophoblast produces proteolytic enzymes that facilitate the penetration in the endometrium and erodes adjacent maternal capillaries.

By the end of the first week, the blastocyst is superficially implanted in the endometrium. Trophoblast and embryoblast start to develop along different lines.[4,5] In the seventh day after fertilization (Carnegie stage 5a) the trophoblast rapidly differentiates into two layers – an inner layer of mononuclear cytotrophoblastic cells and an outer layer of multinucleated syncytiotrophoblast. The syncytiotrophoblast comes into direct contact with the endometrial stroma. The endometrial glands in contact with the trophoblast show degenerative changes; in some instances the glandular epithelium has disappeared and the trophoblast plugs the glandular lumen.[2]

By the eighth day after fertilization, the blastocyst is completely embedded within the endometrial stroma. At the embryonic pole, the primitive syncytiotrophoblast on the surface has some deep indentations, which contain maternal blood cells.

Figure 96.1 Lacunar space blood flow at the periphery of an early gestational sac as seen by color Doppler ultrasound.

The ninth day of development (Carnegie stage 5b) is named the lacunar or previllous stage. At this stage the inner cell mass (embryoblast) is differentiated into a bilaminar embryonic disk.[3]

From the eighth day after fertilization, intercommunicating fluid-filled spaces of lacunae appear in the rapidly enlarging syncytiotrophoblast. Between the 10th and 13th days (Carnegie stage 5c), lacunae convert the syncytiotrophoblast into a sponge-like structure. The lacunae are incompletely separated from each other by trabecular columns of syncytiotrophoblast. The lacunae open into several maternal sinusoids, which have probably arisen from endometrial capillaries. The lacunae become confluent. With further extensions of the maternal sinusoids and more dilatation of the endometrial blood vessels, the supply of blood to the lacunae comes largely from venous sinusoids. The lacunae rapidly become filled with a combination of maternal blood and secretion from eroded endometrial glands.[6] At this stage there is no evidence for direct arterial communication with the lacunae. It would seem that the earliest maternal blood that enters the developing lacunae is not arterial but is derived from the capillaries and venules that dilate to form sinusoids.[2] Using transvaginal color Doppler, venous signals can be clearly obtained from these spaces (Figure 96.1).

With continuing trophoblastic invasion, the maternal vessels disappear progressively back to the level of the spiral arteries and their venules, permitting a true circulation. The trabeculae are called 'primary villous stems'. They are not true villi but serve as the framework from which villi later develop. They are arranged radially and divide lacunae into a labyrinth at the 14th day after fertilization. The placenta at this stage of development is a labyrinthine rather than a villous organ.[7]

Primary chorionic villi develop between 13 and 15 days of development (Carnegie stages 6a and 6b). The trabeculae have a central cellular core produced by proliferation of the cytotrophoblastic cells. At the same time the formation of the first blood vessels starts in the extraembryonic mesoderm of the yolk sac, the connecting stalk and the chorion. The cytotrophoblastic cells extend distally toward the attachment of the syncytiotrophoblast to the endometrium. These cells from the villous tips break through syncytiotrophoblast and expand laterally to fuse with adjacent columns to form a cytotrophoblastic shell. The shell is completed by the 15th day after fertilization. Villi that are attached to the maternal tissue via the cytotrophoblastic shell are 'stem' or 'anchoring villi'. The villi that grow from the sides of the stem villi are 'branch villi'.

Days 15–21 are a period of intensive trophoblastic growth. By the 15th day, the maternal circulation becomes fully functional, when the syncytial lacunae become confluent and connected with endometrial capillaries.[8] The trabeculae, which are at first unoriented, gradually become more regularly arranged. The number of initial villi is determined by the number of trabeculae that are invaded by proliferating cytotrophoblast. On the 16th day, the extraembryonal mesenchyme appears and extends toward the villous distal end. Primary chorionic villi gradually convert into secondary villi.[3] By the 18th day, the villous mesenchymal cells begin to differentiate into blood capillaries forming an arteriocapillary venous network, which is completed by 20 days after fertilization. The villi are called 'tertiary villi'. The villous vessels become connected with the embryonic heart tube via vessels differentiated in the chorion and the connecting stalk.[6]

The establishment of the trophoblastic shell allows rapid circumferential growth of the developing placenta. This leads to the expansion of the intervillous space into which sprouts extend from the primary villous stems. The placenta is, by the 21st day of gestation, a vascularized villous organ.[7] The extensive system of venous sinusoids around the implantation site constitutes venous connections between the intervillous space and the maternal circulation.

In the fourth week of development, the cytotrophoblastic shell is thinner than in the earlier stages. At the junctions of the shell with the decidua, there are many clefts and spaces. Some of them open into the adjacent intervillous space. The 21st day after fertilization (Carnegie stage 10) the primitive embryonal heart begins to beat, and embryonal blood circulates through villous capillaries.[6] The communications with the terminal branches of the spiral arteries have not yet been completely established.[2] There are six to eight endometrial spiral arteries opening directly to the decidua basalis. They possess a wide lumen. The media of the vascular wall becomes attenuated and finally disappears completely. The lining endothelium is surrounded only by a layer of reticular and collagen fibers. As a result of these changes, it is often difficult to identify the spiral arteries and to establish their relationship to the intervillous space. From this region several narrow clefts penetrate the shell to enter to the intervillous space.

There are two types of non-villous migratory trophoblasts: (1) the interstitial or stromal trophoblast, which invades the decidua and myometrium and (2) the endovascular trophoblast, which migrates into spiral arteries and modifies them into uteroplacental arteries. The endovascular trophoblast is closely linked to the development of the trophoblastic shell.[9] It is the key factor for physiological modifications of spiral arteries. These gestational changes are needed for the development of hemochorial placentation.

Migrating trophoblast penetrates the uterine wall and invades venous sinusoids of increasing size and superficial arterioles during the fourth week. The extravillous cytotrophoblastic cells expand from the tips of the anchoring villi into the lumina of the spiral arteries. They convert the thick-walled muscular arteries into flaccid sac-like uteroplacental vessels, which can passively dilate to accommodate the greatly increased maternal blood flow required for fetal oxygenation and growth.[10]

Trophoblastic cells can be found within the spiral arteries in about the sixth week after fertilization. The trophoblastic disruption of the muscular cells and elastic fibers of the spiral arteries has two effects. Increasing blood flow causes progressive distension of these arteries into the uteroplacental arteries capable of accommodating the increasing blood supply. Uteroplacental arteries are not responsive to change within the autonomic nervous system.[6]

In the second lunar month, as a result of the extensive branching villi the intervillous space increases. During the second month many terminal parts of spiral arteries near the intervillous space contain plugs of cytotrophoblastic cells. By the end of this period of development, centrally placed communications between the decidual veins are numerous and large. After 40 days (crown–rump length 15 mm) numerous spiral arteries show direct openings into the intervillous space.[2]

The cytotrophoblastic cells appear within the lumina of the spiral arteries. The maternal blood reaches the intervillous space through the gaps between the cells of the endovascular trophoblast. The persistence of the cytotrophoblastic plugs in the lumina of the spiral arteries suggests that the blood pressure in them is not very high, otherwise the plugs would be dislodged.[2] Maximal trophoblastic activity occurs at the center of the placental bed and then extends centrifugally toward its periphery.

During the third month of gestation, in the lumina of the terminal segments of most of the spiral arteries the cytotrophoblastic plugs are always present. None of the spiral arteries open freely into the intervillous space. Later in this period of development the plugs are more loosely arranged and they are probably then less able to impede maternal blood flow into the intervillous space.[2]

Up to the end of the fourth month of gestation, the chorion frondosum develops into the definitive placenta. The chorionic villi associated with the decidua capsularis degenerate and the associated intervillous space disappears. The smooth avascular chorion laeve forms.[6] There is regression in the trophoblastic shell where the cytotrophoblastic cell columns degenerate. The trophoblastic infiltration of the myometrium occurs between 8 and 18 weeks of development.[10] The endovascular cytotrophoblast partially replaces the endothelium and invades the muscular cells of the myometrial vessels. The result is a progressive distension of these myometrial vessels.

The uteroplacental circulatory system is a low-pressure one because of progressive increase in the diameter of the vessels as they approach their entry into the intervillous space. There is a considerable drop in pressure from the proximal non-dilated portions of the uteroplacental arterioles to the distal dilated portions and full arterial pressure is not transmitted to the intervillous space.[7]

The 'heretic' concept of separation of villous tissue from the maternal circulation

This classic concept of establishment of the intervillous circulation was challenged in 1987 and 1988 by the experiments of Hustin and Shaaps.[11,12] They examined slice radiographs of hysterectomy specimens with pregnancy *in situ* collected at 7, 8 and 9 weeks of gestation and found no contrast medium in the intervillous space. When the examination was performed at 13 weeks of gestation, the placenta was rapidly filled with contrast medium. Histological examination of these hysterectomy specimens showed occlusion of the uteroplacental arteries by trophoblastic cells up to 12 weeks of gestation. Reconstruction of serial spiral arterial sections was also suggestive of the absence of the intervillous circulation before 12 weeks of gestation. At 13 weeks, on the other hand, the uteroplacental arteries were free of trophoblastic plugs, and contrast medium was found in the intervillous space, encircling the chorionic villi. This was partially confirmed *in vivo* by means of hysteroscopy, examination of chorionic villous sampling material and transvaginal sonography. These results suggest that early placenta is bathed predominantly by fluid derived from maternal plasma and uterine gland secretions. The authors believed that blood flow in the intervillous space is absent or incompletely developed before 12 weeks of gestation. Transformation of spiral arteries continues during the first trimester, when they widen progressively. Around 12 weeks of gestation, all trophoblastic plugs are eventually loosened and dislocated. This allows free entry of maternal blood to the intervillous space and establishment of a fully developed placental circulation.

Further support has been supplied by a more recent study[13] using a polarographic oxygen electrode inserted under ultrasound guidance, which demonstrated that

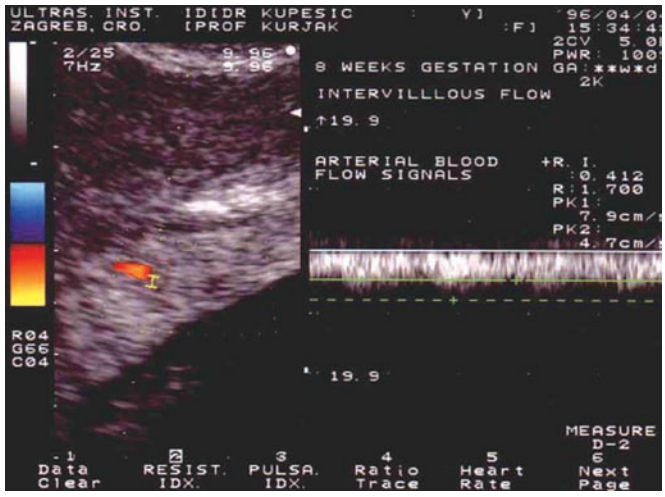

Figure 96.2 Arterial blood flow velocity waveforms from the intervillous space at 10 weeks' gestation demonstrate low impedance (RI = 0.41). Note typical spiky outline of the arterial signal.

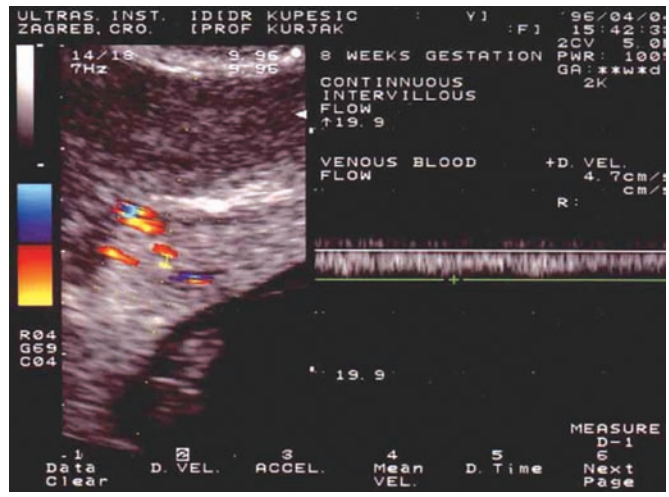

Figure 96.3 Continuous flow of a venous type in the same patient as in Figure 96.2; venous blood flow is easily detectable from the intervillous space.

between 8 and 10 weeks of gestation placental pO_2 levels were significantly lower compared with endometrial pO_2 levels, while between 12 and 13 weeks, the levels were similar. Intraplacental pO_2 levels increased significantly from 8–10 to 12–13 weeks of gestation. These results suggest that the increase of placental pO_2 may be related to the establishment of continuous maternal blood flow in the intervillous space at the end of the first trimester.

The advent and development of transvaginal color Doppler has enabled *in vivo* hemodynamic investigation of almost all segments embryonic/fetal and uteroplacental circulation.[14–21]

In 1991 and 1992, Jauniaux *et al.*[22,23] and Jaffe *et al.*[24] were unable to detect 'intraplacental' flow before 12 weeks of gestation using the transvaginal color Doppler. They found the appearance of intraplacental flow at around 14 weeks of gestation to coincide with the appearance of pandiastolic flow in the umbilical artery and with an abrupt increase in uterine artery peak systolic velocity (PSV). In agreement with the theories of Hustin and Shaaps,[11,12] they hypothesized that the simultaneous appearance of intraplacental flow, pandiastolic umbilical artery flow and abrupt increase in uterine artery blood flow velocity was to be explained by sudden loosening and disappearance of the trophoblastic plugs in the spiral arteries. By this time Kurjak *et al.*[25] were unable to demonstrate an abrupt change in the uteroplacental circulation between 12 and 14 weeks of gestation.

Hi-tech evidences of the 'classic' theory: the circle is closed

It must be emphasized that color Doppler measurements in the studies mentioned above were performed on devices of relatively moderate capability in the detection of low velocities. After the introduction of the new generation of far more sensitive color Doppler devices in the last few years, several authors reported a positive finding of intervillous circulation during first trimester of pregnancy (Figures 96.2 and 96.3).

In 1995, Kurjak *et al.*[26] presented the first report on a combined Doppler and morphopathological study of intervillous circulation. Using a transvaginal color Doppler, continuous intervillous flow of two types was detected in all examined patients: pulsatile arterial-like (Figure 96.2) and continuous venous-like flow (Figure 96.3). Parallel histological study has shown that the lumen of spiral arteries was never completely obstructed by the trophoblastic plugs. These data indicate that establishment of the intervillous circulation is a continuous process rather than an abrupt event at the end of the first trimester. One should note that arterial-like blood flow signals have shown lower resistance and pulsatility index (PI) values than those obtained in spiral arteries.

Shortly after, several other groups of authors reported similar findings. Valentin *et al.*[27] performed a combined study of uteroplacental and luteal flow with pathomorphologic analysis. Color Doppler measurements revealed positive finding of intervillous circulation from the sixth week of normal pregnancy (Figure 96.4). The same two types of Doppler signals, the pulsatile and continuous, were detected and measured with a visualization rate of more than 90% on 64 pregnancies from 5 to 11 weeks of gestation. The authors stated that the high blood velocities recorded from the subchorionic arteries were not compatible with these arteries being completely occluded by trophoblastic plugs. On pathomorphologic analysis, trophoblast plugging of the spiral arteries was incomplete, allowing passage of red blood cells. They concluded that the intervillous circulation was present as early as the first trimester.

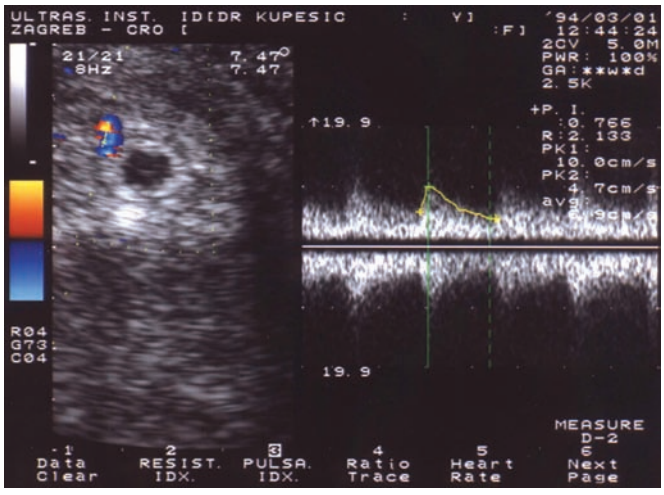

Figure 96.4 Transvaginal power Doppler imaging of a gestational sac at 5/6 weeks' gestation. This technique easily depicts blood flow surrounding the gestational sac.

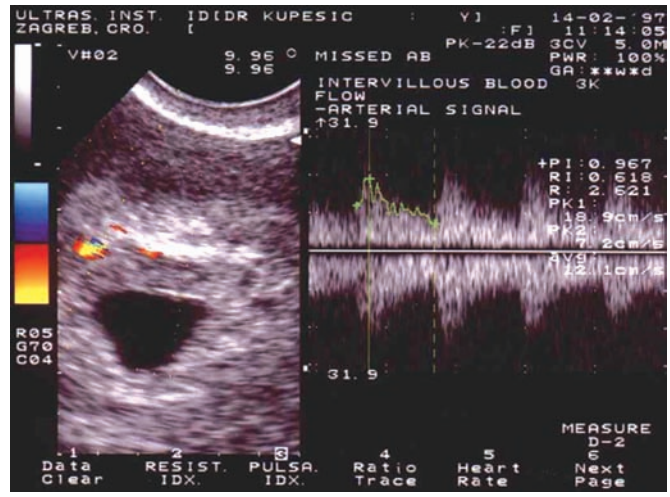

Figure 96.5 A transvaginal scan of the missed abortion at 12 weeks' gestation. Note increased RI value (0.62) of the arterial-like signal from the intervillous space.

Merce *et al.*[28] reported similar results on the group of 108 normal singleton pregnancies of 4–15 gestational weeks. They were able to detect intervillous flow from 5 weeks 6 days of gestation. It was a slightly undulating venous-like signal with tendency of increasing velocity throughout the first trimester. They also recorded arterial signals in retrochorionic segments of uteroplacental vasculature. The conclusion was that their results were in accordance with the classic embryological concept of establishment of the intervillous flow from four to seven weeks of gestation. According to Merce *et al.*,[28] uteroplacental circulation is the earliest to be affected in pregnancy, with pronounced changes from week 4 onward. Intervillous circulation and primitive umbilical blood flow were identified from week five on.

In more recent publications, Kurjak *et al.*[29,30] studied a group of 60 normal pregnancies of gestational age from 6 to 12 weeks and, for the first time, a group of 34 pathological early pregnancies: 22 cases of missed abortion (Figure 96.5) and 12 cases of anembryonic pregnancy (Figure 96.6) between 7 and 12 weeks of gestation. The same Doppler features were detected in the intervillous space of all pregnancies: pulsatile arterial-like signals with characteristic spiky outline and venous-like continuous signals. There was no difference in Doppler parameters between the group with missed abortion and the group of normal pregnancy. However, lower impedance (measured in resistance and PIs) was detected in the group with anembryonic pregnancies. These results are significantly different from those published by Jauniaux *et al.*[31] who found increased intervillous blood flow in 70% of abnormal pregnancies before 12 weeks of gestation. In these cases, a histopathologic examination showed that the trophoblastic shell was discontinuous and thinner, and that the intervillous space had been massively infiltrated by maternal blood. The

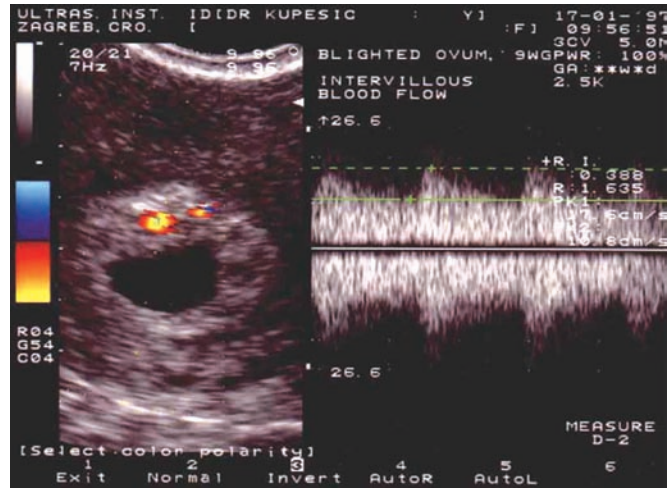

Figure 96.6 The transvaginal scan demonstrates anembryonic pregnancy. Note spiky outline and low vascular resistance (RI = 0.39) of the arterial-like signals obtained from the intervillous space of an anembryonic pregnancy.

authors hypothesized that trophoblast plugs in the spiral arteries restrict the maternal blood to flow in the intervillous space, protecting vulnerable villi from the high pressure of arterial blood. By this concept the premature entry of maternal blood in the intervillous space can disrupt the maternoembryonic interface, causing the separation of early placenta and, eventually, abortion.

In the research on placental development and formation of the uteroplacental circulation system, of crucial importance was experimental work with animal models, particularly with non-human primates, mostly with *Macaca* species. The classical work by Elisabeth Ramsey on the circulation in the intervillous space of the primate placenta is the base for all contemporary research in this field.[1,32] Recently, Nimrod *et al.*[33,34]

reported about the assessment of the early uteroplacental circulation in cynomolgus monkey (*Macaca fascicularis*) by color Doppler technique. They were able to detect the intervillous circulation from 18 days postconception. Regardless of the known differences in the depth of trophoblastic invasion of the spiral arteries between human and monkey, this finding can be considered as an additional evidence of early establishment of intervillous circulation in all primate placentas, although the 'argument by analogy' must be used with caution.

Publication of similar, if not the same, results obtained by few independent groups and published in prestigious journals usually produces a respectful attention of the scientific community. However, a recent editorial by Jauniaux,[35] repeating most of the facts known from his previous papers, did not appreciate enough the early reports on continuous intervillous flow. Although Jauniaux admitted that using a new equipment he was able to detect flow in some areas of intervillous space during the first trimester of pregnancy, his concern, was whether these signals originated from the intervillous space of the definitive placenta or from the chorion laeve area, because very often the areas of detectable color and spectral Doppler signals were visible near the margins of the placenta. From our own experience, we do support this observation; however, there are also signals obtained from below the center of early placenta that are, by no means, signals belonging to the area of chorion laeve. One can speculate that these signals could be from the tips of spiral arteries in the decidua under the early placenta or chorion frondosum. It is our opinion, and it is in concordance with papers by Valentin *et al.*[27] and Merce *et al.*,[28] that the relatively high velocities of blood flow detected in these vessels or vascular spaces are not compatible with complete occlusion by trophoblastic plugs unless there are arteriovenous shunts in the decidual portion of the chorio-decidual junction. Their existence in the myometrium is still controversial. Hustin *et al.*[12] found some evidence while Laurini has not (personal communication). Hustin *et al.*[36] postulate that myometrial arteriovenous shunts exist and are functional, serving to limit considerably the entry of maternal blood in the intervillous space. Even more, they postulate without further explanation that the pressure in the intervillous space is temporarily higher than at the uteroplacental artery level, and thus maintains the intravascular trophoblastic plugs in place. This statement can be an objective for further investigation.

Jauniaux speculated that the finding of focal intervillous flow in the first trimester was a sign of consecutive formation of echo-poor areas as an early sign of pregnancy complications.[37,38] If this is true, how could one explain the high rate of visualization of these signals in normal pregnancies reported by our group[30,39,40,41] (Table 96.1) and Malmo group.[27] It is hard to believe that all these pregnancies were destined to fail. According to Jauniaux *et al.*[31] continuous flow in the intervillous space during the first trimester is a highly pathologic event, causing the disruption of the maternoembryonic interface by high-pressure blood flow and consequent spontaneous abortion. In his opinion,[35] this fact is the most striking evidence in favor of Hustin's concept.[11] In fact, we also do believe that the high pressure of arterial blood can disrupt the maternoembryonic interface and cause spontaneous abortion. However, this fact is not opposite to the finding of a continuous intervillous flow during the first trimester of pregnancy. This means that there are some areas where trophoblastic plugs in spiral arteries are

loosened allowing the intervillous circulation of blood. In the beginning, there are only a few areas of such a flow giving enough oxygen and nutrients for the progression of pregnancy. At this stage, the intervillous space is not undisrupted like in the mature placenta. There are parts with active continuous intervillous flow and parts in which such a flow has not yet been established and nutrients and oxygen diffuse through the intercellular fluid.[42] The number of areas with the established intervillous flow is increasing with embryonic and placental growth in order to keep a state of metabolic balance. This process ends with a fully formed intervillous space under the mature placenta. Such a hypothesis can be in concordance with findings of lower oxygen levels in the placental tissue than in the endometrium between 8 and 10 weeks of pregnancy.[13] Also, it can be in concordance with the fact that in cases of inappropriate trophoblastic plugging of spiral arteries the uncontrolled pressure of arterial blood can mechanically disrupt the maternoembryonic interface.[43–52]

Mercé *et al.*[53] recently reported that the abnormal Doppler patterns, such as the increase of retrochorial vascular resistance and the presence of intervillous flow in pregnancies with gestational sac measuring less than 12 mm, has a greater incidence of miscarriage. However, intervillous flow was also detectable in pregnancies with normal outcome but in a smaller proportion than in those ending with miscarriage (11% vs. 53%). This finding confirms that intervillous circulation does exist throughout early pregnancy, but at the same time limitation of the amount and pressure of incoming maternal blood seems to be of essential importance for normal pregnancy development.

There are numerous data provided by histological and color Doppler studies proving that the intervillous circulation begins early in normal pregnancy, which is in accordance with classical embryological theories. This is possible because the trophoblastic invasion is a progressive process and although some of the spiral arteries are totally occluded, the majority of them are opened or only partially occluded. In this way, the inflow of the blood in the intervillous space is controlled and increased progressively during the first trimester. These changes are complementary to the progressive loss of the endovascular trophoblast and coherently explain the increase in blood flow within the vascular territory of the uteroplacental arteries, a universal finding in all Doppler studies, and are very difficult to explain if these arterial lumens are plugged up with the trophoblast. It is probable that changes occurring in the trophoblast in spontaneous abortions can alter the blood perfusion in both the uteroplacental arteries and intervillous space. However, the importance of these findings in the genesis or in the mechanism of miscarriage has not yet been sufficiently documented.

Furthermore, recent ultrasound technology in terms of three-dimensional (3D) power Doppler angiography offers numerous advantages in the evaluation of intervillous space (Figure 96.7), which have to be clinically tested in future.

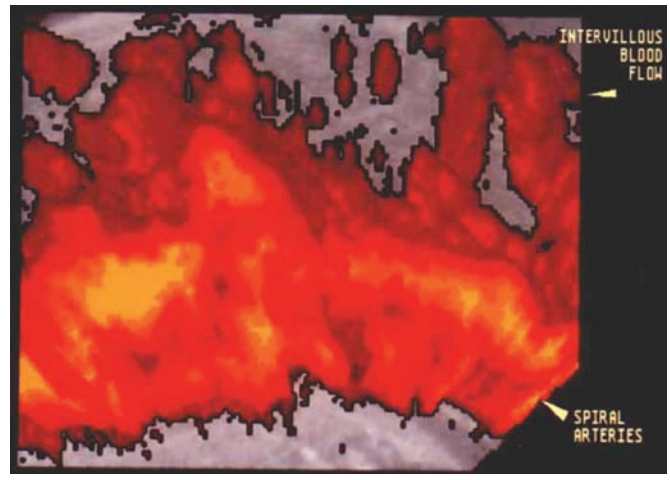

Figure 96.7 Demonstration of the intervillous circulation by three-dimensional power Doppler.

Yolk sac development

The embryonic vascular system includes the heart, the blood and the lymphatic vessels. It is the first functional organ system in the body that pumps blood through the embryonic and extraembryonic vessels to provide nutrition for rapid growth and removal of the waste products.[54] The circulatory system of an embryo is much larger when compared to the body size, and plays an important role during the early embryonic development.

Development of the vascular system begins in the mesoderm of the yolk sac close to the endoderm, at about 17 days after fertilization.[54] It is believed that there are some endodermally produced factors that stimulate the mesoderm to differentiate in this way. The first evident form of the vascular system are aggregations of the cells called blood islands. The central cells will differentiate into red blood cells and the outer cells into flattened endothelial layer. These elements of vascular system are perceptible as red spots in the mesoderm of the yolk sac wall. The blood islands fuse to form primitive vascular networks.

Precursors of the heart and the major paired blood vessels are formed in the mesoderm of intraembryonic coelom. The course of events is analogous with those occurring in the mesoderm of the yolk sac. A very similar process of creating a vascular system occurs in the chorionic mesoderm. Blood vessels formed in this way are dorsal aortae, cardinal veins and the major umbilical arteries and veins.

At first, blood washes back and forth in this primitive network of blood vessels, but eventually it takes on a patterned flow. It seems that these dynamic fluid

effects are very important because they stimulate primitive blood vessels to differentiate further and take their own definitive form. If there is an obstruction to the blood flow, it bypasses the blocked vessel and passes through the surrounding small vessels. In time, one of these vessels will become a major blood vessel and will overtake the role of the blocked one. This sometimes vitally needed ability survives in the adult and leads to anastomoses.

Vitelline blood vessels

The heart begins to beat at about 21 days after fertilization. It pumps blood dorsally through blood vessels called branchial arches.[54] Blood enters the dorsal aortae (paired at this stage) from which the precursors of the internal carotid artery separate and run forward to supply the head. The main direction of blood in the dorsal aortae is toward the tail. It runs through the intersegmental arteries, which are branches of dorsal aortae, and are situated between the developing somites. Furthermore, at the level of the gut, there is an arterial complex of branches separating from dorsal aortae and running toward the site of blood formation in the yolk sac wall. In time, this arterial complex of branches will represent vitelline arteries.

Toward the tail dorsal aortae a plexus is formed from which one single blood vessel branches off and runs into the connecting stalk to the chorionic wall, where the placenta is developing. This single blood vessel is the umbilical artery.

Blood returns from the placenta through the paired umbilical veins, which also pick up blood from the yolk sac. The connection between the yolk sac vascular network and the umbilical veins is a venous complex of branches, which will become vitelline veins. The head veins, which lie just lateral to the neural tube, pick up blood from the head region. Finally, blood enters the sinus venosus and reaches the heart. This is the moment when the circle of the blood circulation around the embryonal body is closed.

The vitelline and umbilical veins have a very important role in further embryonal development. Initially, the liver bud lies between the vitelline veins. Since it enlarges, it comes to incorporate the vitelline and umbilical veins. These blood vessels form a common plexus of sinusoid vessel running through the liver. In time, the vitelline veins and left umbilical vein are converted into the hepatic portal vein. The right umbilical vein decreases in size and forms the ductus venosus, which carries blood to the right side of the heart.[54]

Hematopoiesis in human embryos begins in the yolk sac at about the middle of the third week of embryogenesis. Later, it appears in the liver and bone marrow in the fourth and fifth weeks and the eighth week, respectively.[55,56] At about the 10th to 12th week, hematopoietic tissues are found distributed evenly in the bone marrow throughout the body.[56–58] Maturation of blood cells is considered to take place extravascularly. With occasional exceptions, the blood cells in the endodermal layers are the most immature and maturation appears to proceed as the cells migrate to the mesenchymal layers and further into the blood vessels.

Color Doppler studies of the yolk sac and vitelline duct

Circulation in normal pregnancy

Little is known about a transitory subject such as the yolk sac, an organ that is active only during the first few weeks of embryonic life. The description of the formation of the human yolk sac has proven surprisingly controversial over the years.

Recently, interesting results have been published on the assessment of yolk sac vascularization in normal pregnancy. Kurjak *et al*.[21] performed transvaginal color Doppler study on 105 patients whose gestational age ranged from 6 to 10 weeks from the last menstrual period. Transvaginal color and pulsed Doppler examination was performed before the termination of pregnancy for psychosocial reasons.

The first color and pulsed signals from the yolk sac were obtained between 5 and 6 weeks of gestation. The visualization rate of the yolk sac vessels in the sixth week of gestation was 33.33%, and it increased to a value of 85.71% during the seventh and eighth weeks of gestation. As the functional activity of the yolk sac progressively declined, the visualization rate of 78.26% for 9 weeks' gestation and 61.11% for 10 weeks' gestation paralleled this process (Table 96.2). The overall visualization rate for yolk sac vessels was 72.38%. The highest visualization rates were obtained in the seventh and eighth weeks of gestation, reaching the value of 85.71%. A characteristic waveform profile included low velocity (5.8 ± 1.7 cm/s) and absence of diastolic flow (Figures 96.8 and 96.9). The PI showed a mean value of 3.24 ± 0.94 without significant changes between subgroups ($P > 0.05$). The distribution of mean PI values for yolk sac vascularity is shown in Table 96.2.

Vitelline stalk vessels (Figure 96.10) showed similar PSV (5.4 ± 1.8 cm/s) and PI values (3.14 ± 0.91) ($P > 0.05$) to those obtained from the yolk sac (Figures 96.8 and 96.9). The distribution of the vitelline artery PI values is demonstrated in Table 96.3. The overall visualization rate for vitelline arteries was 66.67%. Color and pulsed Doppler signals could be obtained from the vitelline duct during the seventh week of gestation in 85.71% of patients. The peak of visualization (89.28%) occurred during the eighth week of gestation (Table 96.3). The process of elongation of the vitelline duct together with the removal of the yolk sac from the body wall is paralleled with the decreased rate of vitelline duct visualization during the ninth (73.91%) and tenth (55.55%) weeks of gestation. Furthermore, progressive decrease of the yolk sac

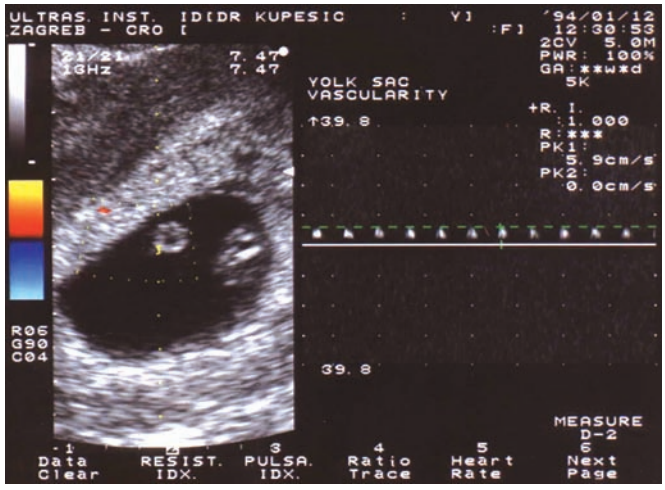

Figure 96.8 A transvaginal sonogram of a gestational sac at the sixth week of gestation. Note regular contours of the yolk sac. Pulsed Doppler signals obtained from the wall of the yolk sac demonstrate low velocity and absence of diastole (RI = 1.0).

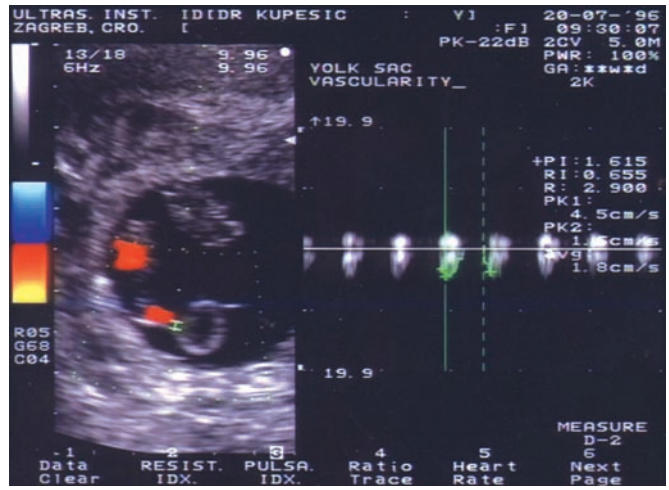

Figure 96.9 A color image of the yolk sac at 7 weeks' gestation. Pulsed Doppler signals isolated from the connection of the yolk sac and vitelline duct show absence of diastolic flow.

Table 96.2 Visualization rate of yolk sac vascularity between 6 and 10 weeks of gestation (from Kurjak *et al.*,[21] with permission)

Gestational age (weeks)	*N*	Visualization rate No.	%	PI ± SD
6	15	5	33.33	3.42 ± 0.58
7	21	18	85.71	3.14 ± 0.82
8	28	24	85.71	3.10 ± 0.94
9	23	18	78.26	3.12 ± 0.85
10	18	11	61.11	3.45 ± 0.72
Total	105	76	72.38	3.24 ± 0.94

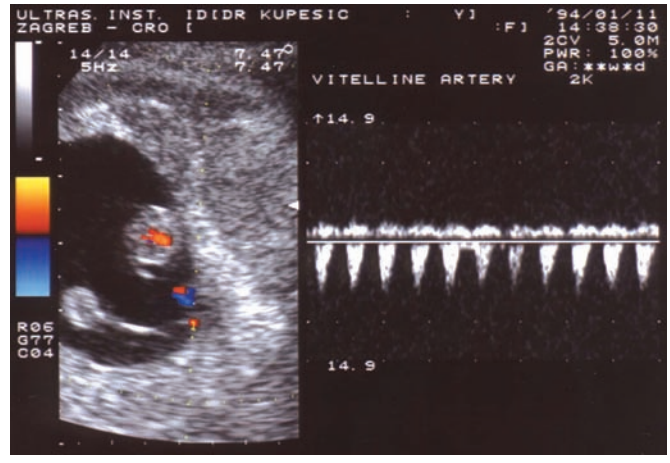

Figure 96.10 Color Doppler signals are easily obtainable from the vitelline stalk.

vascularity at the end of the first trimester coincides with the visualization of more prominent blood flow within the intervillous space.[59]

All these findings will surely help in better understanding the early development of both blood cells and blood vessels.

Vascularization of the yolk sac in abnormal pregnancies

Kurjak *et al.*[21,59] recently performed a research analyzing the vascularization of yolk sac in abnormal pregnancies. The authors analyzed 48 patients with missed abortion between 6 and 12 weeks of gestation. Yolk sac blood flow was detected in 18.54% of missed abortions. They obtained three types of abnormal vascular signals from the yolk sac in these patients: irregular

Table 96.3 Visualization rate of the vitelline duct vascularity between 6 and 10 weeks' gestation (from Kurjak *et al.*,[21] with permission)

Gestational age (weeks)	N	Visualization rate No.	%	PI ± SD
6	15	—	—	—
7	21	18	85.71	3.02 ± 0.92
8	28	25	89.28	3.05 ± 0.89
9	23	17	73.91	3.08 ± 0.91
10	18	10	55.55	3.38 ± 0.82
Total	105	70	66.67	3.14 ± 0.92

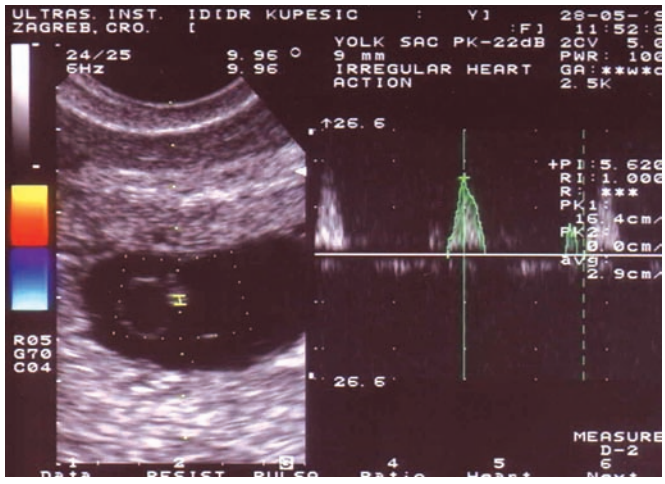

Figure 96.11 Pulsed Doppler signals derived from the yolk sac in a patient with missed abortion. Note larger diameter (7 mm) of the yolk sac and irregular blood flow signals at its periphery.

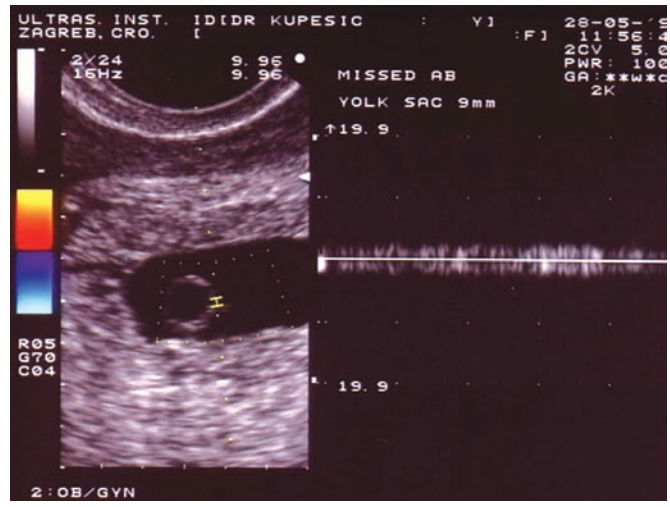

Figure 96.13 Venous blood flow signals obtained from the yolk sac at 8 weeks' gestation in a patient with missed abortion.

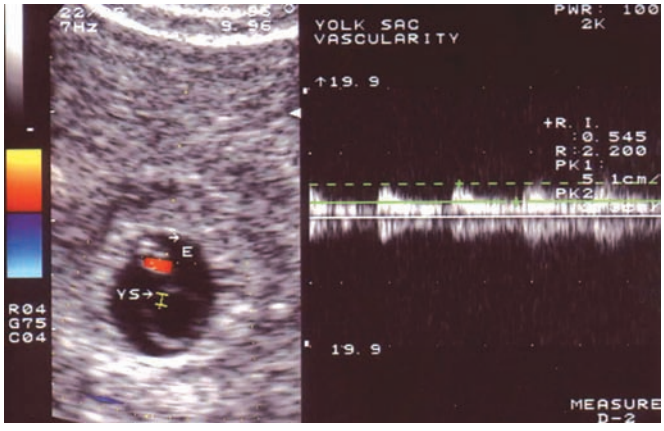

Figure 96.12 The transvaginal scan of a 9 weeks' gestation, complicated by bleeding. The pulsed Doppler waveform analysis indicates continuous blood flow. A few days after examination was completed spontaneous abortion occurred.

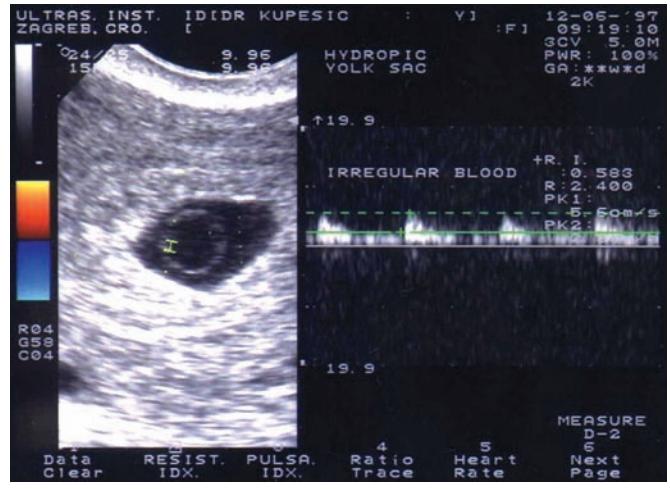

Figure 96.14 A transvaginal sonogram of a hydropic yolk sac at 6 weeks' pregnancy. Continuous diastolic flow is easily obtained from the hydropic yolk sac (RI = 0.58). Patient aborted in 1 week and karyotyping of the residual products of conception revealed trisomy 21.

blood flow (Figure 96.11), permanent diastolic flow (Figure 12) and venous blood flow signals (Figures 96.13 and 96.14).

Changes in vascularization of the yolk sac noticed in missed abortions in this study are probably a consequence of embryonic death and reabsorption of the embryo through the vitelline duct. Abnormal patterns of the yolk sac vascularity can be related to decreased vitelline blood flow, which may cause progressive accumulation of nutritive secretions not utilized by the embryo. This process ends with enlargement of the yolk sac indicative of an early pregnancy failure. Indeed, we were able to detect yolk sac vascularity in 28.57% (6/21) of missed abortions with large diameter of the yolk sac (Figure 96.14), and 20.00% (3/15) of those with normal yolk sac diameter. Sometimes, a careful ultrasonographer can visualize double yolk sac (Figure 96.15) and color Doppler ultrasound may observe abnormal Doppler patterns in these cases.

Cases with echogenic yolk sac walls ($N=7$) were characterized by the absence of blood flow. Yolk sac calcification was reported to result from the typical dystrophic changes that occur in non-viable cellular material.[60] Since studies in lower animals demonstrated that yolk sac endoderm bounds calcium, one can postulate that a derangement in the calcium transport mechanism may lead to accumulation of calcium in the yolk sac cells in humans as well. Therefore, recognition of a calcified yolk sac without blood flow signals suggests long-standing demise in the first trimester, which directs the clinician to further diagnostic workup (Figures 96.16 and 96.17).

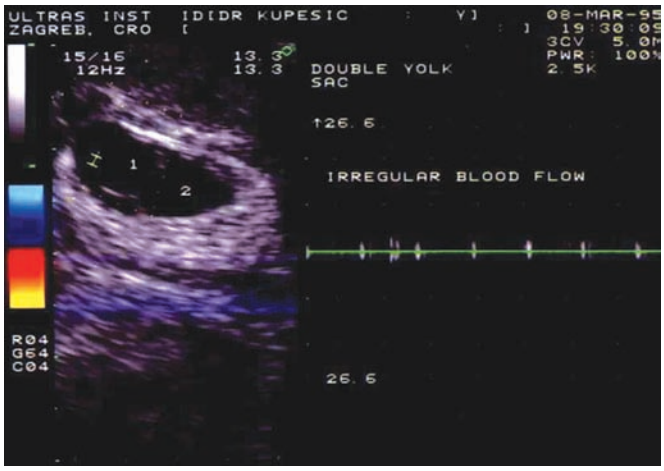

Figure 96.15 A transvaginal color Doppler scan of a gestational sac containing a double yolk sac with irregular blood flow signals.

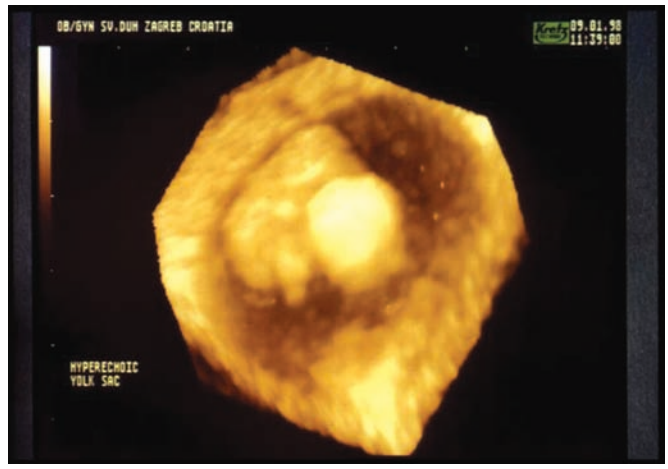

Figure 96.17 Three-dimensional scan of the hyperechogenic yolk sac.

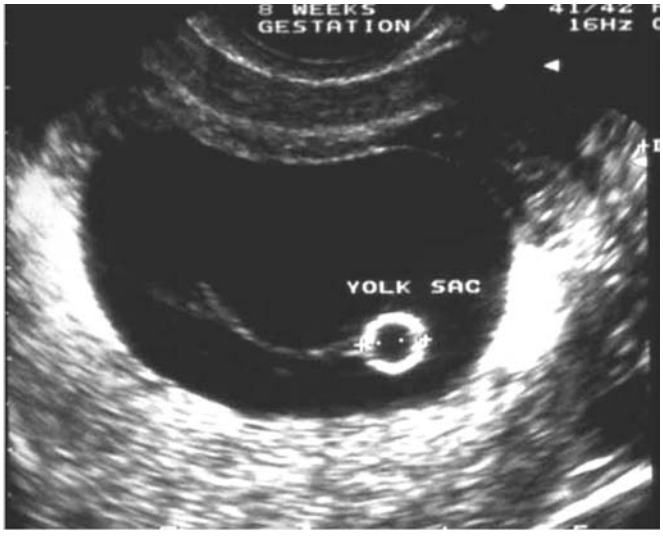

Figure 96.16 Transvaginal two-dimensional image of the hyperechogenic yolk sac.

These data indicate that there is an interaction between the yolk sac vascularity and intervillous circulation in patients with missed abortion. In patients with long-standing demise, vascular signals could not have been extracted from the hyperechoic walls of the yolk sac. Parallel assessment of the intervillous circulation in this subgroup ($N=7$) demonstrated numerous color-coded areas within the intervillous space indicating low mesenchymal turgor and progressive disruption of the maternoembryonic interface. Therefore, the changes in the intervillous circulation noticed in some missed abortions are rather the consequence of embryonic death and inadequate drainage than the primary cause of early pregnancy failure. This is contrary to the statement of Jaffe *et al.*[61] and Jauniaux *et al.*[62] who found that increased continuous intervillous flow during the first trimester of pregnancy is associated with adverse pregnancy outcome. According to their results, increased flow pressure in the spiral arteries may dislocate the thin trophoblastic shell causing the loss of villi to forceful arterial flow, which may result in miscarriage.[63] However, independent Doppler studies from three institutions using sensitive conventional and power Doppler velocimetry found that continuous and pulsatile blood flow can be extracted from intervillous space in both normal pregnancies and those with adverse outcome.[17–21,28,64]

Data presented in this study support the concept that establishment of the intervillous circulation is a progressive process during the first trimester of pregnancy. Between the sixth and tenth weeks of gestation, relatively slow blood flow in the intervillous space is detected. Simultaneously, clear blood flow signals are derived from the walls of the yolk sac supporting the hypothesis that this fragile structure is responsible for optimal delivery of nutrients and oxygen to the developing embryo up to 10 weeks of gestation. Progressive decrease of the yolk sac vascularity coincides with visualization of more prominent color-coded areas within the intervillous space demonstrating the increased metabolic needs of the developing pregnancy.

Volume of the yolk sac – correlation with blood flow studies

It is well known that the prognostic significance of the yolk sac diameter as determined by ultrasound is not clearly established. Most of the abnormal pregnancies were demonstrated to have normal yolk sac measurements,[65–67] while only a minority of abnormal early pregnancies presented either 'too small' or 'too big' yolk sac dimensions.[68,69]

Recently, we performed a study on 80 women with uncomplicated singleton pregnancy (between 5 and 12 weeks of gestation).[70] The volumes of the

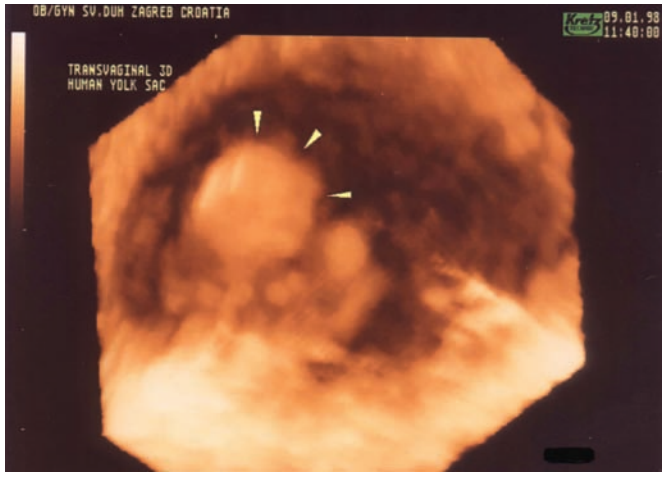

Figure 96.18 Three-dimensional scan of the yolk sac at 8 weeks' gestation. Note the regular echogenicity and contours of the yolk sac.

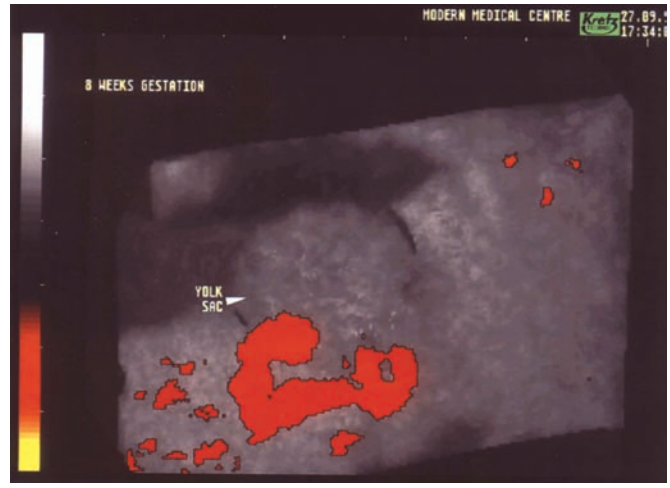

Figure 96.19 Three-dimensional power Doppler demonstrates turgescent blood vessels above the surface of the yolk sac.

gestational and yolk sacs were measured by 3D ultrasound (Voluson 530, Kretztechnik, Austria). Regression analysis revealed exponential growth of the gestational sac volume. The yolk sac volume was found to increase gradually from 5 to 10 weeks of gestation. However, when the yolk sac reaches its maximum size and volume at around 10 weeks, it has already started to degenerate (Figure 96.18), which can be proved by a significant reduction in visualization rates of the yolk sac vascularity (Figure 19). This suggests that the evaluation of the biological function of the yolk sac by measuring the diameter and/or the volume is limited. Therefore, the combination of functional and volumetric studies is necessary to point out some of the important moments during the early pregnancy:[71]

(1) Simultaneous beginning of yolk sac angiogenesis and vascular development of the embryo
(2) Non-invasive evaluation of the functional capacity of the yolk sac
(3) Definition of the shift from embryo-vitelline to embryo-placental circulation[7]
(4) 3D ultrasound studies of the direct connection between the yolk sac and the embryonic gut
(5) Evaluation of the yolk sac degeneration and location by 3D ultrasound at the end of the first trimester

The fact that blood vessels first develop in the secondary yolk sac may be related to the important role of this structure in the process of early embryonic nutrition. Further Doppler studies analyzing large cohort of patients with both normal and abnormal pregnancies will probably answer some of the numerous questions on the role of yolk sac vascularity in early embryonic development. The introduction of 3D ultrasound coupled with power Doppler imaging has produced more accurate information on implantation and the yolk sac and we look forward to the future developments in this field.

97 First-trimester ultrasound

N. Montenegro and A. Matias

Introduction

In obstetrics, ultrasound has been used for many years and, from the beginning, investigators have been interested in changes in the uterus and its contents in early pregnancy.[1]

Moreover, in recent years, the introduction of higher-resolution equipment and transvaginal endosonography has brought new possibilities for the study of early gestational events.[2–4]

Nowadays, ultrasound is increasingly used in early pregnancy, either as a routine procedure or selectively for specific clinical indications. Routine ultrasonography during the first trimester is used for accurate pregnancy dating, early diagnosis of major malformations, characterization of multiple pregnancy and screening of chromosomal anomalies.[5–18]

Although the quality of images obtained during the first trimester seems to be superior when using the transvaginal approach, transabdominal ultrasonography is still widely used in this period of gestation for cultural and practical reasons.[19,20]

The use of diagnostic ultrasound during pregnancy is considered to be safe for both the mother and the fetus. Even in critical periods of development and using high-frequency transvaginal transducers, no adverse bioeffects have been demonstrated.[21–23] The benefits to patients exposed to the ultrasound intensities used at present outweigh the risks, if any.

This chapter will review the main applications of ultrasound examination during early pregnancy, relying on the experience of the authors together with that reported in the literature. Special emphasis will be placed on embryonic development during the first weeks, gestational age determination, characterization of multiple pregnancy and screening and diagnosis of fetal anomalies. In the text, gestational age will be expressed as complete weeks from last menses.

Embryonic development: ultrasound findings

The decidual thickening (Figure 97.1) is the first indirect sign of pregnancy that can be disclosed by ultrasound.[24,25] Although it is seen more often in the early phases of an intrauterine pregnancy, this hyperechogenic mantle filling the uterine cavity can also coexist with an ectopic pregnancy. As the same pattern can be found in the late luteal-phase endometrium, it should be considered as a non-specific sign.

A few days after the expected menses, a typical image of a hyperechogenic ring inside the uterine cavity can be identified by transvaginal ultrasound (Figure 97.2). This corresponds to the gestational sac, the echogenic ring being the chorionic villi surrounding the chorionic cavity. At this time, the mean level of the β-subunit of human chorionic gonadotropin (β-hCG) is found to be about 500 mIU/ml (second reference standard).[26] Thereby, the diagnosis of intrauterine pregnancy can be confirmed and a chorionic sac internal diameter of 2–6 mm will be found, corresponding to a menstrual age of 4 weeks.

During the fifth week, the chorionic sac measures 7–10 mm. When this diameter reaches 9 mm, the yolk sac can always be identified as a round, fluid-filled and eccentric structure with a diameter of 3 mm (Figure 97.3). In the authors' experience, this 9- to 10-mm diameter of the chorionic sac represents an early discriminatory value for the diagnosis of a blighted ovum. At some time during the end of the fifth week, pulsations can be visualized on real-time imaging, close to the wall of the yolk sac and within a 2- to 3-mm echogenic line corresponding to the embryo. After this time, the heart rate can be measured using simultaneous M-mode.

At 6 weeks, the echogenic line corresponding to the developing embryo is always close to the yolk sac and measures 4–6 mm (Figure 97.4). Cardiac motion can be clearly seen and the mean heart rate (Figure 97.5) at this gestational week is about 118 bpm.[26] The amnion is not yet clearly seen, so the embryo and the yolk sac are apparently free-floating in the chorionic cavity, although eccentrically fixed by the connecting body stalk.

During the seventh week, the embryonic length is 7–12 mm and the yolk sac, with a diameter of 5 mm, separates from the embryo, probably owing to the growth of the vitelline duct (Figure 97.6). At this time, the cephalic pole becomes distinguishable and an apparent single hypoechoic cavity can be seen, corresponding to a part of the primitive cerebral ventricle

Figure 97.1 Decidual thickening.

in the rhombencephalic area, probably the future fourth ventricle.[20–24]

At 8 weeks (Figure 97.7), the embryonic length is 12–18 mm and the upper and lower limb buds are now visible. The folding of the hypoechoic cerebral vesicle limits the lateral recesses of the rhombencephalic cavity.[27–30] The placental site can even be identified, following the umbilical cord from the abdominal wall of the embryo. Discrete undulating body movements can be sporadically seen on real-time imaging at the end of the eighth week.

During the ninth week, the embryo assumes a typical C-shaped curvature (Figure 97.8) and the crown–rump length (CRL) will be more than 2 cm (21–31 mm).[31] As landmarks, the head represents

Figure 97.6 Vitelline duct and yolk sac at 7 weeks.

Figure 97.7 An 8-week embryo with the upper and lower limb buds visible: note, in cephalic pole, folding of ventricular cavity.

one-third of the entire body and, inside the head, the hyperechoic falx and choroid plexuses and a hypoechoic heart-shaped structure corresponding to the cerebral peduncles are visible (Figure 97.9). The physiological midgut herniation, which can be identified close to the anterior abdominal wall, will persist until the end of the 11th week (Figure 97.10). Body movements are now more frequently seen.

Between 8 and 10 weeks, the amnion surrounding the embryo is always clearly seen, the yolk sac being outside in the exocelomic/chorionic cavity (Figure 97.11).[26,32]

At 10 weeks' gestation (Carnegie stages 20–23), the CRL is 32–41 mm and the embryo is slightly more

Figure 97.13 Cisterna magna (1) and cerebellum (2) in a 10-week embryo.

Figure 97.12 Lateral ventricles and choroid plexuses in a 10-week embryo.

curved. The choroid plexuses fill the lateral ventricles completely, and are the most prominent structures in the cephalic pole (Figure 97.12). In the posterior fossa, the cisterna magna and cerebellum can be identified, though the development process of the posterior fossa will only be concluded by 16 weeks (Figure 97.13).

In the trunk, the cardiac valvular apparatus can sometimes be distinguished inside the heart by the end of the 10th week, although more accurately from the 11th week onward. Also at the end of the 10th week, the stomach filled with a small amount of liquid, can sometimes be identified in the abdomen (Figure 97.14).

The three segments of the upper and lower limbs are clearly identified with both hands and feet in the midline. The first trimester of pregnancy is the best period to assess the number of fingers as normally the hands are wide open. Abduction of the lower limbs with lateral rotation of the hips is typically encountered between 10 and 13 weeks (Figure 97.15).

Body and even isolated limb movements are often identified on real-time imaging.

At 11 weeks, the fetus (no longer the embryo) acquires a human appearance and the CRL will be greater than 42 mm, reaching 76 mm at 13 weeks. From now on, a more detailed anatomical survey can be obtained, including the cerebral and cardiovascular systems and the digestive and urinary tracts.[33] The midgut is no longer herniated and can be seen as a hyperechoic round image inside the celomic cavity and situated in the median region of the lower abdomen (Figure 97.16).

Between 11 and 14 weeks of gestation, that is, between 45 and 84 mm CRL, a subcutaneous translucency behind the neck region can be disclosed in a sagittal section of the fetus. The maximum thickness between the skin and the soft tissue overlying the cervical spine can be measured, and was called nuchal translucency (NT).[13] Initially the normal values have been reported as less than 3 mm. After the prospective study of 100,000 pregnancies by Snijders and coworkers, increased NT has been defined as the value higher than the 95th centile for gestational age.[34] Increased NT has been found in association with major chromosomal anomalies and cardiac defects, and has been proposed, together with maternal age, as an efficacious screening procedure during the first trimester of pregnancy.[34]

More recently, the first reports on the use of three-dimensional ultrasound in the first trimester of pregnancy suggest its potential for early-pregnancy anatomic survey.[35]

Gestational age determination

Gestational age assignment is one of the most important issues in perinatal medicine for both clinical and research purposes. In addition to an indication of

Figure 97.14 Stomach (E) in a 10-week embryo.

Figure 97.16 Coronal view of lower abdomen showing a hyperechoic image compatible with the gut completely inside the tummy.

Figure 97.15 Upper and lower limbs at 11 weeks. Note the abduction of lower limbs.

medical problems, it could result in serious personal and social implications for the parents.

Even today, worldwide, the last menstrual period (LMP) is still the basis for calculation of gestational age and expected day of confinement. Nevertheless, in clinical practice, health professionals are frequently confronted by difficulties concerning the exact estimation of the LMP, incorrect reporting, cycle irregularities and the recent use of oral contraceptives. It has been estimated that about one-third of women attending antenatal care fall into one of these categories.[11]

Even in the population of women with certain dates and regular cycles, reliable biological correspondence between LMP and ovulation or fertilization is still difficult to obtain. In addition to long-available information about this phenomenon, recent studies in this field provide the confirmation that conception can occur within a 6-day period from intercourse ending at the day of ovulation.[36]

In very early pregnancies, gestational age determination by ultrasound scan is a little inaccurate, and is based on chorionic sac mean or maximum diameters. At the beginning of the fourth week, the diameter is 2–3 mm, reaching 9–10 mm when the yolk sac can be identified.[25] Once the embryo is visible, embryonic length should be measured.

As reported by Goldstein, before 10 weeks' gestation, it is really the embryonic length rather than the CRL that is being measured.[31] On the other hand, operator errors are more frequent below than above 10 weeks.[37]

A large number of reference tables for CRL measurements are available, all showing identical mean values to those originally reported in the literature, despite variations in ultrasound machines, ethnic groups and methodological aspects[31,38–42] (Figure 97.17). However, in a trisomy-18 fetus or in a fetus with triploidy, the CRL is smaller than normal, while in other major chromosomal anomalies, the CRL is not significantly different from normal.[43]

Furthermore, several studies have been reported dealing with the validity and benefits of routine ultrasound examination in the first half of pregnancy, having reduced perinatal morbidity and mortality as end points.[44,45] One of the major goals was improving the determination of gestational age. The ultrasonographic measurement of CRL before 13 weeks' or the biparietal and transverse cerebellar diameters between 14 and 22 weeks' gestation, respectively, have been widely used for this since the beginning of the 1970s.[37–50]

When comparing the accuracy of menstrual dates and ultrasonography in the first half of pregnancy, for calculating the expected date of delivery, dating by ultrasonographic biometry was more predictive than the former or even the combination of both

Figure 97.17 Crown–rump length, the gold standard for dating pregnancy.

Figure 97.18 Triple pregnancy at 7 weeks' gestation.

methods.[12–46] Therefore, even with known menstrual dates, most authors would rather use ultrasound biometry, namely, measurement of the CRL and biparietal diameter (BPD), than the LMP for estimation of gestational age or expected date of confinement.

Clinical and ethical considerations support the medical value of routine ultrasonography in the first half of pregnancy as a standard of obstetric care.[49] If there is a tendency toward an ideal policy in such a field, some of the above-quoted reasons point to the late first trimester as the best gestational age period for a routine ultrasound examination.

Multiple pregnancy

Today, mainly as a result of the expanded use of assisted reproductive methods, multiple pregnancy is more frequently found in antenatal clinics all over the world. In the United States over the past 20 years, births of twins have increased at twice the rate, and multiple births of triplets or more have increased sevenfold faster than births of singletons.[51]

Meanwhile, higher perinatal morbidity and mortality in such pregnancies can be reduced by accurate pregnancy dating, by avoiding unnecessary prolongation of gestation and from determination of chorionicity.[52,53] It is chorionicity rather than zygosity that determines several aspects of antenatal management and perinatal outcome. Antepartum death of one twin is three times more frequent in monochorionic than in dichorionic gestation.[54]

Today, management protocols in multiple pregnancies include successful intrauterine treatments and single invasive diagnostic tests for monozygotic twins, and multifetal reduction in higher-order gestations.[55–58]

Antenatal determination of chorionicity by ultrasound is much easier in the early first trimester when two or more separate gestational sacs and embryos are identified (Figure 97.18). It is also accurate to perform an ultrasound scan between 10 and 14 weeks, relying on

Figure 97.19 Dichorionic diamniotic twin pregnancy with clear lambda sign.

Figure 97.20 Monochorionic diamniotic twin pregnancy with the T-sign.

the demonstration of the lambda sign (Figure 97.19)[47] for dichorionic (with a positive predictive value of 100% for dichorionicity) or the T-sign (Figure 97.20) for monochorionic twin pregnancies. In the second or third trimesters of pregnancy, dividing membranes can be seen (Figure 97.21).[53] Other criteria such as

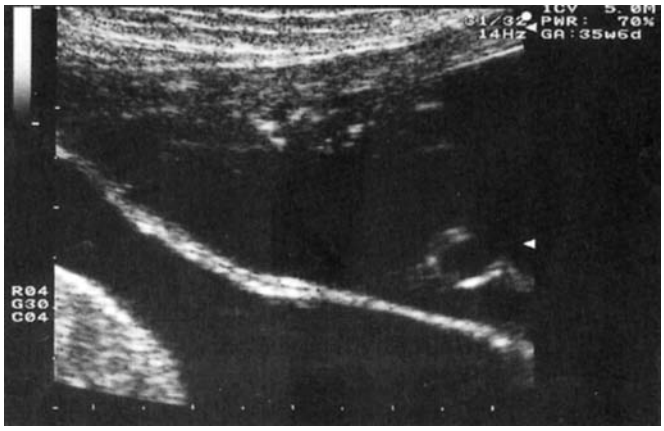

Figure 97.21 Dividing membrane in a 35-week dichorionic twin pregnancy.

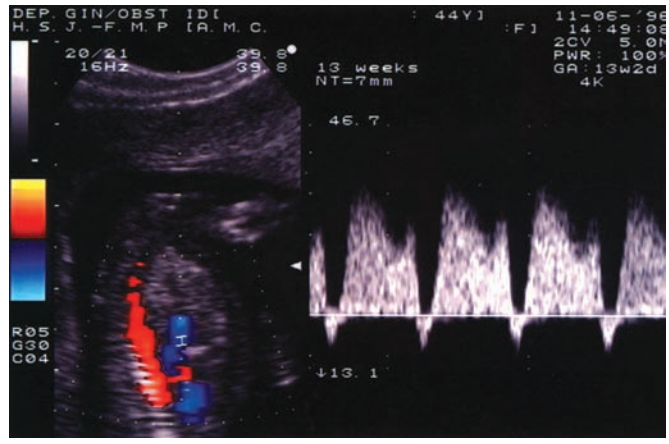

Figure 97.23 Abnormal ductus venosus blood flow in a 12-week fetus with trisomy 21.

Figure 97.22 (a) Sagittal plane of a 12-week fetus showing the adequate plane for measuring nuchal translucency. (b) Increased nuchal translucency (NT = 4 mm) in a 12-week fetus with Down's syndrome.

Figure 97.24 Ultrasound image of nasal bones in a 12-week fetus with normal karyotype.

number of placentas and fetal gender are unreliable, as fused placentas and identical sex are often found in dichorionic twins.

For all these reasons, it seems relevant to advise a routine ultrasound scan at 10–14 weeks' gestation. An earlier examination, although eventually more reliable for the determination of chorionicity, will be less accurate for pregnancy dating.[38] Furthermore, at 10–14 weeks, it will encompass the common event of the vanishing twin, either in spontaneous or in *in vitro* fertilization pregnancies.[58]

Fetal anomalies: screening and diagnosis

The ultrasonographic fetal examination in the late first trimester is useful for both screening and diagnostic purposes.

Concerning chromosomal defects, NT thickness determination between 11 and 14 weeks' gestation was the first marker to be incorporated in first-trimester routine ultrasound examination as a screening procedure.[13,34] Increased NT has been found in association with major chromosomal defects (Figure 97.22b), namely trisomies 13, 18 and 21, Turner syndrome and triploidy as with cardiac defects, other malformations and genetic syndromes.[59,60]

Figure 97.25 Ultrasound image of a 12-week fetus demonstrating the measurement of the maxillary bone measurement in a normal fetus.

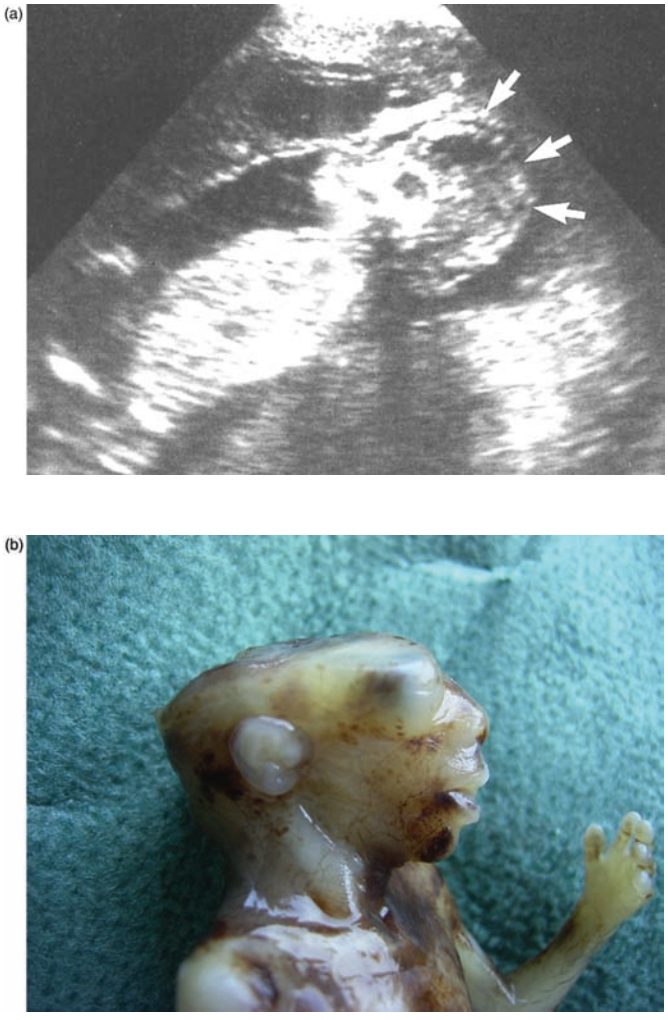

Figure 97.26 (a) Ultrasound image of an exencephaly/acrania detected at 13 weeks of gestation, showing the the absence of cranial bones. (b) Necropsic specimen of the same fetus after termination of pregnancy, confirming the prenatal diagnosis.

Figure 97.27 (a) Ultrasound image of an omphalocele detected at 12 weeks of gestation, showing the outbulging liver and a pronounced lordosis. (b) Necropsic specimen of the same fetus after termination of pregnancy, confirming the prenatal diagnosis.

If increased NT is combined with maternal age and factors concerning trisomy 21, the detection rate for chromosomal anomalies will be 80% with a false-positive rate of 5%. When fetal heart rate or maternal serum-free β-hCG and pregnancy-associated plasma

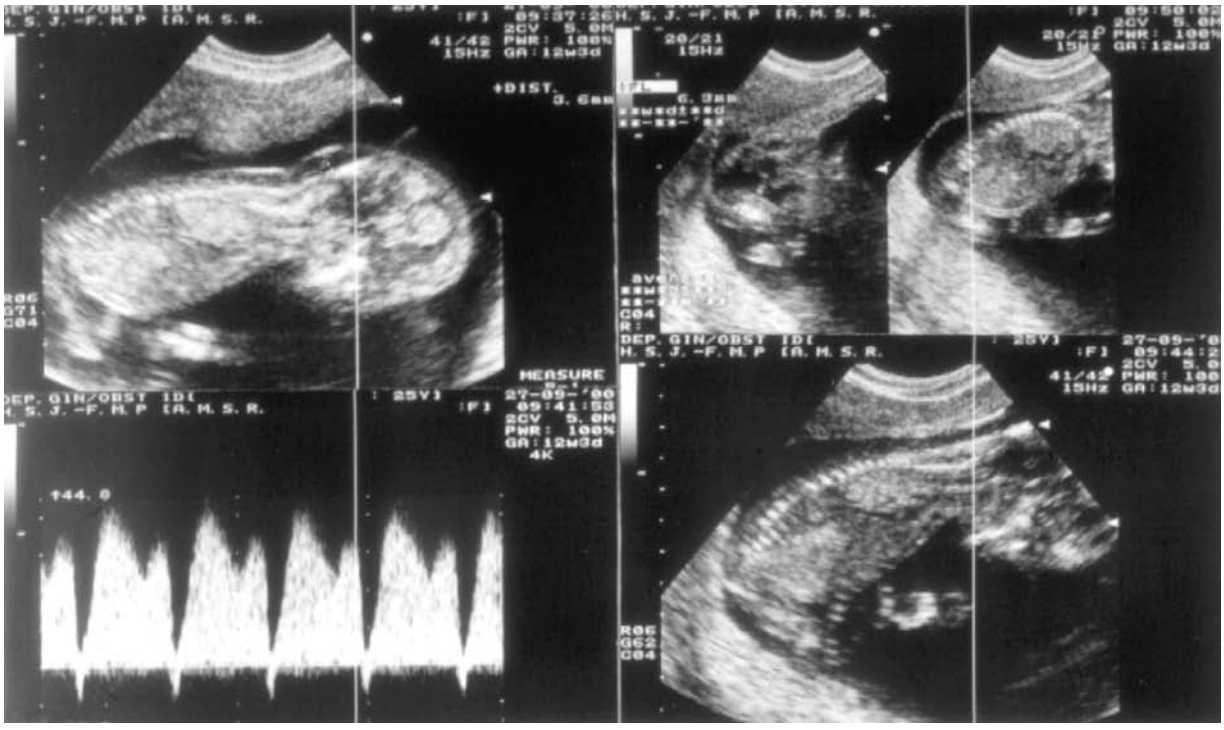

Figure 97.28 Sonographic aspects of a osteochondrodysplasia diagnosed at 12 weeks of gestation, showing short limbs, increased nuchal translucency and abnormal flow in the ductus venosus.

protein A (OSCAR clinic) are also incorporated at 11–14 weeks, detection rates will be 83 and 90%, respectively.[61,62]

The pathogenic basis of increased NT is still obscure, in spite of published work reporting an association of such an increase with cardiac defects/dysfunction.[63–66] Investigational work from our group clearly demonstrated abnormal ductus venosus (DV) blood flow in the majority of fetuses with increased NT and abnormal karyotype[15] and/or cardiac defects.[16] The combination of maternal age, NT and DV evaluation yielded a similar detection rate of NT alone, but decreased significantly the invasive testing rate.[15]

Still emphasizing the importance of ultrasound screening in the first trimester, when we adopt the same sagittal plane used for NT, other sonographic markers can be obtained and have recently been proposed to improve the detection rate for trisomy 21: ductus blood flow evaluation[15,16,63–69] (Figure 97.23), fetal nasal bones[17] (Figure 97.24) and maxillary bone length[18] (Figure 97.25). Preliminary data suggest that combining sonographic and biochemical markers in the first trimester of pregnancy could result in a detection rate of 97% for a false-positive rate of 5%, or a detection of 95% for a false-positive rate of 2%.[62]

Detailed assessment of fetal anatomy in the late first trimester is possible using either transabdominal or higher-resolution transvaginal sonography.[27,70] Therefore, potentially, the antenatal diagnosis of the majority of structural anomalies in this period of gestation can be carried out. Good examples of first-trimester diagnosis of major malformations are exencephaly/acrania (Figure 97.26), omphalocele (Figure 97.27) and osteochondrodysplasia (Figure 97.28).

After the first report of an early ultrasonic diagnosis of anencephaly in the 1970s,[71] many case reports have been published in the literature.

Following the 'natural history of fetal anomalies', the IRONFAN registry has been able to demonstrate how early anomalies can be diagnosed, in particular those that are potentially lethal, such as those occurring in the central nervous and cardiovascular systems, urinary tract and abdominal wall.[72] To date, more than 2000 anomalies, diagnosed between 9 and 15 weeks' of gestation, have been reported.

We consider that the policy of routine ultrasound examination in the second trimester will be reviewed within the next few years, once most, if not all, the lethal defects are able to be diagnosed and managed earlier in pregnancy. Furthermore, late first-trimester scan has other advantages, already discussed above, as a more accurate method of gestational age determination and for sufficiently early characterization of multiple pregnancy.

Conclusions

During recent years, interest in first-trimester pregnancy has been reinforced by the achievement of detailed imaging of early human intrauterine life using high-resolution ultrasound equipment, namely, transvaginal ultrasonography.

It is now possible to look at intrauterine events from the beginning of pregnancy, close to the time of implantation.

Acquired experience of first-trimester ultrasound examination either as a routine procedure or complementary to clinical evaluation demonstrates its essential role in obstetrical care.

Accurate gestational age determination, sufficiently early characterization of multiple pregnancy, early diagnosis of lethal anomalies and screening of chromosomal defects are important end points to be taken into account by health authorities and to recommend routine ultrasound examination in the late first trimester of pregnancy.

98 Hemodynamic assessment of early pregnancy

L. T. Mercé, M. J. Barco, S. Kupesic and A. Kurjak

Introduction

By 'hemodynamic assessment of early pregnancy' we refer to the study of the changes in the utero-placental, intervillous, fetal-placental, embryo-fetal and luteal ovarian circulations during the first trimester of normal pregnancies.

Although several invasive methods have been applied to experimental animal models for the study of early gestation hemodynamics, in the human species it has only been possible since the arrival of Doppler examination. This method has experienced great technological improvements from the continuous and pulsed Doppler to the 3D power Doppler angiography (PDA).

The transvaginal color Doppler has proven to be a highly efficient technique in the assessment of the placental, embryo-fetal and luteal circulations during the first trimester. Nevertheless, the theoretical risk of adverse biological effects on the embryo has restricted significantly its use during this pregnancy period. The 3D Doppler angiography represents a new technological advance that applies the ALARA principle (As Low As Reasonably Achievable), since the acquisition time of the angiograph volumes is shorter. Moreover, it is a process available only in high-technology equipment that fulfills precisely all the international regulations on ultrasound safety. In any case, it seems necessary to have at our disposal new reports that guarantee the possibility of a careful but more liberal use of this new method during early pregnancy.

Utero-placental blood flow

The utero-placental circulation is composed of the uterine vessels and their intramyometrial branches: arcuate, radial and spiral endometrial arteries. The spiral arteries will become utero-placental arteries under the trophoblastic invasion process during the first half of pregnancy.

The utero-placental blood flow increases progressively during the first trimester of normal gestations to accomplish the great demands imposed during the organogenesis period.[1] The invasion of the radial and spiral arteries by the cytotrophoblast is the mechanism to secure the progressive increase of utero-placental perfusion. These arteries lose their autoregulation ability and increase their diameters to become the utero-placental arteries.[2]

The spiral and radial arteries are those showing the greatest and most significant changes under Doppler examination as they are the target vessels of the trophoblastic invasion.[3–7] From the ultrasonographic detection of the gestational sac it is possible to depict a color signal coming out of it and getting inside the myometrium, which was named the 'comet sign'[5–7] (Figure 98.1). The flow velocity waveform (FVW) of these arteries shows a low vascular resistance and usually the protodiastolic notch is absent.

The proximity of the spiral and radial arteries in the placental basal plate rends its differentiation impossible. For this reason we call them retrochorionic arteries. Other authors use the term subchorionic and peritrophoblastic arteries.[8,9] Out of the placental site the radial arteries are placed at the myometrial internal third. The arcuate arteries run along the myometrial external third near the serosa. From the seventh week onward it is possible to identify through transvaginal color Doppler the spiral, radial and arcuate signals in 100% of the examinations.[10,11] The uterine arteries can be explored on both sides of the cervical isthmus. The FVW of the uterine arteries shows a high resistance with a protodiastolic notch usually present (Figure 98.2).

There is a gradual increase in the blood flow in the retrochorionic arteries during the normal first trimester of gestation. The resistance index diminishes from 0.52 ± 0.03 in the 4th week to 0.31 ± 0.05 in the 15th week (Figure 98.3), whereas the systolic and diastolic velocities increase progressively.[5,6] Changes at the placental vascular bed will affect in a retrograde way the entire utero-placental vascular tree. The blood flow will also increase in the radial, arcuate and uterine arteries. The vascular resistance decreases

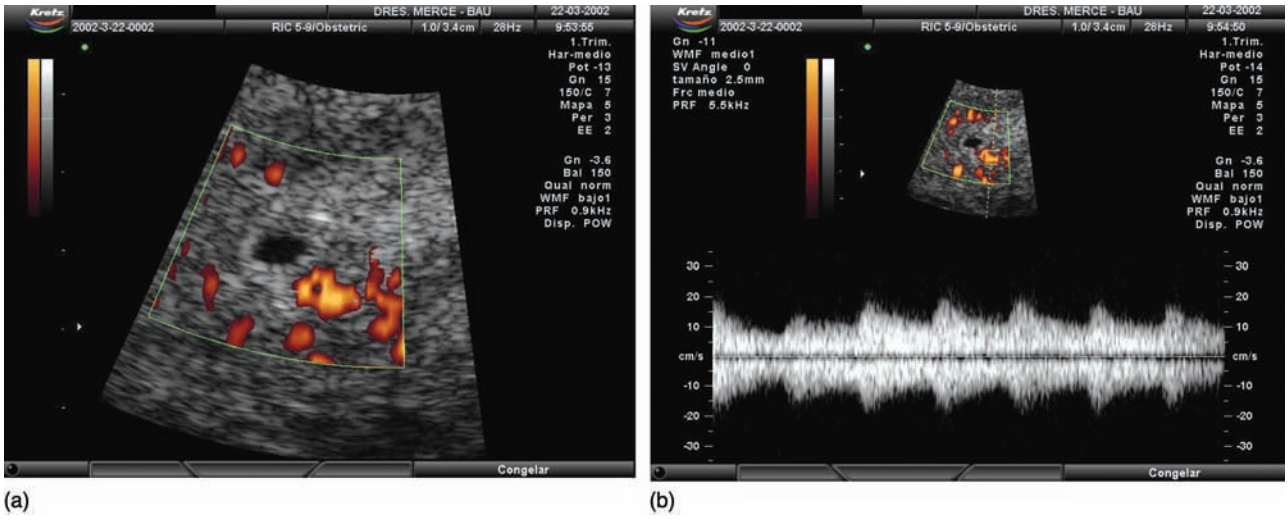

Figure 98.1 (a) Color map of the retrochorionic circulation of a gestational sac of 4 mm. The blood flow increase in the spiral and radial arteries depicts the 'comet sign'. (b) FVW of the retrochorionic circulation in the same gestational sac.

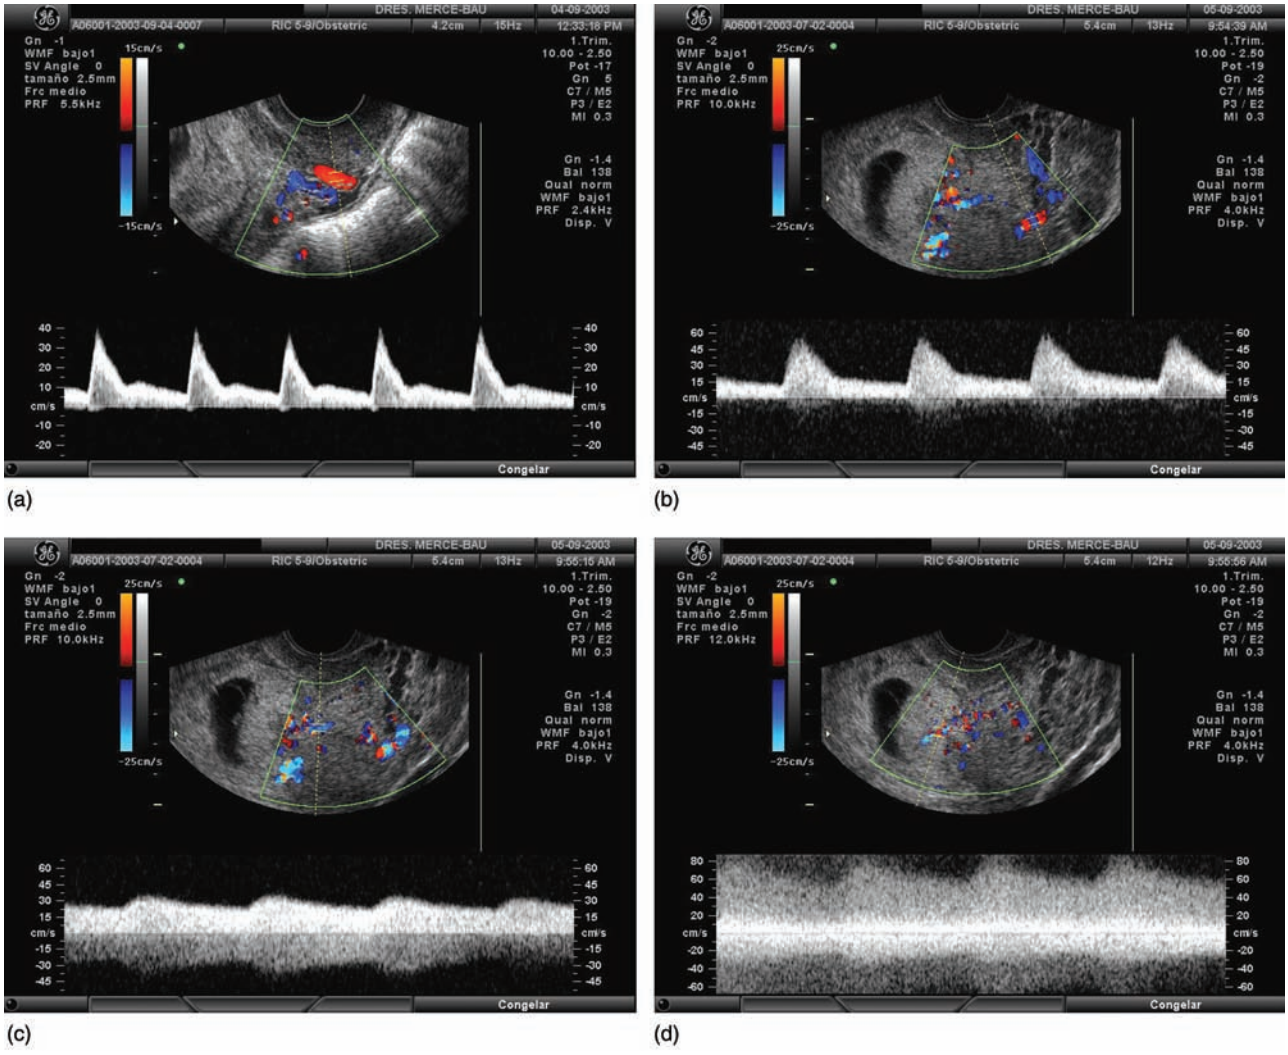

Figure 98.2 FVW of the uterine artery in a normal gestation of 8 weeks of amenorrhea (a), arcuate artery (b), radial artery (c) and spiral or utero-placental arteries (d). The vascular resistance increases as the distance from the placental insertion site increases.

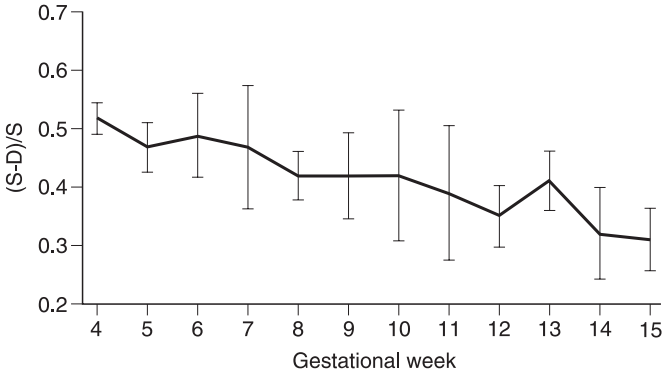

Figure 98.3 Resistance index of the retrochorionic arteries (spiral–radial) during early gestation (mean ± SD).

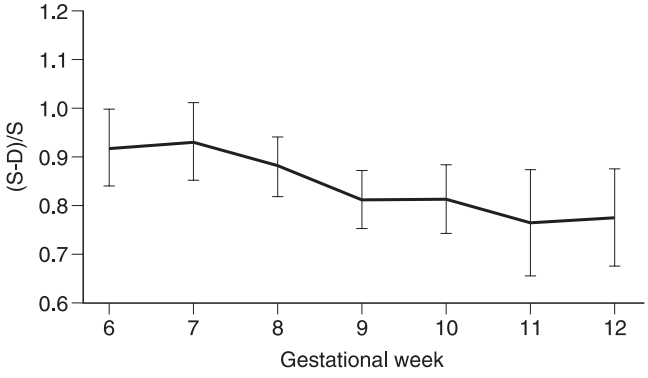

Figure 98.4 Average resistance index from both uterine arteries during early pregnancy (mean ± SD).

gradually in all the utero-placental vessels during the normal first trimester of pregnancy, but it increases along with the distance from the chorionic implantation site[8–15] (Figure 98.2). The average resistance index of the uterine arteries falls from 0.94 ± 0.08 in the 5th week to 0.76 ± 0.09 in the 12th week, while the maximum systolic velocity increases from 43.67 ± 16.72 cm/s to 79.13 ± 26.33 cm/s in the same period of time[3,4] (Figure 98.4). The protodiastolic notch is always present at the beginning but it will disappear in the second trimester.

The utero-placental blood flow, as evaluated by the retrochorionic vascular resistance, increases to 36% during the first trimester of normal pregnancies. This percentage is greater than the 30% observed throughout the remainder of pregnancy and doubles the 16% attributed to the second trophoblastic wave between the 15th and 20th weeks[16] (Figure 98.5). This fact demonstrates the importance of the vascular changes taking place in this gestational period and its unquestionable value for a successful pregnancy outcome.

Intervillous blood flow

From an embryological point of view, the intervillous circulation seems to be initiated around the 12th day

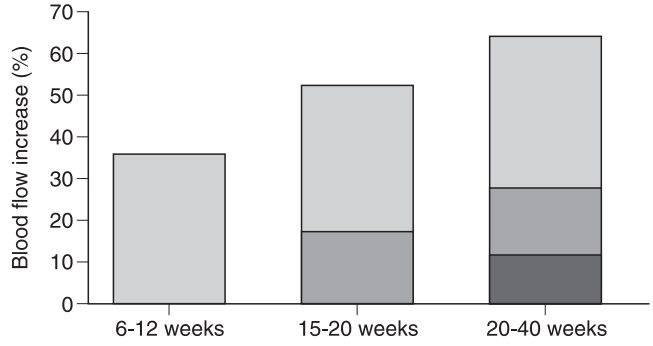

Figure 98.5 Percentage of blood flow increase at the placental site at different stages of normal pregnancy. During the first trimester a decrease in the vascular resistance takes place, which is greater than the rest of gestation.

of embryo development, when the maternal blood flows inside the syncitiotrophoblastic lacunae.[17] Nonetheless, Doppler studies have produced conflicting results.

Jauniaux *et al.*[18,19] and Jaffe and Woods[20] using transvaginal color Doppler did not find intervillous blood flow before 12 gestational weeks. Trophoblastic plugs would occlude the spiral arteries lumen[21,22] to maintain a relatively hypoxic environment to favor embryo development.[23] The intervillous blood flow was only present in miscarriages.[24,25]

Kurjak and Kupesic,[26] Valentín *et al.*[14] and Mercé *et al.*[5,6] using a similar technology were able to detect the intervillous blood flow from the sixth normal pregnancy week onward. Two patterns of flow have been registered: a continuous venous type and a pulsatile arterial type, the latter probably next to the entrance to the utero-placental arteries (Figure 98.6).

The maximum venous velocities in the intervillous space (IVS) are low and increase gradually throughout the first trimester from 2 ± 0.77 cm/s at 6 weeks to 5.12 ± 2.23 at 12 weeks[5,6] (Figure 98.6). For some authors[27] that increase from the 10th week occurs simultaneously with the decline in the vitelline circulation (Figure 98.7). The arterial FVW in the IVS does not experience significant changes during the first trimester.[14,26,27]

Our recent experience with 3D PDA confirms our previous results with transvaginal color Doppler. The virtual organ computer aided analysis (VOCAL) technology allows the differentiation of the IVS and retrochorionic circulations and their independent assessment (Figure 98.8). We have observed a progressive and significant increase in the vascularization, flow and vascularization-flow indices between the 6th and 12th weeks in normal pregnancies (Figure 98.9).

These findings are in accordance with a gradual disappearance of the trophoblastic plugs from the spiral arteries during the first trimester. It would produce an increase in the Doppler signals at the chorion frondosum (vascularization index) and an increase in

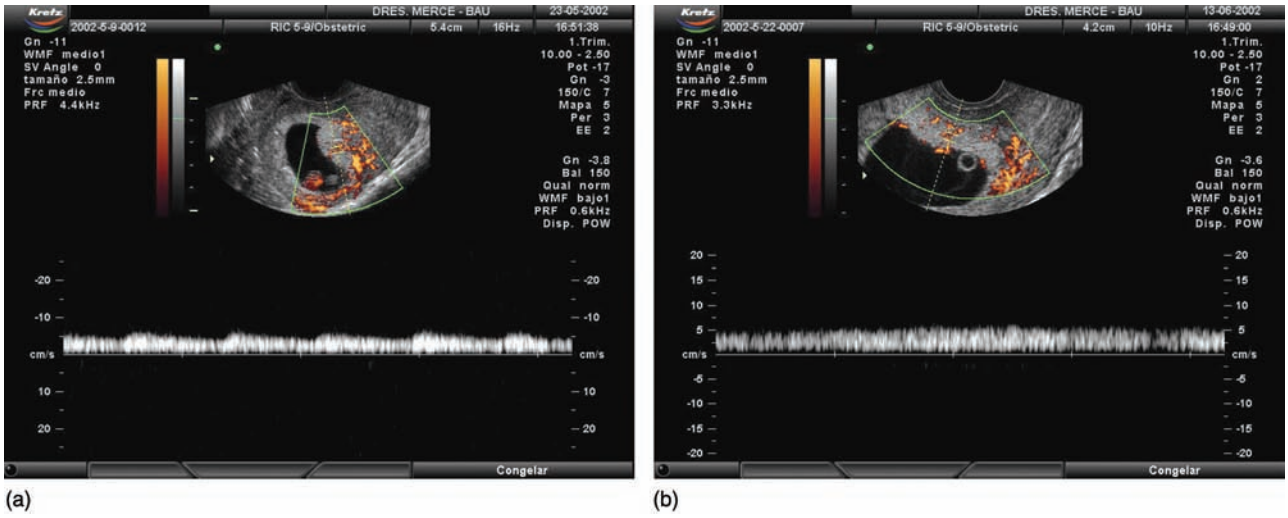

Figure 98.6 Doppler signal from the intervillous circulation of arterial type (a) in the seventh week and venous type (b) in the ninth week.

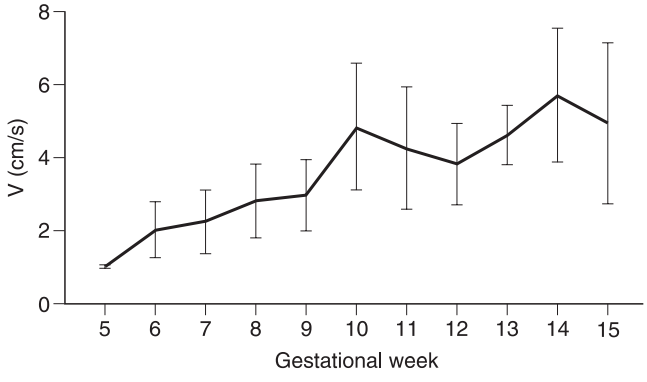

Figure 98.7 Venous maximum velocity of the intervillous circulation during normal early pregnancy (mean ± SD).

their intensity (flow index) that constitute the increase in the IVS blood flow in this period. Jauniaux *et al.*[28] in their last publication seem to admit this possibility that we are defending for more than 10 years.

Blood flow in the yolk sac

The circulation in the yolk sac precedes the fetal-placental or umbilical circulations in embryonic development.[17]

The yolk sac circulation can be detected by Doppler from the fifth week of amenorrhea onward.[29–31] It is feasible to integrate the Doppler signal in the 44[3]–67%[27] of normal gestations. During the sixth week it could be difficult to differentiate from the initial umbilical signal.[30] Its FVW is of arterial type without diastolic flow (Figure 98.10). The blood flow in the yolk sac is characterized by low velocities (between 3 and 7 cm/s) and a pulsatility index ranging from 2.19 to 4.78.[30] The yolk sac blood flow diminishes from the 10th week onward, together with the size of the sac, and coincides with the blood flow increase to the IVS.[27]

Fetal-placental blood flow

The fetal-placental or umbilical circulation links the villous vascular system with the embryo-fetal vascular system. The umbilical artery Doppler signal is detected at the end of the fifth or the beginning of the sixth week of amenorrhea, when the embryo begins to be sonographically detectable. The umbilical artery FVW is characterized by not showing a diastolic component until the 10th week of amenorrhea. The umbilical diastolic flow appears in a small percentage of cases from the 11th week onward and will be constantly present from the 14th week onward[5,6,8,30,32–34] (Figure 98.11).

From the seventh week onward it is possible to register the umbilical vein signal. The umbilical venous blood flow shows a characteristically undulated profile during the first trimester (Figure 98.11). The umbilical vein pulsations are physiological in this period of pregnancy and will disappear from the 11th week onward.[35,36]

The umbilical artery blood flow increases significantly alongside the entire first trimester of normal gestations.[5,6,8,30,32–34] Between the 6th and 14th weeks the maximum systolic velocity is increased from 5.63 ± 2.26 cm/s at 6 weeks to 21.28 ± 4.6 cm/s at 14 weeks, whereas the pulsatility index falls from 4.4 ± 1.1 to 1.38 ± 0.34 (Figure 98.12).

The decrease in the umbilical artery resistance during the first 12 weeks of gestation is essentially due to the maturation of the villous vascular tree. The appearance of diastolic velocities would explain this fact. The beginning of the fetal period will lead to

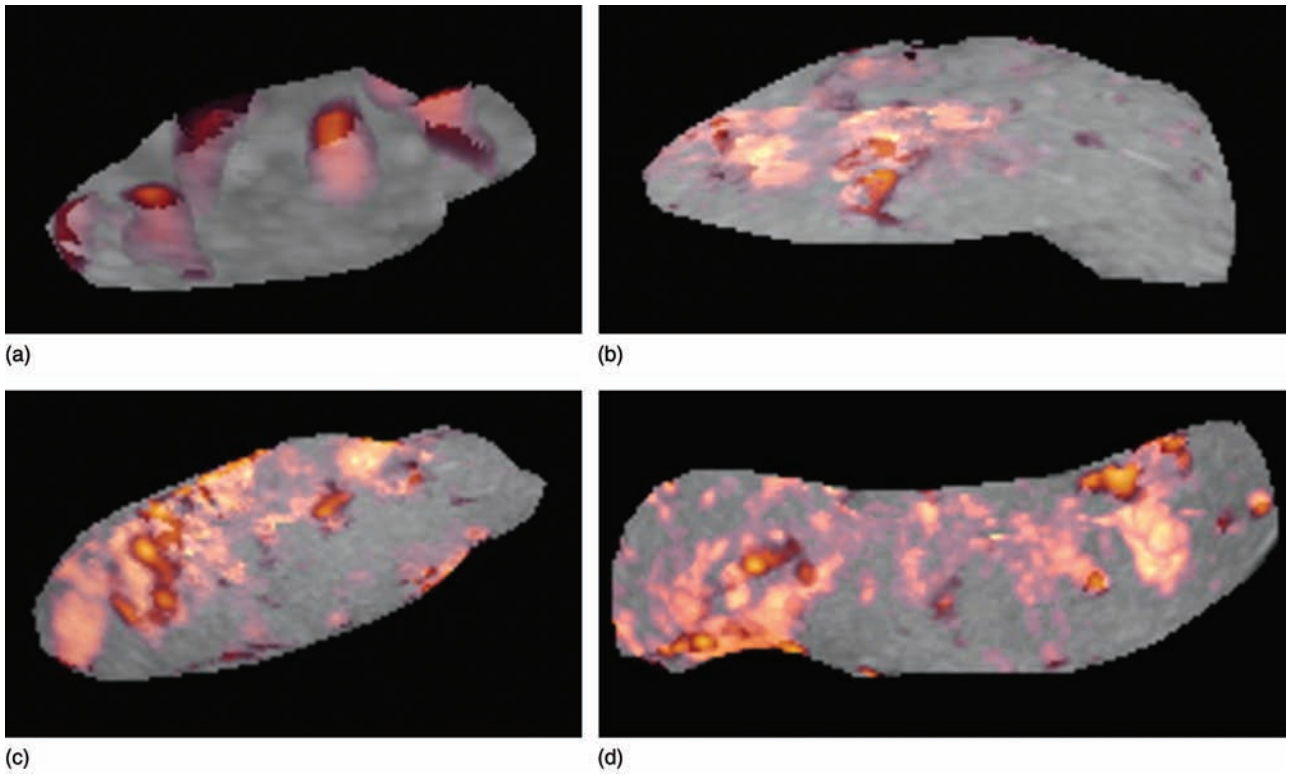

Figure 98.8 3D power Doppler angiography of the intervillous flow at 6 weeks (a), 8 weeks (b), 10 weeks (c) and 12 weeks (d) of normal pregnancies.

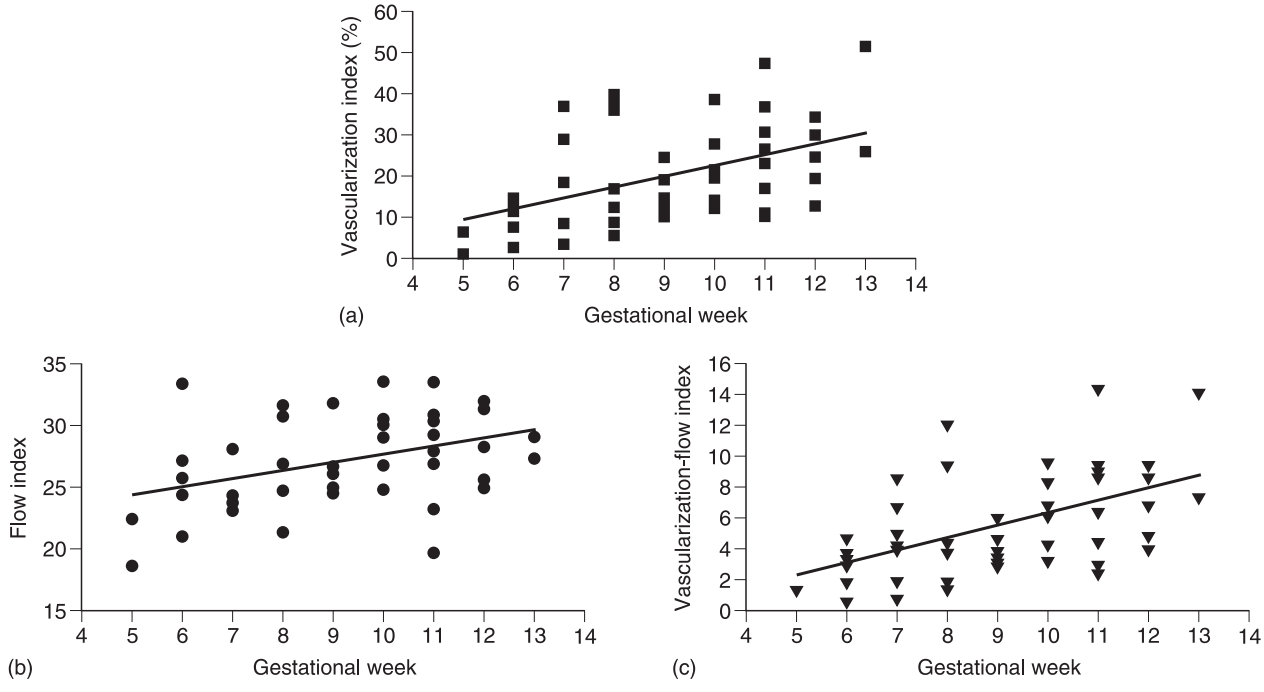

Figure 98.9 Vascularization index (a), flow index (b) and vascularization-flow index (c) of the intervillous circulation during the normal first trimester of pregnancy.

increasing demands of oxygen and nutrients that will be supplied by an improvement in the villous transfer.

Embryo-fetal blood flow

Transvaginal color Doppler allows the evaluation of the whole intraembryonic circulation, but only the blood flow in the aorta, cerebral arteries and ductus venosus has been studied.

The trajectory of the aorta can be clearly visualized from the seventh gestational week onward. As it occurs in the umbilical artery, its Doppler signal is characterized by the absence of diastolic velocities,

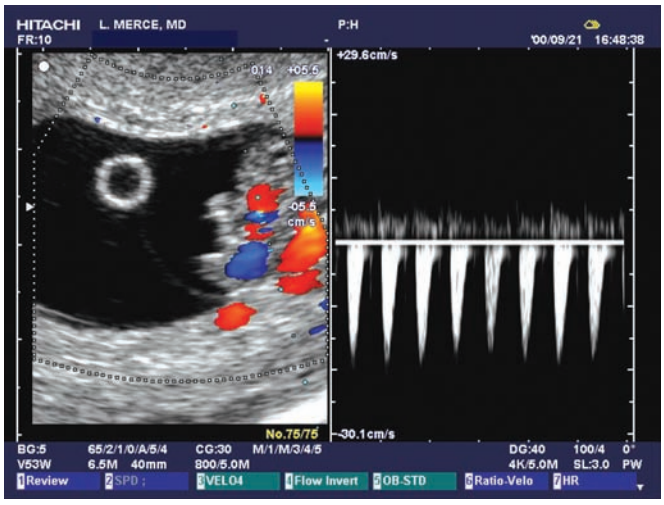

Figure 98.13 Color signal and FVW of the embryonic aorta in the ninth gestational week.

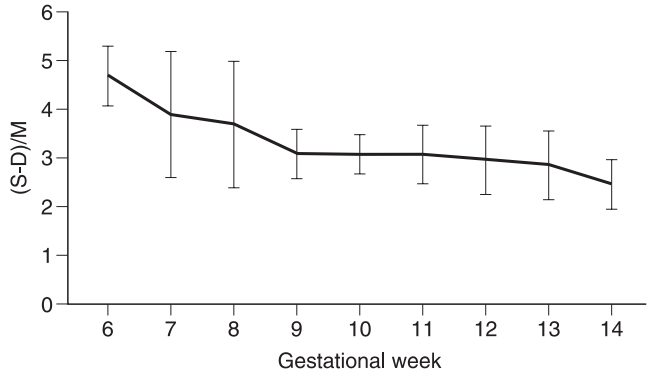

Figure 98.14 Pulsatility index of the embryonic aorta during normal first trimester of pregnancy.

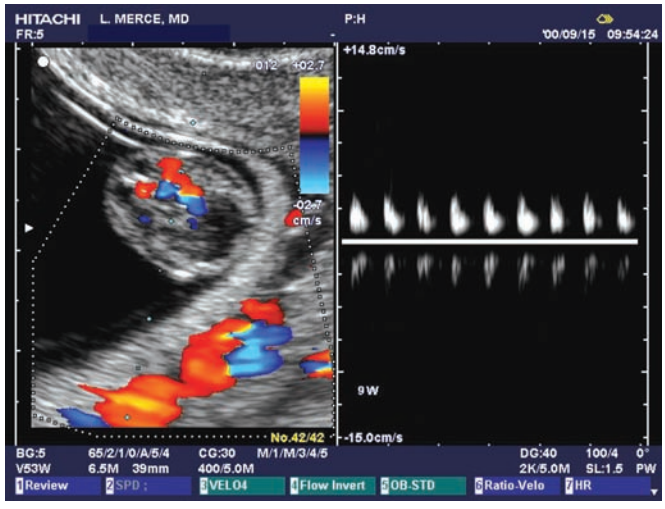

Figure 98.15 Mean cerebral artery FVW in a normal pregnancy of 9 weeks.

that begin to appear around the 13th week, being always present at the 14th and 15th weeks[8,30,33,34] (Figure 98.13). The aortic blood flow increases progressively during the whole first trimester, as proven by

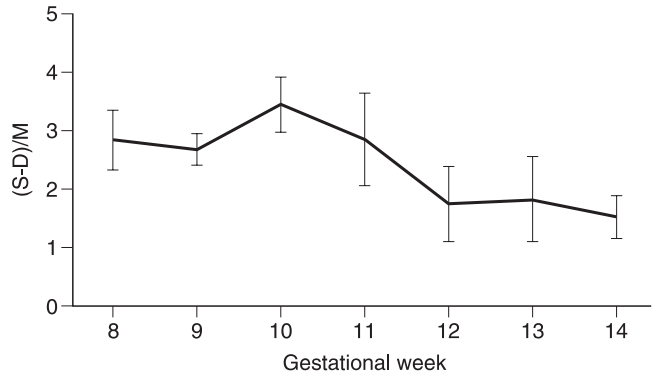

Figure 98.16 Pulsatility index of the mean cerebral artery during normal early pregnancy (mean ± SD).

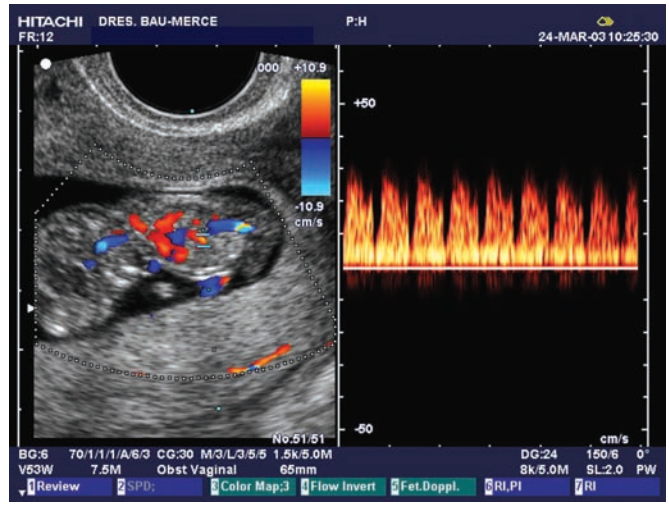

Figure 98.17 Normal Doppler recording of the ductus venosus in the 11th week.

the augmentation of systolic velocity and the reduction of the pulsatility index[8,30,33,34] (Figure 98.14).

Intracerebral signals can be registered by transvaginal color Doppler in the eighth week of amenorrhea. However, the centrifuge trajectory of the mean cerebral arteries can be depicted only from the 10th week. The cerebral blood flow increases between the 8th and 14th pregnancy weeks. Systolic velocities are present from the 11th week onward. They are visible in 80% of the 12th-week registers and are constantly present during the following weeks (Figure 98.15). The maximum systolic velocity is 4.97 cm/s at the eighth week, rising to 19.08 ± 5.21 at the 14th. The pulsatility index decreases steadily from 2.86 ± 0.49 in the eighth week to 1.49 ± 0.37 in the 14th week (Figure 98.16).

The cerebral arteries show diastolic velocities from the 11th week onward, in contrast to their absence in the umbilical and aorta arteries. The ratio between the umbilical and cerebral pulsatility indices is usually

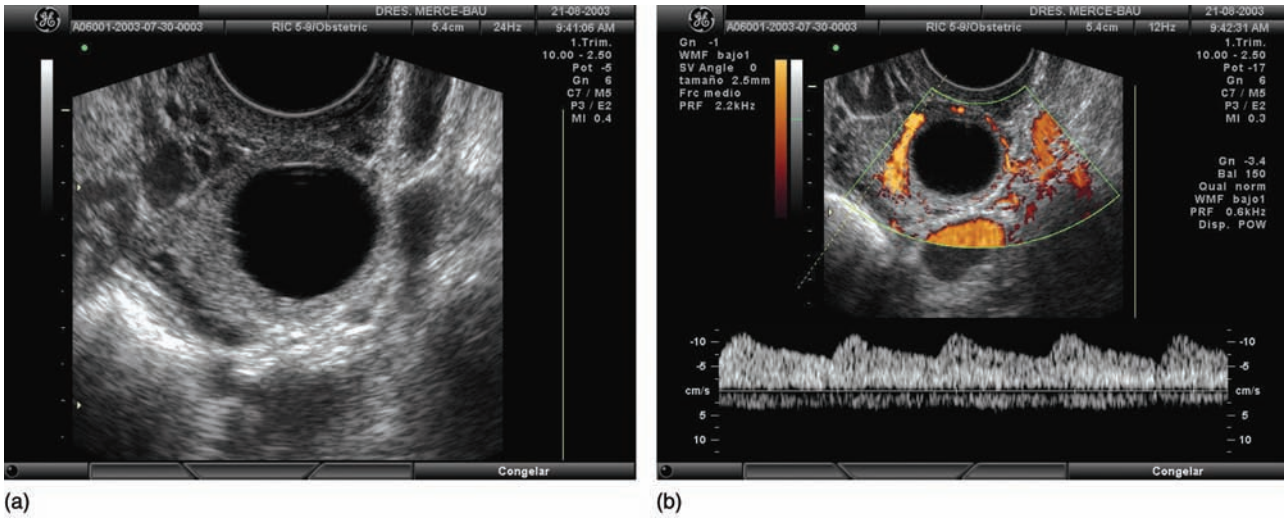

Figure 98.18 Sonolucent corpus luteum image (a) and color signal and FVW (b) in a normal fifth week of gestation.

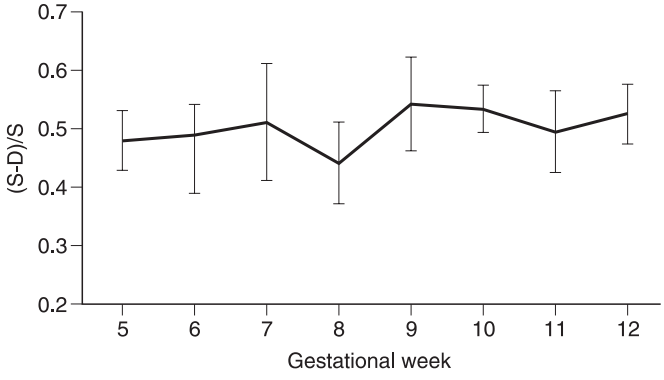

Figure 98.19 Resistance index of the normal corpus luteum vascularity during the first trimester of normal gestations (mean ± SD).

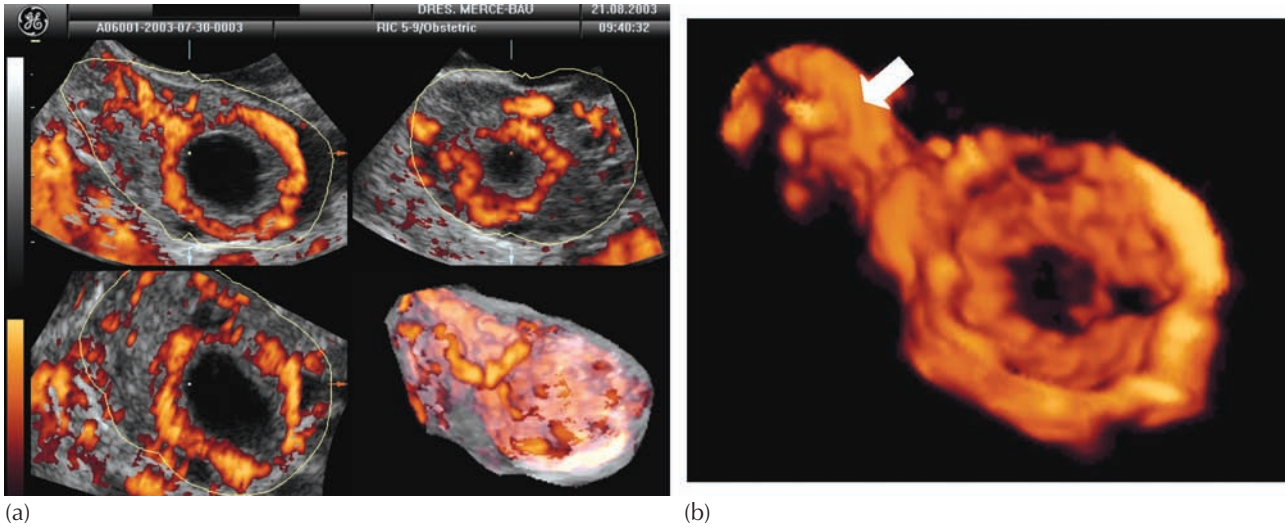

Figure 98.20 Luteal circulation assessment during early pregnancy by 3D power Doppler angiography. (a) Acquisition technique applying the VOCAL software. (b) Three-dimensional angiographic rendering of the vascular network in a gestational corpus luteum. The arrow points to the helical artery.

inferior to 1 during the first trimester.[37] These data suggest that the cerebral blood flow is independent of the vascular changes taking place in the aorta and the villous network. This autoregulation mechanism of the cerebral circulation during early pregnancy should aim to secure a proper blood supply to the growing fetal brain.

The ductus venosus is a circulatory shunt connecting the umbilical vein with the inferior cava vein. The Doppler signal shows a forward flow and triphasic

morphology with three components: ventricular systole, early diastole with passive ventricular filling and late diastole with a nadir in the signal that reflects the active ventricular filling due to the atrial contraction. Although all three components of the ductus venosus FVW can be identified from the ninth week onward,[36] its visualization is more constant from the 12th to 15th week onward[36,38] (Figure 98.17). The blood flow increases progressively in the ductus from the ninth week onward throughout the rest of the pregnancy. Blood flow velocities increase as the vascular resistance decreases.[36–40]

The pulsatility increase in the ductus venosus at the end of the first trimester could indicate the presence of a fetal chromosomal anomaly associated or not associated to a congenital cardiac malformation.[41,42] It has been suggested as a marker for chromosomal abnormalities independent of the nuchal translucency,[43] and in association with it, could increase the specificity by maintaining an adequate detection rate.[44]

Luteal ovarian blood flow

The luteal function is essential during early gestation, given that its hormonal secretion sustains the pregnancy until the functional takeover of the placenta. During the first 12 gestational weeks the luteal blood flow can be easily evaluated by transvaginal color Doppler.

The corpus luteum is visualized from 66%[37] up to 100% of pregnancies.[45] In the majority of cases it has an anechogenic appearance (77%), which can hinder the differential diagnosis with a persistent follicle.[37] The Doppler examination confirms the gestational corpus luteum when it shows a 'luteal conversion' of the FVW, quite similar to that of the second half of the ovarian cycle[16] (Figure 98.18).

The luteal blood flow during early pregnancy is similar to that of the luteal phase of the ovarian cycle and there are no significant differences in the velocimetric parameters.[16,46,47] Maximum systolic velocities are usually high.[46–48] The helical or nutricia artery shows the highest systolic velocities and a low variability.[48] The resistance index ranges from 0.48 ± 0.05 in the 5th week to 0.52 ± 0.05 in the 12th week, with a slight tendency to an increase in the intraovarian vascular resistance[16] (Figure 98.19).

Lately, the 3D PDA allows the representation of the luteal angiogenesis and the study of the blood flow in a more real and precise way (Figure 98.20).

99 Ultrasonographic signs of miscarriage

J. M. Bajo Arenas and T. Perez-Medina

Introduction

Recent advances in ultrasonographic technology along with the availability of high-frequency transvaginal transducers allow for more precise diagnosis. For every sonographist, the decision to inform the patient about the results of sonographic examination in relation to an interrupted pregnancy or embryonic death represents a challenge. The greater the experience, the earlier it can be confirmed that a pregnancy is actually not viable. It is not appropriate to confirm a diagnosis of miscarriage if any doubts exist, when most patients can wait without risk to their health. Nonetheless, it is good practice to write the suspected diagnosis in the clinical history to avoid unpleasant situations at the next sonographic examination. It is preferable to repeat the scan a few days later, to confirm that the pregnancy is 'not viable' if the diagnosis is not absolutely straightforward.

The problems for sonographists, especially for the less experienced ones, arise when they are required to reach definitive conclusions in the presence of signs corresponding to a pregnancy of less size than expected for the last menstrual period (LMP) without the aid of a previous sonographic examination. It needs to be decided if the pregnancy is of shorter duration or aborted. Some of the data that can be obtained will help in performing a diagnosis, and in other situations, enough information should be provided by the first sonographic examination to reach a definitive diagnosis; that is to say does not require confirmation with a subsequent sonographic examination. Repetition of the sonographic examination, 7–10 days later, should allow, in most of the cases, a definitive diagnosis to be reached.

Normal development of the pregnancy in the first trimester

If we know the chronology of appearance of the visible embryonic structures from sonography and its variations, it is possible to know whether the pregnancy is correctly evolving or not.

When findings that do not correspond to the gestational age are detected, the first thing to do should be to assess the possibility that an error exists in the LMP or that ovulation has not occurred on the 14th day of the cycle. In this situation, when the embryo is alive (positive heart beat) the only requirement is to correctly date the pregnancy in most cases. The LMP is calculated from the crown–rump length (CRL) and the date of the conception and the probable date of the childbirth are obtained. This is especially true when the pregnancy is of a longer duration than that corresponding to the LMP. When the data from the sonographic examination correspond to a pregnancy of shorter duration, that is to say, retarded ovulation, the approach is different, since finding a smaller embryo than expected is a risk factor for poor pregnancy outcome.

A useful adjunct to ultrasonography is the plasmatic determination of the β-hCG (hCG, human chorionic gonadotrophin) hormone (mIU/ml) between the fourth and eighth weeks of pregnancy. This determination is, among all those that can be performed during this period, the one from which the best clinical outcome has been obtained. Although there are wide variations from one pregnancy to another, it can be very useful. Normal course pregnancies duplicate the β-hCG levels in a period from 2 to 3 days, while abnormal pregnancies (ectopic or interrupted) usually show as irregular increases or, even, decreases. Simultaneous biochemical and sonographic data permit a useful perspective on the expected outcome in normal pregnancies. Essentially, it is necessary to know the β-hCG measurement system used in each one's own laboratory and adapt it to the medium.

Based on the capacity of sonography to predict the actual gestational age of different structures (the diameter of the gestational sac, the yolk sac and the CRL) within a 1-week margin, the diameter and growth of each structure from the moment of appearance are reflected in many tables by different authors.

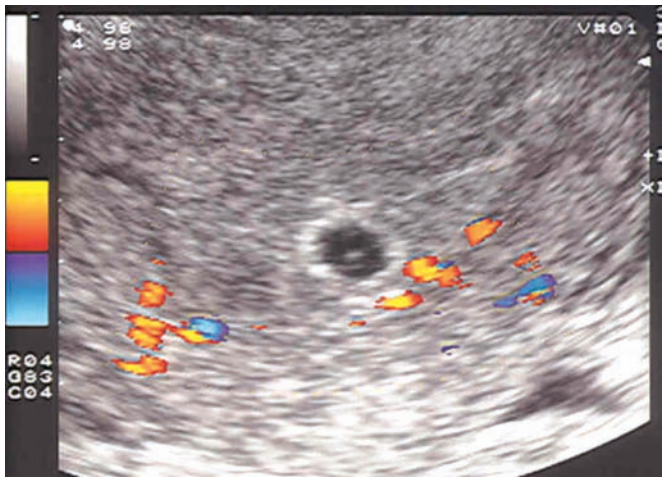

Figure 99.1 Gestational sacs more than 3–4 mm in diameter can be usually seen.

Figure 99.3 A 2–4 mm CRL embryo may be seen in the exploration.

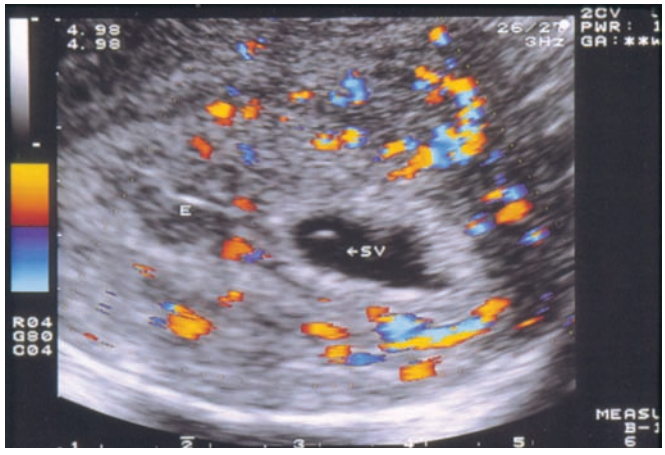

Figure 99.2 The yolk sac can be observed and measures 2–3 mm.

Figure 99.4 The amniotic vesicle is usually observed at the same time that the yolk sac (double bled sign).

Generally, a gestational sac of 3–4 mm average diameter can usually be seen (Figure 99.1). The size of the yolk sacs is 2–3 mm (Figure 99.2) and embryos have a CRL of 2–4 mm (Figure 99.3). The amniotic vesicle is usually identified at the same time as the yolk sac, and is known as the double-bled sign (Figure 99.4). The heart beat can be detected starting from a CRL of 3–4 mm in most cases (Figure 99.5), and is frequently detected before the embryonic echoes. Goldstein[1] states that the heart beat is present in the embryo a few days before detection by sonographic examination.

All the data obtained correspond to what is possible to visualize in normal pregnancies in patients in whom conception began 14 days after the LMP. Normal pregnancies that have begun before or after this will have differences with regard to the prospective findings, but the rhythm of change among successive sonographic examinations will be the same. So, after two sonographic examinations performed at least 1 week apart, starting from the moment when a gestational sac 5–10 mm in diameter has been visualized, a definitive diagnosis of the viability of the pregnancy can be obtained.

More than 80% of the sonographic examinations performed in the first trimester of pregnancy, in asymptomatic women without risk factors, will be normal. The earlier the first sonographic examination is performed, the higher will be the probability that we will find abnormal data or uncertain diagnoses, and the greater the probability that repetition of the sonographic examination will confirm normality. A pregnancy of 2 weeks less, in the 10th week will allow us to see a normal sac and a live embryo with 16 mm CRL, but if the sonographic examination is performed in the seventh week a small gestational sac of 8 or 10 mm diameter will probably be the only finding. The confirmation that a pregnancy is evolving correctly with a predicted of good outcome (low abortion probability) is only obtained when a live embryo is visualized and a history of associated risks does not

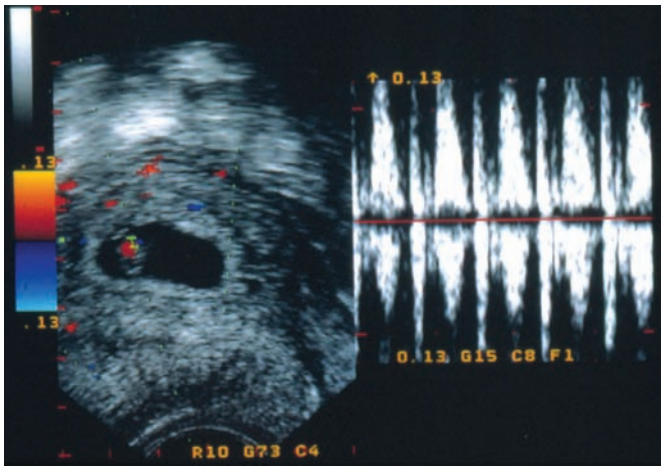

Figure 99.5 The heart motion can be detected in most cases starting from a 3–4 mm CRL embryo.

exist. On the other hand, confirmation that a pregnancy has been interrupted can only be made when an embryo is visualized of a certain size without heart beat. When there is no embryo, except in cases when the gestational sac has reached a large size, another sonographic examination 7–10 days later should be performed.

Spontaneous interruptions of the development of conception

The frequency of spontaneous interruptions of the reproductive development process is very high, especially when considered from the earliest stages. It is calculated that of each 100 potential pregnancies only 31 will carry to term with a live fetus.[2,3] The frequency of miscarriage, considered as the spontaneous interruption of the pregnancy before the fetus has reached viability, depends therefore on the approach that we use to define pregnancy. When considering pregnancies reaching implantation (biochemical pregnancy), the miscarriage frequency ranges from 30% to 40%.[4,5] On reaching the clinical diagnosis of pregnancy, the frequency is reduced to 10–15%. If the pregnancy progresses until the 12th week, the probability of abortion decreases to 3–4%. When the embryo is alive in the 12th week, the abortion rate until the 20th week is only 2%.[6]

Siddiqi *et al.*[7] report that in pregnancies under 12 weeks, controls had 5.2% of miscarriages, while cases that presented with bleeding had 16.4%. Also, when the patient is older than 34 years, the frequency increased to 11.1%, in comparison with patients under 35 years, in whom the frequency was only 4.4%. Levi *et al.*[8] found a 24% rate of abortions when positive heart beat existed but the embryo has a CRL less than 5 mm.

Table 99.1 Probability of spontaneous abortion according to the sonographic findings (from Goldstein[9])

Structure visualized	Probability of abortion (%)
Gestational sac	11.5
Yolk sac	8.5
Embryo CRL < 5 mm	7.2
Embryo CRL 6–10 mm	3.3
Embryo CRL > 10 mm	0.5

Goldstein[9] presents his data with great clinical applicability, allowing us to assess the probability of miscarriage as a function of the sonographic findings, as shown in Table 99.1.

Choong *et al.*,[10] in a series of 322 pregnant women, conclude that the most discriminatory test for predicting spontaneous miscarriage of a live embryo is a personalized multivariate analysis model, constructed with the LMP, CRL, embryonic heart rate, mean sac diameter and maternal age as the variables, with an area under the curve equal to 0.87 in their receiver operating characteristic (ROC) curve.

Embryonic and fetal causes, basically chromosomal anomalies, are the most frequent causes of miscarriage.[11] The different rates reported depend on the approaches used (whether only clinical pregnancies are considered or not). In the first weeks they can account for 80–90% of the cases. After the 12th week, the chromosomal anomalies and malformations are less relevant, although they continue to be an important cause. From this time on, maternal and environmental causes acquire more importance.

Knowledge of the frequency of spontaneous miscarriage, from the very beginning, along with theoretical knowledge of the causes of the abortion, should provide a perspective to the obstetrician who, when performing a sonographic examination, finds parameters not corresponding to a normal pregnancy. Earlier sonographic examinations in the pregnancy will allow diagnosis of many more cases of spontaneous interruptions in pregnancy.

Poor prognosis of pregnancy. Sonographic findings (Table 99.2)

Some circumstances, when present in a sonographic examination performed in the first trimester of the pregnancy, indicate a poor prognosis. Although they do not allow a definitive diagnosis of 'interruption of development,' they indicate that the prognosis for normal outcome is reduced. In the days prior to their detection, some phenomena are usually observed.

However, none of them are sufficiently reliable to give a definitive diagnosis. To be able to diagnose an abortion, or embryonic death, it is necessary to check the existence of an embryo of 5 mm CRL minimum in which heart beat is lacking.

Anomalies of the gestational sac

The gestational sac and the CRL develop simultaneously. It is possible to check whether, between the 6th and the 10th weeks, the difference usually overcomes the 15–20 mm limit. Other authors[12,13] report that when the difference between the diameter of the gestational sac and CRL is less than 5 mm (*precocious oligoamnion*), miscarriage occurs in 95% of cases (Figure 99.6). Dickey *et al.*[14] report that when the difference between these two measures was less than 5 mm, miscarriage occurred in 80% of the cases; when the difference was between 5 and 7.9 mm, miscarriage occurred in 26.5% of cases, and when the difference was more than 8 mm, miscarriage occurred in only 10.6% of cases.

Figure 99.6 Gestational sac showing precocious oligoamnion; a good predictor for abortion.

Anomalies of the heart frequency interpreted as a function of the gestational age or CRL

Bradycardia or relative bradycardia

Increase in the fetal heart rate (FHR) until the 10th week is characteristic; it rises from 90 beats per minute (bpm) in the first weeks of visualization up to 180–190 bpm in the 12th week. From this time, FHR diminishes progressively until it reaches 140–150 bpm in the 20th week. However, important variations exist in the frequency reported by different authors in every week of pregnancy. Merchiers *et al.*[15] give importance to the observation that a decrease of the heart frequency occurs in two successive sonographic examinations. For Laboda *et al.*[16] a FHR under 85 bpm indicates a very poor prognosis, since in their series all the embryos that presented this finding, ended in miscarriages. May and Sturtevant[17] also associate poor prognosis with this finding: 6 out of 11 cases with FHR under 85 bpm between the 4.5th and the 7.3rd week miscarried.

Benson[18] sets the limit as 90 bpm for the whole first trimester to indicate a poor prognosis. In his series, all cases that had a FHR under 70 bpm ended in abortion; between 70 and 79 bpm, 91% had abortions, and between 80 and 89 bpm, 70% had abortions. Doubilet and Benson[19] suggest that a FHR more than 100 bpm until the 6.2nd week and more than 120 bpm between the 6.3rd and the 7th week, are signs of a good prognosis. They consider it a sign of a poor prognosis if a FHR of less than 110 bpm in the 7th and 8th weeks is observed. Stefos *et al.*[20] report in their series that when there is a FHR under 85 bpm between the sixth and eighth week, it is unlikely any fetus will survive. For these authors, when the FHR is between 116 and 125 bpm between the sixth and the seventh week, the prognosis is good, as it is when the FHR is more than 146 bpm between the eighth and the ninth week. No finding, except the absence of heart beat, provides a definitive diagnosis of embryonic death. However, the scientific evidence allows a more precise diagnosis. In general, heart frequencies under 85 bpm until the seventh week and under 100 bpm from this time on, are associated with an adverse result and high probability of abortion.

Anomalies of the yolk sac (size, shape, ecogenicity)

The yolk sac is the first extraembryonic structure that appears and it is visible in practically all pregnancies between the 5th and the 12th weeks. The yolk sac can be observed initially when the diameter of the gestational sac reaches 3.7 mm, on the 36th day from the LMP and is reliably observed when the diameter is 6.7 mm, on the 40th day of amenorrhea. Furthermore, according to Levi *et al.*[8] the yolk sac should always be observed when the diameter of the gestational sac is more than 8 mm (corresponding to 33 days), so that its absence would mean a better approach for gestational loss.

The importance of the visibility of the yolk sac for ecographists arises from the fact that it is the first identifiable structure in the gestational sac, preceding by 4–7 days visualization of the embryo. Its characteristic feature is an ecogenic circle that defines a sonoluscent area inside an extra-amniotically located chorionic cavity.

Some anomalies are described in their initial development as shape and volume alterations.[21,22]

In general, it is difficult to make important clinical decisions (such as diagnosing a pregnancy interruption) based on findings related to the yolk sac. This is a structure with important variations with regard to its size and dimensions. Visualization is also not absolutely safe, even in pregnancies of normal course. The

alterations at this level are usually late, and it is believed that they are a consequence of the process that determines the miscarriage, not the cause. However, several publications have reported their measurement, the assessment of their characteristics, and the analysis of their association with a poor pregnancy outcome.

Lindsay *et al.*[23] report that the existence of a yolk sac of more than 2 standard deviations (SD) above that expected for the gestational age indicates a poor prognosis. All cases evolved unfavorably when a yolk sac bigger than 5.6 mm was observed before the 10th week in their series (Figures 99.7–99.9). This agrees with the data from Kupesic and Kurjak,[24] who report a poor prognosis with yolk sacs with abnormal size and abnormal Doppler vascularization. Perez-Medina *et al.*[25] report the changes in the yolk sac with respect to size, shape or the echogenicity are parameters that guide the normal or pathological development of the pregnancy. Of the 100 patients in their series, 87 (87%) had a normal development and evolved correctly until the end of the first trimester (control group); 13 (13%) had an abnormal course of the pregnancy (study group). Of the 87 patients with correct development, three had a yolk sac diameter of more than 1 SD. Of the 13 patients with abnormal course, six had a yolk sac diameter greater than 1 SD. They conclude that the sensitivity of the size of the yolk sac to predict an abnormal course of the pregnancy is 92.3%, the specificity is 66.6%, the positive predictive value (PPV) is 96.5% and the negative predictive value (NPV) is 46%; and when some of these anomalies appear, it is necessary to follow the pregnancy closely.

The regressive yolk sac is sonographically observed by a progressive increase of refrigency until a more extreme form that would indicate calcification of the sac (Figure 99.10).

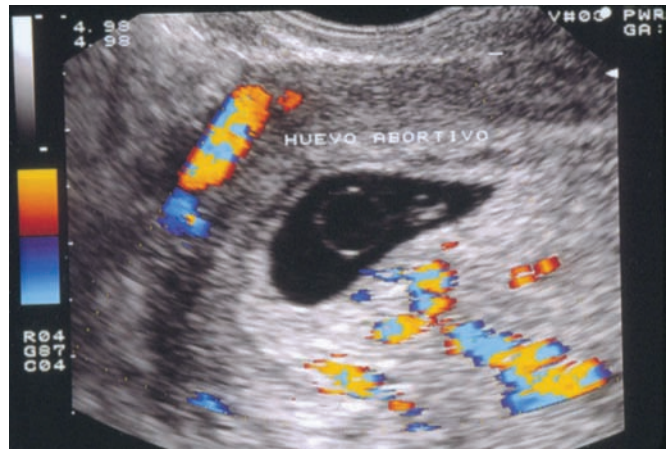

Figure 99.7 Yolk sac of 8 mm (more than 2 standard deviations for the gestational age).

Figure 99.8 Giant yolk sac, a sign that is rapidly and easily appreciated in the sonographic examination.

Trophoblastic thickness at the embryonic implantation site

Bajo and colleagues[26] describe the trophoblastic thickness at the embryonic implantation site in a prospective, observational study in 592 normal pregnancies in whom serial ultrasound scans were performed from the 5th to the 12th week of pregnancy. Trophoblastic thickness was measured at the embryonic implantation site to determine the significance of the difference between the gestational age in weeks and the trophoblastic thickness in millimeters. A difference of more than 3 was highly predictive of a poor pregnancy outcome (Figure 99.11). The sensitivity of this sign in the prediction of spontaneous abortion was 82%, the specificity was 93%, the positive predictive value was 63% and the negative predictive value was 97%.

Figure 99.9 Gestational sac of 9 mm. This is a very sensitive marker for abortion.

Intra-uterine bleeding. Subchorionic and retroplacental hematomas

The existence of liquid collections, mainly in subchorionic locations, is a relatively frequent finding in the sonographic examinations performed during the first trimester of pregnancy (Figure 99.12). From some of these images it is evident that some have a huge size and coincide with clinical symptomatology

Figure 99.10 The regressive yolk sac is observed when there is a progressive increase of the internal refrigency as seen in both yolk sacs of this double pregnancy.

Figure 99.12 The existence of subchorionic liquid collections is a frequent finding in examinations performed in the first trimester.

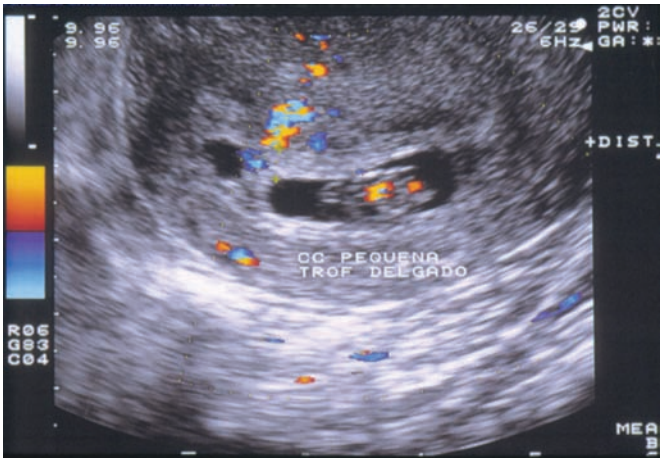

Figure 99.11 A thin trophoblast is observed. A difference of more than 3 between gestational age (weeks) and the trophoblastic thickness (mm) is highly predictive of a poor pregnancy outcome.

(vaginal bleeding), while others are casual findings in asymptomatic women and have a minimum volume. Discrepancies exist with regard to the risks and their association with abortion when used for the diagnosis of intra-uterine hemorrhage. Dickey *et al.*[27] demonstrated using Doppler color that in 37% of sonographic examinations in the first trimester subchorionic bleeding exists, and that in 47% of cases, subchorionic liquid is detected. They conclude that the liquid and the subchorionic bleeding are frequent findings during early pregnancy and are not associated with embryonic death unless accompanied by vaginal bleeding. Stabile *et al.*[28] state that the existence of small subchorionic hematomas (less than 16 ml) in women with genital bleeding does not increase the risk of miscarriage in comparison with women with bleeding without hematoma.

With regard to the diagnosis from the size and the localization of the hematoma, Glavind *et al.*[29] do not find a relationship between the size of the hematoma and the week of pregnancy in which the diagnosis was performed. For these authors retrochorionic or subplacental localization have a worse prognosis than subchorionic localization (Figure 99.13). According to Kurjak *et al.*[30] subchorionic hematomas influence abortion frequency (17% in a study group vs. 6.5% in a control group). Neither has a significant influence on the size of the hematoma, the localization being more important. Hematomas in the uterine corpus or fundus have a worse prognosis than those located near the uterine cervix (Figure 99.14). In another report, Kurjak *et al.*[31] find a higher RI of the spiral arteries in cases with retrochorionic hematoma than in controls, due to compression from the hematoma.

According to Ball *et al.*[32] it is not clear if the subchorionic bleeding is the cause or simply an underlying process that produces negative effects. They present an interesting study in which the patients are divided into three groups: the first is formed of women who present with subchorionic bleeding; the second is a control group of women without hematoma, and the third is another control group without hematoma but with vaginal bleeding. When these authors perform comparisons with controls without bleeding, an odds ratio (OR) 2.8 is obtained for abortion, 4.5 for stillbirth, 11.2 for abruptio placentae and 2.6 for preterm birth. When compared with controls with bleeding all the ORs increase except that for abortion. The weight at birth is diminished when compared with the two control groups. Genital bleeding by itself is able to increase the risk of miscarriage. Bennet *et al.*[33] compare the abortion frequency in women with genital bleeding and subchorionic hemorrhage. When the hematoma is big, the frequency of abortions is 18.8%; if medium, 9.2%; and if small 7.7%. When the

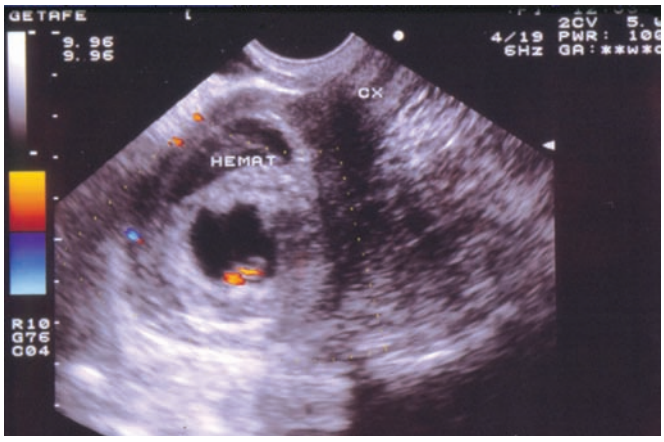

Figure 99.13 Retrochorionic or subplacental localization has a worse prognosis than subchorionic localization.

Figure 99.15 Large hematoma causing distortion in the gestational sac.

Figure 99.14 Hematomas located in the uterine corpus or fundus have a worse prognosis than those located near the uterine cervix.

woman is older than 35 years, the abortion rate is 13.8%, in comparison with 7.3% in women younger than 35 years. When the bleeding appeared before the eighth week, the frequency was 13.7%, while if it appeared later than the eighth week, the rate was reduced to 5.9%.

The presence of a small quantity of retrocorial liquid has fewer implications, when it is observed as an isolated finding, and in the context of a normal sonographic examination in a pregnancy of normal course. The existence of a subchorionic hemorrhage, especially when associated with vaginal bleeding, increases the abortion risk and requires another sonographic examination a few days later. New sonographic examinations are justified when small or moderate hemorrhages exist. The worst prognosis comes with large-sized hematomas (more than 40–50 ml), especially if located next to the uterine cervix, in the uterine corpus or fundus. Retrochorionic or subplacental hematomas, especially if moderate or big, always carry a poor diagnosis. The frequency of visualization of these images is low, probably because a rapid corial detachment develops leading to the miscarriage, with bleeding and expulsion of debris. Another uncommon type of hematoma or intra-uterine bleeding is the preplacental bleeding that appears after invasive techniques that require the introduction of a needle into the uterine cavity. In general, these hematoma are moderate and evolve favorably although threatened miscarriage in the first trimester is associated with an increased incidence of adverse pregnancy outcome, independent of the presence of an intrauterine hematoma.[34] Nagy *et al.*[35]compared perinatal outcome in 187 pregnant women with intrauterine hematoma and 6488 controls in whom hematomas were not detected in the first trimester. They conclude that the sonographic presence of an intrauterine hematoma during the first trimester identifies a population of patients at increased risk for adverse pregnancy outcome.[35] On other occasions they reach such a volume that they result in occupation of the chorionic cavity, with the end effect of fetal death because of the compression (Figure 99.15).

Small CRL for the gestational age

In general, when a small-for-gestational-age CRL with positive heart beat embryo is observed, a pregnancy of shorter duration is the first diagnosis to exclude. This is frequent in women with long or irregular cycles. However, sometimes this may be observed in women with normal cycles. First of all, the date of conception should be corrected, but data that allow the association of this alteration with a higher risk of poor pregnancy outcome exist (Figure 99.16).

Koornstr and Exalto[36] report that 22.7% of embryos from women with regular cycles have a lower CRL in 1 week or more than expected from the LMP. On analyzing the results it is observed that among these embryos a rate of abortions of 16% existed, in comparison with only 5% in the embryos with a correct LMP.

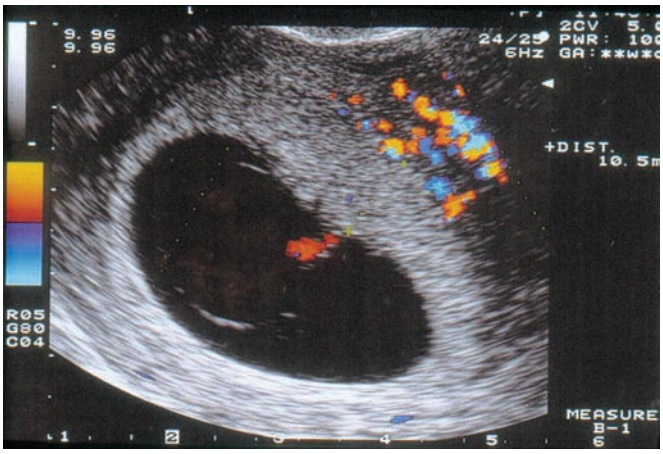

Figure 99.16 Small CRL for the gestational age, as referred to the gestational sac.

Leelapatana *et al.*[37] report that a small CRL for gestational age during the first trimester of pregnancy could be associated with tryploidies, but not with trisomy 18 and 21. Later, Bessho *et al.*[38] reported that fetuses ending in miscarriage had a quotient of measured CRL/ expected CRL of 0.74, in comparison with the 0.98 observed in fetuses that did not miscarry. These authors did not find differences in the quotient among chromosomally normal and abnormal fetuses. This result has also been confirmed in the series from Coulam *et al.*[39] who found no differences in the frequency of blighted ovum and small CRL for gestational age among chromosomally normal and abnormal fetuses.

Pattern of fetal movements

Along with the sonographic chronology of findings in a normal pregnancy, the existence and verification of fetal movements should be observed.

In a classic publication by Anderson[40] the results presented were obtained in a series of 149 cases of threatened abortion and of more than 7 weeks of gestational age. Only 2 of 65 pregnancies that later aborted presented fetal movements. On the other hand, 64 of 72 normal pregnancies presented fetal movements. So the absence of fetal movements after a relatively long period of sonographic examination, especially after the eighth week, should also be considered as a sign of poor prognosis.

Doppler flow alterations

The number of publications during the few last few years regarding the Doppler velocimetry in the first stages of normal and pathological pregnancies is large. The data that the investigators have contributed has enormously improved our knowledge of the phenomena that exist in the placentation process and development of the embryo. Kurjak and Kupesic[41] report that the process of trophoblastic invasion of the decidua is progressive, mediated by the action of proteolytic enzymes that facilitate the penetration and maternal erosion of the capillary arteries and the formation of lagoons. There are flow changes that can be measured in the uterine, retrochorionic and intervillous arteries during the first trimester of pregnancy (Figure 99.17). This is the reason why the pulsatility index (PI) and high resistance index (RI) in the first trimester should not be interpreted as a bad result, as it would be in the second trimester, as Jaffe *et al.*[42] report. Jaffe and Woods[43] explain how the intervillous circulation persists until the late first trimester. In complicated pregnancies, analyzed early, the uteroplacental circulation is different from that in normal pregnancies. In these abnormal pregnancies the intervillous flow is increased. The hypothesis, based on other studies, is that the embryo of a pregnancy of normal course favors an atmosphere with a low concentration of tissular oxygen in placental tissues. Martin *et al.*[44] explain that the increased impedance to flow in the uterine arteries in the first trimester is associated with the development of pre-eclampsia and intrauterine growth retardation (likelihood ratios of 5 and 2, respectively).

Mercé *et al.*[45] measured the velocity of systolic peak, PI and RI in retrochorionic arteries and the fetal umbilical artery in 108 pregnancies between the 4th and 15th weeks. The earliest sign in the retrochorionic circulation was obtained in the 4.5th week, and the earliest in the umbilical artery at the end of the 5th week. Their results indicate that, as gestational age increases, the systolic peak of the retrochorionic, intervillous and umbilical arteries increase, while PI and RI diminish. Kurjak and Kupesic[46] assessed yolk sac morphology and vascularity, and intervillous blood flow in normal early pregnancy and missed abortion, in a prospective analysis of 87 normal pregnancies and 48 missed abortions between 6 and 12 weeks' gestation. They concluded that progressive decrease of the yolk sac vascularity coincides with visualization of more prominent color-coded areas within the intervillous space. In patients with missed abortion, such changes do not occur.

In general, most authors do not find differences in the Doppler indexes among normal outcome pregnancies and those ending in miscarriage. Jauniaux *et al.*[47] compared 30 confirmed abortions with 30 normal pregnancies. The PI of the uterine artery was higher in the abortions than in the normal pregnancies. Differences were not observed in RI and systolic peak of the uterine artery, nor in PI nor RI of spiral arteries among abortions and normal pregnancies. These authors concluded that the velocity of abnormal flow found in some complicated pregnancies with embryonic death could be related to a defective placentation and 'dislocation' of the trophoblastic wall, after which embryonic death follows. The premature access of maternal blood to the intervillous space could break

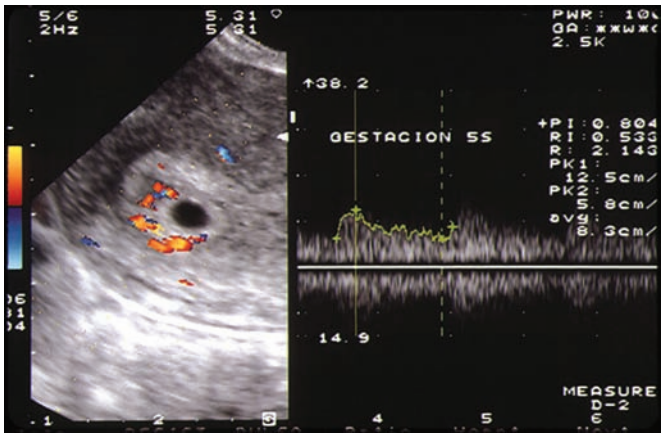

Figure 99.17 Doppler flows can be obtained in the retrochorionic and intervillous arteries in the first trimester of pregnancy.

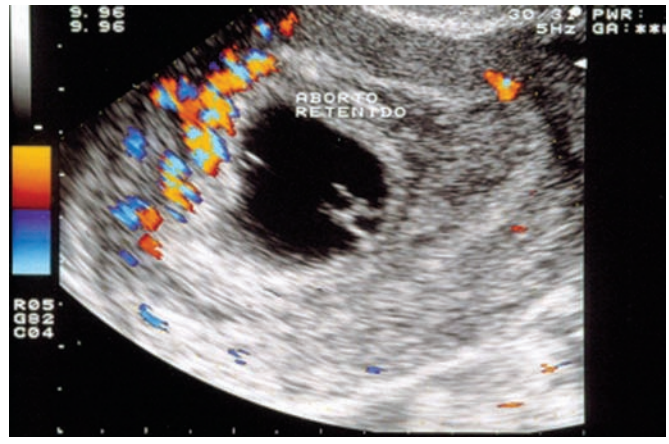

Figure 99.19 The use of transvaginal color Doppler is not helpful for predicting pregnancy outcome in living embryos.

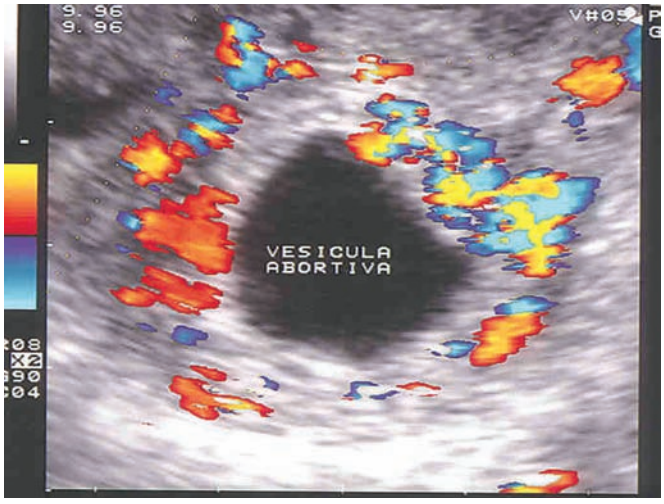

Figure 99.18 The premature access of maternal blood to the intervillous space has broken the embryonic–maternal interface, probably the cause of abortion.

the embryonic–maternal interface, and could be the cause of miscarriage (Figure 99.18). Alcazar and Ruiz-Perez[48] report that no apparent alteration occurs in the early uteroplacental circulation in patients with threatened abortion with a living embryo. So the use of transvaginal color Doppler ultrasound is not helpful for predicting pregnancy outcome in cases of threatened abortion (Figure 99.19).

Salim *et al.*[49] measured PI and RI at the level of the corpus luteum. The pregnancies with threatened abortion or ending in abortion show higher values than normal pregnancies. However, they did not observe differences when comparing data from ectopic pregnancies, hydatidiform moles, or anembryonic pregnancies. Alcazar *et al.*[50] measured the flows at the level of the corpus luteum, and did not find differences among controls, threatened abortion or blighted ovum. In pregnancies with confirmed miscarriage, the values of RI are higher.

Other factors to consider (clinical factors)

- Maternal age more than 35–40 years
- Presence of uterine bleeding
- Time of commencement of uterine bleeding
- Hormonal dynamics determination (β-hCG)
- Reproductive history (one or more previous miscarriages)
- Existence of associate pathology (multiple myomas or submucosos, uterine malformations).

Sonographic findings to diagnose an interrupted pregnancy (Table 99.3)

The two types of spontaneous interruptions of pregnancy in patients without bleeding are, from a practical point of view, deferred or missed abortions, and the blighted ovum or anembryonic pregnancies. Academically, *deferred* abortions were considered as those in which the measured CRL corresponded to 6 weeks less than that expected in an embryo lacking heart beat (Figure 99.20). Nowadays, due to the greater availability of initial sonographic examination, the diagnosis is made before the bleeding begins. Therefore, this kind of miscarriage, when the interruption is recent and bleeding has not begun, is called *missed* abortion. With regard to the anembryonic pregnancies, their frequency is much lower than is thought from a clinical point of view. There could be pregnancies initially with an embryo, that died precociously and was reabsorbed, so was not sonographically visualized. Not all gestational sacs in which an amniotic or a yolk sac is observed, although an embryo is not seen, correspond to anembryonic pregnancies, since these structures require the development of an embryo if they are to appear (Figure 99.21).

The false positive diagnoses, the really important fails, are of two types. The first is when the sonographist is not able to detect the heart beat in an embryo that actually has heart motion. This can be

Table 99.2 Ultrasonographic signs of a poor prognosis for embryonic viability

Anomalies of the gestational sac	Precocious oligoamnion: when the difference between the diameter average of the gestational sac and the CRL is smaller than 5 mm, poor prognosis
	Very thin decidual reaction (mm) for the corresponding gestational age (weeks) (difference > 3)
	Low implantation
	Distorted aspect
Alterations of the heart frequency	Bradycardia is always a sign of poor prognosis. It should be interpreted as a function of the gestational age
	Frequencies under 85 bpm until the 7th week and under 100 bpm from then on indicate poor diagnosis
Small live embryo for the LMP	Especially in women with regular cycles, the visualization of a CRL smaller by at least 1 week to that corresponding to the LMP, increases the risk for abortion
Anomalies of the yolk sac	Alterations in size (big vesicles, more than 6 mm in diameter) increase the risk
	Alterations in the structure (hyperecogenic vesicle), poor prognosis
Reverse implantation	Risk of abortion increases
Intra-uterine bleeding (hematomas)	Big hematomas, mainly retrochorionic, maximum risk. Subchorionic hematomas located in corpus or fundus, more risk than next to the uterine cervix
	If no vaginal bleeding or small size of hematoma, low risk
Fetal movements	Absence of fetal movements, starting from the 8th week
Doppler	Poor color map around the gestational sac
	Values of Doppler flow in uterine, radial, arcuata, spiral, retrochorial and intervillous arteries, as well as the umbilical artery in the first trimester of pregnancy have limited clinical applicability
Other factors	Existence of associated pathology: myomas, malformations
	Uterine hemorrhage
	Maternal age over 35 years
	History of one or more abortions (more abortions, more risk)
	Serial hormonal determinations. Two β-hCG determinations separated by2–3 days

Table 99.3 Ultrasonographic signs in the interrupted pregnancy

Embryonic death (deferred or missed miscarriage)	Absence of heart beat in embryo of minimum 5 mm CRL (even in the first sonographic examination)
Blighted ovum or anembryonic pregnancy	Gestational sac of 25 mm or more without embryo (even in the first sonographic examination)
	For some authors, gestational sac of 20 mm or more without yolk sac
	Gestational sac of 16 mm or more with yolk sac and amniotic vesicle without embryo ('empty amnion')
Interrupted pregnancy	Successive sonographic examinations: absence of significant changes in two sonographic examinations separated by 7–10 days when in the first sonographic examination a gestational sac of 15–20 mm minimum has been visualized

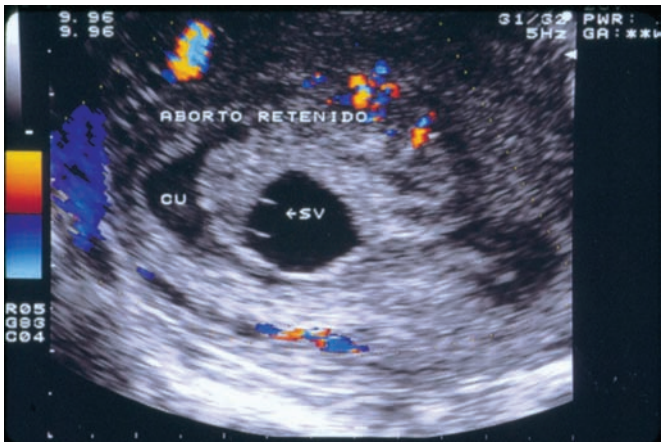

Figure 99.20 Deferred abortion.

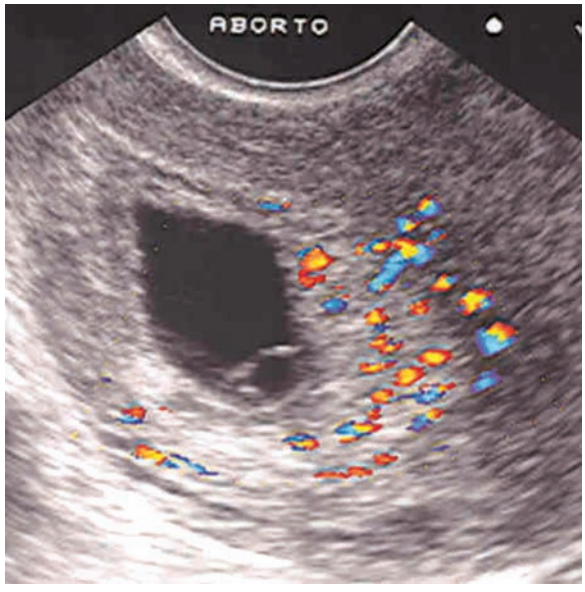

Figure 99.21 A gestational sac with a yolk sac but lacking embryo corresponding to a missed abortion.

caused by a small size of the embryo, inadequate or obsolete equipment, or suboptimal visualization due to patient's characteristics. The other type of error would be to consider that before a certain size of gestational sac an embryo must be seen. This error is caused by the selection of a low level from which to diagnose anembryonic pregnancy, and this level could correspond to the highest range in normality. In the first case, for instance, in an embryo of 4–5 mm in which one had not seen a heart beat, after one week one might see it when measured at 9–10 mm. In the second case, in a 21 mm diameter vesicle, in which the embryo was not seen, after 1 week a 5–6 mm CRL and positive heart beat embryo may be observed.

According to Daya *et al.*[51] an embryo is not seen until the gestational sac measures 8.3 mm diameter, coincident with the 41st day of amenorrhea. However, it is always observed when the gestational sac reaches 14 mm in diameter, on the 46th day of amenorrhea (6 weeks and 4 days). Goldstein *et al.*[52] report that when the pregnancy is correctly developing, the gestational sac is reliably observed in the fifth week. When the sac measures 20 mm in diameter, the embryo is observed in 100% of the cases. At 6 weeks and 4 days (46th day of amenorrhea) a heart beat is observed in 100% of cases, and when the diameter is 30 mm, in 100% of the normal cases, embryonic movements are already present (8 weeks).

Norwitz *et al.*[53] confirm the importance of examination at the very beginning of the pregnancy. To confirm the diagnosis of 'embryonic death' at the first sonographic examination, the CRL should be longer than 10 mm. Levi *et al.*[8] consider all gestational sacs of more than 8 mm diameter without yolk sac and of 16 mm or more without embryo as 'not viable'. They diagnose embryonic death when the embryo is between 4 and 5 mm CRL. Several cases with CRL smaller than 4 mm in which heart beat was not detected evolved correctly in their series.

Brown *et al.*[54] recommends waiting until the CRL is 5 mm to confirm embryonic demise if a heart beat is not detected. Bernard and Cooperberg,[55] in differentiation among blighted ovum and 'viable precocious pregnancy', consider that although the visualization of sacs with 20 mm or more without embryo is a sign of poor prognosis, definitive signs do not exist, and so recommend repeating the sonographic examination after 1–2 weeks. Nyberg *et al.*[56] wait to observe a gestational sac of more than 20 mm in diameter without yolk sac or a sac of 25 mm diameter with distorted aspect without embryo before considering a pregnancy as not viable.

McKenna *et al.*[57] report that between the 6th and the 10th week, the amniotic cavity is similar to the size of the embryo, and the visualization of an amniotic cavity without embryo corresponded to an 'empty amnion' and diagnosed interrupted pregnancy. These authors report that before the gestational sac reaches 16 mm or more, when the yolk sac is identified and neither embryo nor heart beat are detected, and an empty amniotic sac is seen, an interrupted pregnancy can be diagnosed.

In conclusion, to diagnose embryonic death, it is essential to wait to see an embryo lacking heart beat with a CRL of 5 mm minimum. For the diagnosis of blighted ovum or anembryonic pregnancy at a first sonographic examination, it seems reasonable to wait till the gestational sac reaches 25 mm, equivalent to 7 weeks pregnancy with conception on the 14th day of the cycle. This corresponds to a pregnancy in which, in 100% of cases, a live embryo would be visualized if correctly developed. In all other cases, the sonographic examination must be repeated after 7–10 days. In the great majority of cases, the second examination will allow us to confirm a normal or interrupted pregnancy.

100 2D and 3D Doppler assessment of abnormal early intrauterine pregnancy

J. L. Alcázar, L. T. Mercé and M. García-Manero

Introduction

The introduction of transvaginal ultrasound allowed assessing *in vivo* and non-invasively an, until then, unexplored area: early gestation. This technique revolutionized the evaluation and management of many clinical situations during this period of pregnancy. The advent of color and power Doppler ultrasound, as a further step, allowed the assessment of early pregnancy hemodynamics. Traditionally, two-dimensional (2D) color and pulsed Doppler has been applied to evaluate early human pregnancy hemodynamics during the last 15 years.[1] In recent years, a new technological advance has been introduced: 3D power Doppler ultrasonography. This new technique allows a more objective and global assessment of organ vasculature.[2]

The scope of the present chapter is to address the assessment of ovarian, uteroplacental, yolk sac and embryo-fetal hemodynamic changes in abnormal early intrauterine pregnancy by means of 2D and 3D transvaginal color and power Doppler ultrasonography. We shall review missed abortion and anembryonic pregnancy, threatened abortion and complete/incomplete abortion.

Hemodynamic changes in normally developing pregnancy have been dealt with in another chapter in this book, so we shall address specifically what happens in abnormal early pregnancy.

Abnormal early pregnancy

Missed abortion and anembryonic pregnancy

Luteal circulation

Three studies have found that luteal blood flow resistance was increased in missed abortion.[3–5] This finding may be a consequence rather than a cause of missed abortion, because missed abortion consists of a failure of early pregnancy to develop, in which the production of human chorionic gonadotropin is impaired, which in turn could have a negative effect on luteal function. However, Frates *et al.* did not find any difference between missed abortions and normal pregnancies.[6]

Regarding anembryonic pregnancies, Alcázar *et al.*[3] and Salim *et al.*[4] did not find any differences in luteal blood flow as compared with normal developing pregnancies. This could be explained by the fact that in an anembryonic pregnancy trophoblastic activity continues for a time without the presence of the embryo. Furthermore, some studies have demonstrated that luteal activity in anembryonic pregnancy, as assessed by progesterone serum levels, does not differ from normal pregnancies but is impaired in missed abortions.[7]

Uteroplacental circulation

Several authors have investigated uteroplacental circulation in abnormal early pregnancies. In the case of missed abortion and anembryonic pregnancy, most studies did not find significant differences as compared with normal pregnancies in uterine, arcuate, radial and spiral arteries or retrochorionic arteries.[8–13]

Regarding intervillous flow conflicting data have been reported. According to embryological studies, uteroplacental circulation is established around day 12 of embryo development, when maternal blood flows into the syncytiotrophoblast lacunae. Therefore, actual blood flow in the intervillous space begins around days 14–15 of embryonic development (fourth week of amenorrhea) and never later than day 40 (7 weeks + 5 days).[14,15]

However, Hustin and Schaaps challenged this concept and brought up a new theory.[16] They stated that intervillous blood flow does not actually exist until the 12th week. Their theory was based on the findings from *in vitro* studies using four placentas perfused with barium sulfate and hysteroscopic

Figure 100.1 Intervillous blood flow in early pregnancy. Vessels penetrating the chorion can be clearly seen.

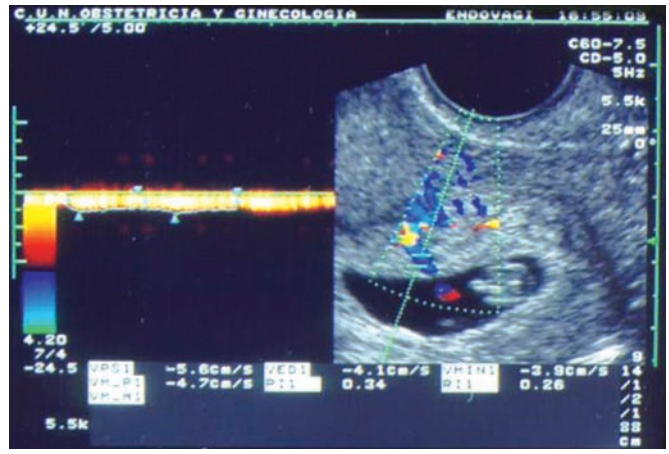

Figure 100.3 Arterial-like FVW from intervillous space.

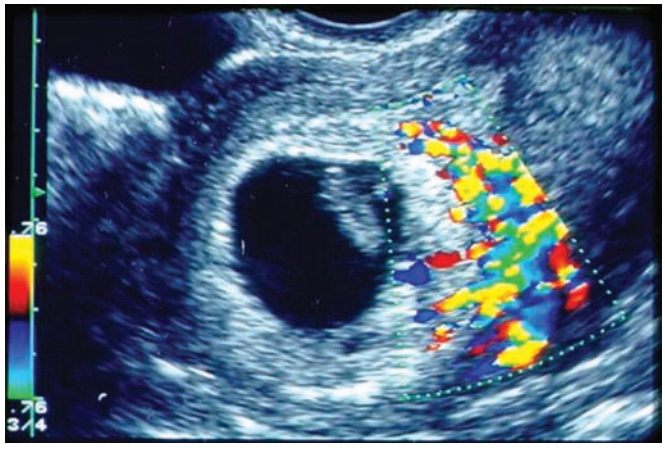

Figure 100.2 Intervillous flow in early pregnancy.

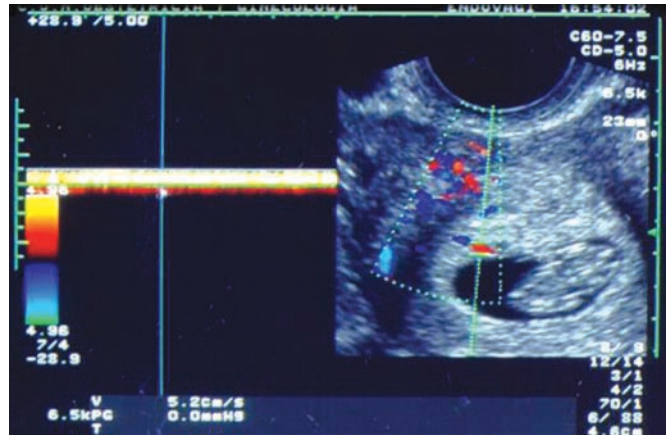

Figure 100.4 Venous-like FVW from intervillous space.

studies in 10 patients. Using transvaginal color Doppler, Jauniaux,[17] Jaffe and Woods[18] and Coppens *et al.*[19] supported this theory because they did not detect intervillous flow until the 12th week.

However, several studies have reported that intervillous flow can be detected from the sixth week onward in normal early pregnancy.[20–23] This agrees with our findings (Alcázar, unpublished data) (Figures 100.1 and 100.2). We agree with Mercé *et al.*[20] and Kurjak and Kupesic[21] that two types of intervillous flow can be found: pulsating arterial (Figure 100.3) and continuous venous (Figure 100.4).

In abnormal pregnancies, Jauniaux *et al.* found that 70% of complicated pregnancies showed intervillous flow as compared with 0% in normal developing pregnancy.[24] However, a more recent study from this group showed that intervillous flow may be detected in around 60% of normally developing pregnancies between the 7th and 13th weeks,[25] being a progressive phenomenon (36% at 8–9 weeks, 60% at 10–11 weeks and 90% at 12–13 weeks). They found that in abnormal pregnancy, the number of cases in which intervillous flow could be detected were higher than in normal pregnancies at 8–9 and 10–11 weeks, but not later. They did not discriminate between missed abortions and anembryonic pregnancies. They speculated that a premature entry of maternal blood in the intervillous space disrupts the materno–embryonic interface and is probably the final mechanism causing abortion. Similar findings have been reported by Jaffe and Warsoff.[26]

Kurjak and Kupesic found that a significant increase of venous peak velocity in the intervillous flow occurs in normal pregnancies from the 11th week onward. This change does not occur in missed abortion or anembryonic pregnancy.[21] These authors did not find differences in arterial intervillous flow between normal and abnormal pregnancies.[21,27]

Yolk sac circulation

Analyzing yolk sac hemodynamics, Kurjak and Kupesic reported that yolk sac blood flow was detected only in 19% of patients with missed abortion as compared with 67% in normal pregnancies.[27]

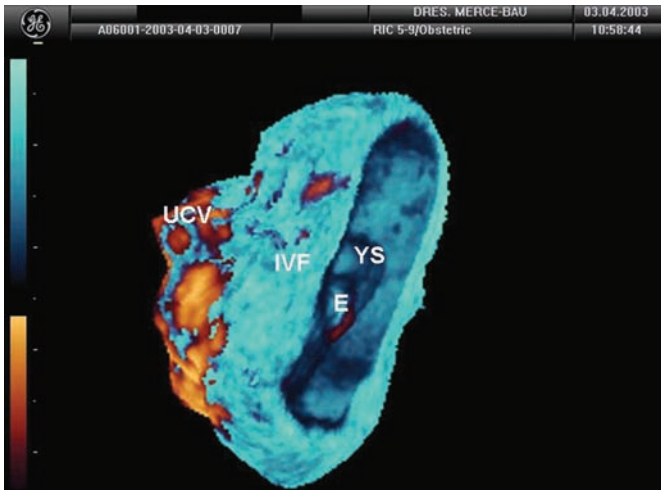

Figure 100.5 Rendering of uterochorionic vessels (UCV) and intervillous blood flow (IVF) by power Doppler three-dimensional angiography in a 7-week normal pregnancy. YS, yolk sac; E, embryo.

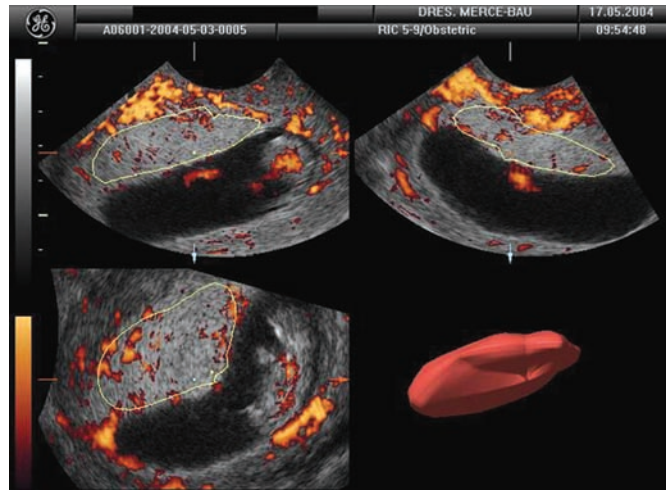

Figure 100.6 Intervillous blood flow assessment by VOCAL software during early pregnancy.

Threatened abortion

Those studies addressing hemodynamic changes in missed abortion or anembryonic pregnancy are interesting from a pathophysiologic point of view but may not be relevant to clinical practice because diagnosis can be made with B-mode ultrasound and assessment of the uteroplacental circulation does not add clinical or prognostic information. However, this situation is different in patients with threatened abortion, even more if a living embryo is identified.

Luteal circulation

Salim *et al.*, analyzing luteal blood flow found a significantly higher mean RI in threatened abortion.[4] However, we did not find any difference in luteal blood flow in threatened abortion as compared with normal developing pregnancies.[3] This difference regarding our results might be explained by the fact that all cases of threatened abortion in our study had an uneventful outcome, indicating that luteal function might be normal. Frates *et al.* reported similar findings to ours. They did not find any relationship between luteal blood flow and first-trimester pregnancy outcome.[6]

Uteroplacental circulation

Most studies assessing uteroplacental blood flow in threatened abortions conclude that Doppler assessment does not provide prognostic information because no significant differences between pregnancies with normal outcome and those that ended in abortion were found.[28–31]

Some authors have evaluated the predictive value for abnormal outcome of uteroplacental blood flow assessment in early pregnancy. Jaffe *et al.* found that an abnormally high RI (cutoff RI = 0.55) in the spiral arteries was associated with a higher probability of spontaneous abortion.[32] Leible *et al.* showed that a discordant uterine artery pulsatility index (PI) (> 1.1) would predict a subsequent miscarriage in otherwise normally developing pregnancies during the first trimester (odds ratio: 2.9, 95% CI: 1.5–5.8).[33]

On the other hand, uteroplacental blood flow assessment seems to be useless to predict pregnancy outcome in women with recurrent spontaneous abortion.[34]

Regarding intervillous flow, Mercé *et al.* observed an increase in venous velocity in 64% of spontaneous abortions before embryo death.[35]

We have evaluated the role of 3D power Doppler ultrasound in assessing intervillous flow in normal pregnancy (Figures 100.5–100.7). This technique has been shown to be reproducible,[2] overcoming one of the main problems of 2D color or power Doppler ultrasound and allowing an assessment of the entire chorion and early placenta. We found that flow index was significantly higher in pregnancies that ended in spontaneous abortion as compared with those that had normal outcome (Figure 100.8). No differences were found in vascularity and vascularity-flow indexes (Figures 100.9 and 100.10). This finding is very interesting because the flow index reflects flow velocity, thus confirming the previous finding by Mercé *et al.*[35]

Yolk sac circulation

Makikallio *et al.* have reported that yolk sac hemodynamics is not affected in cases of threatened abortion with or without retrochorionic hematoma.[36]

Embryo-fetal circulation

The assessment of embryo-fetal circulation in abnormal early pregnancy is unique to threatened abortion with a living embryo. Assessment of embryo-fetal circulation has been focused in three arterial vessels: umbilical artery, abdominal aorta and cerebral vessels.

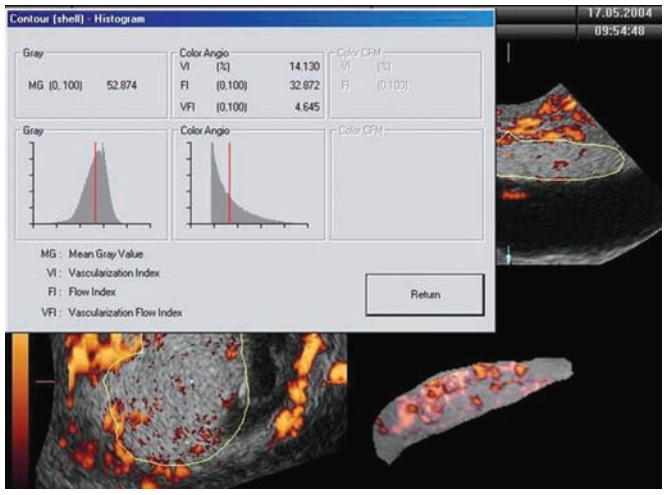

Figure 100.7 Vascularization index (VI), flow index (FI) and vascularization-flow index (VFI) are useful to evaluate intervillous blood flow during normal and abnormal early pregnancy.

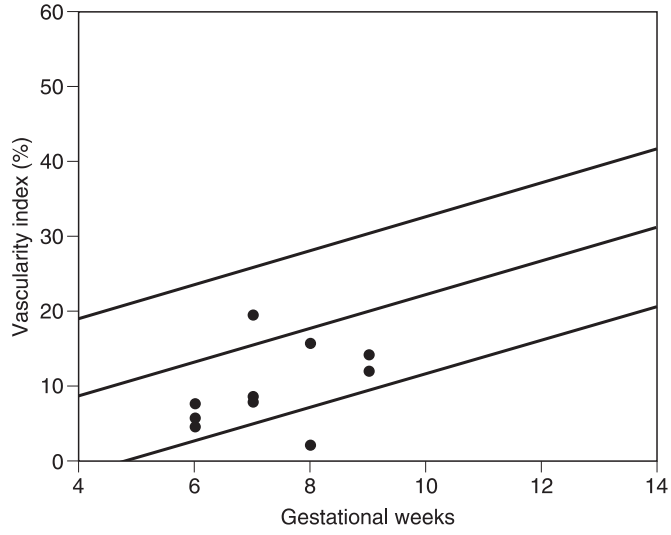

Figure 100.9 Vascularity index in cases of spontaneous abortion (closed circles). Regression line for normal pregnancies: $y=7.018+2.892$ (gestational age), $R^2=0.28$. It can be seen how most cases of spontaneous abortion are within the normal range.

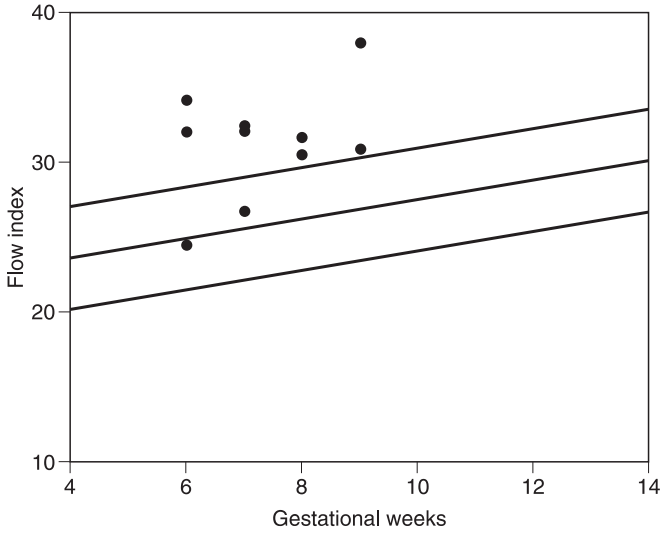

Figure 100.8 Flow index in cases of spontaneous abortion (closed circles). Regression line for normal pregnancies: $y=21.050+0.659$ (gestational age), $R^2=0.16$. It can be seen how most cases of spontaneous abortion are outside the normal range.

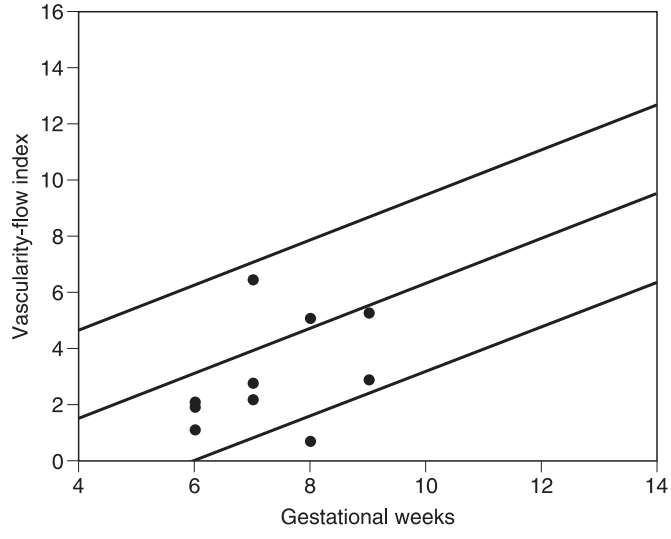

Figure 100.10 Vascularity low index in cases of spontaneous abortion (closed circles). Regression line for normal pregnancies: $y=2.383+0.859$ (gestational age), $R^2=0.29$. It can be seen how most cases of spontaneous abortion are within the normal range.

Some authors have evaluated the role of fetal hemodynamics assessment for predicting pregnancy outcome in cases of threatened abortion with retrochorionic hematoma. All studies concluded that fetal circulation assessment is not useful to predict pregnancy outcome.[29,37,38]

Complete and incomplete abortion

Differentiating between incomplete and complete spontaneous abortion is one of the most difficult tasks that a clinician has to deal with. Management may be quite different if the presence of retained tissue can be ruled out.

The use of transvaginal color Doppler ultrasonography for detecting retained products of conception after spontaneous first-trimester abortion has not been extensively evaluated to date. In our experience, this technique can be useful to detect retained trophoblastic tissue in patients with suspected incomplete abortion.[39] The presence of focal areas highly vascularized within the myometrium just beneath the endometrium or even within the endometrium (Figure 100.11) with flow velocity waveforms (FVWs) characterized by high peak systolic velocity and low impedance (Figure 100.12) was associated with the presence of retained tissue in the vast majority of the

Figure 100.11 Transvaginal color ultrasound after D&C and persistent spotting. This figure shows a focal area of vascularization at the level of fundus and posterior myometrium. Retained tissue was found after D&C.

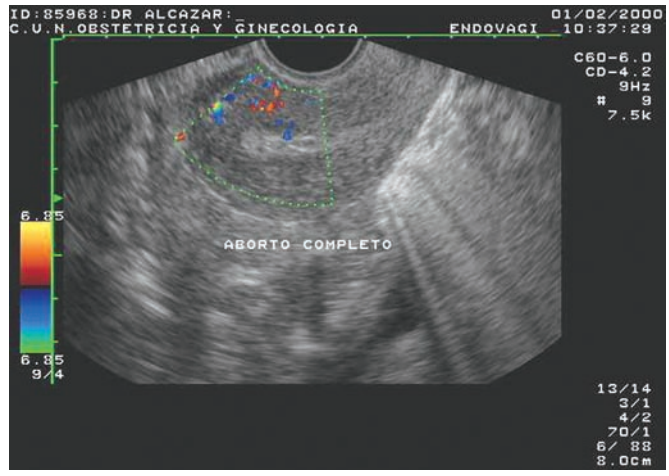

Figure 100.13 Transvaginal color Doppler ultrasound after heavy vaginal bleeding in first trimester. Scanty flow was found, suggestive of no retained tissue.

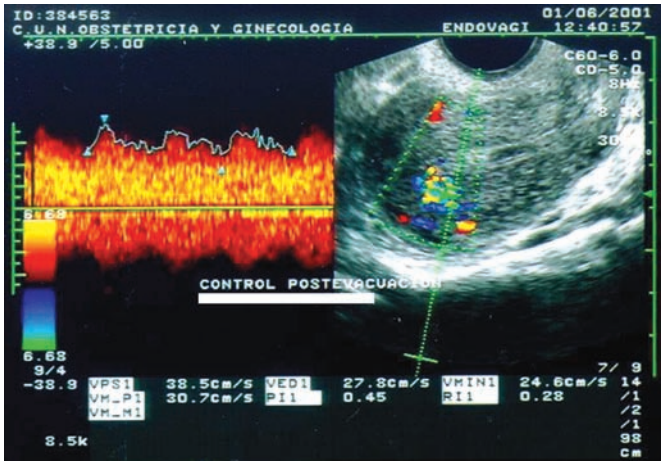

Figure 100.12 Same patient as in Figure 100.11. A low-resistance and high-velocity FVW, suggestive of trophoblastic flow is clearly found.

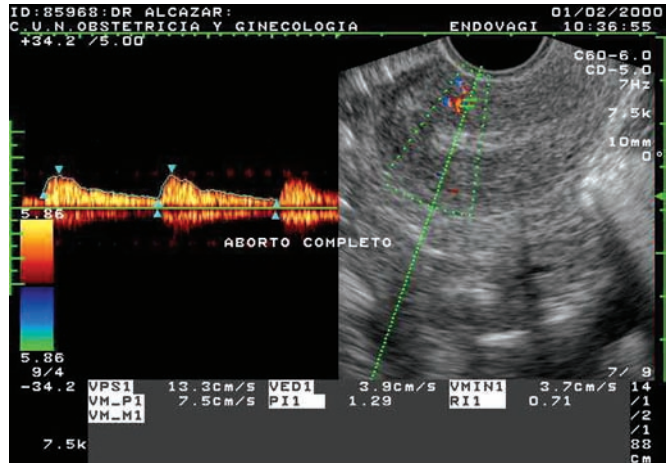

Figure 100.14 FVW from an arterial vessel in the case of Figure 100.13. High-velocity and high-resistance flow was found. Typical in absence of retained tissue.

cases. On the contrary, the absence of color signals or the presence of scanty color signals (Figure 100.13) with high-resistance blood flow (Figure 100.14) was associated with the absence of retained tissue. In our study, the sensitivity and specificity of color Doppler ultrasound in detecting retained tissue was 93.3% and 96%, respectively.

We have evaluated prospectively the role of transvaginal color Doppler ultrasonography in the management of first-trimester spontaneous abortion and we found this technique quite useful to rule out retained trophoblastic tissue.[40] Similar results have been reported by other authors.[41]

Conclusion

Transvaginal color and power Doppler allows the assessment of abnormal early pregnancy hemodynamics. The results of most published studies reveal that 2D Doppler assessment of luteal, uteroplacental and yolk sac circulations are conflicting or conclude that this assessment has a low clinical value, except for discriminating complete from incomplete abortion.

3D power Doppler ultrasonography provides promising results and opens a formidable new field of research.

101 Ultrasonography of ectopic pregnancy

S. Iniesta, F. Salazar and J. M. Bajo

Definition

The term *ectopic pregnancy* is applied to pregnancy following implantation of the fertilized ovum on any tissue other than the uterus endometrium.

The tubal presentation is the most common one, especially if it is in its distal third portion or the middle third one (both of them constitute nearly 95–97% of all ectopic pregnancies). Occasionally, it can appear in the interstitial portion (cornual pregnancy, 2–5%) and exceptionally in the ovary (0.5–1%), the cervix (0.1–0.15%) or the abdomen (1.4%).[1,2]

The common denominator in this group of patients is delay in the transport of the ovum fertilized in the ampulla of the tube to the normal implantation site in the uterus.

Incidence

The incidence of ectopic pregnancy has been increasing during the last few years.[3–5] Although it is difficult to estimate, it is nearly 0.94–2.6% of all pregnancies. This increased incidence is due to the use of reproduction treatments, the use of some contraceptive methods and pelvic inflammatory disease.

Day by day, with the development of vaginal ultrasound and the earlier detection of beta-subunit human chorionic gonadotropin (β-HCG) by radioimmunoassay, the diagnosis of ectopic pregnancies is improving, and it is possible to recognize an ectopic pregnancy in earlier stages (days or weeks earlier) than a few years ago, including some cases that had earlier occurred unnoticed.

Etiology

Although the etiology of ectopic pregnancy is still unknown, there are several risk factors that can be associated to ectopic pregnancy.[3,6]

- Previous pelvic inflammatory disease.[7] This is the most important cause of ectopic pregnancy and increases its incidence by 4. The presence of circulating *Chlamydia* antibodies alone increases its incidence by 2.[8]
- Previous tubal surgery (for infertility, because of previous ectopic pregnancies, bipolar tubal coagulation in the sterilization context, etc.) or any other kind of surgery in the inferior hemiabdomen that may cause tubal adhesions as well.
- Other organic tubal alterations: tubal tumors, endometriosis, peritubal adhesions, etc.
- Reproduction treatments (some factors have been associated, such as ovulation induction treatments, assisted hatching, etc.).[9]
- Contraception failures. Intrauterine devices do not increase the incidence of ectopic pregnancy by themselves, but once the pregnancy is established, the possibility of its becoming ectopic is much higher. The lowest ectopic pregnancy rates are observed with the high-copper-dose intrauterine devices, instead of the ones with low copper dose or the ones that release progesterone, which have the highest rates of ectopic pregnancy. Nevertheless, the levonorgestrel intrauterine devices result in a low rate, similar to those with high-dose copper loads.[10] Failures of tubal coagulation techniques also increase the risk of ectopic pregnancies because they may cause tubal fistulas.[11]
- Previous ectopic pregnancies.
- Tobacco.
- Infertility.

All these factors could be involved in the transportation of the fertilized ovum to the uterus, although there are also some embryonic factors that can be responsible for ectopic pregnancy and, more or less, a third of them involve chromosomal abnormalities.

Symptoms and signs

Physical findings are quite variable, and the clinical presentation has changed considerably over the past few years because of earlier diagnosis. Although the

incidence of ectopic pregnancy has increased, the frequency of its complications (such as ectopic pregnancy rupture, tubal abortion, etc.) is decreasing at a very significant rate because the greater exactitude of the diagnosis methods allows detection of ectopic pregnancy in asymptomatic women and in precocious phases of the process.[12,13]

This has also allowed development of different protocols for non-surgical treatment of ectopic pregnancy, as well as less invasive surgical procedures.

Clinical situations of ectopic pregnancy

- Asymptomatic women.
- Vague abdominal pain, without any specific findings, in unruptured cases. Sometimes we can find vaginal bleeding, usually in scanty amounts. The classic clinical triad of ectopic pregnancy is *pain, vaginal bleeding* and *amenorrhea*, although the amenorrhea is sometimes difficult to assess because of the vaginal bleeding.
- Acute hemorrhagical accident, generally caused by tubal rupture or by tubal abortion with peritoneal hemorrhage. In this case, patients will present all the symptoms and signs of acute abdominal (positive Blumberg, peritoneal defense) and hypovolemic signs (extreme pallor of the skin and mucous membranes, tachycardia, hypotension, etc.).

The first symptom noticed by patients is likely to be a 1 or 2 weeks' delay in menstruation, followed by slight bleeding, which persists, with perhaps only a scant show of blood, almost every day. Although this spotting type of bleeding is rather characteristic, not infrequently the bleeding may be somewhat freer, but it is rarely so profuse as in an incomplete abortion. Instead of the menstrual period being delayed, there may be an apparent anticipation of the flow by a few days.

Pain is an early symptom, although it is sometimes very slight. In the beginning there may be only a vague tenderness in the affected side of the pelvis, but often the patient complains of sharp colicky pain occurring from time to time. When rupture or tubal abortion takes place, the pain may be very severe, and it may be associated with faintness or actual syncope and often nausea and vomiting. These symptoms are the result of the peritoneal reaction produced by the escape of blood from the tube.

Diagnosis

The clinical image of ectopic pregnancy is so typical in many cases that diagnosis is very easy, but often errors occur, so we always have to keep in mind the possibility of ectopic pregnancy if we do not want to make a wrong diagnosis.[14,15]

The diagnosis is actually based on:

- Anamnesis, insisting on the classic clinical triad and on the investigation of ectopic pregnancy risk factors.
- Abdominal and pelvic examination.
- Pregnancy test.
- Ultrasonography.

Some recent studies[16] describe novel placental and nonplacental serum markers in ectopic pregnancies, such as PAPP-A, SP-1 and human placental lactogen (HPL), but these factors have to be further studied.

If we have a positive pregnancy test and any gestational vesicle within the uterine cavity is observed by transvaginal ultrasonography, it is necessary to determine the β-hCG levels in maternal serum.

The hCG is a glucoprotein composed of two subunits, alpha and beta, joined by non-covalent unions by disulfide bonds. The alpha subunit is composed of 92 amino acids and the beta subunit, 145. The latter is responsible for the biological activity and it is the one that allows the production of some highly specific antibodies very important for radioimmunoassay detection.

The hCG is produced in the syncytiotrophoblast and its detection in maternal serum is possible 1 day after the blastocyst implantation.

In a normal gestation (non-ectopic one), the circulating β-hCG level at the time of the first delay of menstruation is, approximately, 100 UI/l, and it reaches its maximum (50,000–100,000 UI/l) between the 8th and 10th gestational weeks. Later, it decreases to around 10,000–20,000 UI/l at 18–20 weeks and remains more or less constant until the end of pregnancy.[17]

On the other hand, the β-hCG levels in an ectopic pregnancy can be very variable; cases of ectopic pregnancies with β-hCG levels as low as 14 UI/l have been documented, as well as others with 100,000 UI/l. Thus, a single determination of β-hCG level is often of little use for the diagnosis of ectopic pregnancy. Nevertheless, consecutive determinations of β-hCG levels allow differentiation between a normal gestation and an ectopic one, since the increase of the β-hCG levels is different in both.

In an intrauterine pregnancy of normal course, the serum β-hCG concentration follows a linear pattern in the first 6 weeks and it is duplicated in 2 days when its level is lower than 10,000 UI/l.

The trophoblast tissue in an ectopic pregnancy usually produces less hCG than in an intrauterine pregnancy and, therefore, its increase in the same period of time is usually smaller.

Nevertheless, some cases of ectopic pregnancy with the same increased levels of β-hCG as in intrauterine pregnancy have been described (nearly 13%), at least for a period of time. In addition, 10% of the

Figure 101.1 Decidual reaction of the endometrium. Positive β-hCG. Ectopic pregnancy with a tubal gestational sac.

Figure 101.2 Pseudosac image inside the endometrium.

normal intrauterine pregnancies can present alterations in the increase of the β-hCG.

Some studies, during the past few years, have tried to predict the tubal rupture, the possibility of resolution or the possibility of hemorrhage by using β-hCG levels or other factors.[18,19] Although some authors have found good results by using β-hCG levels to predict tubal rupture,[20] considering that its occurrence is not probable with values lower than 2000 UI/l, with a predictive value of 80%, other authors have observed this complication with levels as low as 100 UI/l and even lower.[21–24] Therefore, occurrence of hemorrhage is not probable, although it is not impossible, with low levels of β-hCG, and its decreasing levels do not guarantee that rupture cannot take place. However, most of the authors find a statistically significant difference in the values of β-hCG between ruptured and non-ruptured ectopic pregnancies.

The decreasing levels of β-hCG combined with ultrasonography findings allow us to avoid surgical treatment in non-ruptured cases, although a very careful follow-up is needed because, as we have just discussed, the possibility of rupture exists even with decreasing levels of β-hCG. This situation can occur if the trophoblast is separated from the tubal wall, which may cause intratubal bleeding with accumulation of intratubal clots, which increase the pressure, and may cause distension and necrosis.

With transvaginal ultrasound an intrauterine gestational sac can be identified with 1000 UI/l of β-hCG ('discriminatory level'),[25] which is usually observed after 1 week of delay of menstruation. In a twin gestation this discriminatory level can be slightly higher and an ultrasonography control must be carried out within 2 or 3 days to try to find the gestational vesicle.

Once we have determined the β-hCG levels, if we do not find any gestational vesicle, we must consider two situations: the first takes place when we find a β-hCG level below 1000 UI/l, and the second when it is higher than 1000 UI/l.

β-hCG < 1000 UI/l without intrauterine gestational sac

In asymptomatic patients or with those with slight symptoms, the ultrasonography, as well as determination of β-hCG level, must be repeated in 1 week. At this time, it will be possible to find a β-hCG level higher than 1000 UI/l and also to observe an intrauterine gestational sac.[26]

Nevertheless, it is necessary to keep in mind that ectopic pregnancies produce in the endometrium some changes very similar to those induced by normal intrauterine pregnancies:[27]

- In 50% of ectopic pregnancies it is possible to observe a deciduate endometrium that appears ultrasonographically as a thickened and hyperrefringent endometrium (Figure 101.1).
- In 10–20% of ectopic pregnancies it is possible to observe a gestational pseudosac[28] (Figure 101.2), which appears as an echogenic image, located centrally in the endometrium and surrounded by a single echogenic ring. This image really corresponds to the presence of liquid in the deciduate endometrium. In a real gestational sac, a double echogenic ring is seen, composed of the vera decidua and the capsularis decidua, which form two concentric rings around the gestational sac (*double decidua sign*). This sign can be observed between the fifth and ninth gestational weeks and its presence makes the differential diagnosis easier.

Figure 101.3 Ectopic pregnancy with ultrasound findings type 1. Outside the uterus and inside the tube an anechoic formation is visible, corresponding to the gestational vesicle.

Figure 101.4 Ectopic pregnancy with ultrasound findings type 1. The corpus luteum closse to the gestational vesicle and the tube wall are visible.

- The color Doppler can also contribute to the diagnosis. An intrauterine gestational sac shows peritrophoblast vascular signals with a low resistance index (0.40–0.45). The pseudosac does not present an increase of the local flow and its resistance index may be higher (> 0.55).[29–32]

Another common problem when making the diagnosis is to differentiate the ectopic pregnancy from a complete or incomplete abortion. In the latter, ultrasonography shows a hyperechogenic image inside the uterine cavity that corresponds to clots or retained abortion rests. These findings can delay diagnosis in nearly 21% of the patients.

Also, the possibility of differentiating an ectopic pregnancy from a spontaneous abortion according to the reduction pattern of β-hCG levels in a period of time more than 48 h has been investigated. Some authors diagnose a complete abortion when the average life of the β-hCG is less than 1.4 days, whereas if it is more than 7 days, the ectopic pregnancy diagnosis is much more probable. Similarly, a plateau level of β-hCG (which has been defined as a duplication of its levels equal or higher in 7 days) is very suggestive of ectopic pregnancy.

The simultaneous presence of an intrauterine pregnancy and an ectopic one (heterotropic gestation) is not frequent at all, although its incidence is higher in pregnancies induced by reproductive techniques. It occurs in nearly 1 out of 100 of these pregnancies, which suggests a much higher frequency than the one referred historically (1 out of 30,000).[33,34]

β-hCG >1000 UI/l without intrauterine gestational sac

In this situation a high suspicion of ectopic pregnancy exists, and the gestational sac must be looked for outside the uterus, considering that the most common location is the tube. Ultrasound findings can be categorized, depending on the visible structures, into five types:

(1) *Ultrasound image type 1*: A vesicle within the tube is visualized. The yolk sac and the embryo are not visible. The size of the gestational sac is over 3 mm (ultrasound resolution limit). It appears as a clear formation, in the parauterine region, with a central echogenic area surrounded by a hyperechogenic ring (Figures 101.3 and 101.4) that corresponds to the trophoblastic tissue, which presents an abundantly colored map because of its significant retrochorionic vascularization proliferation (Figure 101.5). The Doppler signals show a low or medium resistance index, which is very different from that found in normal tube walls, which show a high resistance. It is usual to find an average decrease of 15.5% in the ectopic pregnancy side with respect to the contralateral one. This ultrasound image is not easy to find and sometimes the gestational vesicle has less relevance than the corpus luteum that appears close to it, which we have to differentiate.

(2) *Ultrasound image type 2*: It is possible to obtain the same findings as in the previous type, but inside the gestational vesicle, the yolk sac can be visualized (Figure 101.6). The finding of the yolk sac is not a trivial matter because it makes the diagnosis easier, making possible to characterize the gestational vesicle, which is very difficult to see, especially when it is small. The presence of the yolk sac alone clarifies everything, and there is now no doubt about the presence of an ectopic pregnancy. The fact that the embryo cannot be seen does not mean that it does not exist, because we know that it is the embryo that induces the formation of the yolk sac. In the yolk sac

Figure 101.5 Ectopic pregnancy with ultrasound findings type 1. There is a significant vascularization around the gestational coat that corresponds to the trophoblast.

Figure 101.7 Ectopic pregnancy with ultrasound findings type 2. It's possible to see the yolk sac. The trophoblastic vascularization is also visible.

Figure 101.6 Ectopic pregnancy with ultrasound findings type 2. The gestational sac has the yolk sac inside.

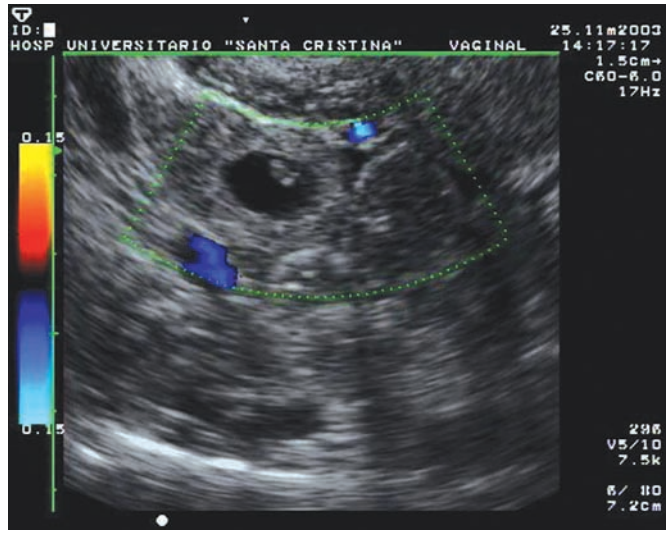

Figure 101.8 Ectopic pregnancy with ultrasound findings type 3. Gestational sac with the yolk sac and an embryo of very small size inside, in which the heartbeat is still not seen.

surroundings it is possible to observe blood flows with abundant Doppler signal and low resistance index as well as in the type 1 image (Figure 101.7).

(3) *Ultrasound image type 3*: It is possible to visualize the gestational vesicle, the yolk sac and also the embryo, but not its heart beating (Figures 101.8 and 101.9). The size of the embryo usually is not very big (Figure 101.10). It seems like it is going to start a reabsorption process and soon it disappears or is confused with the gestational sac.

(4) *Ultrasound image type 4*: The typical image of a gestational vesicle with the yolk sac and the embryo is visualized, but this time with visible cardiac beat inside the embryo. It is very easy to see the beat by using the color map or the flow wave (Figures 101.11 and 101.12). When this image appears, the diagnosis of ectopic pregnancy is made. With an abdominal probe it is possible to visualize this image in only 10% of the cases, but with the transvaginal one, in 21% of all the ectopic pregnancies.

(5) *Ultrasound image type 5*: This image corresponds with tubal rupture or with tubal abortion. In these cases the acute accident is present and the symptoms and signs are usually important. The most important sign is the hemoperitoneum (Figure 101.13), and the patient may present

Figure 101.9 Ectopic pregnancy with ultrasound findings type 3. Inside the gestational sac, the yolk sac and also an embyo with no visible heart activity are seen.

Figure 101.11 Ectopic pregnancy with ultrasound findings type 4. Inside the gestational sac the yolk sac and a live embryo are visible. The heart activity is shown by using the color signal.

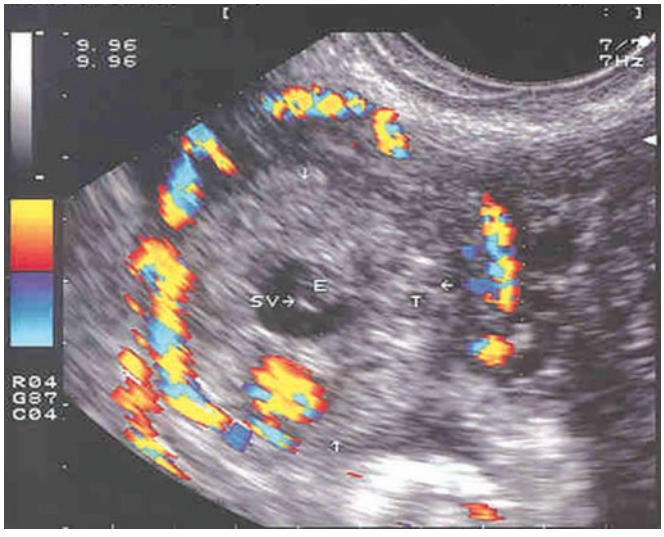

Figure 101.10 Ectopic pregnancy with ultrasound findings type 3. The yolk sac is visible inside the gestational sac and also an embryo with no visible heart activity. The Doppler signal is captured only on the peritubal trophoblast.

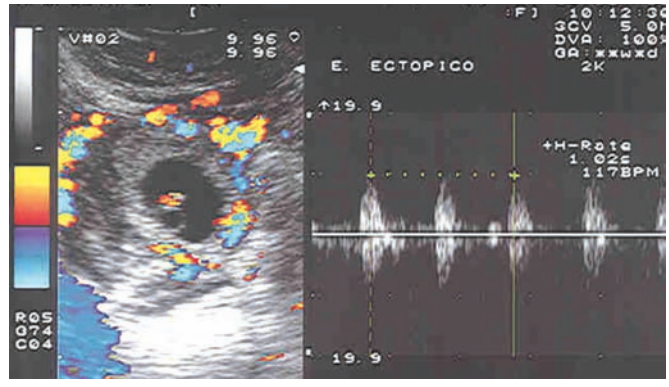

Figure 101.12 Ectopic pregnancy with ultrasound findings type 4. Inside the gestational sac the yolk sac is visible, and also an embryo with its heart beating.

hypotension and anemia. A large amount of fluid may be visible in the abdomen, in the flanks and in the cul-de-sac if a tubal rupture is present. These fluid collections may be presented as free fluid or as organized blood clots in the cul-de-sac lateral and cranial to the uterus. The clots exhibit the sonographic features of solid masses, appearing homogenous and contrasting poorly with the surrounding tissues. The tube appears refringent ultrasonographically, thickened or included in a mass of blood clots. In some cases the tube appears normal, and the blood located around it draws it, showing its shape and the fimbrias.

The mere presence of fluid in the cul-de-sac is not a specific sign of ectopic pregnancy.[35] It is present in nearly 40–83% of all ectopic pregnancies but small collections of free fluid may be seen under normal conditions in non-gravid patients, especially during the periovulatory period, and also in 20% of intrauterine pregnancies and in some other pathologies.

The total absence of ultrasonographic findings in the adnexal area does not exclude the ectopic pregnancy diagnosis. In these cases it is necessary to determine the β-hCG level again, to establish its decreasing or increasing pattern, and to repeat the ultrasonography to look for the gestational vesicle in

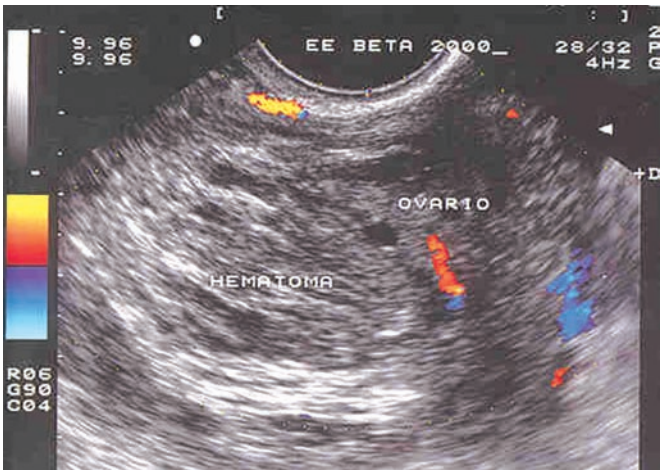

Figure 101.13 Rupture of an ectopic pregnancy (ultrasound findings type 5). An important hemoperitoneum is visible, with clots.

any location. If the patient is stable, we should not undertake laparoscopy so early, since the initial phases of ectopic pregnancy have been described with absolutely normal laparoscopy.

Generally, in all previous assumptions, the existence of a corpus luteum can be observed. It is visualized as a round hypoechogenic structure, surrounded by a ring of ovarian tissue. It can appear in the contralateral ovary in 13–23% of the cases. The transvaginal ultrasound sensitivity for the ectopic pregnancy diagnosis is very high, nearly 99%, with 98% of specificity, 98% of positive predictive value and 99% of negative predictive value.

Ultrasonography aid to conservative treatment

Ultrasound is useful as a diagnostic tool in the observation of a gestational sac inside or outside the uterus.

At present, the precocious diagnosis of ectopic pregnancy allows treatment possibilities other than surgical boarding, which was the only option considered traditionally.[36–38] These treatment possibilities are:

- expectant handling
- systemic methotrexate administration
- local methotrexate administration.

The surgical handling can be performed by laparoscopy or by laparotomy.

Expectant handling

With a precocious diagnosis of the ectopic pregnancy, before symptoms appear, and adopting a more conservative attitude, it has been possible to see that the spontaneous regression of the tubal ectopic pregnancy is a phenomenon much more common that we thought previously. This fact means that there is a high percentage of ectopic pregnancies that are resolved with no need of treatment, and that is why expectant handling has a place in the management of ectopic pregnancy.[39,40]

The main advantages of expectant handling are that it avoids the risks of surgery, general anesthesia and the potential indirect effects of the drugs used in the treatment of ectopic pregnancy.

The great difficulty in expectant handling is to select suitable patients for it. The selection criteria used differ for different authors, but in most cases there are some common aspects; the most outstanding ones are:

- Asymptomatic patient, clinically stable.
- Size: maximum diameter of the ectopic pregnancy of 2–4 cm, according to the authors.
- Absence of embryonic cardiac beat (ultrasonography finding types 1, 2 or 3).
- Decreasing values of β-hCG levels (also variable according to the authors, but at least a decrease of 2% in two determinations with a delay of at least 24 h).
- Little amount of free fluid in cul-de-sac.

Patients will have to be under periodic ambulatory control with multiple determinations of β-hCG levels and with an ultrasound following, three times a week in the beginning, and later once a week, according to the different protocols.[41] The signs that orient to a reabsorption and therefore to a spontaneous resolution of the problem are:

- β-hCG decreasing levels: it is important to be aware that sometimes it takes 70 days for the β-hCG value to become negative because of the trophoblast persistence. Serially monitored β-hCG results after conservative treatment of ectopic pregnancy may show plateaued values without indicating failure of treatment.[42]
- The gestational vesicle, the yolk sac and all the embryonic structures are wrapped into a reabsorption process, becoming increasingly small (Figure 101.14), refringent (Figure 101.15) and finally disappearing, replaced by a solid complex image (Figure 101.16).
- The color map inside the trophoblast is smaller each time (Figure 101.17), with a slight Doppler signal, which is sometimes very difficult to find.
- The resistance and pulsatility indexes inside the trophoblastic vessels are increased and, in the end, it is impossible to identify anything objectively.

The percentage of success of the expectant handling varies between 57% and 100%, although in the studies with more cases it is estimated around 70%. The best results are observed when the β-hCG levels are below 2000 UI/l.

Figure 101.14 Ectopic pregnancy with spontaneous reabsorption. A yolk sac less visible and a refringent ring around it are visible.

Figure 101.15 Ectopic pregnancy with spontaneous reabsorption. The yolk sac has nearly disappeared.

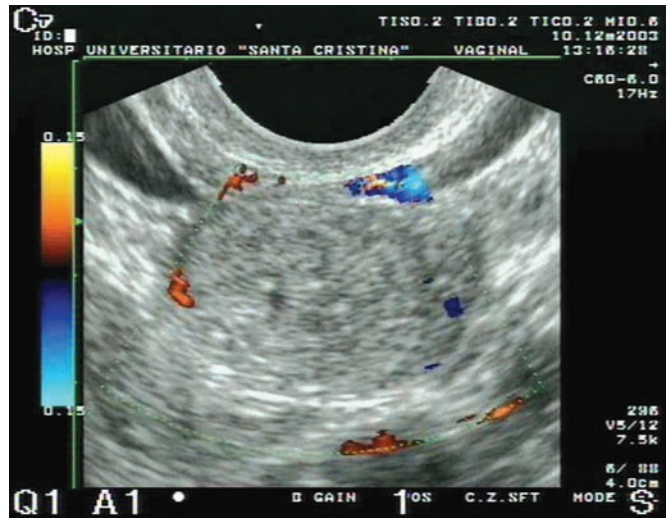

Figure 101.16 Ectopic pregnancy with spontaneous reabsorption.The yolk sac has disappeared and has been replaced by a refringent area that shows the tube more compact.

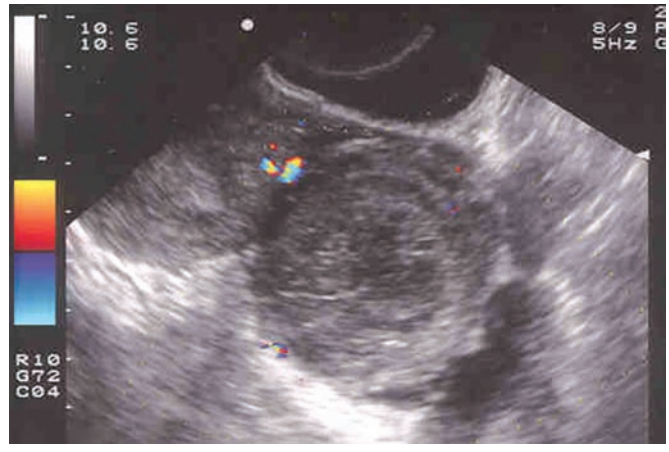

Figure 101.17 Ectopic pregnancy with spontaneous reabsorption. Color map progressively fades away.

The following are the most important indications for surgery in the cases in which expectant handling fails: abdominal pain, β-hCG levels increased or similar to the previous ones, appearance or increase of the liquid in the Douglas sac and increase of the size of the adnexal formation.

Among the disadvantages of expectant handing, it is necessary to mention, on the one hand, the prolonged period of follow-up that patients have to be put under, and on the other, the possibility of persistence of trophoblast tissue inside the tube, which could cause adhesions and great tubal damage. Nevertheless, when comparing the reproductive results of patients under expectant handling with those of patients under conservative surgery, there are no differences between the two groups in subsequent gestations, either intrauterine or ectopic rates.

Finally, it is very important to point out that this kind of treatment can be applied only if ultrasounds are used to make the diagnosis.[43]

Systemic methotrexate administration

The most common drug used in the treatment of ectopic pregnancy is methotrexate, which interferes in trophoblastic development.

Methotrexate inhibits the reduction of folic acid to tetrahydrofolic acid. Because tetrahydrofolic acid is essential in the transfer of one-carbon fragments in the synthesis of DNA, methotrexate effectively blocks DNA synthesis, inhibiting cell replication.

In the 1960s, methotrexate was used for the treatment of persistent trophoblastic tissues after an abdominal pregnancy. In 1982 it was used, for the first time, in the treatment of ectopic pregnancy.

As with expectant handling, administration of methotrexate depends on the patient's profile. The selection criteria are different for several authors, but most of them agree in using methotrexate in hemodynamic stable patients, with a non-ruptured ectopic pregnancy, with a small amount of liquid in the Douglas sac and with less than 4-cm diameter of tubal affection, with ultrasonography finding types 1, 2 or 3.

The presence of embryonic heart movements is for some authors an absolute contraindication for this kind of treatment, because results in these cases are worse and it would be better to recommend surgical treatment.

Before methotrexate administration, a complete hemogram (including platelet count) and some biochemical values to ensure that hepatic and renal functions are normal are needed.

The doses of methotrexate that have been used in different studies are quite variable. The most usual dose is 1 mg/kg, intramuscularly, every 48 h, until a total of four doses are completed or until a reduction of β-hCG levels in two consecutive days is observed. Methotrexate is usually combined with folinic acid (0.1 mg/kg) on alternate days.

At present, a single dose of 50 mg/m^2 of methotrexate is being used, and has proved to be as effective as the multiple-dose therapy. This model does not need the combination with folinic acid, and it has fewer secondary effects.

The β-hCG levels can increase during the first 3 days after the treatment, but they must be lower on the seventh day. If this reduction is smaller than 15%, it is necessary to repeat the methotrexate administration (which is necessary in nearly 8% of the cases).

Oral administration has also been used, but its results are not as good as with intramuscular administration.

Toxicity to methotrexate frequently involves the mucous membranes, with stomatitis, esophagitis, vaginitis and, occasionally, gastrointestinal ulcerations, but these are not very common, and are dose-dependent. Bone narrow suppression with granulocytopenia and thrombocytopenia is common, but generally not severe. Skin rashes and alopecia are uncommon, but they do occur; nephrotoxicity, hepatotoxicity and pulmonary fibrosis are very rare.

After 3 or 4 days of methotrexate administration, the presence of abdominal pain of variable intensity is common, described in 60% of the patients. It is usually a side effect that disappears spontaneously in 1 or 2 days, although sometimes a visit to the hospital is needed to rule out hemodynamic instability and possible rupture.

The success rate is 83–100% according to different studies.

Periodical ultrasonography and control of β-hCG levels are needed after the conservative treatment. The ultrasonographic image of the ectopic pregnancy can continue to be observed when the β-hCG values are negative. The persistence of this negative value does not have to be interpreted as a failure of treatment, and it can even take months to disappear.[44]

Asymptomatic tube ectopic pregnancy with live embryo

If the gestational sac is visualized inside the tube and we can see an embryo with positive heart movements, there are two treatment options: laparoscopic extirpation and transvaginal punction with methotrexate injection inside the gestational sac, which is used only in selected cases.[45]

One of the most important indications for local methotrexate administration is the presence of embryo heart activity. In these cases, with the local punction, we have the methotrexate local action and the blast effect of the needle. With this direct administration it is possible to reduce the dose of the drug, diminishing therefore its side effects.

The gestational sac punction has to be guided by transvaginal ultrasonography or carried out by laparoscopy. After the punction, the first thing that we have to do is to aspirate the sac content and after that to inject the methotrexate. The methotrexate dose used is variable in different studies, but it is around 10–50 mg.

After the punction, a very refringent image is visible (Figures 101.18–101.19), which changes very slowly in some cases, as described before, during reabsorption.

The success rate is nearly 85–100%, according to different authors.

Some other substances have been used for local administration instead of methotrexate (such as prostaglandins, potassium chloride, hyperosmotic glucose, etc.) for the treatment of ectopic pregnancy, but their use has now been discontinued because of their considerable secondary effects and their minimal action.

The local or systemic administration of methotrexate is also indicated in cornual or cervical ectopic pregnancies, to avoid surgical treatment, in an attempt to preserve fertility.

If the tube has not been blown apart by rupture, it can be preserved by making a longitudinal incision along the antimesenteric border of the tube and suturing the incision with fine material.

Treatment of acute rupture of tubal ectopic pregnancy

If the intraperitoneal bleeding is very profuse, symptoms of shock occur and it is obvious that surgical attention is required.

The treatment in this case consists of evacuating the hemoperitoneum and excising the ectopic pregnancy

Figure 101.18 Ectopic pregnancy treated successfully with methotrexate. The reabsorption process of the tubal formation is visible.

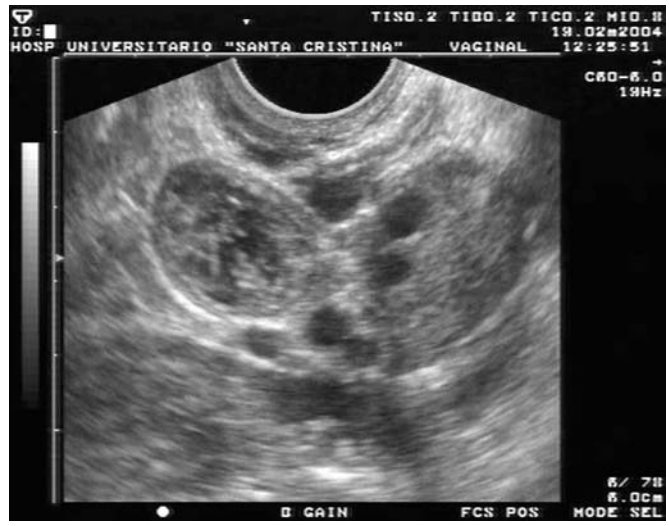

Figure 101.19 Ectopic pregnancy after intrasac methotrexate injection. Both the gestational vesicle and the embryo have been transformed into a refringent structure that will initiate the same process of reabsorption that happens when it does it spontaneously.

by laparoscopy or laparotomy, once the patient is in a stable state.

Treatment of abdominal ectopic pregnancy

The treatment in these cases consists of evacuating the fetus outside the abdominal cavity with ligation of the umbilical cord. It is not necessary to remove the placenta, which may be firmly fixed to the mesentery and the abdominal viscera. Profuse hemorrhage can occur on manipulation, and the placenta, if left *in situ*, resorbs without sequelae in most instances.

In these cases, it is also possible to use the methotrexate intramuscularly and to perform ultrasonography and control of β-hCG levels after it. Some authors have suggested the use of methotrexate to facilitate devascularization and absorption of any unremoved placenta.

Ultrasonography makes it possible to monitor the placenta left *in situ* after removing the fetus,[46] whose image can be seen inside the abdomen for a long time.

SECTION XII

Prenatal diagnosis and therapy

Section Editors: **K. Nicolaides and A. Antsaklis**

102 Chorionic villus sampling

B. Brambati and L. Tului

Introduction

Chorionic villus sampling (CVS) has gained a growing popularity since its inception as a means of rapid prenatal diagnosis in early pregnancy.[1,2] The International CVS Registry provides statistics for the first 13 years of use.[3–6] The first clinical experiences were published between 1982 and 1983, and in 1 year less than 200 cases were reported by six groups from five countries, whereas in September 1996 more than 200,000 cases were registered, and more than 180 centers from the six continents were on the CVS Registry mailing list.

The ability to achieve first-trimester fetal diagnoses reduces emotional and physical stress in couples at risk, maximizes patient privacy, and permits access to termination at an earlier stage of pregnancy. Prenatal diagnosis by CVS in the first trimester, when physical awareness of the conceptus may still not be present and pregnancy is not physically apparent, is expected to have less profound psychological and behavioral effects on the mother. Reports comparing the emotional distress experienced by women undergoing amniocentesis and CVS, respectively, have shown that the latter approach evokes less anxiety, which lasts a shorter period of time, than amniocentesis.[7] Moreover, women undergoing CVS report significantly greater attachment to the fetus than women undergoing amniocentesis.[8] Although the miscarriage rate was shown to be a determinant factor of the patient's attitude toward prenatal procedures, the great benefit of an early diagnosis prepared patients to accept the higher risk of CVS, which is up to five times that of amniocentesis.[9–11]

Several clinical trials have provided information about the comparative risks of first-trimester CVS and mid-trimester amniocentesis. In national collaborative studies, the likelihood of successful pregnancy outcome has been reported to be similar for both sampling approaches.[12–15,21] However, in the early 1990s concern arose from the publication of small early first-trimester sampling series describing clusters of limb defect cases after CVS.[16–18] Although these cases could indicate a relationship between early CVS and placental damage, no evidence of teratogenic effects has been observed by the analysis of more than 200,000 CVS cases reported to the CVS International Registry.[19] There is a general agreement that no procedure-induced limb defects are expected to follow CVS when sampling is performed after 10 completed weeks of gestation by skilled and experienced operators.

Requirements for a chorionic villus sampling program

The most important requirement for a successful CVS program is technically competent staff. CVS should be performed by an obstetrician experienced in first-trimester ultrasonography, who is an expert in the pathophysiology and clinical aspects of early pregnancy, and who is well-informed about human genetics and the laboratory methods used for genetic analysis. CVS and other sampling techniques should be performed only at centers having a high level of expertise and experience, capable of applying any sampling approach as appropriate and of following the cases to delivery.[19] Training can be performed in both experimental and diagnostic cases under direct supervision of a senior expert operator. A WHO meeting set out the following criteria for self-evaluation of the expertise of centers[19]:

(1) A sampling success rate of about 90% at the first insertion (of sampling device) and up to 98% after two insertions;
(2) Laboratory success in more than 95% of all patients sampled;
(3) Capability to utilize both transcervical and transabdominal routes for CVS;
(4) A total fetal loss rate to 28 weeks of chromosomally normal pregnancies of less than 6%. Centers with a low-risk patient population (young, economically advantaged, non-smoking, sampled close to 12 weeks) should expect to do better than this; and
(5) Data collection and surveillance programs that include follow-up to delivery and infant outcome for more than 95% of all cases.

It is to be expected that these levels would ordinarily be achieved by groups with experience of 200–250

procedures. However, expertise cannot be maintained with occasional sampling; the more cases sampled per year the better the results are likely to be.

Transabdominal continuous guidance of the sampling device by a high-quality ultrasound machine is mandatory. In principle, sector and convex probes are preferred: their small contact surface allows an optimal fitting to the maternal abdomen with a comprehensive visualization of the uterus frequently still situated near or below the pubis.

CVS is performed in an outpatient facility. No medical preparation is needed before transabdominal sampling, whereas treatment of vaginal infection might be necessary before transcervical sampling. A full bladder is not required, but some degree of filling may be required in some circumstances, for instance to straighten the angle of a pronounced anteflexion of the uterus for easier transcervical sampling, or to push intestinal loops away from the anterior uterine wall for safer transabdominal sampling in a retroverted uterus. Postoperative care includes some rest only when cramping or bleeding would otherwise appear; in cases of spotting and bleeding complications, vaginal exploration should be avoided and daily vaginal douches are recommended for cleaning the vagina and thereby avoiding bacterial proliferation as much as possible.

Sampling methods

The placenta can be reached either through the maternal abdomen by needling,[22,23] or via the cervical canal by catheter or biopsy forceps.[24–26] A transvaginal chorionic needle aspiration guided by vaginal ultrasound probe has also been developed, but it is indicated only in patients where sampling by the other conventional methods appears to be hazardous.[27]

Transcervical sampling is most frequently performed using a polyethylene cannula 26 cm long and 1.5 mm in outer diameter, with a soft stainless-steel blunt obturator.[24] Recently, CVS experiences have also been reported using round-tip curved steel forceps 1.9 mm in diameter and 25 cm in length, and flexible biopsy forceps 3 mm in outer diameter and 25 cm long.[25,28] With the patient in the lithotomy position, and after antiseptic preparation of the external genitalia, the cervix is visualized and cleaned with a broad-spectrum antiseptic solution. The cervix may be grasped with a tenaculum to straighten the cervical canal, although this usually produces discomfort and may sometimes be very painful.

Two methodological approaches for transabdominal sampling have been described.[22,23] A double coaxial needle system can be inserted percutaneously through a needle guide attached to the ultrasound probe.[23] An 18-gauge, 15-cm guide needle is first introduced and then stopped at the edge of the placenta. Thereafter, a thinner 22- or 20-gauge, 20-cm needle is passed through the outer needle and repeatedly inserted until an adequate sample is obtained. As an alternative a single 20-gauge, 9- or 12-cm spinal needle can be used and inserted by a freehand ultrasound-guided approach (Figure 102.1). In the latter case, the aspirating syringe can be mounted onto a holder to make the aspiration easier. The freehand needle-insertion technique has some advantages when compared with the two-needle system. The needle is thinner and its direction can be easily adjusted when necessitated by abdominal wall or uterine displacements. Moreover, as the needle is not in direct contact with the transducer, neither a sterile ultrasound system nor sterile contact gel are needed. In addition, the sampling procedure takes less time, and the sampling device is cheaper. However, the freehand technique is a two-person approach and demands good co-operation between the sonographer and the operator.

Contraindications

Because of the specificity of the sampling route, transabdominal and transcervical sampling techniques are expected to have different types of contraindications. Vaginismus and stenotic or tortuous cervical canal, as well as myomas of the lower uterine segment, may severely hamper the introduction of either catheter or forceps. Active vaginal infection may also be an absolute contraindication to the cervical route. In the latter condition, vaginal and cervical culture and specific treatment do not seem sufficient to remove any risk of ascending infection. Transabdominal sampling may be relatively or absolutely contraindicated when obstacles such as intestines, large myomas or the gestational sac cannot be avoided.

Some conditions may be considered common contraindications for both transabdominal and transcervical sampling, namely active vaginal bleeding and an Rh-isoimmunized patient. If bleeding is present at the time of scheduled sampling, although no specific data are available, it is advisable to postpone any sampling procedure until bleeding has stopped. Feto-maternal transfusion, frequently observed following chorionic villus biopsy,[29–33] might enhance the antibody response of isoimmunized mothers and threaten fetal outcome. The patient should be informed about this potential adverse effect of CVS, and amniocentesis or cordocentesis should be evaluated as potential alternative approaches.

Indications

At the individual level, the advantages of first-trimester CVS are evident when compared with mid-trimester amniocentesis (Table 102.1). Shorter pre- and post-test waiting periods are required, and the decision to end a pregnancy is less stressful, because by that time maternal–fetal bonding is not clearly established and the gestational process is generally not visible to those in the mother's social environment, so that the social consequences of late abortion are avoided. First-trimester voluntary abortion is expected

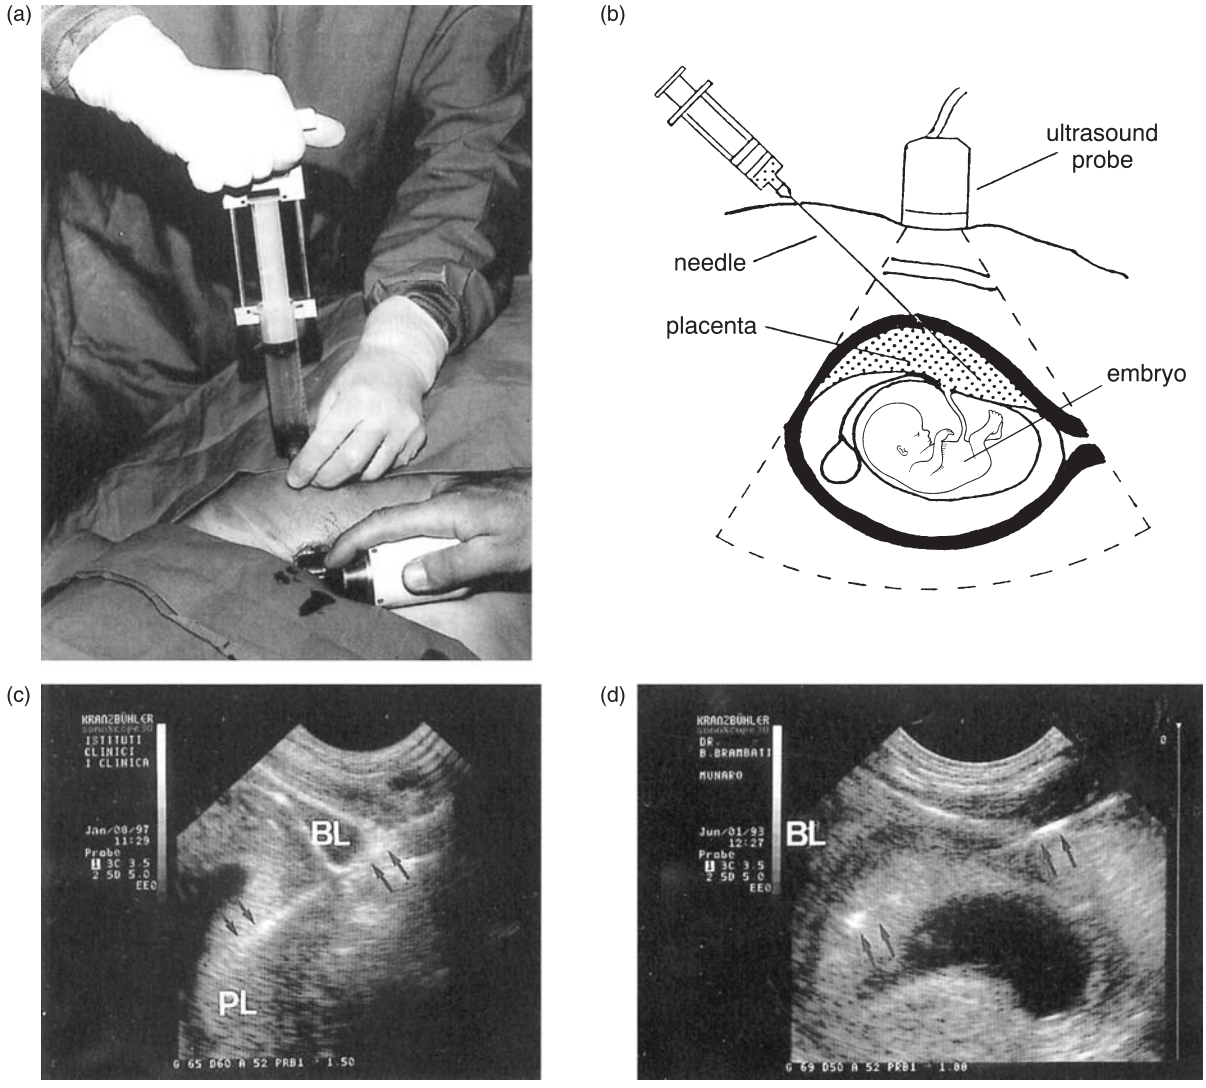

Figure 102.1 (a) Freehand needle insertion under ultrasound guidance; (b) diagram of transcervical chorionic villus sampling (CVS) by a freehand needle insertion approach; (c) transabdominal CVS in a 11.2-week pregnancy with retroflexed uterus and posterior placenta (PL). The needle (arrows) enters straight into the placenta by proceeding close to the bladder (BL) wall, thereby avoiding intestinal loops. (d) Transabdominal CVS in a 10.3-week pregnancy with antiflexed uterus and anterior placenta. The needle pathway is indicated by arrows.

to have a significantly lower rate of clinical complications. Moreover, at this time of pregnancy general anesthesia and dilatation and surgical uterine evacuation have less profound emotional effects on the patient than labor induction and delivery at about 20 weeks.

Chromosomal abnormalities are undoubtedly the most common indication for first-trimester CVS (Table 102.2). Banding of high quality can be obtained by culturing mesenchymal cells of chorionic villi, and this process usually takes 10–15 days. Rapid karyotyping may be performed by examining cytotrophoblastic cells arrested in metaphase, either immediately (a few hours) after sampling or after short-term (24–48 h) culture. However, chromosome preparations obtained by the direct method are difficult to band and would not be suitable for the detection of subtle chromosome anomalies. Moreover, false-negative results for chromosomal aberrations are expected to be about 1 per 3000 (100), whereas the rate falls to less than 1 per 10,000 if cytogenetic analysis is carried out concomitantly on long-term culture.[34,35] Placental-confined mosaicism and non-mosaic rare trisomies give rise to concern regarding proper counseling and pregnancy management. The potential adverse affects on pregnancy outcome of some chromosomal abnormalities confined to the placenta (chromosome 2, 7, 9, 14, 15, 16, 18, and 22, tetraploidy) have documented.[38,109] Whenever a high degree of mosaicism is found in both trophoblast and mesenchyme cells, uniparental disomy in the fetus with normal karyotype ascertained on amniotic or fetal blood cells should be suspected and molecular studies undertaken.[37]

Chorionic villi provide large amounts of metabolically active cytoplasm, therefore for many inherited metabolic diseases direct assay is possible, yielding diagnostic results within hours or a few days. Moreover, the amount of DNA obtained from a conventional sampling allows reliable analysis by recombinant

Table 102.1 Advantages of first-trimester chorionic villus sampling compared with mid-trimester amniocentesis

Individual and social advantages	Diagnostic advantages	Clinical advantages
Higher privacy	Rapid karyotyping	Previous cesarean section
Less emotional impact	Enzymatic assay and DNA analysis on fresh tissue	Pending cerclage
		Multiple pregnancy (and selective abortion)
Fewer legal limitations	Screening 'package' (CF, NSCD, fragile X, paternity, and so on)	General anesthesia and dilatation and curettage for voluntary abortion
Higher acceptability		Stem cell transplantation

Table 102.2 Indications for chorionic villus sampling in 10,123 cases performed at the Mangiagalli Clinic, University of Milan, and at Center for Prenatal Diagnosis, Milan[94]

Indication	No. of cases	No. of affected cases (%)
Karyotyping*		
Maternal age (years)		
< 30	1146	14 (1.22)
30–34	2239	18 (0.80)
35–39	3966	77 (1.94)
=40	1966	103 (5.24)
Previous offspring with chromosome abnormality	556	17 (3.05)
Balanced parental chromosome rearrangement or parental sex chromosome aneuploidy	141	10 (7.09)
Suspicious ultrasonic findings	44	9 (20.45)
Second-trimester Down's syndrome screening	75	0
Enzymatic analysis		
Mucopolysaccharidoses	17	7 (41.2)
Lipidoses	71	19 (26.7)
Amino acid disorders	24	9 (37.5)
Carbohydrate metabolism disorders	12	4 (33.3)
Miscellaneous indications	21	4 (19.5)
DNA analysis		
Thalassemia	823	187 (22.7)
Duchenne/Becker muscular dystrophy	358	81 (22.6)
Hemophilia A/B	107	24 (22.4)
Cystic fibrosis	95	25 (26.3)
Congenital adrenal hyperplasia	33	10 (30.3)
Other monogenetic diseases	62	17 (27.4)
Infectious diseases	19	2 (10.5)
Paternity testing	19	–

*Fetal karyotyping was also performed in all the cases with primary indication other than chromosomal abnormalities

DNA technologies. This is not the case with amniotic fluid cells, which provide too little DNA, which is frequently fragmented. Chorionic tissue is therefore at present the material of choice for prenatal diagnosis of Mendelian diseases. The rapid progress of human genome research is very much broadening the range of gene defects directly detectable, and makes it possible to offer a prenatal diagnosis screening package in low-risk populations for some of the most frequent and severe conditions, e.g., cystic fibrosis (CF), non-syndromic congenital deafness (NSCD) and fragile-X mental retardation, and Rh typing in cases at risk of Rh-isoimmunization.[38,39,99]

Multiple pregnancies

Twin and higher-order multiple pregnancies are specific conditions in which first-trimester CVS can generally offer several technical advantages over mid-trimester anniocentesis. The easy evaluation of the membranes by ultrasound[40] makes both the prediction of chorionicity and amnionicity and the identification of the affected twin(s) more reliable, the use of rapid analytical methods makes substantial changes in the uterine topography very unlikely, and if same-sex dichorionic twins are diagnosed, DNA polymorphism markers may be easily checked to assure retrieval of villi from the individual placentas.[41]

Dichorionic pregnancy can easily be predicted when either two distinct placental sites are detected or, if the placentae are confluent, the septal thickness is 2 mm or more and the lambda sign is present.[40,88] Fused placentae and the presence of empty sac(s) may represent a potential source of contamination: to minimize this inconvenience the main criteria should be to guide the extremity of the aspirating device to the proximity of the umbilical cord insertion, or as far as possible from the confluence of placentas. However, in some conditions a reliable sampling could be easily achieved by the combined use of TA- and TC-CVS or, as an alternative, by using a double coaxial needle system made by a 19-gauge 9-cm-long guide needle and a 21-gauge 15-cm-long sampling needle.[88] The guide-needle is first introduced through the co-twin placenta

and stopped just after reaching the placenta to be sampled, thereafter sampling is performed by passing the thinner needle through the outer one.

In the hands of experienced operators and by appropriate methodological approach, CVS has been reported to be highly effective in multiple gestations: genetic diagnosis was correct on all 338 fetuses sampled from 169 twin pregnancies,[88] while sampling was incorrect in only three out of 771 fetuses (0.4%) sampled in 424 multiple pregnancies undergoing fetal reduction to a single fetus or twins.[43] Moreover, in both experiences sampling was successfully performed in all cases by a single needle insertion. The relative risks of first-trimester CVS and mid-trimester amniocentesis have been documented in two series of 161 and 72 twins.[42] Sampling was performed at 10–12 weeks for CVS and at 16–18 weeks for amniocentesis. No differences were observed between procedures in the rates of spontaneous abortion and perinatal mortality. However, if only cases with chromosomally normal fetuses and placentae were considered, the total fetal loss rate was significantly lower in the CVS series (3.9% vs. 9.3%). In cases of twins discordant for a serious disorder, selective reduction should be considered: the advantages of the first-trimester approach include a significantly lower emotional impact and a lower risk of clinical complications.[43,44]

Timing of chorionic villus sampling

The generally accepted lowest limit of gestational age for sampling is 10 completed weeks. By that time, embryo viability is easily detectable, the placenta is clearly identifiable and adequately thick, and embryogenesis is concluded. The upper limit for transcervical sampling has been suggested to be 12–13 weeks. Indeed, by the end of the first trimester, the gestational sac becomes attached to the decidual wall. Thereafter, any attempt to insert either a catheter or a biopsy forceps entails a higher risk of indenting and damaging the membranes. These difficulties can also be accentuated by the fact that the proximal placental edge may move far from the internal cervical os.

The extension of transabdominal CVS beyond the first trimester has proven to be convenient as an alternative to amniocentesis for a prompt answer in case of late booking, suspicious ultrasonic findings, or increased risk of chromosomal abnormalities as a result of first trimester screening. Low risk and high effectiveness of transabdominal CVS in the early second trimester were clearly reported in a study[45] comparing two large series at 13–14 weeks and at 15–20 weeks with a control series al 11–12 weeks: a very low total fetal loss rate ($\leq$24 weeks) of 0.86%, 0.46%, and 1.02% was respectively observed; a trend towards lower values is apparent, although differences were not statistically significant. Sampling was successful in all cases of the three series, however a posterior and unreachable placenta was the reason for transferring to mid-trimester amniocentesis 4.2% of cases recruited for CVS at 15–20 weeks, whereas in the series at 13–14 weeks this was required in only 0.9% of cases.

The choice of route for sampling

Transcervical and transabdominal techniques appear to be comparably efficient between 8 and 12 weeks, when the overall success rate after two sampling device insertions is considered to be very near to 100%. This efficiency has been confirmed in three national randomized trials of transabdominal vs. transcervical CVS.[14,46,47] Although the data appear to confirm that the two techniques are equally effective in obtaining adequate amounts of chorionic tissue, and in two of the three randomized trials the fetal loss rate was not affected by the sampling technique,[46,47] transabdominal needling entailed a significantly smaller proportion of repeated device insertions (3.3% vs. 10.3%) and of low weight specimens (3.2% vs. 4.9%).[46] Moreover, the deviation from the allocated procedure (15.8% vs. 3.1%), due to previously undetected vaginal infection or anatomical problems, was much higher in the transcervical group.[46]

Transabdominal sampling, in our experience, has definitely become the method of choice, and our preference for this approach is based on the shorter learning time, the lower rate of immediate complications, the higher practicality and success rates at the first device insertion, the lower hazard of intrauterine infection, the opportunity to extend sampling beyond the first trimester, and the wider range of diagnostic indications. However, it is plainly advisable that a complementary approach, namely transcervical or transvaginal sampling, should be mastered for appropriate chorion biopsy in any case. Finally, the high efficiency, the absence of complications after sampling, and the very low total abortion rate observed after 12 gestational weeks, have made the use of second-trimester CVS a valuable alternative to early and mid-trimester amniocentesis, even in genetically low-risk populations.

Complications

Among early post-procedural complications, spotting within a few hours has been more frequently observed in patients undergoing transcervical rather than transabdominal CVS (3.2% vs. 1.5%, $P < 0.001$).[46] Localized peritonitis immediately after sampling occurs in very few cases, and only after transabdominal sampling, with an overall rate of 0.04%. Intrauterine infection (acute chorionamnionitis) should be considered a potential, although very rare, complication of transcervical CVS, having been reported in 0.1–0.5% of cases, and in some large series no cases at all were observed.[48] However, there is some concern about the role of less serious infection in women who experience fetal loss after transcervical CVS. Because transcervical

CVS involves passage of a cannula or forceps through the cervical canal from the perineum and vagina, microbial colonization and infection, with consequent morbidity for both mother and fetus, may result. Clinical symptoms of localized peritonitis have been reported in three cases after transabdominal CVS. Bacteria were cultured only in one of the three cases, which strongly suggested that puncture of the large intestine had caused *Escherichia coli* invasion of the peritoneum.[49] In the two other cases, the chorionic tissue culture medium was sterile, and symptoms were milder, suggesting that the peritoneal reaction resulted from bleeding from the needle puncture of the external uterine surface.

Feto-maternal transfusion has been postulated as a possible side-effect of CVS. At the end of 5 menstrual weeks, the intravillous vascular network connects with the umbilical-allantoic vessels and integrates into the general embryonic circulation. Thereafter, any disruption of villus integrity may cause fetal blood leakage. Feto-maternal hemorrhage following CVS has been demonstrated by a significant increase in maternal serum a-fetoprotein in 40–72% of cases, and in 6–18% of these the amount of blood transfused was calculated to exceed 0.1 ml.[29–31] Fetal hemorrhage should therefore be capable of initiating an immune response in RhD-negative women bearing an RhD-positive fetus. Moreover, an association between maternal serum a-fetoprotein increase and frequency of spontaneous fetal death has been suggested for the cases with the highest maternal serum a-fetoprotein levels.[32]

No increased frequency of perinatal complications, i.e. preterm birth, small-for-dates neonates, perinatal mortality and congenital malformations, have been observed both in randomized and clinical control studies.[12–15,21,48,50]

Data on pediatric follow-up of infants resulting from CVS-tested pregnancies are very scarce. Clinical evaluation was reported in 53 (9–14 years old) of 66 babies born after the earliest Chinese experience, and in 274 children in Milan evaluated at 3–5 years of age.[51,52] All the children were normally developed at the time of the study. Although these two reports seem to exclude any gross long-term effect of CVS, they lack matched controls. In the very near future, when pediatric follow-up data will be available from randomized studies comparing CVS and mid-trimester amniocentesis, it will be possible to reach more reliable conclusions about possible long-term sequelae.

Fetal loss

Several variables, both technical and biological, make it hazardous to evaluate risk based only on clinical studies. For these reasons, a randomized trial to evaluate fetal losses due to the procedure was recommended when CVS was introduced in clinical practice.[53] The overall pregnancy loss rate has been reported in a number of relatively large clinical studies, and the values range from 2.2% to 5.4%.[54–66] The data of the International CVS Registry reveal a striking difference between those centers with the largest experience and those with the least, as well as between different sampling methods.[4–6,67] In our experience,[35] in 9471 continuing pregnancies sampled by the same operator, the overall loss rate (including perinatal mortality up to 28 days after birth) was 3.38% (Table 102.3). Logistic regression analysis of the procedure-related variables showed a significant association between fetal loss rate and maternal age, the lowest rates occurring in the youngest women (1.22%) and the highest in the women of 40 years and over (odds ratio 2.52), while gestational age affected the abortion rate only at 8 weeks (3.78%), no differences in the odds ratio being present at 9–12 weeks. Sampling approach does not seem to affect fetal loss rate. No significant difference between transabdominal needling and transcervical aspiration methods resulted from two of the three randomized trials comparing techniques.[46,47] The only plausible explanation for the higher rate reported for transcervical aspiration in the Danish study[14] is the low operator experience suggested by the higher rate of complicated procedures reported for transcervical sampling. In the light of this evidence it may be inferred that, given the necessary skills, both routes are comparably safe. The number of sampling device insertions may influence pregnancy outcome: a higher fetal loss rate was demonstrated for three or more attempts in the same sampling session. This substantiates our protocol, which limits the number of device insertions in a single sampling session to 2.[13,51,55,61] Failure to obtain adequate tissue on two attempts may imply major obstacles, and the operator should reconsider the case or select a different sampling method.

Six control studies concerning risk assessment were published between 1989 and 1999.[12–15,21,50] Three of them were multicenter studies,[12,13,50] while the Danish study[14] included two single-operator centers. In the Finnish[15] as well in the Spanish[21] studies all procedure were performed at a single center by more than one operator. The sizes of four of the trials[12–14,50] were equivalent, and allowed detection of a 1% fetal loss difference between sampling methods, whereas the number of cases involved in the Finnish and Spanish studies was lower. 800 and 1011, respectively. In the US study,[13] the control group undergoing amniocentesis could not be randomized because of an almost total non-acceptance of the method. The Canadian[12] and US studies compared mid-trimester amniocentesis and transcervical CVS performed at 9–12 weeks, with the exception of 1.3% of cases performed before 9 weeks in the US study. Sampling in the Danish study was performed at 9–11 weeks, and patients were randomly assigned to amniocentesis or CVS. In the Medical Research Council (MRC) European trial,[50] the patients were recruited in the first trimester, but the range and distribution of gestational ages at CVS were not reported.

Four of the five control trials were unable to find statistical differences between first-trimester CVS and mid-trimester amniocentesis, and a significant excess of fetal losses (4.6%) was only demonstrated in the MRC European study (Table 102.4). However, a number of aspects make the latter trial unreliable. First, two of the 31 participating centers contributed more than one-third of the total number of cases, while the number of cases provided by the remaining centers ranged between 4 and 81. Second, no specifications were reported regarding the technical characteristics of the sampling devices, as well as the gestational age distribution at CVS. Lastly, the high rate of repeated insertion would suggest that the average operator skill during the study was low. The multiplicity of sampling approaches, some with potentially higher risk, and the poor technical competence of the majority of operators are confounding variables that might have caused the higher fetal loss rate in the CVS group.

In the mid-1980s, early amniocentesis (10 to 14 weeks) was offered as a safer alternative to CVS.[68–74] However expectations were not confirmed by the randomized trials comparing transabdominal CVS and early amniocentesis: fetal losses (< 20 weeks) and complications (amniotic fluid leakage, talipes equinovarus) were significantly higher for early amniocentesis;[103] fetal losses and complications were also significantly higher in the CEMA study comparing early and mid-trimester amniocentesis.[104]

Table 102.3 Outcome of 10,133 consecutive singleton pregnancies undergoing CVS at Mangiagalli Clinic, University of Milan, and at Center for Prenatal Diagnosis, Milan[35]

Voluntary abortion	
Genetic	553
Non-genetic	74
Pregnancies intended to continue	9506
Termination of pregnancy following sonographic diagnosis of malformation after CVS	35
Fetal loss (< 28 weeks)	2.69%
Stillbirth (=28 weeks)	0.32% (0.7%)
Live births	96.61%
Neonatal death (< 28 days)	0.37% (1.05%)
Premature delivery	
< 37 weeks	3.28% (9.20%)
< 32 weeks	0.59 % (0.91%)
Gestational age at birth (days)	275.2 ± 12.3
Birth weight (g)	3315.4 ± 525.2
Birth weight < 2500 g	3.70% (3.07%)
Birth weight < 1500 g	0.59% (0.85%)
Malformations	2.13% (1.9%)*
Lost to follow-up	0.41%

The limb reduction defect controversy

In 1991, Firth *et al.*[16] reported an unusual cluster of four children with limb defects and oromandibular hypogenesis among 289 pregnancies in which CVS was performed at 8.0–9.3 weeks of gestation. Sampling was carried out by transabdominal needling, but data on technical performance were not available. Subsequently,

two other clusters of four limb defect cases were published in series of about 300 cases.[17,18] In addition, five limb defect cases collected from different centers were reported in Taiwan, but no data were available on the total number of procedures, the sampling techniques, and the gestational ages at CVS.[75,76] Many reports supporting or denying any association between limb defects and CVS then followed.[77–87] However, a WHO statement based on the analysis of about 80,000 CVS cases with completed follow-up did not find any evidence (Table 102.5) to suggest an increased risk of limb defects when CVS was performed after the 8th completed gestational week.[21]

Excessive trauma to the placenta and surrounding tissues is often believed to be an important causal factor of abnormalities during the phenocritical stage of embryological development. Poor expertise and improper sampling techniques were common to the experiences reporting limb defect clusters. The analysis of the WHO-CVS Registry data was recently updated for 216,381 cases[19], respectively, and the results show no increase in the overall incidence of limb defects (Table 102.5). Firth *et al.*,[89] in a literature review, collected 75 limb defects in babies exposed to CVS, to determine the temporal relationship between CVS and limb defects, and claimed a possible inverse correlation between severity of defect and gestational age at CVS. Unfortunately, the diversity in the limb defect classification between this study and population-based studies used for comparison, and the several erroneous duplications of cases, make the conclusions of the study unreliable. The pattern of distribution of limb defects has been evaluated on 77 infants or fetuses with limb defects from 138,996 pregnancies reported to the WHO registry, and compared with the data of the population-based British Columbia Registry for malformations, using the same classification and pattern analysis.[20] The analysis of this cohort did not show any differences from the background population in the overall frequency or pattern distribution of limb defects. There was also no correlation between gestational age at CVS and severity of defects. In conclusion, these results do not indicate any increased risk of limb defects after CVS.

Conclusions

Our practice and critical analysis of the literature demonstrates that where experience and skill are available, first-trimester CVS should be considered the gold standard for prenatal diagnosis of genetic diseases: the rate of complications is very low and fetal loss rate is at least comparable with mid-trimester amniocentesis. The transabdominal sampling technique, in our experience, has become the method of choice. Our preference for this approach has been based on a number of reasons: shorter learning time,[40] lower rate of immediate complications,[48] higher practicality and success rate at the first device insertion,[46] no hazard of intrauterine infections,[107] opportunity to extend sampling beyond the first trimester.[45] Given the promising development of first-trimester screening of aneuplodies by biochemical[92] and sonographic markers,[93] the use of CVS for prompt and reliable diagnosis seems assured.[108]

103 Amniocentesis

A. Tabor

Introduction

Amniocentesis is the method by which amniotic fluid is removed from the pregnant uterus. Amniotic fluid cell culture from second-trimester amniocentesis has been one of the primary tools of prenatal diagnosis: hundreds of thousands of pregnancies have provided extensive experience of monitoring for chromosomal disorders, as well as many hundreds of diagnoses of metabolic disorders. The vast majority of amniocenteses are carried out to diagnose cytogenetic disorders, inborn errors of metabolism and other genetic disorders using chromosome analysis, biochemical studies and recombinant DNA analysis. Therapeutic amniocentesis will not be considered here. This chapter will consider the technique of amniocentesis, the possible complications of the test, and its diagnostic accuracy.

Indications

The commonest indications for performing amniocentesis are increased risks of Down's syndrome or neural tube defects. The indications for performing fetal chromosome analysis vary slightly from country to country. In Western societies, amniocentesis is mostly offered to the following groups, considered to be at an increased risk:

(1) Increased risk of Down's syndrome, following first trimester risk assessment using nuchal translucency and double test;
(2) Maternal age above 35 years (the age limit varies between 35 and 40 years);
(3) Prior birth/abortion of a child/fetus with a chromosome abnormality;
(4) Abnormal parental karyotype; and
(5) Fetal structural abnormality detected on ultrasound scan.

During the last decade the concept of prenatal diagnosis has changed, with the discovery of biochemical and ultrasonic markers for Down's syndrome. A woman's risk of having a Down's syndrome fetus may now be estimated by combining her age-related risk with the risk attributable to the markers. It has been estimated that 90% of Down's syndrome fetuses could be detected by using the nuchal translucency scan in combination with the double test (free β-HCG and pregnancy associated plasma protein A) and maternal age at an amniocentesis rate of 5%.[1] The addition of more biochemical and ultrasonic markers may further increase the detection rate. These markers permit a more selective approach to invasive testing and may in the future be offered to all pregnant women. It should, however, be emphasized that markers can only be used as screening tests, the only diagnostic test being chorionic villus sampling or amniotic fluid cell culture. The proportion of invasive prenatal diagnostic tests being performed such as amniocentesis is increasing due to the increasing use of first trimester Down's syndrome screening. As the result of this screening is available for around 12–13 weeks, women will increasingly opt for chorionic villus sampling.

Technical aspects

Amniocentesis has been performed for prenatal diagnosis for more than 40 years. However, very few randomized controlled trials have evaluated the risks of the procedure, or assessed the optimal technique. Such studies are difficult, as they require a very large number of patients.

Ultrasonography

The failure rate of amniocentesis is reduced by using real-time ultrasound[2] (Figure 103.1). Whether ultrasonography may also reduce the abortion rate after the procedure has not been investigated.

Placental perforation

The abortion risk has been shown in some large studies[3,4] to be increased when the placenta is perforated, while in other studies this was not the case.[5,6] Although the evidence is inconclusive, it is widely agreed that placental perforation should be avoided.

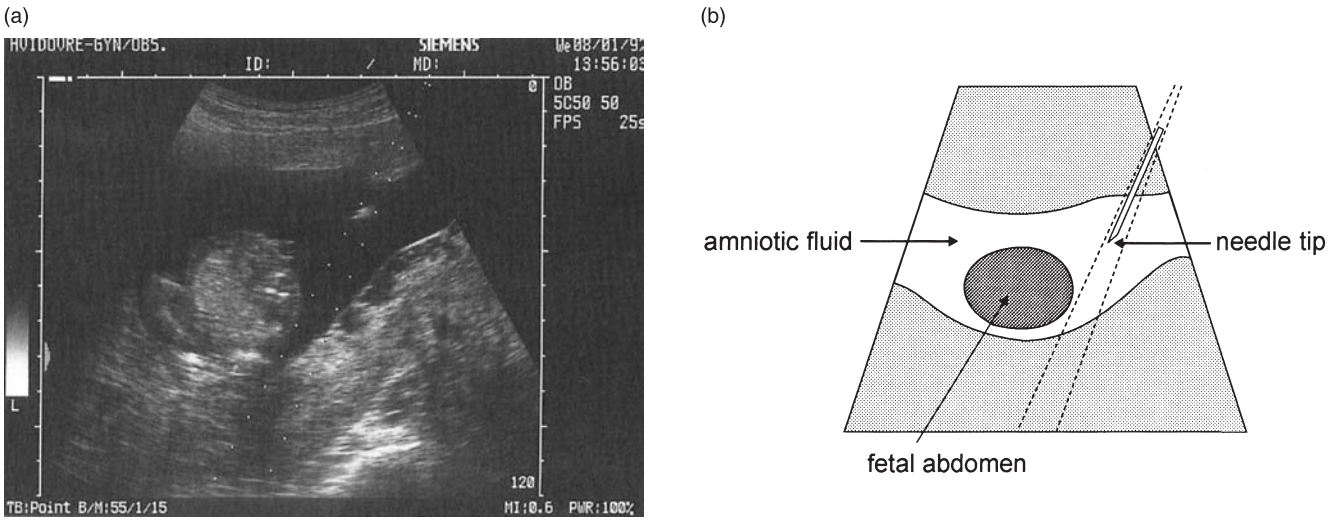

Figure 103.1 Ultrasound-guided second-trimester amniocentesis (a) on the ultrasound screen and (b) in a line drawing. The dotted line represents the needle-guide.

Needle size and number of insertions

Needles larger than 18 or 20 gauge are associated with an increased abortion rate. The risk of fetal loss increases with the number of needle insertions.[7,8]

Operator

The abortion rate[9] as well as the failure rate of amniocentesis[2] have been shown to be inversely correlated with the experience of the operator. In Denmark, the National Board of Health recommends that a gynecologist should perform 50 amniocenteses under supervision, and then 25 amniocenteses per year to keep up the routine.[10]

Timing and volume

Most amniocenteses have been performed early in the second trimester, i.e. from week 14 to 17. A maximum volume of 20 ml is removed, allowing material for polymerase chain reaction (PCR) or fluorescent *in situ* hybridization (FISH), duplicate culture flasks to be set up as well as α-fetoprotein determination. During the last decade, amniocentesis has been performed earlier in the second and even in the first trimester. The technique of early amniocentesis is similar to amniocentesis performed at later gestational ages. However, in the first trimester there are two sacs, the amniotic cavity and the extra-embryonic coelome. The incomplete fusion of the amnion and chorion in early gestation may result in tenting of the membranes, which may necessitate more needle insertions.[11] It is important to distinguish the two sacs ultrasonographically at the time of the amniocentesis, as the fluid in the extra-embryonic coelome is jelly-like, difficult to aspirate, and has a different α-fetoprotein concentration than amniotic fluid.[12] Retrieval of fluid from this sac should be avoided, as it will only rarely produce enough cells to allow a cytogenetic diagnosis. After 11 completed weeks of gestation, the sampling success rate is nearly 100%.[13]

The volume of amniotic fluid is approximately 100 ml in the 12 weeks of gestation, and it has been shown, that the abortion risk as well as the rate of talipes equinovarus is significantly increased, when amniocentesis is performed before 15 weeks.[14,15] It is therefore recommended not to perform amniocentesis before 15 weeks.

Multiple pregnancy

In order to assess whether amniotic fluid has been retrieved from both sacs in twin pregnancies, a marker (a dye or a biochemical substance) may be injected into the first sac.[17] When the second sac is punctured, the absence of the marker in the amniotic fluid indicates that both sacs have been sampled. However, real-time ultrasound allows visually-guided amniotic fluid sampling from both sacs,[18] thus making dye-injection obsolete.

Whether amniocentesis in twin pregnancies should be performed by using one or two needle insertions remains to be shown. A single needle insertion could reduce the abortion risk, but may on the contrary create the problems of amniotic band syndrome or a mono-amniotic twin pregnancy, or give rise to cytogenetic problems.[19]

In conclusion, amniocentesis should be performed after 15 weeks of gestation, under aseptic conditions, using real-time ultrasound, by a trained operator, avoiding placental perforation, using needles no larger than 20 gauge, and performing at the most two insertions on the same day.

Cytogenetic and biochemical aspects of amniocentesis

Amniotic fluid cells are derived from the fetus as well as from the extra-embryonic membranes and the trophoblast. The cells from the latter two tissues may differ in karyotype from the fetus itself, thus causing mosaicism. Viable cells in the amniotic fluid are cultured and used for karyotyping, and investigation of metabolic and biochemical disorders. Uncultured cells may be used to detect specific chromosome aberrations by using chromosome-specific probes and FISH on interphase cells,[20] but complete karyotyping is not yet possible on uncultured cells.

Culture failure

In large laboratories, culture failure occurs in less than 1% of second-trimester cases. The culture failure rate increases with decreasing gestational age: after 11 completed weeks the culture failure rate is the same as in the second trimester,[21] while in weeks 8–9 culture is unsuccessful in more than 30% of cases.[22] Culture failure seems to occur more often in cases of fetal aneuploidy,[23] emphasizing the importance of counseling, further ultrasonic investigation and secondary testing in these cases.

Maternal cell contamination

Maternal cell contamination may cause misdiagnosis, if only maternal cells are examined or mosaicism is suspected. The rate of maternal cell contamination is 1–3 per 1000 cases,[24] but this figure should probably be doubled as maternal cell contamination is only detected when the fetus is male. The contamination rate may be lowered by using a stylet in the needle when performing the amniocentesis, and by aspirating the first 2 ml in a separate syringe to be used for amniotic fluid α-fetoprotein determination.[24] Screening for maternal cell contamination may be considered in blood-stained amniotic fluid samples. An assay using fluorescent labeled microsatellites provides results quickly and seems promising.[25]

Diagnostic accuracy of amniocentesis

The level of α-fetoprotein is determined and a fetal karyotype test is performed routinely on amniotic fluid samples in most laboratories.

Amniotic fluid α-fetoprotein and acetylcholinesterase

The concentration of α-fetoprotein in amniotic fluid is increased when the fetus has an open neural tube defect. The accuracy of this test may be improved by combining it with acetylcholinesterase electrophoresis, giving a detection rate for anencephaly and spina bifida of more than 99.5%, with a false-positive rate of 0.03%.[26]

Amniotic fluid α-fetoprotein may no longer be necessary in centers where high-resolution ultrasonography is available.[27]

Accuracy of fetal chromosome analysis

A large-scale study to assess the accuracy of fetal chromosome analysis has never been performed. This would require complete follow-up on all pregnancies and chromosome analysis of live-born children as well as abortions, whether induced or spontaneous. In a literature survey of 57,921 cases, the accuracy of fetal chromosome analysis was established to be between 99.2% and 99.9%, based on the phenotype at birth.[28]

Mosaicism remains the main problem in prenatal diagnosis and is seen in 0.1% of all samples.[29] When two or more different cell lines are detected in the same amniotic fluid sample, this may reflect a true mosaic abnormality in the fetus, an abnormality in the trophoblast, or a culture artifact (pseudo-mosaicism).[30] While repeat amniocentesis cannot be recommended to solve this problem, fetal blood sampling may determine the karyotype of the fetus *per se*.[30] A 100% detection of mosaicism cannot be expected, when only a limited number of amniotic fluid cells are examined.

It may be concluded that fetal karyotyping is a test with a very high detection rate and a very high accuracy. It should, however, be remembered that false-positive results do occur, although very rarely.

Complications

Maternal

Infection

There is minimal risk to the mother. The risk of amnionitis is less than 0.1% for all procedures.[8]

Immediate complications

In the Danish randomized trial,[3] women in the study and control groups were specifically asked about bleeding, abdominal pain and amniotic fluid leakage 4 weeks after amniocentesis or ultrasonography. The complication rate was higher after amniocentesis (12.1%) than after ultrasonography (5.8%). Vaginal bleeding occurred equally often in the two groups, but amniotic fluid leakage was reported four times more often in the study group (39 vs. 10 women).

The earlier amniocentesis is performed, the higher the leakage rate.[3,15,16]

Rhesus isoimmunization

Feto-maternal hemorrhage (FMH) occurs in approximately half of all pregnant women,[31] and therefore it is not surprising that rhesus immunization may occur during normal pregnancy. The immunization incidence has been reported to be 1.1–1.6% among primigravidas and 2.2% among multigravidas.[32,33] FMH occurs during amniocentesis in one out of six women,[34] and may therefore theoretically give rise to subsequent isoimmunization.

In two retrospective studies, the immunization incidences after amniocentesis were 2.1%[35] and 3.4%.[36] In

a prospective cohort study,[37] the immunization rate was 1.4% (95% confidence limits 0.2–2.6). This may be an overestimation of the immunization rate attributable to the present pregnancy, as the five immunized women were multiparous, and at least three of them had had events in a prior pregnancy which may have presensitized them. The observed 1.4% immunization rate is not different from the spontaneous immunization rate. However, due to the wide confidence interval it cannot be excluded that amniocentesis exposes the rhesus-negative woman to a slightly higher immunization risk. In a population-based study of long-term outcome after amniocentesis,[38] ABO isoimmunization was found significantly more often in the infants subjected to amniocentesis. A protective effect of anti-D immunoglobulin administration after amniocentesis was suggested by the results of the Medical Research Council (MRC) study,[2] which reported that none of 59 women who had been given anti-D were isoimmunized, as compared to three cases among untreated women.

The World Health Organization recommends that a small dose of anti-D be given at the time of amniocentesis to D-negative women.[39] Practice differs between countries regarding whether this recommendation is followed or not. In the United States and in the United Kingdom a dose of 100–125 μg is administered.

Anxiety

In Italian[40] and Danish[41] controlled studies using self-rating scales, anxiety and depression varied similarly in women having amniocentesis and in control women. The variations in anxiety level observed throughout pregnancy in both these studies correspond to those changes observed during normal pregnancy.[42] However, among women having amniocentesis due to advanced maternal age, the anxiety level was increased while awaiting the results of the test.[41,43] It seems that amniocentesis generally has little, if any, psychological impact on pregnancy.

Fetal

The risks to the fetus may either be direct, leading to subsequent abortion, or indirect secondary to removal of amniotic fluid.

Fetal loss rate

The fetal loss rate associated with amniocentesis is superimposed on a background spontaneous abortion rate, which is higher the earlier amniocentesis is performed. The 'background' risk of spontaneous abortion varies with maternal age, parity and social variables.[44,45] In ultrasonically-proven viable pregnancies, the abortion rate after week 15 varies between 1% and 2%,[3,46,47] and as many as 0.7% of women referred for amniocentesis have been shown to have had a missed abortion.[7] In studies designed to assess the fetal loss rate, it is therefore evident that comparability of study and control groups is of major importance, as well as assessment of fetal viability in both groups.

In the 1970s three large cohort studies recruited women 'at risk' to the study group, and all included a matched control group. The National Institute of Child Health and Human Development (NICHD) multicenter study[8] compared 1040 subjects having amniocentesis with 992 controls matched for age, race, parity and socioeconomic factors. The total fetal loss rate and the second-trimester abortion rate were similar in the two groups (3.5% and 2.3% in the study group, compared with 3.2% and 2.1% in the control group). Amniocentesis was performed following ultrasonography in 30% of the women, while amniocentesis was carried out blindly in the rest of the group. In the control group, assessment of fetal viability was not carried out at entry into the study.

In a Canadian multicenter study,[7] 1020 women having amniocentesis were compared to women admitted in early pregnancy. The rate of conception loss was 2.3% before the 24th week in the study group as well as in the control group. Women in the control group may however have had a higher than average risk of fetal loss, as they had been admitted due to pregnancy complications. Amniocentesis was performed following ultrasonography for 98% of the women, while no assessment of fetal viability at entry into the study was carried out in the control group.

In an English multicenter study[2] a 1.2% increased rate of spontaneous abortion was found among 2428 women having amniocentesis and as many matched controls. The main part of this study was criticized for ascertainment bias, due to methodological problems such as differences between the study and control groups regarding maternal age and gestational age at entry into the study, inclusion in the study group of women with increased levels of serum α-fetoprotein, and exclusion from the control group of women who had aborted spontaneously. However, a supplementary, methodologically correct, study confirmed the finding of an increased abortion rate following amniocentesis. Although not significantly different, the size of the risk was 1.0–1.5%. Amniocentesis was performed following ultrasonography in approximately two-thirds of the subjects, while no assessment of fetal viability at entry into the study was carried out in the control group.

The results of the above three large multicenter studies[2,7,8] may have been affected by selection. Furthermore, only the largest study detected an increased fetal loss rate after amniocentesis. In the two smaller studies, involving approximately 1000 women in both the study and the control groups, there was no difference; this could, however, be ascribed to the sample size.

In the only randomized controlled trial of amniocentesis[2] the total sample size was calculated to be

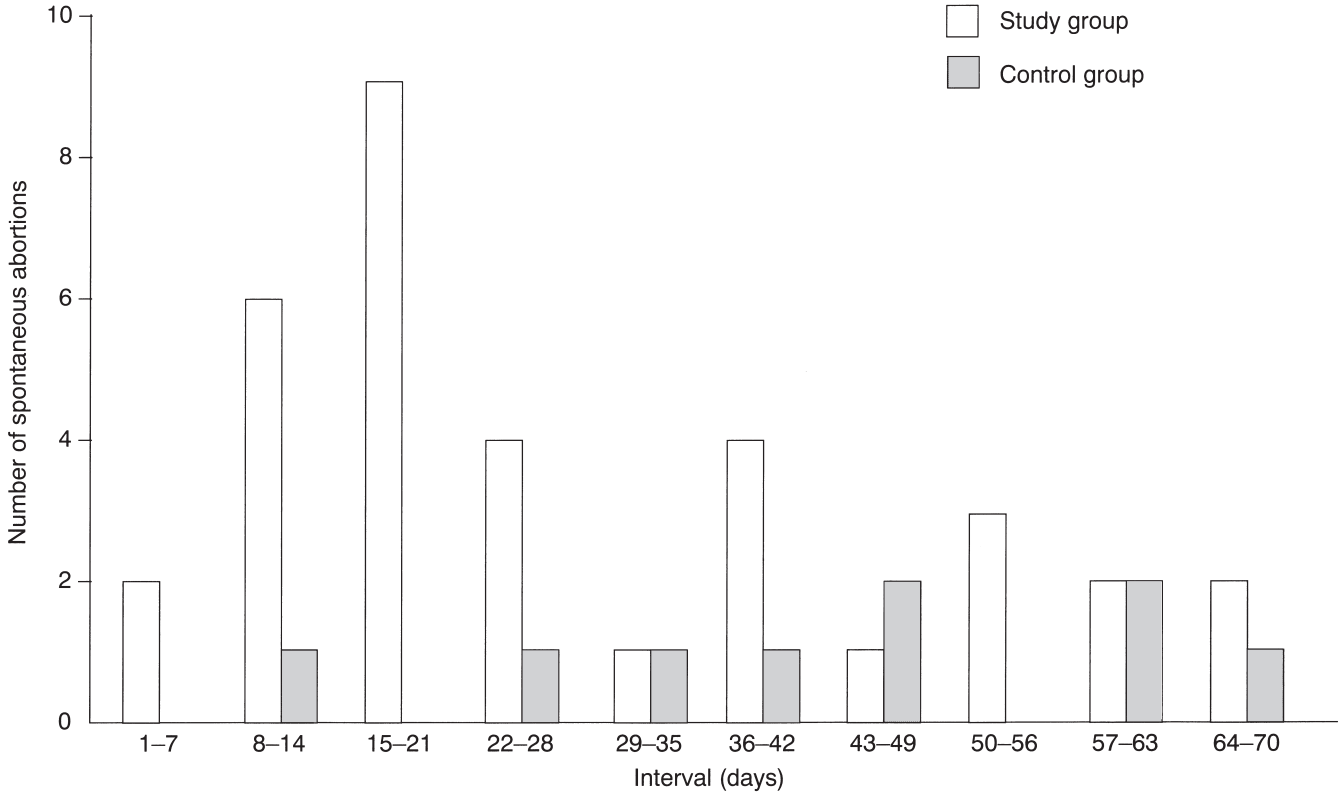

Figure 103.2 Interval between amniocentesis (study group) or ultrasound scan (control group) and spontaneous abortion.

approximately 4800 women, in order to have an 80% chance of detecting an increase in miscarriage rate from the estimated 1.5% in the general population to 2.5% following amniocentesis. The study included 4606 women aged 25–34 years, who would not otherwise have been offered genetic amniocentesis. By choosing this group of women, it was ethically possible to perform a randomized trial. Apart from the fact that women in the study group had amniocentesis and women in the control group an ultrasound scan at the same gestational age to assess fetal viability, antenatal care was similar for the two groups. Randomization achieved comparability between the study and control groups regarding age, background factors and time of entry into the study. The follow-up rate was high (99.9%), as well as the compliance (99.1% in both groups). The design and conduction of this study therefore do not seem to have been biased in any major way.

The fetal loss rate after the 16th week (mean gestational age of amniocentesis in the study group and of ultrasonography in the control group) was 1.7% in the study group and 0.7% in the control group. Amniocentesis was thus associated with an increased fetal loss rate of 1.0% (95% confidence limits 0.3–1.5%), which corresponds to a relative risk of 2.3 (1.3–4.0). There is no reason to believe that the procedure-related risk of amniocentesis should be any smaller in older women. There was a substantial increment in the number of abortions in the first 3–4 weeks after amniocentesis (Figure 103.2).

The 1.0% increased miscarriage rate may actually underestimate the true difference between the two groups, as chromosomally abnormal fetuses are at an increased risk of being aborted spontaneously.[48] Eleven pregnancies in the study group and only one in the control group were terminated due to fetal chromosome abnormality.

Women who miscarried after amniocentesis could not be distinguished from the rest of the study group by obstetrical or social variables, but they had significantly more often had transplacental taps, retrieval of miscolored amniotic fluid or an elevated level of maternal serum α-fetoprotein before amniocentesis. The last two variables are more likely to be reflections of an abnormal pregnancy than a complication of amniocentesis.

Early amniocentesis (before 15 weeks). Early amniocentesis has been compared to chorionic villus sampling (CVS) or amniocentesis in weeks 15–18, taking into account the background rates of pregnancy loss at earlier gestational ages. In the first study, which included a randomised sub-group, the fetal loss rate was significantly higher after early amniocentesis than following CVS.[14] In a larger Canadian randomised trial, the spontaneous fetal loss rate was also significantly higher following early amniocentesis as

compared to traditional amniocentesis in weeks 15–18.[15] In a smaller Danish randomised trial, the spontaneous fetal loss rate was significantly higher after early filtration amniocentesis compared with transabdominal CVS.[16]

It may therefore be concluded, that amniocentesis should not be performed before 15 weeks gestation.

Multiple pregnancy. The fetal loss rate in multiple gestations has not been estimated in a controlled trial and is difficult to determine due to the increased miscarriage rate *per se* in twin pregnancies.

An increased postamniocentesis abortion rate in multiple gestations may be expected, since most operators use more than one needle insertion, a variable associated with an increased fetal loss rate. The fetal loss rate has been reported to be between 2 and 8%,[17,49,50] but most studies have small sample sizes. In the largest series of 476 twin pregnancies, the fetal loss rate was 2.7% before 28 weeks of gestation, comparable to that in the control group.[51]

We may thus conclude that the fetal loss rate following amniocentesis in weeks 16–18 is around 1.0% (95% confidence limits 0.3–1.5%) in singleton pregnancies; in twin pregnancies the fetal loss rate may be more than doubled. Amniocentesis should not be performed before 15 weeks of gestation.

Complications to the infant

Amniocentesis does not affect the preterm birth rate, the stillbirth rate or the perinatal mortality rate.[3,7,8] The mean birth weight of the infants was also independent of whether amniocentesis had been performed. In a randomized controlled trial of amniocentesis,[3] the rate of low birth weight infants (i.e. < 2500 g) was similar in the study and control groups. The number of very low birth weight infants (i.e. < 1500 g) was, however, significantly higher in the study group.

Perinatal morbidity

Lower limb malformations. In the main part of the MRC study,[2] congenital dislocation of the hip and talipes equinovarus were found more often among subject infants. This finding could not be confirmed in the methodologically more correct supplementary part of the MRC study,[2] nor in the other controlled studies.[3,7,8] Furthermore, a case–control study[52] of 1342 infants found no association between amniocentesis and talipes or hip malformations. Amniocentesis in week 16–18 thus does not seem to be associated with an increased rate of congenital malformations. In the two randomized trials of early amniocentesis,[14–16] however, the prevalence of talipes equinovarus at birth was significantly higher after amniocentesis than after CVS.

Neonatal respiratory distress. Severe unexplained respiratory difficulties at birth were found significantly more often in study group babies as compared to the controls in the MRC study.[2] This increase was most marked in those infants born between 34 and 37 weeks of gestation (8.2% in subjects and 0.9% in controls). The mortality attributable to respiratory distress was also higher among subjects than controls (0.26 compared with 0.13%).

The suggested association between amniocentesis and respiratory difficulties was confirmed in the Danish randomized trial[3]; 25 infants in the study group (1.1%) developed respiratory distress syndrome (RDS) as compared to 12 infants in the control group (0.5%). Pneumonia was also diagnosed more often in the study group (15 infants compared to six). The association between amniocentesis and RDS was independent of birth weight and of gestational age. The hypothesis that amniocentesis may produce a relative pulmonary hypoplasia in some fetuses is supported by animal studies. Structural changes were observed in the lungs of baby monkeys after amniocentesis compared with control monkeys,[53] and in guinea pigs even transient oligohydramnios led to pulmonary complications.[54] In newborn children, a lower ratio of crying vital capacity to birth weight was found in 10 infants whose mothers had had amniocentesis, in comparison with 10 infants born after uneventful pregnancies.[55] However, the two groups of mothers may not have been comparable. In another study of 39 infants born after pregnancies subjected to amniocentesis and 42 controls, the lung growth and development also seemed affected by amniocentesis.[56]

There is thus some evidence suggesting that amniocentesis may increase the rate of respiratory difficulties in the newborn. It may be that altered amniotic fluid volume after amniocentesis or subsequent chronic amniotic fluid leakage interferes with normal lung development and lung structure at term, thus giving rise to pulmonary hypoplasia and consequently to RDS in the newborn.[57] Whether these antenatal and neonatal changes have any long-term impact on lung development remains to be shown. In a large population-based study of long-term outcome after amniocentesis including 1296 cases and 3704 controls, respiratory problems were reported more often among controls.[38]

Infant follow-up

Two of the large controlled studies[2,8] followed up the infants at the age of 10–12 months, and found no difference in physical growth or neurological development between study- and control-group infants. Few studies have followed up the children beyond infancy. In a large population-based database study, no group differences were revealed at the age of 7–18 years.[38] In a prospective longitudinal follow-up study, Finegan *et al.*[58] found no difference between

91 infants whose mothers had had an amniocentesis, and 53 control infants, regarding mental and motor development, temperament or physical growth at the age of 6 months. At the ages of 4 and 7 years, there was no difference between the two groups regarding intelligence, language or physical growth.[59,60] Subject children were, however, more likely to have had an ear infection than the control infants. The size of this study may be too small to detect anything but large differences between the groups.

It may be concluded that, apart from an increased risk of developing respiratory problems, amniocentesis in weeks 16–18 does not seem to influence newborn infants. A possible long-term impact on the upper as well as on the lower respiratory tract has yet to be studied.

104 Cordocentesis: indications

F. Daffos

Cordocentesis opened the fetal vascular compartment to diagnosis and therapy.[1–3] It contributed to the notion that the fetus was a patient, and transformed the view of antenatal diagnosis from the normal/abnormal dichotomy, in which abortion was the only 'therapeutic' option, into a field in which a fine prognosis could be made and antenatal therapy envisaged. In the last 15 years fetal blood sampling has become a major diagnostic tool in a new field, namely fetal medicine, which for practical reasons is considered a part of gynecology and obstetrics, but which is in fact closer to 'antenatal pediatrics' in view of the disease conditions treated, warranting specific training.

Advances in our knowledge of fetal pathophysiology and fetal blood biology in the last 10 years mean that the indications for fetal blood sampling are no longer classified in terms of antenatal diagnosis of a given abnormality, but are integrated into a medical approach.

Fetal malformations

Fetal karyotyping

Karyotyping is always indicated when there is a malformation, regardless of its nature; the use of fetal blood has specific indications, as it can provide etiologic information according to the type of malformation.[4]

Cytogenetic analysis from amniocentesis is rarely possible in less than 8 days. In contrast, the karyotype from fetal blood is obtained within 48 h, and is therefore particularly indicated in advanced pregnancies where management decisions will depend on whether a chromosome abnormality is associated with the observed malformation.[5] In addition, long delays in obtaining results have adverse psychological effects for the mothers.

Fetal blood sampling is also indicated for karyotyping when there is mosaicism on amniotic fluid culture. The karyotype from fetal blood generally confirms that the result was due to maternal blood contamination in cases of sexual mosaicism, or due to culture artifacts in cases of autosomal mosaicism.[6,7]

Abnormalities of hands and arms

The TAR syndrome (thrombocytopenia and absence of radius) is confirmed by the presence of fetal thrombocytopenia (generally below 50,000). For the diagnosis of Fanconi's anemia, chromosome strand breaks are easier to identify on lymphocytes.

Cardiac malformations

These can be part of the Di George syndrome, in which case T lymphocytes are absent, as shown by the study of lymphocyte subpopulations. In this particular case, unsuccessful fetal blood culture for karyotyping can be a sign of Di George syndrome, as it is T cells that divide in culture.

Microdeletion of chromosome 22, found in certain familial forms of the Di George syndrome, is generally less difficult to identify on a blood karyotype which, in trained hands, is of better quality than a karyotype on fibroblasts derived from amniotic fluid.

Cerebral abnormalities

Non-specific abnormalities can result from an intracerebral hemorrhage syndrome. They are found increasingly often and can be due to auto- and especially alloimmune fetal thrombocytopenia, or to a hemorrhagic syndrome such as fetal intravascular coagulopathy which is sometimes encountered in very severe fetal infections. Thorough testing of fetal coagulation is warranted in these cases.

Infectious syndromes

Fetal blood sampling initially had a major place in the diagnosis of the main pathogenic agents interfering severely with fetal development. Prenatal diagnosis of toxoplasmosis, rubella, cytomegalovirus, parvovirus and varicella was first carried out using fetal blood. Recent progress, especially in cell culture and polymerase chain reaction (PCR) amplification, has improved the reliability of the diagnosis. In addition, pathogenic agents can be detected in amniotic fluid obtained by simple amniocentesis.[8]

In prenatal diagnosis of congenital toxoplasmosis, tests for parasite DNA by PCR on amniotic fluid have eliminated this indication for fetal blood sampling since 1993. In the same way, several publications

have shown that cytomegalovirus can readily be detected by culture and PCR in amniotic fluid, perhaps more easily than in fetal blood. However, diagnosis of some infections, such as parvovirus B19, still warrants fetal blood sampling.

Diagnostic value

Congenital rubella

The drastic reduction in cases of rubella during pregnancy in the last 15 years, thanks to vaccination, has meant that research on prenatal diagnosis of this infection has waned. The diagnosis is highly reliable when specific anti-rubella immunoglobulin M (IgM) is found in fetal blood, together with acid-labile interferon and elevated total IgM.[9,10] The reliability of diagnosis based on amniotic fluid has not been studied; it should be possible but further studies are necessary.

Parvovirus B19 infection

This virus, which specifically infects fetal erythropoietic precursors, is easier to detect in fetal blood than in amniotic fluid.[11]

Prognostic value

The indications for fetal blood sampling for the diagnosis of infections have become more limited in recent years. In contrast, simple diagnosis is no longer sufficient, and an attempt must also be made to assess the prognosis according to the pathogen, gestational age and the severity of fetal disease.

Congenital toxoplasmosis

With the exception of fetal thrombocytopenia, which correlates with the severity of infection, we have found no other useful blood parameters in this setting.

Cytomegalovirus

If the infected fetus has normal laboratory values,[12,13] there is a chance that it will be a healthy carrier and have no congenital manifestations. This is generally the case. Signs of severe fetal hepatic involvement, and especially intravascular coagulopathy, are a major risk factor for severe congenital abnormalities.

Parvovirus B19

Fetal blood sampling can be used to assess the degree and severity of fetal anemia due to this virus.[14–16] In addition, the stage of the disease can be determined by counting erythroblasts and studying erythropoietic precursors. In the regenerative phase, when anemia and erythroblastosis are present, the outcome is spontaneously favorable and transfusions are unnecessary. In the non-regenerative phase, with more or less profound bone marrow aplasia, transfusions are necessary until marrow function recovers. In every case of fetal infection, severe thrombocytopenia indicates a very poor prognosis.

Anemic syndromes

The most frequent anemic syndromes are rhesus and erythrocyte alloimmunization, parvovirus infection, congenital rubella after the acute hepatic and erythroblastocytic phase, and spontaneous and traumatic feto-maternal bleeding which leads to acute anemia with signs of fetal distress (Kleihauer's test is strongly positive). In these anemic syndromes fetal blood sampling is the main tool used for diagnosis, prognosis and treatment.[17–21] The hemoglobin concentration, hematocrit, erythroblast count and mean corpuscular volume must be taken into account when assessing the type of anemia, its course and its severity. Hyperbilirubinemia, which is never very elevated (because of transplacental filtration), points to a hemolytic cause of the anemia.

The prognosis of fetal anemia depends not only on its etiology but also on the hemoglobin level and the chronic (rhesus incompatibility) or acute/subacute (parvovirus infection or feto-maternal hemorrhage) nature of the anemia. Anemia with a hematocrit below 16% (hemoglobin 5 or 6 g) is frequently accompanied by signs of fetoplacental hydrops on ultrasound. In chronic anemia, the acid–base balance and fetal pH seem to remain normal down to a hemoglobin level of approximately 3 g. In cases of such extremely severe anemia, anoxia leads to often irreversible cell damage, even when the anemia is corrected by transfusion.

The universally accepted treatment for anemia is *in utero* transfusion with specially prepared red cell concentrates. Ultrasound-guided puncture is also indispensable in this indication. It allows red cells to be transfused directly into the fetal vascular compartment, and can be used to check efficacy by measuring the hemoglobin and hematocrit at the end of the transfusion.

Anoxemic syndromes

In cases of severe intrauterine growth retardation, when ultrasound malformations have been ruled out together with infectious and chromosomal abnormalities, a diagnosis of chronic fetal distress of anoxemic origin can be made.[22–25] Without replacing the prognostic information provided by the fetal heart rate and the different items of Manning's biophysical score,[26] fetal blood sampling helps with decision-making by revealing chronic fetal distress and acute decompensation (Table 104.1). A good deal of research is being conducted to identify other biological markers.[27–30]

Fetal blood sampling has also been used to check the efficacy of experimental treatment by maternal hyperoxygenation or fetal nutrition by intra-amniotic injection of amino acids and glucose.

Table 104.1 Biological signs of acute and chronic fetal distress

Chronic fetal distress	Acute fetal distress
Stimulation of erythropoiesis	Acidosis
Rise in erythroblasts	Hypoxia
	Hypercapnia
Cell damage	
Shortened red cell lifespan	
Hepatic cytolysis	
Decrease in fat storage	
Hypertriglyceridemia	
Modification of cortisol and ACTH levels	
Rise in cortisol	
Fall in ACTH	
Change in maternal supply	
Hypoglycemia	
Fall in essential amino acids	
Modification of growth hormones	
Hypoinsulinemia	
Decrease in IgG-1	

ACTH, adrenocorticotropic hormone; IgG-1, immune gamma globulin-1

Hemorrhagic syndromes

These syndromes are far more frequent than previously realized.

Hereditary hemorrhagic syndromes

These are due to genetic clotting factor deficiency (hemophilia A or B, factor V and VII deficiency, and afibrinogenemia) or to abnormalities of the platelet count or function (May Hegglin syndrome, Glanzmann thrombasthenia, etc.).[31]

Except in cases where the gene is known and the mutation identified in the family (permitting diagnosis by molecular biology on trophoblast or amniotic fluid), these conditions are diagnosed phenotypically using fetal blood by clotting factor assays (relative to fetal standards) or by studies of fetal platelet function.

Acquired hemorrhagic syndromes

Intravascular disseminated coagulation

As in adults, this leads to a fall in fetal fibrinogen levels and platelet counts, and to the presence of fibrin products. The most frequent causes are very severe congenital infections (especially those due to cytomegalovirus and *Toxoplasma gondii*).

Immune-mediated thrombocytopenia

The most severe and earliest of these are of alloimmune origin (especially involving the PLA-1 or HPA-1a system), but fetal thrombocytopenia due to antiplatelet antibodies, e.g. idiopathic thrombocytopenic purpura, can sometimes be severe (< 50,000 platelets),[32–36] Fetal blood sampling is the only way of diagnosing these forms of thrombocytopenia, as there is no correlation between fetal and maternal platelet counts or antiplatelet antibody titers. According to the severity of the thrombocytopenia, fetal blood sampling can also be used to select the method of delivery that will be least traumatic for the fetus and therefore avoid intracerebral hemorrhage.

These hemorrhagic syndromes can be treated by *in utero* transfusion of platelet or clotting factor concentrates, whose efficacy depends on their half-life.

Other indications for fetal blood sampling

Diagnosis

Many hereditary diseases cannot be diagnosed by means of molecular biology, as the culprit gene has not yet been identified. Only studies of fetal serum or blood components can provide the antenatal diagnosis.[37–40]

Therapeutic interventions

Intravenous injection of drugs into the fetal circulation is currently limited to curare before invasive procedures (transfusion, vesical or pulmonary shunt) that necessitate complete fetal immobility. This method has occasionally been used to correct the fetal heart rate after failure of maternal treatment.[41]

Pharmacological studies

Access to the fetal blood compartment allows studies of transplacental drug passage and efficacy by simultaneous maternal and fetal blood sampling. Vitamin K1 is a good example of the complexity of antenatal pharmacology. It crosses the placental barrier very readily but has no therapeutic effect, as it does not affect vitamin K1-dependent clotting factors in the fetus.[42]

For obvious ethical reasons, prenatal pharmacology is rarely used. However, many maternal drug treatments have been studied by using fetal blood samples obtained for other purposes.

Conclusion

Fetal medicine has been transformed in the last 15 years. 'Prenatal diagnosis' is now too limited a term, as we are able not only to diagnose, but also to establish a prognosis and to treat many conditions, exactly in the same way as in adult medicine.

The place of fetal blood sampling in fetal medicine has seen a similar change. Less useful for diagnostic purposes than 10 years ago, because of advances in molecular biology (especially PCR), it remains an irreplaceable prognostic and therapeutic tool.

Fetal blood sampling has now become part of an impressive therapeutic arsenal, alongside imaging methods, invasive techniques and laboratory investigations. Its main indications now are in establishing the prognosis of infections, and in the prognosis and treatment of anemic and hemorrhagic syndromes.

105 Fetal pharmacological therapy

M. I. Evans, Y. Yaron, P. Lewis and R. F. Hume Jr

Introduction

The concept and reality of fetal therapy is now entering its fourth decade. Ever since Lilley's first attempt to treat fetal anemias in the 1960s, physicians have wondered what else could be attempted. First thoughts centered on surgical approaches, and these have been detailed elsewhere. However, medical approaches, while not as glamorous, have made significant contributions to our understanding of fetal physiology, and the process of disease.

For decades, drugs and other agents have been administered to pregnant women for treatment of fetal disorders not usually classified as metabolic in the hope of improving the capacity for postnatal adaptation. Well-known examples include exchange transfusions in Rhesus disease, the administration of corticosteroids for the prevention of respiratory distress syndrome in premature infants, and the administration of phenobarbital prior to birth in the hope of inducing liver enzymes for postnatal reduction of serum bilirubin concentration. However, there are very few examples of attempted prenatal treatment for genetically determined metabolic defects.

Errors of metabolism

Congenital adrenal hyperplasia

The most common and the best described adrenal abnormality affecting the fetus is congenital adrenal hyperplasia (CAH). This comprises a group of autosomal recessive disorders characterized by a deficiency in one or more of the enzymes required for adrenal cortisol biosynthesis. The most common abnormality, responsible for $> 90\%$ of patients with CAH, is caused by a deficiency of the enzyme 21-hydroxylase (21-OH), also known as p450c21.[1] Other, less common causes for CAH include enzyme deficiencies in 11β-hydroxylase, 17α-hydroxylase, p450scc deficiency, and 3β-OH-dehydrogenase. Diminished 21-OH activity results in accumulation of 17-hydroxyprogesterone (17-OHP) due to the decrease in its conversion to 11-deoxycorticosterone (Figure 105.1). The excess 17-OHP is then converted via androstenedione to androgens, the levels of which increase by as much as several hundred fold. The excess androgens cause masculinization of the undifferentiated female external genitalia. The degree of masculinization may vary from clitoral hypertrophy to complete formation of a phallus and scrotum. By contrast, genital formation in male fetuses is normal, but signs of androgen excess develop in childhood, and may manifest in precocious masculinization, and accelerated growth and development. The 'classical' form of CAH involves an almost complete block of enzyme activity and is clinically present at birth. The 'non-classical' form involves only partial blockade of the enzymatic activity and is usually clinically apparent later in life. 21-OH deficiency is inherited as an autosomal recessive trait in close linkage to the HLA major histocompatability complex on the short arm of chromosome 6.[2] The gene for 21-OH (CYP21B) has been mapped, allowing direct mutation analysis in informative families.[3]

Historically, in the late 1970s and early 1980s, diagnosis of CAH was made by the finding of elevated levels of 17-OHP in amniotic fluid. With the development of chorionic villus sampling (CVS) in the 1980s, linkage-based diagnosis in the first trimester became available. Since discovery and mapping of the allelic variants in the 1980s, direct DNA analysis has become the routine approach. In addition, the sonographic detection of an abnormally enlarged phallus should alert the physician to investigate for CAH.[4]

The fetal adrenal gland can be pharmacologically suppressed by maternal replacement doses of dexamethasone.[5] In an attempt to prevent female genital birth defects, Evans *et al.*[5] first administered dexamethasone at a dose of 0.25 mg *quater in die* to a mother known to be at risk for CAH, beginning at 10 weeks of gestation. Serial maternal estriol and

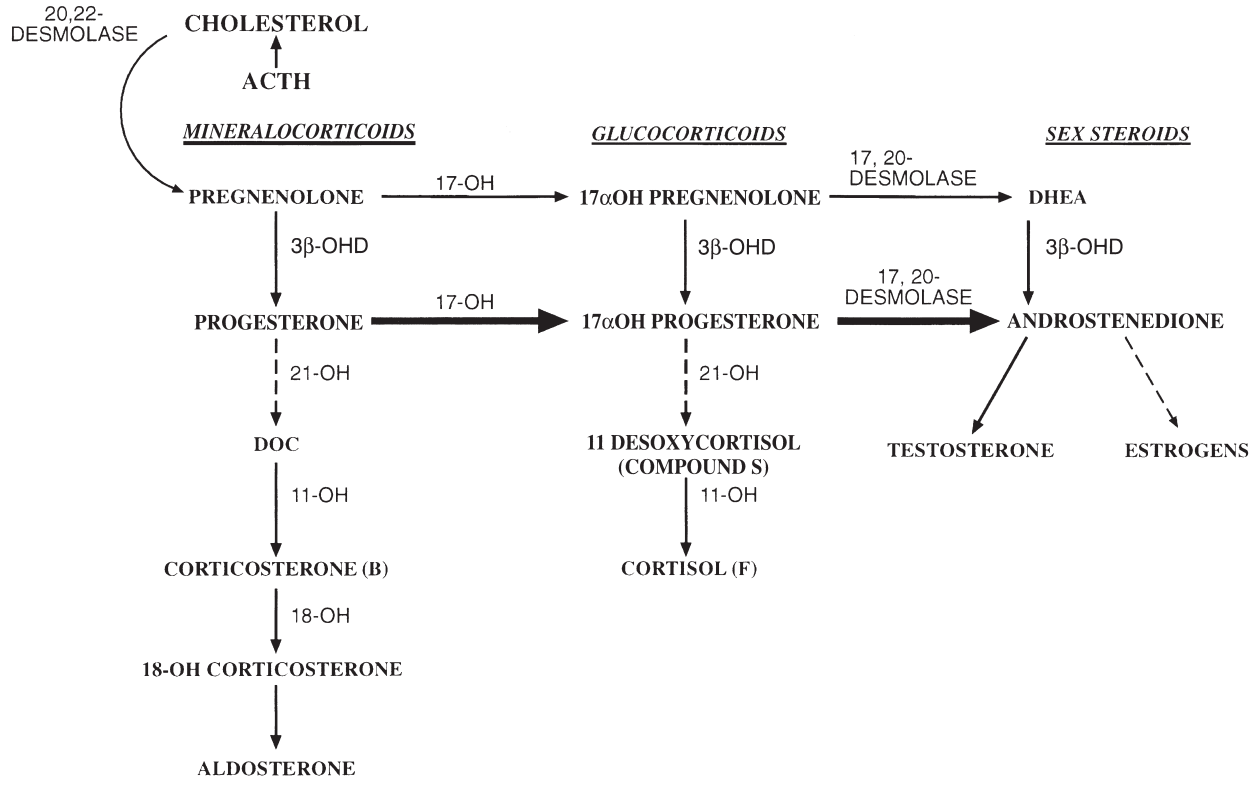

Figure 105.1 Pathway of congenital adrenal hyperplasia with blockage at 21-hydroxylase leading to excess androgens.

cortisol levels indicated that adrenal gland suppression had been achieved. The fetus, ultimately found to be affected, was born at 39 weeks of gestation with normal external genitalia. Forrest and David[6] then employed a similar protocol beginning at 9 weeks of gestation to treat several fetuses known to be at risk for CAH. Subsequently, those female fetuses confirmed to be clinically affected with the severe form of CAH were spared masculinization of the external genitalia.

Since the differentiation of the external genitalia begins at about 7 weeks of gestation, diagnosis by amniocentesis or even CVS comes too late to prevent masculinization. Thus, for patients at risk of having an affected fetus, pharmacological therapy has to be initiated prior to diagnosis. This implies that therapy needs to be administered to all patients at risk despite the fact that the chance of an affected female fetus for carrier parents is only 1 in 8 (i.e. 1/4 affected ∞ 1/2 female). Direct DNA diagnosis or linkage studies may then be performed by CVS in the first trimester. Thus, for seven out of eight patients, therapy can be discontinued as soon as the diagnosis of CAH is ruled out. If the fetus is indeed found to be an affected female, then therapy is continued throughout gestation. Stress-dose corticosteroids should be given to the mother during labor and tapered gradually postpartum. If, however, the fetus is a male, or is unaffected, the therapy is discontinued at the time of diagnosis.

To date, several infants who have inherited the classic CAH mutation, and who clearly would have been masculinized, were born with normal genitalia. In a few cases some masculinization has still been observed following this regimen beginning at 9 weeks. Our current protocol, therefore, is to begin at 7 weeks, although there have been too few cases to assess this modification.[7,8] These events represent the first prevention of a birth defect and may serve as a model for other attempts at pharmacological fetal therapy.

Although this therapy is widely accepted it is still considered experimental by some, especially insurance companies. A recently published commentary written in the *Journal of the American Medical Association* advocates Institutional Review Board approval be obtained on all patients offered this treatment. As long-term follow-up has not been documented on individuals who received *in utero* steroid treatment for CAH, a registry has been proposed by the Lawson Wilkins Pediatric Endocrine Society for studies in North America.[9] This should help to assess the long-term outcome of fetuses exposed to high-dose steroids.

Methylmalonic acidemia

Methylmalonic acidemia is related to a functional vitamin B_{12} deficiency. Coenzymatically active B_{12} is required for the conversion of methylmalonyl-coenzyme A to succinyl-coenzyme A. Several genetically determined etiologies for methylmalonic acidemia include

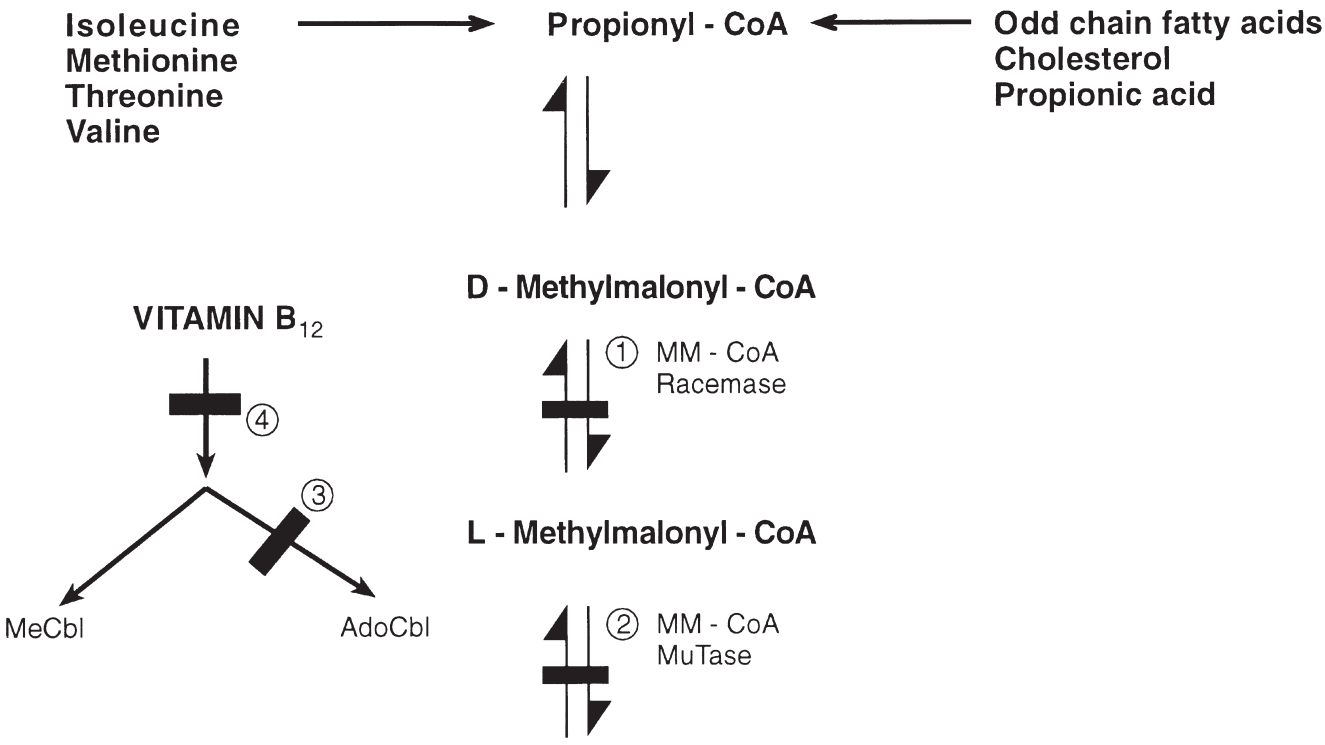

Figure 105.2 Pathway of methylmalonic aciduria and reaction driven by excess vitamin B_{12}.

defects in methylmalonyl-coenzyme A mutase or in the metabolism of vitamin B_{12} to the coenzymatically active form, adenosylcobalamin, by the converting enzyme. Some patients may respond to administration of large doses of B_{12}, which can enhance the amount of active holoenzyme (mutase apoenzyme plus adenosylcobalamin) (Figure 105.2).

It was already known that fetal methylmalonic acidemia is associated with increased methylmalonic acid excretion in maternal urine. Ampola *et al.*[10] documented increased methylmalonic acidemia in a maternal urine sample first collected at 23 weeks of gestation; the methylmalonic acid excretion per milligram of creatinine was approximately twice the upper normal limit and demonstrated a further rise by 25 weeks. Urinary methylmalonate excretion is not abnormal in heterozygous females carrying a normal fetus, as shown subsequently by these same investigators.

Very late in pregnancy, cyanocobalamin (10 mg/day) was orally administered to the mother in divided doses. The treatment only marginally altered the maternal serum B_{12} level; however, there was a slight reduction of urinary methylmalonic acid excretion that remained several-fold above normal. At approximately 34 weeks of gestation, administration of 5 mg of cyanocobalamin per day intramuscularly was begun. The maternal serum B_{12} level then rose gradually to more than six-fold above normal and was accompanied by a progressive decrease in urinary methylmalonic acid excretion. Maternal urinary methylmalonate was only slightly above the normal range when delivery occurred at 41 menstrual weeks. Amniotic fluid methylmalonic acid concentrations were three times the normal mean at 19 menstrual weeks and four times the normal mean at term, despite prenatal treatment.

Postnatally, the diagnosis of methylmalonic acidemia was confirmed. The infant suffered no acute neonatal complications and had an extremely high serum B_{12} level. Long-term postnatal management involved protein restriction; however, no continuous B_{12} treatment was required.

In this instance, prenatal treatment certainly improved the fetal and, secondarily, the maternal biochemistry. Whether there was any significant clinical benefit to the fetus by *in utero* treatment cannot be assessed adequately. It seems likely that reducing the fetal burden of methylmalonic acid should have some beneficial effect on fetal development and could reduce the risks in the neonatal period. However, this is only speculation.

Evans *et al.* have recently documented the changing dose requirements necessary over the course of pregnancy to maintain adequate levels of B_{12}. They sequentially followed maternal plasma and urine levels in a prenatally treated pregnancy.[11] Data such as these suggest that modulation of maternal–fetal pharmacological interchange of therapeutic drugs will be difficult to control precisely.

Multiple carboxylase deficiency

Biotin-responsive multiple carboxylase deficiency is an inborn error of metabolism in which the mitochondrial biotin-dependent enzymes, pyruvate carboxylase, propionyl-coenzyme A carboxylase, and β-methyl-crotonyl-coenzyme A carboxylase have diminished activity. Affected patients present as newborns or in the early childhood period with dermatitis, severe metabolic acidosis, and a characteristic pattern of organic acid excretion. Metabolism in patients or in their cultured cells can be restored toward normal levels by biotin supplementation. There have been two reports of prenatal administration of biotin to fetuses affected with this disorder.

Roth *et al.*[12] treated a fetus without the benefit of prenatal diagnosis in a case in which two siblings of the fetus had died of multiple carboxylase deficiency. The first sibling had died within 3 days of birth, and in the second the diagnosis of biotin-responsive carboxylase deficiency was made posthumously.

The patient was first seen at 34 weeks of gestation. Prenatal diagnosis was not attempted because of the late stage of pregnancy. The maternal urinary organic acid profile was normal throughout the final 4 weeks of pregnancy. Because of severe neonatal manifestations in the previous siblings and the probable harmlessness of biotin, oral administration of this compound to the mother was begun at a dose of 10 mg/day. There were no apparent untoward effects; maternal urinary biotin excretion increased by a factor of approximately 100 during biotin administration.

Non-identical twins were subsequently delivered at term. Cord blood and urinary organic acid profiles were normal, and cord blood biotin concentrations were four to seven times greater than normal. The neonatal course for both twins was unremarkable. Subsequent study of the cultured fibroblasts of both twins compared under biotin-rich and biotin-depleted growth conditions indicated that, in biotin-depleted medium, the cells of twin B (but not of twin A) had virtually complete deficiency of all three carboxylase activities. Genetic complementation studies confirmed that, despite the normal clinical presentation during the newborn period, twin B was homozygous for the disease mutation.

Packman *et al.*[13] have also reported prenatal diagnosis and treatment of biotin-responsive multiple carboxylase deficiency for a mother who had previously given birth to a male with the neonatal-onset form of this disease. In the next pregnancy, maternal urine organic acid profiles were normal. The three carboxylase activities were assayed in cultured amniotic fluid cells obtained by amniocentesis at 17 menstrual weeks. In biotin-restricted medium, the amniotic cells demonstrated the characteristic severe reduction in carboxylase activities.

The preceding two cases provide compelling evidence that biotin administration effectively prevents neonatal complications in certain patients with biotin-responsive multiple carboxylase deficiency. No toxicity from treatment was observed. At this time, it is not possible to assess definitively the relative advantages or disadvantages of prenatal treatment, although such therapy appears both effective and logical.

Galactosemia

Galactosemia is an inborn error of metabolism caused by diminished activity of the enzyme galactose-1-phosphate uridyltransferase. It is inherited in an autosomal recessive manner and results in cataracts, growth deficiency and ovarian failure. Galactosemia can be diagnosed prenatally by study of cultured amniocytes and chorionic villi. Clinical symptoms appear in the neonatal period and can be largely ameliorated by elimination of galactose from the diet. However, oocytes have already been damaged irreversibly long before birth. Cellular damage in galactosemia is thought to be mediated by accumulation of galactose-1-phosphate intracellularly and of galactitol in the lens.

There are suggestions that even the early postnatal treatment of galactosemic individuals with a low galactose diet may not be sufficient to ensure normal development. Some have speculated that prenatal damage to galactosemic fetuses could contribute to subsequent abnormal neurological development and to lens cataract formation. Furthermore, it has been recognized recently that female galactosemics, even when treated from birth with galactose deprivation, have a high frequency of primary or secondary amenorrhea because of ovarian failure. There may also be some subtle abnormalities of male gonadal function.

Exposure to a high-galactose diet has been considered to represent an animal model for human galactosemia. Chen *et al.*[14] have observed a reduction in the oocyte content of rat ovaries after prenatal exposure to a 50% galactose diet. No analogous alterations in the testes were observed in prenatally treated males. Experiments in rats suggest that toxicity to the female gonads from galactose or its metabolites is most obvious during the premeiotic stages of ovarian development.

These observations in animals and human beings have led to speculation that galactose restriction during pregnancy may be desirable if the fetus is affected with galactosemia. In the human female, ovarian meiosis begins at 12 and is complete by 28 menstrual weeks. Thus, ovarian damage, and perhaps neurological or lens abnormalities, might occur prior to the usual time when prenatal diagnosis by amniocentesis can be accomplished. Thus, anticipatory treatment in pregnancies at risk for having a galactosemic fetus might best be initiated very early in gestation or even preconceptually.

Despite these experiments and speculations, we are unaware of studies that adequately assess the impact

of prenatal administration of a low-galactose diet to galactosemic infants. For obvious reasons such data, especially controlled, will be difficult to obtain. Nevertheless, prenatal galactose restriction is probably desirable in galactosemia and should be harmless. There is little reason to suppose that galactose restriction would have adverse consequences, since galactosemic and normal fetuses are both capable of some endogenous galactose synthesis.

Hypothyroidism

Fetal hypothyroidism may have severe fetal and neonatal consequences. Fetal esophageal obstruction, secondary to a goiter, can lead to polyhydramnios, and may result in preterm delivery. Furthermore, a fetal goiter can cause extension of the fetal neck leading to dystocia. Without treatment, postnatal growth delay and severe mental retardation can ensue. Even with immediate diagnosis and treatment at birth, long-term follow-up of children with congenital hypothyroidism has shown them to have lower scores on perceptual-motor, visuospatial and language tests.[15]

Maternal hyperthyroidism is often associated with fetal hypothyroidism. This may be secondary to the suppression of the fetal thyroid by maternally administered propylthiouracil. Conversely, fetal hypothyroidism may also result from transplacental passage of maternal blocking antibodies. These antibodies, known as TB1Ab (or TBII), block thyroid-stimulating hormone (TSH) binding. Occasionally, fetal hypothyroidism is the result of inadvertent use of TBII in the pregnant women, maternal ingestion of amiodarone or lithium, or excessive maternal iodine intake, sometimes in the form of vaginal douching. Fetal hypothyroidism caused by an intrinsic fetal abnormality is uncommon, occurring in 1 in 4000–5000 births.[16] The most common form of such permanent hypothyroidism in infants is thyroid dysgenesis. This may include hypoplastic and ectopic thyroid, or the total absence of thyroid tissue (athyreosis) which is associated with undetectable levels of thyroglobulin. Congenital hypothyroidism is only rarely associated with errors of thyroid hormone synthesis, TSH insensitivity or absence of the pituitary gland.

Inquiry regarding a history of maternal hypothyroidism is considered as routine. In patients with this history, routine maternal thyroid hormone levels as well as blocking immunoglobulin levels should be measured. In addition, all women with a history of any thyroid disease (both hypothyroidism and hyperthyroidism) are advised to have monthly fetal ultrasound to screen for goiter, polyhydramnios or fetal tachycardia.[17]

Fetal goiterous hypothyroidism is initially identified by ultrasound. Most commonly, the indication for the ultrasonographic scan is a fundal height greater than expected by gestational age. In such cases the increased uterine size is caused by polyhydramnios, resulting from esophageal obstruction and impaired swallowing. Sometimes, a fetal goiter is incidentally discovered on a routine scan. Finally, some cases are diagnosed on serial scans in fetuses with either known elevated maternal thyroid immunoglobulins, or maternal treatment with antithyroid medications. Before the advent of cordocentesis, amniotic fluid levels of TSH and free thyroxine (FT4) were used as potential indicators of fetal thyroid function. However, these proved inconsistent.[18] Currently, with cordocentesis, fetal thyroid status can be directly and accurately evaluated and fetal response to therapy reliably measured, using available nomograms.[17,19] Fetal hypothyroidism is diagnosed by measuring fetal serum levels of free T4, total T4, free T3, total T3 and TSH.

In utero treatment was initially suggested by Van Herle *et al.*[20] using intramuscular injection of levothyroxine sodium. Subsequent studies, however, have indicated that intra-amniotic administration of thyroxine is superior. The doses commonly used for treatment range from 200 to 500 mg intra-amniotic every week.[21] More recently, it has been recommended that the dosage be adjusted for the fetal weight using 10 mg/kg, similar to the recommended dose for neonates.[22] With this regimen, fetal goiters have been shown to regress, and fetal and newborn TSH levels have normalized.

Hyperthyroidism

Neonatal hyperthyroidism is rare with an incidence of 1:4000 to 1:40,000.[23] In these cases, fetal thyrotoxic goiter is usually secondary to maternal autoimmune disease, principally Graves' disease or Hashimoto's thyroiditis. It is estimated that as many as 12% of infants of mothers with a known history of Graves' disease are affected with neonatal thyrotoxicosis. This may even occur despite the fact that the mother may be euthyroid.[24] As with hypothyroidism, inherent to the underlying mechanism is the transplacental passage of maternal IgG antibodies. In this case the antibodies, known as TSAb (or TSI), are predominantly directed against the TSH receptor.

Usually, the investigation of fetal hyperthyroidism begins only after the discovery of fetal goiter. Often, the goiter is diagnosed on ultrasound in patients referred due to elevated thyroid-stimulating antibodies. In some cases, fetal goiters are realized serendipitously on routine ultrasonography. Others may be discovered in patients referred for scan because the fundal height measures greater than expected by gestational age. In these cases there is often polyhydramnios as a result of the goiter. Once a fetal goiter is identified, biochemical evaluation is indicated. Historically, amniotic fluid levels of TSH and FT4 were used as potential indicators of fetal thyroid function. These, however, proved inconsistent in that amniotic fluid levels of these hormones do not

always correlate with their serum levels. Some controversy still exists regarding their use; however, and they may be of some benefit in centers that do not have available cordocentesis.[18] With the advent of cordocentesis, fetal thyroid status can be reliably documented[17,19] and treatment planned according to the results (Figures 105.1 and 105.2).

Once the diagnosis of fetal hyperthyroidism is confirmed, fetal treatment should be initiated. Authors have attempted treatment of fetal hyperthyroidism with maternally administered antithyroid drugs. Porreco and Bloch[25] have reported maternal treatment of fetal thyrotoxicosis with propylthiouracil which led to a good outcome. The initial dose used was 100 mg orally three times a day, which was later decreased to 50 mg orally three times a day. Wenstrom *et al.*[26] described a favorable outcome using maternal methimazole to treat fetal hyperthyroidism in a patient who could not tolerate propylthiouracil. Hatjis also treated fetal goiterous hyperthyroidism with a maternal dose of 300 mg propylthiouracil. This patient, however, required supplemental synthroid to remain euthyroid. There was good fetal outcome in this case as well.[27]

Abnormalities of mineral metabolism

Specific prenatal mineral supplementation has yet to be reported for prevention of human fetal disease. However, such additives have been used in animals with genetic deficiencies. Animal studies are of considerable interest and suggest the possibility of analogous human treatment.

Manganese

The effects of prenatal manganese supplementation on the prevention of otolith defects in mice affected with the pallid mutation have been investigated. Pallid mice have defective pigmentation, including an absence of pigment from the membranous labyrinth. This pigmentary characteristic is fully penetrant in the pallid homozygous recessive, whereas another manifestation, impaired otolith formation, is variably expressed. A significant correlation between litter size and the expression of the otolith abnormalities in the offspring have been known for decades; the otolith defect may be influenced by competition *in utero* for an unidentified substance.

Hurley and Bell[28] reported that development of the inner ear in normal rats and mice was affected by decreased manganese. In mice, experimental manganese deprivation *in utero* induced a defect of the inner ear that was morphologically and behaviorally indistinguishable from pallid, although manganese deficiency did not mimic the effect of the mutant gene on pigmentation. Subsequently, these investigators observed that manganese supplementation of pallid mice throughout gestation with a diet containing from 45 to 2000 parts per million of manganese yielded a dose-dependent decrease in the percentage of abnormal otoliths.

These data have been extended to a genetic basis for susceptibility. In several studies on prenatal manganese restriction, the percentage of otolith abnormalities was influenced by the strain of mice studied. Thus, interactions of manganese intake and genetic predisposition influence otolith development in several strains. These observations suggest that, at low or borderline levels of dietary intake of many nutrients, the genotype of the fetus can substantially alter fetal responses.

There are a number of genetic defects in animals with associated pigmentary and inner ear abnormalities. Some data suggest that manganese may play a role in modifying the expression of such defects. Hurley and Bell have suggested that a sex-linked form of ocular albinism in humans, associated with labyrinthine dysfunction, may be analogous to some of these animal models. We are unaware of any studies of manganese metabolism in human ocular albinism, or of attempts to administer manganese prenatally in the hope of ameliorating expression of any associated labyrinthine defects.

Copper

Hurley and Bell[28] have investigated possible deleterious effects of prenatal copper administration on mice with the recessive mutant 'crinkled' gene. These investigators have suggested that the 'crinkled' gene produces many phenotypic characteristics common to patients with Menkes' kinky-hair syndrome. Dietary supplementation of pregnant mice with copper sulfate partially ameliorated the effects of the crinkled gene in the offspring. Different prenatal copper regimens have resulted in varying degrees of success. Copper nitrilotracete appeared to be superior to copper sulfate in increasing postnatal survival and body copper content of the mutant offspring of heterozygous dams. Postnatal supplementation with copper did not increase survival of the mutants.

These studies may lead to insights relevant to prenatal treatment of Menkes' syndrome, a sex-linked disorder characterized by progressive degeneration of neurological function in infants. Alterations suggestive of functional copper deficiency are present in affected infants. Fibroblasts from patients with Menkes' disease accumulate excess copper probably present in an abnormally bound form. Menkes' disease has been refractory to postnatal therapy with copper, and it is conceivable that, by analogy to the crinkled mutation, prenatal treatment might be of benefit.[29]

Despite apparent responses to prenatal mineral administration of pallid and crinkled mutations, the relationships of these mutants, if any, to ocular albinism and Menkes' disease, respectively, remain

speculative. Although animal studies have proved encouraging, they have not yet led to trials of prenatal mineral supplementation in genetically defective human beings.

Nutritional approaches

It might be appropriate to consider suppressing excessive cholesterol production prenatally in severe hypercholesterolemia if a safe and effective agent for accomplishing this were available (although there is no clear evidence for hypercholesterolemic prenatal damage). If cysteamine or related agents were to prove an effective treatment for lethal variants of cystinosis, prenatal therapy might be considered, because excessive and possibly harmful cystine accumulation is evident in cystinotic fetuses. Cysteamine levels have been detected in chorionic villi, and significant elevations even at 10 weeks of gestation have been hypothesized. Inhibitors of gamma-glutamyl transpeptidase, if safe, would elevate intracellular glutathione levels and inhibit oxoproline production in glutathione synthase deficiency, thereby averting the characteristic neonatal acidosis. In theory, it would be desirable to minimize copper accumulation in Wilson disease as early as possible. If and when reliable prenatal diagnosis of Wilson disease is possible, cautious administration of penicillamine prenatally might be considered. This would be a double-edged sword, however, as the teratogenic and lathyritic potential of penicillamine would demand careful evaluation. Batshaw *et al.* have treated certain urea cycle defects by administering arginine and benzoate. Since hyperammonemia in some of these entities develops very acutely after birth, it might be desirable to consider pretreating the fetus with these compounds just prior to, or during labor to minimize postnatal hyperammonemia.[30] Conversely, it may be desirable to consider drug avoidance as an approach to fetal treatment. For example, fetuses with glucose-6-phosphate dehydrogenase deficiency are sensitive to a variety of drugs that induce hemolysis. It would probably be appropriate to avoid administering such agents to women carrying or known to be at risk for carrying fetuses deficient in glucose-6-phosphate dehydrogenase.

Umbilical cord catheterization under ultrasound guidance may lead to the development of other types of fetal treatment.[31] Systems such as gene replacement are being developed for certain lysosomal storage disorders. Progress is being made in postnatal experimental models on administration of thymic cells for certain immune deficiency states, bone marrow transplantation for a variety of genetic disorders and gene transfer. The development of better and earlier techniques for prenatal treatment will be complex, especially with regard to gene transfer, but progress will be made, and access to the fetal vasculature may be required for these methods to have a chance for success.

Bone marrow transplantation or thymic cell infusion is actually only a specialized example of organ transplantation. In the future, fetal organ transplantation may become possible and may open many prospects for surgical treatment of certain biochemical genetic disorders.

One can also speculate about the therapeutic possibilities involving compounds administered directly into the amniotic fluid or into the fetal intestinal tract. It might be possible, for example, to administer thyroid hormone in this fashion or to prevent meconium ileus in cystic fibrosis by instilling not yet determined enzymes into the fetal intestinal tract.

Multifactorial disorders

Cardiac fetal therapy

Although great strides have been made in the diagnosis of fetal cardiac anatomical and functional abnormalities, *in utero* cardiac therapy currently is limited to the treatment of significant arrhythmias. In the future, treatment of some congenital anomalies, particularly valvular anomalies, may be attempted prenatally. Treatment of fetal arrhythmias is discussed elsewhere.

Neural tube defects

Animal studies suggest that neural tube defects (NTDs) can arise from a variety of vitamin or mineral deficiencies. There are historical data in humans suggesting increased NTD frequencies in subjects with poor dietary histories or with intestinal bypasses. Biochemical evidence of suboptimal nutrition is present in some women bearing infants with NTDs. In 1980, Smithells *et al.*[32,33] suggested that vitamin supplementation containing 0.36 mg folate can reduce the frequency of NTD recurrence by sevenfold in women with one or more prior affected children. For almost a decade, there has been a great deal of controversy regarding the benefit of folate supplementation for the prevention of NTDs.[34–37] Finally, in 1991, a randomized double-blinded trial designed by the Medical Research Council Vitamin Study Research Group demonstrated that preconceptual folate reduces the risk of recurrence in high-risk patients.[38] Subsequently, it was shown that preparations containing folate and other vitamins also reduce the occurrence of first-time NTDs.[39] In response to these findings, guidelines were issued calling for consumption of 4.0 mg/day folic acid by women with a prior child affected with an NTD, for at least 1 month prior to conception and through the first 3 months of pregnancy. In addition, 0.4 mg/day folic acid is recommended to all women planning a pregnancy to be taken preconceptually.

Conclusion

There are several different systems that have been clearly shown to be amenable to prenatal pharmacological intervention. For some, such as CAH and NTDs, birth defects can be prevented. For others, physiology can be altered, but the long-term consequences of earlier intervention are not yet clear and will require much more work. Nevertheless, these efforts have given us a better understanding of fetal physiology, and help us to design better approaches to treatment.

106 Management of red cell isoimmunized pregnancies

K. H. Nicolaides and N. J. Sebire

In red cell isoimmunized pregnancies, the degree of severity of hemolytic disease in the infant varies from none apparent at birth to fetal hydrops and intrauterine death at as early as 17 weeks of gestation. Without any form of treatment, 45–50% of affected infants have no or mild anemia, and a further 25–30% have some degree of hepatosplenomegaly, moderate anemia and jaundice, which develops rapidly within the first 24 h of life. If appropriate treatment (exchange transfusion) is not carried out, the progressive jaundice leads to brain damage (kernicterus) which will culminate in death or severe handicap (deafness, spasticity and choreoathetosis). The remaining 20–25% become hydropic and usually die either *in utero* or in the neonatal period; in half of these the hydrops develops at between 18 and 30 weeks of gestation.[1] In the antenatal management of red cell isoimmunized pregnancies, the aim is firstly to predict whether the fetus is severely affected, and if so, at what stage of pregnancy fetal hydrops will develop or intrauterine death will occur, and secondly to correct the fetal anemia and to deliver the baby at the optimal time. There are at least 100 red cell surface antigens and the development of maternal antibodies to approximately 30 of these can lead to fetal hemolytic disease. However, the vast majority of cases are the result of either ABO incompatibility (two-thirds of cases) or rhesus incompatibility.

ABO incompatibility

Although ABO feto-maternal incompatibility occurs in about 20% of all pregnancies, fetal hemolysis occurs rarely (< 2%), and this is usually mild.[2] The condition is almost exclusively confined to group A and B infants born to group O mothers, since some group O mothers have anti-A and anti-B antibodies from the IgG class, which can cross the placenta. Group A and B individuals usually have only immunoglobulin M (IgM) anti-B and anti-A antibodies which do not cross the placenta. The reasons for the mildness of the condition are: (a) there is a small number of A and B antigenic sites on the fetal red cell membrane and full expression of these antigens does not occur until the age of 2–4 years; and (b) the A and B antigens are present in all tissues and secretions and they compete with the red cell antigens for the small number of maternal IgG antibodies entering the fetal circulation. Because of the mildness of the fetal disease, no special antenatal measures are necessary for the management of these pregnancies. After delivery the baby is tested for the development of hyperbilirubinemia, and if this occurs exchange transfusions are performed.

Rhesus incompatibility

Management of rhesus-negative women without antibodies

In rhesus-negative women, the rhesus status of the partner is determined; if he is also rhesus-negative then the fetus must necessarily be rhesus-negative and the pregnancy is therefore not at risk of rhesus isoimmunization disease. If the father is rhesus-positive then further maternal antibody screening should be undertaken at 20 weeks and at 4-weekly intervals thereafter until delivery. Following delivery, umbilical cord and maternal blood are tested. The cord blood is tested for the rhesus status of the fetus, the Coombs' test is carried out for the presence of antibodies on the fetal erythrocytes, and the hemoglobin concentration is measured. The maternal blood is tested for antibodies, and a Kleihauer test[3] is performed to estimate the degree of feto-maternal hemorrhage. If the mother has no antibodies and the baby is rhesus D-positive, anti-D IgG is given.

Prevention of rhesus D isoimmunization

Anti-D administration is effective in preventing immunization in a rhesus-negative woman, but has no effect if the woman is already isoimmunized. The

administration of 100 μg anti-D IgG to a mother will neutralize at least 4 ml of rhesus D-positive fetal erythrocytes that might have entered her circulation; this is equivalent to a Kleihauer count of 80 fetal cells per 50 low-power fields. This dose of anti-D IgG should be given to all rhesus-negative, unimmunized women within 72 h of the delivery of a rhesus-positive baby. Furthermore, a Kleihauer test should be performed on the maternal blood and further anti-D given if the feto-maternal hemorrhage is greater than 4 ml. Anti-D should also be administered antenatally if abortion, antepartum hemorrhage, amniocentesis or other potentially immunizing episodes occur. In some countries there is a policy of antenatal prophylaxis for all rhesus-negative women (anti-D IgG 300 μg is given at 28 weeks, or 100 μg at 28 and 34 weeks).

Atypical blood group incompatibility

With the use of anti-D prophylaxis and the fall in incidence of rhesus D isoimmunization, an increasing proportion of isoimmunized pregnant women have either non-rhesus antibodies or rhesus antibodies other than D antibodies. The main reason for the development of these antibodies is blood transfusions. So-called compatible blood transfusions are compatible to ABO and D, but transfused red cells have many antigens that are missing in the recipient. Following blood transfusions, 1–2% of recipients develop 'atypical' antibodies. The majority of these are either IgM or very weakly immunogenic and either do not produce hemolytic disease in the fetus (e.g. anti-P) or very rarely do so (e.g. anti-M, anti-N, anti-S). Some of the antibodies, however, such as anti-C, anti-E and anti-Kell, can cause severe hemolytic disease and intrauterine death. Pregnancies complicated by the presence of these antibodies should therefore be managed in the same way as those with rhesus D incompatibility.

Pathophysiology of fetal anemia

In normal pregnancy, the fetal mean hemoglobin concentration increases linearly with gestation from 10 g/dl at 16 weeks to 15 g/dl at 40 weeks, and 1 SD is approximately 1.2 g/dl.[4] In red cell isoimmunized pregnancies the lifespan of fetal erythrocytes is reduced, because antibody-coated red cells are destroyed in the reticuloendothelial system. Moderate anemia is defined by a hemoglobin concentration deficit of 2–4 SD, and severe anemia by a deficit of more than 4 SD. The fetal blood oxygen content decreases in proportion to the degree of anemia, but the fetal blood pO_2, pCO_2 and pH usually remain within the normal ranges.[5]

The fetus compensates for anemia by hemodynamic adjustments as demonstrated by Doppler ultrasound studies.[6] Furthermore, in anemia the fetal 2,3-diphosphoglycerate concentration is increased and the consequent decrease in hemoglobin oxygen affinity presumably improves delivery of oxygen to the tissues.[7] In moderate anemia, the umbilical arterial plasma lactate concentration is increased, but this is cleared by a single passage through the placenta and normal umbilical venous levels are maintained.[8]

In severe anemia, the placental capacity for lactate clearance is exceeded and the umbilical venous concentration increases exponentially. When the hemoglobin deficit exceeds 5 SD, the functional reserve of the cardiovascular system is exhausted and hydrops fetalis develops.[4] Furthermore, with severe anemia there is concomitant occurrence of erythroblastosis.[4] Since the latter reflects recruitment of hepatic erythropoiesis, fetal hydrops may be a consequence of portal hypertension and/or hypoproteinemia due to expansion of erythropoietic tissue in the liver.[9–12]

Prediction of fetal anemia

The severity of fetal hemolysis can be predicted from (a) the history of previously affected pregnancies, (b) the level of maternal hemolytic antibodies, (c) the amniotic fluid bilirubin concentration, (d) the altered morphometry of the fetus and the placenta, (e) the presence of pathological fetal heart rate patterns, and (f) changes in the flow velocity waveforms obtained by Doppler studies of the fetal circulation. However, there is a wide scatter of values around the regression lines describing the associations between the degree of fetal anemia and the data obtained from these indirect methods of assessment.

History of previously affected pregnancies

The disease tends to be progressively more severe with successive pregnancies because of the 'boosting' effect of small feto-maternal hemorrhages during pregnancy and delivery. Thus, once a rhesus stillbirth or hydrops has occurred in a family, there is a 90% chance that the next rhesus-positive infant, if left untreated, will also die *in utero*. It has been estimated that after one previous stillbirth 50% of subsequent stillbirths occur *in utero* before 35 weeks, but after more than one stillbirth 50% die before 32 weeks of gestation.[13]

Maternal hemolytic antibody concentration

The association between maternal serum hemolytic antibody concentration and pregnancy outcome has been recognized from the 1950s, and measurement of maternal anti-D has been the main method of managing red blood cell isoimmunized pregnancies. The traditional method of detecting rhesus antibodies in the maternal serum is the indirect Coombs' test.[14] Low titers ($< 1/32$) correspond to mild disease in the

fetus.[15,16] When the titer is >1/32 the disease may be severe. In a study of 208 rhesus isoimmunized pregnancies at 17–36 weeks of gestation, the maternal serum anti-D concentration was measured and the fetal hemoglobin concentration was determined; there was a significant association between the maternal hemolytic antibody concentration and the fetal hemoglobin concentration deficit.[17] However, there was a wide scatter of results which could be due to individual variation in the rate of transfer of antibody across the placenta, expression of antigens in fetal red cells, and fetal erythropoiesis in response to hemolysis. Nevertheless, the association allowed estimation of probabilities of different degrees of fetal anemia from measurement of maternal anti-D concentration. If the maternal anti-D concentration is =5 IU/ml there is a 97% chance that the fetus is not anemic. Levels between 5 and 14 IU/ml are associated with moderate but not severe anemia. In contrast, if the anti-D concentration is >15 IU/ml there is a 30% chance that the fetus is anemic, and in more than 5% of cases, depending on the actual level, the degree of anemia is severe and in such cases cordocentesis is indicated.

Pollock and Bowman[18] suggested that instead of measuring total IgG, a more accurate prediction of the degree of fetal anemia could be provided by examining different subclasses, since IgG3 is less likely to be associated with hydrops, while a combination of IgG1 and IgG3 is associated with the most severe disease. Similarly, *in vitro* assays of cell-mediated immune response against Rh-positive cells can be performed, but there is no clear relationship with the degree of anemia in such studies.[19–21]

Amniocentesis and cordocentesis

Measurement of the bilirubin concentration in the amniotic fluid gives an indirect indication of the degree of fetal hemolysis.[22,23] Although there are many methods for the interpretation of the amniotic fluid AOD 450,[24] the most widely employed method is that of Liley.[25,26] Amniocentesis has been recommended when the maternal antibody level is more than 4 IU/ml, or 10 weeks before the gestational age at which the patient had a previous fetal death or delivery of a severely affected baby.[27] For the third trimester of pregnancy amniocentesis and interpretation of amniotic fluid OD 450 values by the Liley method has proved to be reliable.[28] However, the validity of extrapolating the Liley charts to the second trimester has been questioned, and it has been suggested that amniocentesis does not provide more accurate information than other non-invasive tests for predicting the degree of fetal anemia.[17]

Cordocentesis provides the most direct, therefore accurate, measure of fetal anemia. In addition to fetal hemoglobin concentration, it is possible to measure other hematologic and biochemical indices which may provide further prediction of the degree of anemia. For example, the reticulocyte and nucleated red cell count may be increased,[29,30] serum bilirubin levels increased,[31] fetal erythropoietin levels increased,[32] and blood gases perturbed, although this is a late feature of the disease. All such additional results, although improving our understanding of the pathophysiology of the disease, have not been proven useful in the clinical management of affected patients.

Fetal–placental morphometry

Attempts have been made to identify by ultrasonography those fetuses whose condition is deteriorating, before the development of ascites and hydrops. These studies have assessed changes in placental, hepatic, splenic or cardiac appearance, which are logical choices considering the pathophysiology of the condition. Vintzileos *et al.*[33] suggested that an ultrasonographically-detected increase in the size of the fetal liver is an early sign of fetal anemia. DeVore *et al.*[34] proposed that enlargement of the fetal liver would compress hepatic vessels, leading to decreased venous drainage of the umbilical vein, and therefore umbilical vein dilatation. Grannum[35] suggested that an increase in placental thickness usually indicates worsening fetal anemia. Chitkara *et al.*[36] documented fetal anemia by cordocentesis and demonstrated that in moderate to severe disease the development of polyhydramnios was the earliest sonographic abnormality. DeVore *et al.*[37] found the detection of a fetal pericardial effusion using real-time-directed M-mode echocardiography to be a valuable sign, while Benacerraf and Frigoletto[38] have noted that visualization of both sides of the fetal bowel wall may be the earliest evidence of fetal ascites. Oepkes *et al.*[39] measured the fetal spleen by ultrasound and found splenomegaly in all non-hydropic anemic fetuses.

In a study investigating the relationship between placental thickness, umbilical vein diameter or fetal abdominal circumference, head-to-abdomen circumference ratio and intraperitoneal volume and the degree of fetal anemia, assessed by direct fetal blood sampling, in 50 pregnancies complicated by rhesus isoimmunization it was concluded that: (a) in the presence of hydrops the fetuses are always severely anemic; and (b) in the absence of hydrops there are no consistent ultrasonographically-detectable markers that can reliably distinguish mild from severe hemolytic disease.[40]

Fetal heart rate patterns

In red cell isoimmunized pregnancies, reports on fetal heart rate monitoring have focused on the association between fetal compromise and the sinusoidal fetal heart rate pattern. Rochard *et al.*[41] reported the presence of a sinusoidal pattern in severely compromised fetuses that are either hydropic or die in the perinatal period. Studies examining the relationship between fetal heart rate patterns and fetal blood gases and

hemoglobin concentrations obtained at cordocentesis have established that: (a) severe fetal anemia or oxygen content deficit are commonly associated with a sinusoidal fetal heart rate pattern; and (b) although a non-reactive or decelerative fetal heart rate pattern is suggestive of fetal anemia, the vast majority of moderately anemic fetuses have a reactive fetal heart rate pattern.[42,43]

Doppler ultrasound

Doppler ultrasound provides a non-invasive method for the study of fetal hemodynamics. Investigation of the uterine and umbilical arteries gives information on the perfusion of the utero-placental and feto-placental circulations, respectively, while Doppler studies of selected fetal organs are valuable in detecting the hemodynamic rearrangements that occur in response to fetal hypoxemia or anemia. In red cell isoimmunization, impedance to flow in the uterine and umbilical arteries is normal. However, fetal anemia is associated with increased cardiac output, increased blood flow in the umbilical vein, and increased blood velocity in the inferior vena cava, the descending thoracic aorta, and the common carotid and middle cerebral arteries.[44–47]

Treatment

Determination of fetal blood type

Fetal blood type can be reliably determined by fetal blood sampling.[48] More recently, however, with the use of molecular biology techniques, specifically the polymerase chain reaction, it is possible to identify the rhesus D gene[49] from diverse samples including fetal blood, amniotic fluid, chorionic villus biopsy, and even nucleated fetal cells in the maternal circulation.[50–57] This information in early pregnancy may avoid unnecessary invasive testing in later pregnancy if negative, and allow planning of subsequent samplings and/or transfusions if positive. Further modifications of the technique of isolating fetal cells in the maternal circulation (to eliminate false-negatives in particular) may lead to this becoming a routine part of antenatal care in such pregnancies.

Experimental techniques for therapy

During the last 50 years, several therapeutic approaches have been undertaken in the management of red cell isoimmunized pregnancies, with the aim of ameliorating the severity of the condition and preventing intrauterine fetal death. These include (a) reduction or alteration of maternal rhesus antibodies by such measures as plasmapheresis or the injection or ingestion of material prepared from rhesus-positive red cells,[58–62] (b) prevention of fetal hemolysis by immunosuppression with corticosteroids and promethazine hydrochloride,[63–66] (c) increasing fetal red cell production by the administration of high doses of vitamin B_{12}, folic acid and other known hematinics,[67] and (d) alteration of the fetal blood group by bone marrow transplantation from rhesus-negative donors to erythroblastotic fetuses at 12–17 weeks of gestation.[67,68] However, these attempts have been mainly experimental and have not gained widespread application.

The first intrauterine intravascular fetal blood transfusions for severe rhesus disease were performed in the 1960s by cannulation of the fetal femoral artery, the saphenous vein or a chorionic plate vessel, which were exposed by hysterotomy.[69–71] These techniques of open fetal transfusion were associated with high rates of fetal mortality, mainly due to preterm delivery, and were subsequently abandoned in favor of the less invasive percutaneous intraperitoneal route.[72] Nonetheless, they had the advantage of providing accurate data regarding the degree of fetal anemia and the severity of the disease.

Intraperitoneal transfusions

During the 1960s and early 1970s the reported fetal survival rates with intraperitoneal transfusions were 24–56%, and the procedure-related fetal mortality rate was 5–10%.[73] More recently, the extensive use of ultrasonography in the assessment, treatment and follow-up of affected fetuses has contributed to a dramatic improvement in survival rates of non-hydropic fetuses. Nevertheless, the outlook for hydropic fetuses remains poor,[74] possibly because in the presence of ascites resorption of erythrocytes is impaired.

Intravascular transfusions

In the 1980s, interest in the intravascular route was renewed with the development of a technique for transfusion through an umbilical cord vessel by fetoscopy.[75,76] More recently, fetoscopy was replaced by cordocentesis[48,77,78] or needling of the intrahepatic umbilical vein.[79]

At cordocentesis, a fetal blood sample is first obtained and the hemoglobin concentration determined. If this is below the normal range, the tip of the needle is kept in the lumen of the umbilical cord vessel and fresh, packed, rhesus-negative blood compatible with that of the mother, or irradiated maternal blood, is infused into the fetal circulation. The fetal heart rate and the flow of the infused blood are monitored continually throughout the procedure by ultrasonography. At the end of the transfusion, a further fetal blood sample is aspirated for determination of the final hemoglobin concentration.

Transplacental, rather than transamniotic, entry of the umbilical cord reduces the risk of displacement of the needle by fetal movements, and avoids both leakage of amniotic fluid and intra-amniotic fetal bleeding since the amniotic membrane is not punctured.

However, feto-maternal hemorrhage is more likely, which may increase the severity of the disease.

Theoretically, the umbilical artery should be the preferred route for intravascular fetal blood transfusion, both in order to achieve oxygenation and buffering of the acidotic donor blood in the placenta before it enters the fetus, and because thrombotic occlusion of one of the two umbilical arteries rather than the single umbilical vein may not be fatal. However, in practical terms it is more advantageous to transfuse into the vein because: (a) the sonographic observation of the intravascular flow of blood provides constant reassurance that the tip of the needle has not slipped into the Wharton's jelly, where injection of even 1 ml of blood could lead to cord tamponade and fetal death; (b) fetal bradycardias occur more often and last longer when transfusing into an artery than a vein, presumably as a result of procedure-related spasm of the more muscular umbilical artery; and (c) intra-amniotic bleeding occurs more often and lasts longer after withdrawal of the needle from an artery than a vein, presumably as a result of the higher arterial than venous blood pressure.

Transfusions are given at a rate of approximately 10 ml/min without inducing fetal heart rate decelerations. The advantage of rapid 'top-up' transfusions is that the duration of transfusion and therefore the risks of procedure-related complications such as infection, or cord accidents as a result of fetal movements (tamponade, vasospasm or hemorrhage), is decreased. The volume of donor blood necessary to correct fetal anemia can be calculated by considering the pretransfusion fetal hemoglobin concentration, the hemoglobin of the transfused blood, the desired post-transfusion hemoglobin, and the normal mean feto-placental blood volume for that gestation.[80] After transfusion of the calculated volume of donor blood, the fetal hemoglobin is measured, and further blood transfused as necessary to bring the final value to around the 75th percentile of the reference range.

For patients with a previous red cell isoimmunization-affected pregnancy, an effort should be made to perform the first cordocentesis at approximately 10 weeks before the time of the earliest previous fetal or neonatal death, fetal transfusion, or birth of a severely affected baby, but not before 16–17 weeks of gestation. In our experience, from the management of more than 500 rhesus isoimmunized patients, fetal death or the development of hydrops rarely occur before this stage of gestation, presumably because the fetal reticuloendothelial system is too immature to result in massive destruction of antibody-coated erythrocytes. In patients without a previously-affected pregnancy, cordocentesis should be performed (a) if the fetus develops ultrasound features of hydrops such as ascites, (b) when the maternal hemolytic antibody level is 15 IU/ml or more, (c) if the fetal heart rate is sinusoidal or decelerative, and (d) if Doppler studies demonstrate hyperdynamic fetal circulation.

Subsequent transfusions are timed on the basis of the fetal hemoglobin achieved at the end of the previous transfusion, and the observation that following a transfusion the rate of decrease in fetal hemoglobin is approximately 0.3 g/dl per day and in fetal hematocrit is 0.01 g/dl per day.[48,81] However, although this figure is useful in timing the next transfusion, there is a wide range of results and it is therefore necessary to use additional criteria, such as weekly ultrasound scans to detect early ascites and blood velocity measurements to detect the hyperdynamic circulation of developing anemia. Transfusions are repeated up to 35–38 weeks and delivery is aimed at 34–38 weeks.

The reported overall survival rate of red cell isoimmunized pregnancies treated with intravascular transfusions is more than 85% (Table 106.1). The survival rate for non-hydropic fetuses is more than 90%, whereas in the presence of hydrops the survival rate is less than 80%.[30,78,79,81–97]

Summary

The only accurate method for determining the severity of disease is blood sampling by cordocentesis and measurement of the fetal hemoglobin concentration. However, cordocentesis may result in feto-maternal hemorrhage,[98] an increase in the maternal hemolytic antibody concentration,[99] and consequent worsening of the disease. It should therefore be reserved for those patients with a history of severe disease and those with high hemolytic antibody levels, pathological fetal heart rate patterns or abnormal flow velocity waveforms.

In patients with a history suggestive of severe disease, cordocentesis should be performed 10 weeks before the time of the earliest previous fetal or neonatal death, fetal transfusion or birth of a severely affected baby. For patients with mild or no previous rhesus-affected pregnancies, the maternal hemolytic antibody levels should be determined every 2–3 weeks from 16 weeks of gestation onwards. In those pregnancies where antibody concentrations are persistently below 15 IU/ml, delivery should be allowed to occur spontaneously at term. However, if the antibody levels are $\geq$15 IU/ml, the disease may be severe and the degree of the hemolytic process in the fetus should be determined by cordocentesis.

If the fetus is not anemic, another cordocentesis should be considered if (a) the mother reports decreased fetal movements; (b) there is a sharp increase in the maternal hemolytic antibody concentration; (c) there is ultrasonographic evidence of fetal hydrops, early ascites or dilated heart with a pericardial effusion; (d) there is cardiotocographic evidence of a sinusoidal or decelerative fetal heart rate pattern; or (e) Doppler studies indicate the development of hyperdynamic fetal circulation.

At cordocentesis, the degree of fetal anemia can be defined accurately by measurement of the fetal hemoglobin concentration, and corrected by intrauterine blood transfusion. While this can be given intraperitoneally, the intravascular route is preferred.

107 Management of fetal and neonatal alloimmune thrombocytopenia

M. F. Murphy

Introduction

Neonatal alloimmune thrombocytopenia is the platelet equivalent of hemolytic disease of the newborn. Fetomaternal incompatibility may cause maternal alloimmunization against a fetal platelet antigen inherited from the father and absent in the mother, and fetal and neonatal thrombocytopenia may result from placental transfer of immunoglobulin G (IgG) antibodies.

Most cases are diagnosed after birth, hence the term 'neonatal alloimmune thrombocytopenia'. However, the condition develops *in utero*, and the fetus may be severely affected. It is appropriate to emphasize this through the use of alternative terminology, such as 'fetal and neonatal thrombocytopenia' or 'fetomaternal alloimmune thrombocytopenia' (FMAIT).

Considerable progress has been made in laboratory aspects of platelet immunology since FMAIT was first recognized,[1] allowing a more precise diagnosis of the condition, and there have been advances in fetal medicine and transfusion medicine resulting in considerable improvements in its antenatal and neonatal management. However, there remains a need for a better understanding of the natural history of FMAIT and for improved methods for identifying high-risk pregnancies so that antenatal intervention can be directed at those cases at greatest risk of severe thrombocytopenia and hemorrhage.

Pathophysiology

Platelet alloantigens

FMAIT is caused by the destruction of fetal platelets by maternal alloantibodies against platelet-specific alloantigens. There are a number of well-characterized biallelic platelet alloantigen systems, and a number of rare, private, or low frequency antigens have also been described (Table 107.1). Most were first discovered during the investigation of cases of FMAIT. In addition to these platelet-specific alloantigens, platelets express antigens found on many other cells, including ABO blood group and human leukocyte antigen (HLA) class I. Platelet antigens are known to be expressed from 16 weeks of gestation,[2] and placental transfer of IgG antibodies can occur from 14 weeks, so thrombocytopenia can occur very early in pregnancy.

Platelet-specific alloantigens are located on platelet membrane glycoproteins involved in hemostasis through interactions with the vascular endothelium and plasma coagulation proteins. Most of these antigens are on the GPIIb/IIIa complex, which plays a central role in platelet aggregation as a receptor for fibrinogen. Other important glycoproteins are GPIb/IX, which is the main receptor for von Willebrand factor involved in platelet adhesion to the damaged vascular endothelium, GPIa/IIa, which is involved in adhesion to collagen and CD 109 which also appears to be a collagen receptor. Congenital absence or deficiency of these glycoproteins results in bleeding disorders; for example, lack of GPIIb/IIIa causes Glanzmann's thrombasthenia and absence of GPIb/IX results in Bernard–Soulier syndrome.

Table 107.1 shows the platelet-specific antigens implicated in FMAIT according to the current human platelet alloantigen (HPA) nomenclature, in which each system is numbered consecutively (HPA-1, -2, -3, etc.) according to its date of discovery and the high-frequency allele in each system is designated 'a' and the low-frequency allele, 'b'.[3] Table 107.1 also includes the glycoprotein localization of the antigens, their frequency in a Caucasian population, and the amino acid difference on the relevant glycoprotein between the alleles in each system; for example, there is a single C–T point mutation on GPIIIa resulting in the substitution of leucine by proline in HPA-1b.[4,5] Knowledge of the genetic basis of platelet-specific antigens makes it possible to carry out molecular genotyping on whatever material is available, for example, platelet typing using fetal DNA from amniotic fluid or chorion villus

Table 107.1 HPA systems

samples. Various techniques are available, but the most commonly used is the polymerase chain reaction with sequence-specific primers (PCR-SSP).[6]

Platelet alloantibodies

Series of cases of FMAIT with detectable platelet-specific alloantibodies have shown that the commonest antibody in Caucasian women is anti-HPA-1a in 78–89% of cases, followed by anti-HPA-5b in 6–15%, and the remainder are due to other specificities.[7,8] In Japan, anti-HPA-5b and anti-HPA-4b are the most frequent antibodies. The HPA-1a/1b polymorphism is very rare in Japan and anti-HPA-1a antibodies have never been found.[9]

HLA antibodies are frequently found in pregnant women, but are not thought to cause FMAIT. This is

Table 107.2 FMAIT due to HPA-1a alloimmunization during pregnancy

Study	Number of pregnant women studied	HPA-1a-negative mothers	HPA-1a-positive fetuses (if tested)	Maternal anti-HPA-1a	Overall incidence of FMAIT
Mueller-Eckhardt *et al.* (1989)[7]	1211	26 (2.2%)	23/25	2/23 (8.7%)	2 (0.16%)

*Twins equally affected

because antibodies against fetal HLA are absorbed by placental HLA; only HLA antibodies against HLA not expressed by the fetus pass into the fetal circulation.[10]

Incidence

The incidence of FMAIT is between 1 in 1000 and 1 in 5000 live births (Table 107.2).[7,11–16] This is surprisingly low, considering that 2% of women are HPA-1a negative and that 98% of men are HPA-1a positive. However, only about 10% of HPA-1a-negative women develop anti-HPA-1a (Table 107.2).

Alloimmunization to HPA-1a appears to be HLA class II restricted. Reznikoff-Etievant and colleagues reported a strong association with HLA-DR3, which was present in 71–95% of women developing anti-HPA-1a.[17] It was later found that all alloimmunized women were positive for HLA-DRw52, and all responders tested by restriction fragment length polymorphism had the DRw52a allele at the DRB3 locus.[18,19] Further studies using the PCR-SSP showed that two cases previously typed as HLA-DRw52a (HLA-DR3*0101) were in fact HLA-DRw52c (HLA-DR3*0301), and one additional case out of seven new ones was found to be HLA-DRw53 (HLA-DR4*0101).[20] This means that FMAIT is not always associated with HLA-DRw52a, and that pregnancies in HPA-1a-negative women without this HLA type cannot be excluded from the group at risk of FMAIT. There is no similar association between HPA-1b alloimmunization and HLA-DRw52a,[21] but a significant association has been reported between HLA-DRw6 and alloimmunization to HPA-5b.[22]

It is important to note that the presence of platelet-specific alloantibodies does not necessarily mean that there will be fetal or neonatal thrombocytopenia (Table 107.2). The factors influencing the development of thrombocytopenia and its severity are poorly understood, and there is no obvious correlation with the titer or isotype of the IgG antibodies.

Diagnosis

Clinical aspects

The diagnosis of FMAIT is usually made on clinical grounds, but it can be discovered incidentally when a blood count is carried out routinely or for other reasons. Most frequently, a neonate who is otherwise well is observed to have widespread purpura at or soon after birth. The mother is healthy, and her first child is affected in 50% of cases.[7,23] These studies also found that 10–15% of infants had no evidence of bleeding, but the remainder had purpura, bruising, and/or more severe hemorrhage.[7,23] Intracranial hemorrhage (ICH), which is the major cause of mortality and long-term morbidity, occurred in 15–20% of cases. In the study of Kaplan and associates,[23] involving 127 cases, death due to severe hemorrhage occurred in 7% and there were neurological sequelae in 21%. Although there is a serious risk of severe hemorrhage at the time of delivery, nearly 50% of ICH cases occur *in utero*,[7] usually between 30 and 35 weeks of gestation, but sometimes even before 20 weeks.[8] There may be more unusual presentations, such as isolated fetal hydrocephalus, unexplained fetal anemia, or recurrent miscarriages.[24,25]

The first step in the diagnosis of FMAIT is confirmation of isolated thrombocytopenia, followed by exclusion of other causes of neonatal thrombocytopenia, such as infection, disseminated intravascular coagulation, maternal autoimmune thrombocytopenia, and conditions causing impaired neonatal megakaryocytopoiesis.

Laboratory investigations

A diagnosis of suspected FMAIT on clinical grounds requires laboratory confirmation. Testing is aimed at detection of a maternal platelet-specific alloantibody against the paternal platelets, which are a more convenient source of platelets expressing the relevant antigen

than the baby's own platelets, and determination of the platelet antigen types of the mother and father.

The investigation is best carried out in a reference laboratory which is able to carry out the necessary tests speedily and advise on clinical management. Testing usually comprises the combination of a sensitive assay using intact platelets, such as the platelet immunofluorescence test,[26] with a glycoprotein-specific antigen capture method, such as the monoclonal antibody-specific immobilization of platelet antigens assay,[27] which allows detection of weak antibodies and mixtures of antibodies. Molecular methods, such as PCR-SSP,[6] are now used for platelet genotyping.

Investigation becomes more complicated if it is not possible to demonstrate parental incompatibility for platelet-specific alloantigens by detection of the corresponding maternal antibody. Maternal platelet-specific antibodies have been reported to be undetectable in up to 20% of cases,[23] but this may be less with improved methods for detecting antibodies, and it may now be possible to demonstrate parental incompatibility for HPA-1a or another HPA in this situation. Another cause of difficulty in laboratory investigation is if a rare private antigen is involved; the mother has an antibody against the paternal platelets, but this antibody reacts with platelets from very few or no normal donors and its specificity is not obvious.

Management

Unexpected neonatal thrombocytopenia

There is as yet no routine antenatal screening for FMAIT, so most cases will be unexpected. The need for immediate treatment depends on the presence of bleeding and the severity of the thrombocytopenia. Any delays or difficulties in the laboratory confirmation of the diagnosis of FMAIT should not prevent prompt treatment of an infant with bleeding or severe thrombocytopenia.

The best way of raising the platelet count rapidly is to transfuse compatible platelets. These can be provided by plateletpheresis of the mother, in which case the concentrate should be irradiated to prevent transfusion-associated graft-vs-host disease. Ideally, a platelet concentrate prepared from the mother should also be washed to remove platelet antibodies. However, in practice, washing platelet concentrates is technically demanding and the transfusion should not be delayed unduly, as the initial transfusion may be extremely important in minimizing the risk of postnatal hemorrhage. A better strategy for providing compatible platelets before the results of serological testing are available is to transfuse platelets from HPA-1a-negative donors. Some transfusion centers ensure that HPA-1a-negative, or HPA-1a- and -5b-negative, platelet concentrates are always available for this eventuality. Often only one transfusion of compatible platelets is sufficient, as the thrombocytopenia is self-limiting. The clinical condition of the infant should be carefully monitored and the platelet count measured at least once daily until it is obvious that it has reached a 'safe' level and is increasing spontaneously. If there has been severe thrombocytopenia, a cerebral ultrasound or nuclear magnetic resonance scan should be performed to detect clinically silent ICH.

The transfusion of platelet concentrates from random donors is unlikely to be effective. There has only been one formal study of the use of intravenous immunoglobulin for the neonatal management of FMAIT; the response rate was 75% and the increase in platelet count was delayed for 24–48 h, during which time the infants remained at risk of ICH.[28]

Antenatal management

The recurrence of FMAIT in subsequent pregnancies is very high (> 85%) and the condition tends to become more severe.[23,29] If a previous sibling has suffered ICH, the risk of antenatal ICH is high in a subsequent pregnancy, and it is easy to justify antenatal intervention. If the previous infant was thrombocytopenic, but did not have a major hemorrhage, the risk of antenatal hemorrhage is more difficult to assess. There are no non-invasive tests for the prediction of which fetuses are at greatest risk of hemorrhage. The levels of maternal platelet antibodies have not been found to be predictive of the severity of thrombocytopenia,[23,30] and cerebral ultrasound scans will be abnormal only if ICH has occurred.

The only method available at the present time for assessing the fetal platelet count is fetal blood sampling,[31] which allows the diagnosis of FMAIT *in utero* and the assessment of severity to be made with certainty. In addition, this technique provides a means for transfusing compatible platelets to severely affected fetuses. The procedure usually takes only a few minutes, and a few milliliters of pure fetal blood is obtained. Fetal platelet counts are reliable and it is unusual to have problems because of contamination of the sample with maternal blood or amniotic fluid;[32] the normal range is similar to adults and there is no significant variation with gestational age.[33]

The main risks of the procedure are severe hemorrhage from the cord puncture site and obstruction of the cord circulation due to a hematoma. The main problems are most likely to occur with the initial blood sampling at around 20–22 weeks' gestation, when the cord is small and the platelet count may be very low. Fetal blood sampling for FMAIT should be performed at referral centers, where the risk is about 1%. In one series,[34] which now extends to nearly 200 fetal blood samplings for FMAIT, there have been two fetal deaths, one due to bleeding and one due to a cord hematoma. Severe bleeding requiring fetal red cell transfusions occurred in two other pregnancies, but there was eventually a successful outcome in these pregnancies. Another group has reported five fetal

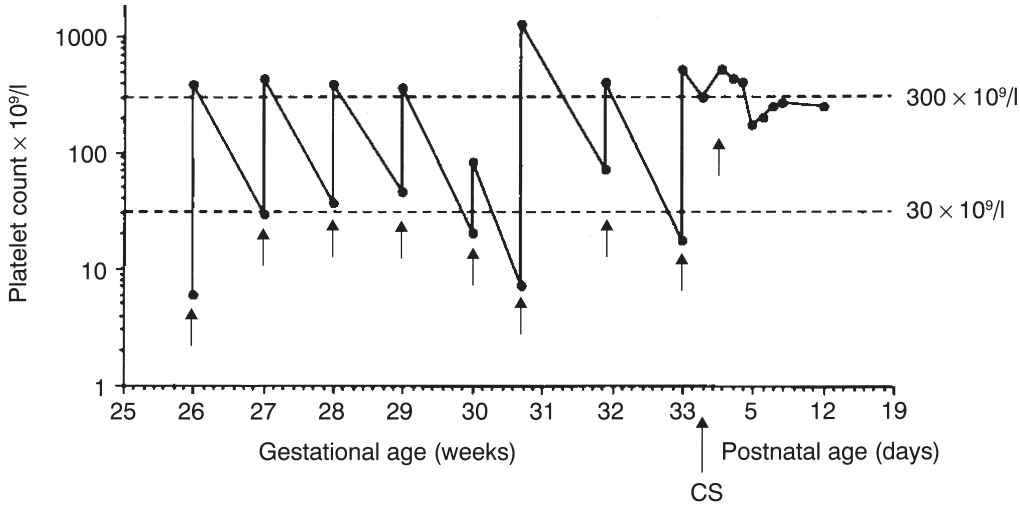

Figure 107.1 The seventh pregnancy of a patient who had already had five miscarriages. The last of these was shown to have hydrops and hydrocephalus and a platelet count of only 17×10^9/l, and the serological findings supported a diagnosis of FMAIT due to anti-HPA-1a. The fetal platelet count was less than 10×10^9/l at 25 weeks of gestation in the sixth pregnancy, and a cord hematoma developed during fetal blood sampling, resulting in fetal death. In the seventh pregnancy, prednisolone 20 mg/day and intravenous immunoglobulin 1 g/week were administered to the mother from 16 weeks until delivery. The figure shows pre- and post-transfusion platelet counts following serial fetal blood samplings and platelet transfusions (arrows). The fetal platelet count was less than 10×10^9/l at 26 weeks. The aim was to maintain the fetal platelet count above 30×10^9/l by raising the immediate post-transfusion platelet count to above 300×10^9/l after each transfusion. The fetal platelet count fell below 10×10^9/l on one occasion following a transfusion when there were problems in preparing the fetal platelet concentrate and the dose of platelets was inadequate. CS, cesarean section.

deaths due to exsanguination.[35] Because of the risk of bleeding, it has become routine practice to transfuse platelets to the fetus following fetal blood sampling for suspected FMAIT.[34,35]

The aim of antenatal management where there has been a previously affected pregnancy is to minimize the risk of severe hemorrhage such as ICH, but the optimal management remains controversial.[36] The therapeutic options being explored include maternal administration of intravenous immunoglobulin[37] and fetal platelet transfusions; early cesarean section alone is not considered to be effective in preventing antenatal or perinatal hemorrhage. Counselling of couples with an index case about the risks of severe fetal/neonatal thrombocytopenia in a subsequent pregnancy needs to be based on the severity of disease in the index case and the outcome of immunological investigations. The following should be taken into account:

- thrombocytopenia in subsequent cases is as or, generally, more severe
- the best predictors of severe fetal thrombocytopenia in a future pregnancy are the occurrence of antenatal intracranial hemorrhage and severe thrombocytopenia (platelet count $< 20 \times 10^9$/L) in a previous pregnancy
- the antibody specificity and titre do not reliably correlate with the severity of NAIT, and are of no value in the management of individual cases
- the zygosity of the partner. If the father is heterozygous for the relevant HPA e.g. HPA-1a/1b, fetal platelet typing can be performed using a fetal blood sample obtained at 18 weeks of gestation or using chorionic villus or amniotic fluid samples obtained earlier in pregnancy.

As few trials have been performed on the antenatal management of FMAIT, it is difficult to make definite recommendations. Weekly platelet transfusions by FBS have been shown to prevent ICH even in high risk cases (Figure 107.1), but are technically demanding, invasive and associated with a high mortality due to hemorrhage, cardiac dysrhythmias and premature labour.[34,38,39]

The high incidence of complications associated with FBS, and the effectiveness of maternal therapy in about 67% of cases,[39,40,41,42] suggest that treatment with IVIgG (1g/kg/week) without an initial FBS should be used as initial management.[43,44] This should be considered from or before 16 weeks' gestation in the cases where there is a history of antenatal ICH in previous pregnancies, because the earliest reports of ICH are at 16 weeks.[34] IVIgG could be started a few weeks later (20–22 weeks) for those fetuses with a sibling history of severe thrombocytopenia but no antenatal ICH. FBS may be used to monitor the effect of maternal therapy (4–8 weeks after starting IVIgG) and to indicate if alternative therapy is required. Failure with maternal therapy may potentially be rescued by the addition of oral prednisolone (0.5 mg/kg/day) and/or an increased dose of IVIgG (2g/kg/week), serial fetal platelet transfusions or by early delivery at an acceptable gestation.

Further studies are required to determine the optimal antenatal management for FMAIT.

Antenatal treatment appears to have improved the outcome of severely affected cases of FMAIT. However, there is little information on the long-term development of the children who have been treated *in utero*. All apparently successfully treated infants should probably have a cranial ultrasound or nuclear magnetic resonance scan performed after birth and developmental follow-up for at least 2 years to detect neurological impairment caused by occult ICH.

The main issues in the preparation of platelet concentrates for fetal transfusions are compatibility with maternal antibodies, adequate dosage without volume overload, and avoidance of transfusion-transmitted infections and transfusion-associated graft-vs-host disease. The mother is a convenient source of platelets for single transfusions, but use of the mother for repeated transfusions is not practical, and panels of selected donors need to be established, particularly for types HPA-lb/lb and HPA-5a/5a, as the most frequent antibodies responsible for FMAIT are anti-HPA-1a and anti-HPA-5b.[7,8] The blood group of the fetus should be determined at the first fetal blood sampling, and fetal hemolysis due to high-titer anti-A and anti-B should be avoided by testing donors for these antibodies. Maternal HLA antibodies may occasionally be responsible for the shortened survival of platelets transfused to the fetus, in which case the concentrates should be prepared from the mother or HLA-matched HPA-compatible donors.[45]

The risk of transfusion-transmitted infection should be minimized by standard microbiological screening of blood donors, who should in addition be cytomegalovirus seronegative. The concentrates should be gamma irradiated to prevent transfusion-associated graft-vs-host disease. Concentration of the platelet concentrate to a platelet count of 2500–4000 $\times 10^9$/l is essential to achieve satisfactory post-transfusion platelet counts without an unacceptably high transfusion volume. If the fetal platelet count is raised to 300–500 $\times 10^9$/l after each transfusion, it should be no lower than 30 $\times 10^9$/l 1 week later; this is thought to be a 'safe' level for the fetal platelet count, and 1 week is an acceptable interval for patients receiving serial transfusions.

In summary, the optimal antenatal management of FMAIT remains uncertain. More information is needed about the frequency and timing of ICH, and the benefits and notes of different management strategies.

Antenatal screening

Progress in the antenatal management of FMAIT in women who have had previously affected pregnancies draws attention to the issue of how to identify and manage the first affected infant.[46] The diagnosis of FMAIT in first-affected infants is usually made only after birth, by which time serious hemorrhage might have already occurred. Improvements in methods for large-scale platelet antigen typing and platelet antibody detection have raised the possibility of antenatal screening for pregnancies at risk of FMAIT alongside established programs of screening for hemolytic disease of the newborn. Recent studies in London and Cambridge, UK, have demonstrated the feasibility of such programs in determining the frequency of HPA-1a alloimmunization and its clinical sequelae.[15,16] The inclusion of typing for HLA-DR3*0101 following the initial identification of HPA-1a-negative pregnant women would focus on women most likely to develop anti-HPA-1a, but would not identify all affected pregnancies.[20]

An important obstacle to the introduction of antenatal screening is that the optimal management of women with anti-HPA-1a with no previous history of affected pregnancies is uncertain. Reliable non-invasive methods for identifying the fetuses at greatest risk of antenatal ICH are not available. Antenatal management has significant risks, which have to be balanced against those of a conservative policy with no antenatal intervention but prompt identification and treatment of affected cases after delivery, and only large scale trials will clarify this issue.

108 Severe twin-to-twin transfusion syndrome: diagnosis and endoscopic laser coagulation

N. J. Sebire, J. Hyett and K. H. Nicolaides

In monozygotic twin pregnancies, early embryonic splitting, which occurs in approximately one-third of cases, results in dichorionic placentation and two independent placental circulations.[1,2] Splitting after the third day of fertilization is associated with monochorionic placentation, with vascular communications between the two fetoplacental circulations; if cleavage occurs after day 12 the fetuses are conjoint. The clinical entity of severe twin-to-twin transfusion syndrome (TTS) is a result of imbalance in the net flow of blood across the placental vascular anastomoses from one fetus, the donor, to the other, the recipient, and occurs in about 15% of monochorionic pregnancies.

Pathophysiology

The phenomenon of a shared circulation between monochorionic twins was first described by Schatz in 1875.[3] Although anastomoses may be arterial–arterial or veno–venous, it is the arterio–venous anastomoses that are primarily responsible for the development of TTS. These arterio–venous anastomoses are usually deep in the placenta, but almost always proceed through the cotyledonary capillary bed.[1] Mild, moderate or severe TTS may develop, depending on the net flow between these anastomoses, which are variable in size, number and direction.[1]

The precise underlying mechanisms by which a subgroup of monochorionic pregnancies with vascular communications go on to develop TTS are not fully understood. However, it has been suggested that the primary defect is abnormal development of the placenta of the donor twin, which causes increased peripheral resistance in this placental circulation, promoting shunting of blood to the recipient. The donor therefore suffers from both hypovolemia, due to blood loss, and hypoxia, due to placental insufficiency.[4,5] The recipient fetus compensates for its expanded blood volume with polyuria,[6] but since protein and cellular components remain in its circulation the consequent increase in colloid oncotic pressure draws water from the maternal compartment across the placenta. A vicious cycle of hypervolemia, polyuria and hyperosmolality is established, leading to high-output heart failure and polyhydramnios.

In contrast to neonatal TTS, studies examining fetal blood obtained by cordocentesis in pregnancies with severe TTS have reported large intertwin differences in plasma albumin and total protein concentrations,[7,8] but no consistent differences in hemoglobin concentration between donor and recipient fetuses.[4,7–9]

Diagnosis

Traditionally, the diagnosis of TTS has been made retrospectively, in the neonatal period, on the basis of an intertwin difference in birth weight of 20% or more and in hemoglobin concentration of 5 g/dl or more.[10–12] These observations were made in live births, and therefore the criteria apply only to moderate TTS, since severe cases result in miscarriage or intrauterine death. Additionally, large intertwin differences in hemoglobin and birth weight are found in some dichorionic twin pregnancies and are not pathognomonic of TTS.[13]

Severe disease manifests clinically in the early second trimester of pregnancy with the mother complaining of a sudden increase in abdominal girth associated with extreme discomfort, and occasionally respiratory distress. On examination, there is tense polyhydramnios, which is pathognomonic of TTS

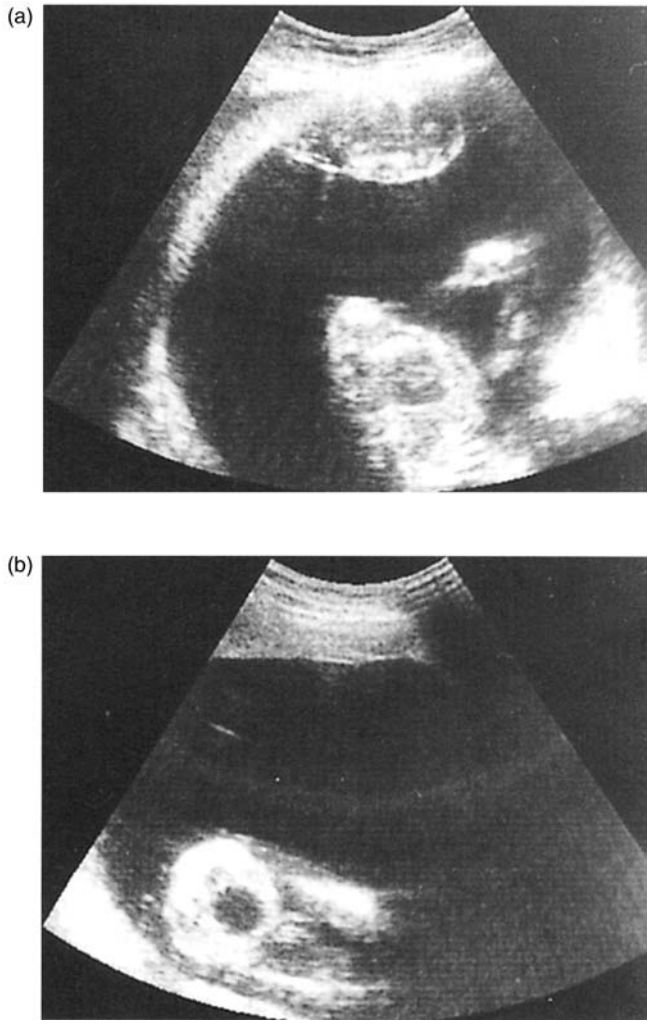

Figure 108.1 Ultrasound images demonstrating the features of TTS. (a) The 'stuck' donor fetus is in an anhydramniotic sac with no visible bladder. (b) The recipient fetus has a large bladder and polyhydramnios.

when observed at this early stage of gestation. In such cases of severe TTS, ultrasound examination will reveal a twin pregnancy with the polyhydramnios/anhydramnios sequence, with or without discordance in fetal size. However, the pathognomonic features of severe TTS are the presence of a large bladder in the polyuric recipient fetus in the polyhydramniotic sac, and a non-visualized bladder in the anuric donor that is found 'stuck' and immobile at the edge of the placenta or the uterine wall, where it is held fixed by the collapsed membranes of the anhydramniotic sac (Figure 108.1).

Other sonographic findings that may prove to be of prognostic significance include the presence of a hypertrophic, dilated and dyskinetic heart in the recipient fetus, while in the donor the heart may be dilated and the bowel hyperechogenic; these features are manifestations of hypoxia and are commonly seen in hypoxemic fetuses from pregnancies complicated by severe uteroplacental insufficiency. The donor fetus may also demonstrate ventriculomegaly and/or microcephaly secondary to hypoxia.

Color Doppler studies in severe TTS presenting with acute polyhydramnios during the second trimester of pregnancy have demonstrated the presence of several superficial vessels connecting the two circulations.[14] Additionally, the umbilical artery pulsatility index (PI) has been reported to be increased in both donor and recipient fetuses; in the former, this may be the consequence of abnormal placental development, and in the latter this may be the result of polyhydramnios-related compression.[15]

Doppler findings in the circulation of the donor fetus (decreased blood flow velocity in both the thoracic aorta and the middle cerebral artery) suggest that this fetus is compromised by severe uteroplacental insufficiency, but with the additional disadvantage imposed by chronic hemorrhage and hypovolemia.[15] In the recipient fetus, there may be a decreased PI in the middle cerebral artery and decreased velocity in the aorta, which may be the consequence of hypervolemia-related congestive heart failure, which worsens with advancing gestation.

Although Doppler abnormalities have been described in TTS, at present the use of these investigations is generally limited, because they are neither useful in the diagnosis of TTS nor do they appear to provide useful prediction of prognosis.

Screening for TTS

Although severe TTS presents in the second trimester, the underlying hemodynamic alterations must begin much earlier in the pregnancy. In a screening study involving 485 twin pregnancies with live fetuses at the 10–14-week scan, the risks of subsequent miscarriage before 24 weeks of gestation and perinatal death after 24 weeks were 2% and 1%, respectively, for dichorionic twins, and 12% and 2%, respectively, for monochorionic twins.[16] It was postulated that the high risk of fetal loss in monochorionic twins could be attributed to the development of TTS.

Early sonographic features that have been examined as possible predictors of subsequent development of TTS are large intertwin disparities in crown–rump length (CRL) and nuchal translucency thickness at the 10–14-week scan[17] and intertwin membrane folding at 15–17 weeks. We have reviewed 69 monochorionic twin pregnancies, diagnosed by ultrasound examination at 10–14 weeks of gestation; at 15–17 weeks, 18 (26%) of the cases demonstrated intertwin membrane folding with large discrepancies in amniotic fluid volume. In 10 of these cases there was subsequent development of severe TTS. In the other eight cases, large discrepancies in amniotic fluid volume and intertwin differences in size persisted throughout pregnancy, but all these cases with moderate TTS resulted in healthy live births without the need for any antenatal

intervention. Similarly, the 51 pregnancies with no membrane folding resulted in live births. Large intertwin disparities in fetal CRL at the 10–14-week scan were observed only in the moderate TTS group, whereas intertwin disparities in fetal nuchal translucency thickness were observed both in the moderate and in the severe TTS groups.

Laser coagulation of the communicating placental vessels

Technique

The method of choice for treating severe TTS is endoscopic Nd:YAG laser coagulation of the placental blood vessels that connect the circulations of the two fetuses. De Lia *et al.*[18] described a technique involving general or regional anesthesia in which the endoscope was introduced into the uterus after laparotomy, hysterotomy and the insertion of a purse-string suture to control bleeding and amniotic fluid leakage. This was attempted in 30 twin pregnancies and successful laser coagulation was achieved in 26 of these; 18 of the pregnancies resulted in the delivery of at least one live baby.[19] However, despite the advantages of this approach, the technique has not gained widespread application, presumably because of its invasive nature.

Ville *et al.*[20,21] reported a sonoendoscopic technique performed under local anesthesia for the successful separation of chorioangiopagus twins. Detailed ultrasound examination, including color flow mapping, is first performed to localize the placenta, the intertwin amniotic membrane, the placental insertion of the umbilical cords and the communicating blood vessels on the chorionic plate. The appropriate site of entry on the maternal abdomen is chosen to avoid injury to the placenta or fetuses and to allow access to the suspected area of vascular communications.

Under continuous ultrasound visualization, a rigid 2-mm-diameter fetoscope (field of vision 75°) housed in a 2.7-mm-diameter cannula (KeyMed, Southend, UK) is introduced transabdominally into the amniotic cavity of the recipient twin. A 400-μm-diameter Nd:YAG laser fiber (MBB, Munich, Germany) is then passed down the sidearm of the cannula to 1 cm beyond the tip of the fetoscope. A combination of ultrasonographic and direct vision is used to examine systematically the chorionic plate along the whole length of the intertwin membrane and identify the crossing vessels, which are coagulated by the administration of a total of 1000–4500 J delivered in 3-s shots using an output of 30–50 W at a distance of 1 cm. Subsequently, amniotic fluid is drained through the fetoscope cannula over a period of 10–15 min to obtain subjective normalization of the amniotic fluid volume on ultrasonographic examination. The total procedure usually takes 30–45 min to complete.

Rationale and advantages

The aim of systematic coagulation of all superficial placental vessels that cross or are adjacent to the intertwin amniotic membrane is to interrupt the vascular communications between the circulations of the two fetuses. Arterio–venous anastomoses (which are thought to play a major role in the hemodynamic disturbance underlying feto-fetal transfusion) are found deep in common cotyledons, but their afferent and efferent branches are superficial.[1] Although the intertwin membrane does not necessarily overlie these common cotyledons,[22] coagulation of all crossing vessels will inevitably include the afferent and efferent branches of these anastomoses. In reality, the main problem with endoscopic laser surgery is that coagulation of all placental vessels that cross the intertwin membrane interrupts the vascular supply to more than the common cotyledons and this may account for many cases where the donor twin dies following the procedure. The extent to which we will be able to restrict coagulation to the common cotyledons, and the potential increase in survival without increasing handicap, remain to be determined.

Laser coagulation of the communicating vessels potentially avoids many of the complications associated with severe TTS treated by other means. Cerebral palsy with periventricular leukomalacia is a well-recognized complication of monochorionic twin pregnancies and is usually attributed to vascular accidents following the intrauterine death of one of the fetuses.[23–26] This complication is commonly seen in survivors after amniodrainage or other methods of treatment. Suggested mechanisms include a severe hypotensive episode due to hemorrhage from the survivor into the placenta of the dead fetus, or disseminated intravascular coagulation after the release of thromboplastin from the dead twin. Laser coagulation of communicating vessels should potentially avoid these complications. However, brain damage observed in association with TTS does not occur only when one of the fetuses dies, and in some cases it may be the consequence of intrauterine ischemic-hypoxic brain injury; in the donor, fetus hypoxia may be the consequence of hypovolemia and uteroplacental insufficiency, whereas in the recipient hypoxia may be due to increased blood viscosity and hypervolemia-related congestive heart failure.

Endoscopic laser coagulation was performed in our center on a total of 137 completed pregnancies. In 45 pregnancies both babies survived, in 46 one baby survived and in 46 there were no survivors. There were, therefore, 91 (67%) pregnancies with at least one survivor and the total number of babies that survived was 136 of 274 (50%). In the 136 survivors, regular examinations were carried out and 134 (98%) are developing normally. However, two of them are handicapped or will potentially become handicapped.

Alternative methods of management

Expectant management

In twin pregnancies with presumed TTS, development of acute polyhydramnios at less than 28 weeks of

gestation is associated with a high perinatal mortality rate, primarily because of spontaneous abortion or very preterm delivery of growth-retarded babies or babies with hydrops. Saunders *et al*.[5] reviewed 53 such pregnancies in the literature and the fetal survival rate was only 5%. In the few babies that survive with expectant management there is a high incidence of morbidity. Brain damage may occur due to a combination of factors including intrauterine hypoxia and preterm delivery.[5,27] In addition, death of one fetus, usually the donor, may be associated with subsequent death or hypoxic/ischemic sequelae in the cotwin.[23–29]

Medical therapy

Indometacin has been used in an attempt to prevent the onset of preterm delivery, both through its tocolytic properties and through its action in reducing fetal urine production and therefore polyhydramnios. In a study reporting the administration of indometacin in three pregnancies with TTS presenting with polyhydramnios at 20–25 weeks of gestation, one patient delivered at 25 weeks and both the babies died.[30] In each of the other two pregnancies one fetus died within 4 days of the onset of treatment; the pregnancies continued to 30 and 36 weeks, respectively, and the two babies survived but one of the neonates had multicystic encephalomalacia.

Selective fetocide

The poor prognosis of untreated TTS, particularly when one of the fetuses is severely compromised, has led various groups to consider selective fetocide as a method of treatment. The rationale behind this approach is to interrupt TTS and maximize the chances of survival of one of the fetuses, mainly by potentially reducing the chance of severe preterm delivery. Several techniques have been described, including: (1) surgical removal of one fetus by hysterotomy;[31] (2) ultrasound-guided pericardial injection of saline to achieve cardiac tamponade or the intracardiac injection of potassium chloride;[7,26,32–35] (3) ultrasound-guided insertion of thrombogenic coils or fibrin into the heart or the umbilical vein of one of the fetuses[36,37] and (4) ultrasound-guided ligation of one umbilical cord.[38] In 15 pregnancies that were managed by selective fetocide at 20–26 weeks of gestation there were eight survivors (27% of the total).

Serial amniodrainage

The traditional method of treating severe TTS is by serial amniocenteses and drainage of large volumes of amniotic fluid. This treatment presumably prevents the polyhydramnios-mediated risk of spontaneous abortion or very premature delivery.[5,39–41] It is also possible that with advancing gestation and increasing fetoplacental blood volume the relative significance of the hemodynamic effects of placental anastomoses is reduced. In this respect, repeated amniocentesis may, at least in some cases, allow the fetal cardiovascular system to outgrow the deleterious effect of placental anastomoses.[5,6] In addition, amniodrainage reduces amniotic fluid pressure and may relieve the compression of the membranously inserted cord or superficial vessels, which could improve blood flow in the donor fetus.[42]

In studies published before 1992, amniodrainage was associated with survival in 30–40% of cases.[5] Subsequently, six papers from four centers have reported survival of 57–83% of fetuses, and 76–100% of the pregnancies had at least one survivor.[39,40,43–45] It is possible that the marked improvement in survival with serial amniodrainage, compared to previous studies that apparently used the same treatment protocols, presumably reflects differences in the severity of the disease. A major difference, in terms of outcome, between treatment with endoscopic laser and serial amniodrainage may be in the rate of neurological handicap in the survivors. Thus, with endoscopic surgery, both in our first series and in the current extended group, the rate of handicap is less than 5%. In contrast, in all three studies with amniodrainage that reported on rates of neurological handicap, the rate was much higher at 25%, 37% and 18%, respectively.[5,41,45]

Conclusion

Severe TTS complicates 10–15% of monochorionic twin pregnancies and characteristically presents with the oligohydramnios/polyhydramnios sequence in the second trimester. Increased fetal nuchal translucency thickness at 10–14 weeks of gestation and folding of the intertwin membrane at 15–17 weeks may be the first sonographic signs in the development of severe TTS. The most rational method of treating the condition is interruption of the placental vascular anastomoses by endoscopic laser ablation. This therapy is associated with survival of at least one baby in about 70% of pregnancies and more than 95% of survivors are healthy.

109 Fetal stem-cell and gene therapy

Y. Yaron, A. W. Flake, M. P. Johnson and M. I. Evans

Introduction

Surgery is the logical approach for structural problems. Medicines can replace enzymatic deficiencies, but drugs are by definition essentially palliative approaches. Gene therapy can, in theory, replace the missing substance, but at the same time give the individual the ability to make the substance itself. Gene therapies *per se* have been divided into two categories: classic gene therapy and stem-cell therapy.

Gene therapy

Gene therapy refers to the correction of a disease state by introduction of foreign nucleic acid sequences designed to target the affected tissue. The term 'gene therapy' was brought into use to avoid the negative connotations of the term 'human genetic engineering', first used at the 6th International Congress of Genetics held in 1932 to imply 'the application of genetic principles to animal and plant breeding'.[1] Any form of genetic manipulation, however, was limited to the application of Mendelian principles for breeding until the basics of molecular genetics and techniques for transfection of genes in bacteria became available in the 1960s. Several approaches for gene transfer were investigated before viral vectors were shown to be the first relatively efficient methods for gene transfer into mammalian cells in culture. By the late 1970s, transfection techniques became more efficient as a result of selection systems for cultured cells and recombinant DNA technology. The development of retroviral vectors in the 1980s further improved the efficiency of gene transfer into mammalian cells for the purpose of gene therapy.[1] Finally, the last few years have seen an explosion of experimental studies and clinical trials of gene therapy in almost every discipline of medicine. Many genetic disorders are already manifest in the newborn with irreversible organ damage: hence the attractiveness of *in utero* gene therapy. This section will review some of the advances in gene therapy in general and focus finally on the possible future applications of *in utero* gene therapy.

Therapeutic gene design

Gene therapy may be applied to all diseases that have a clear genetic cause such as the inborn errors of metabolism. There are several approaches to the treatment of different diseases by gene therapy. Not all approaches currently share the same popularity or effectiveness. However, by outlining the different approaches the reader can appreciate the tremendous opportunities that this mode of treatment presents.

Gene replacement therapy

Loss-of-function mutations are responsible for a wide range of human diseases. Such mutations result in absence, reduction or faulty production of an essential protein such as an enzyme or a receptor. Restoring the lost function can, theoretically, be achieved by introducing the normal or wild-type gene in a manner that would facilitate the production of the missing gene-product in the affected tissues at the appropriate timing. This appears to be the most useful approach for *in utero* gene therapy.

Vitally directed enzyme pro-drug therapy – suicide genes

Suicide genes encode novel non-mammalian enzymes that can convert a relatively non-toxic pro-drug into a highly toxic agent. Cells genetically transduced to express such genes essentially commit metabolic suicide in the presence of the appropriate pro-drug. Such metabolic suicide genes may include viral enzymes like the varicella zoster or herpes simplex-derived thymidine kinase (HSV-Tk1) or enzymes of bacterial origin like the *Escherichia coli*-derived cytosine deaminase.[2] Only cells transfected with these enzymes metabolize the pro-drug thereby causing cell death. This approach may be applied to the therapy of cancer or retroviral infections.[3] Insertion of HSV-Tk1 gene confers a sensitivity to the antiherpes drug ganciclovir.

The enzyme phosphorylates the non-toxic ganciclovir to a potent DNA synthesis inhibitor.[4] The selective effect of such suicide genes can further be perfected by employment of a triggering mechanism. This approach takes advantage of the unique production of embryonic and fetal molecules by some tumor types. For example, the alpha-fetoprotein (AFP) gene which is normally expressed in fetal liver is transcriptionally inactive in the adult, but is reactivated in hepatocellular carcinoma. This fact can be utilized in creating a hepatocarcinoma-specific gene-targeting mechanism. A hybrid gene can be constructed consisting of HSV-Tk1 gene under the control of the human AFP gene promoter. This hybrid gene can then be transferred into AFP-producing hepatoma cells. Although the gene construct can transfect many cell types, only AFP-producing cells will express the HSV-Tk1 gene, rendering them increasingly sensitive to ganciclovir treatment.[5] This approach is most commonly used in cancer gene therapy.

Gene suppression therapy

Another approach is the employment of foreign genes to oppose the expression of what are, usually, dominant genes that may cause diseases ranging from cancer to viral infections. This may also be used to oppose the expression of genes that are responsible for genetic diseases that are caused by a mutated protein that assumes an altered function which is responsible for the disease manifestations [i.e., sickling caused by sickle cell hemoglobin (HbS)]. Several strategies have been employed to achieve this goal.

Antisense RNA. With this approach, oligodeoxyribonucleotide sequences (oligos) are designed to target certain key regulatory elements of genes that are implicated in disease states. For example, by binding to promoter regions of certain proto-oncogenes (e.g., c-*myc*) it is possible to block the binding of regulatory molecules that activate the oncogene, thus rendering it inactive.[6] These oligos have the advantage of being relatively short sequences, several-fold smaller than whole genes, making them suitable for transfer by viral vectors.[7]

Ribozymes. It is believed that RNA molecules were, evolutionarily, the first class of molecules that possessed enzymatic activity. Ribozymes are such a class of RNA molecules that can perform catalytic activity in the absence of proteins. Specifically, they hybridize to and cleave target messenger RNA (mRNA) molecules thereby preventing their translation into specific proteins. This approach may have a therapeutic application by targeting ribozymes to specific mRNA of key proteins implicated in disease states.[8]

Gene delivery techniques

With recombinant DNA technology and the ever-increasing number of newly mapped and cloned genes, the construction of therapeutic gene sequences seems to be relatively straightforward, as outlined in the previous section. In contrast, the rate-limiting step towards gene therapy appears to be the development of safe and efficient gene delivery techniques that would bring the therapeutic gene into the target tissue where it is to be expressed. Currently employed techniques include various viral vectors, lipofection, naked plasmid DNA, gene guns, electroporation, multiple injections, ingestion or inhalation and selective organ perfusion. All these are currently in the early stages of investigation and development.

Viral vectors

By far the most widely employed techniques for gene delivery make use of viral vectors. Many protocols use an *ex vivo* approach, whereby cells are removed from the patient, genetically modified and then re-implanted. This approach, however, is both cumbersome and costly, requires high-tech facilities, and most importantly, is limited to cell that can readily be obtained and cultured such as blood cells. This approach cannot be applied to solid tissues and non-dividing cells such as muscle cells or neurons. The *in vivo* approach for gene delivery by viral vectors can greatly facilitate gene therapy protocols of the future, by enabling transfection into non-dividing cells. However, before *in vivo* gene therapy may safely be employed, some significant problems must be overcome. Ideally, therapeutic genes should be exclusively expressed only in the relevant cell type and be free of any untoward effects on healthy cells. Several different types of viral vectors have been employed for gene delivery.

Retroviruses. Retroviruses have two identical single-stranded RNA genomes packaged into a viral particle, composed of a viral-encoded envelope *env* protein which is embedded in a lipid bilayer derived from the host plasma membrane. The viral core consists of virally encoded proteins such as *reverse transcriptase* and *integrase* enzymes that are essential for viral replication and integration of viral DNA into host chromosomes. Because the genome of retroviral vectors is incorporated into the host cell genome, the transgenic cells retain the new genetic information through subsequent cell divisions. Thus, the transgene is relatively stable. Vector titers however are low, require dividing cells for effective transfection to occur and thus are unsuitable for non-dividing cells like neurons or muscle cells.

Adenoviruses. Adenoviral vectors usually do not incorporate their DNA into the genome of the host cell and generally remain within the host cell as episomes. This is of concern since it may limit the longevity of the expressed transgene. However, unlike retroviruses, they do not require actively dividing cell lines and high titers can be generated. Such vectors, therefore, would theoretically be more suitable for targeting

non-dividing cells. This is especially true for the treatment of muscle cells, in particular myoblasts, since myoblasts have an abundance of 3β,5β-integrin, which is the main component of the internalization receptor for adenoviruses (AVs). This could contribute, among other things, to the relatively high susceptibility of myoblasts to AV infection and AV-mediated gene transduction.[9]

Adeno-associated virus. Adeno-associated viral (AAV) vectors are non-pathogenic, integrating DNA vectors in which all viral genes have been removed and helper virus co-transfection is virtually eliminated. These vectors tend to persist in infected cells for prolonged periods of time, with no significant untoward effect on the host. Like AVs, AAV vectors may also persist in an episomal state. Although AAV vectors may exhibit a relative preference for actively dividing cells, they do not require host-cell proliferation. Thus, AAV is an excellent vector candidate for gene transfer in both *ex vivo* and *in vivo* gene therapy.

Non-viral vectors

Unlike the risks associated with viral transfection, non-viral gene delivery techniques appear to be as safe as conventional pharmaceutical products. Various non-viral vectors are currently being assessed in a variety of experimental studies and clinical trials of gene therapy for a variety of disorders, including cystic fibrosis, cancer and peripheral vascular disease.[10]

Lipofection. In contrast to the stable transfection of cells by some viral vectors, other gene delivery techniques may induce only a transient gene expression, a concept known as 'gene therapeutics'. An example of this approach is lipofection whereby DNA plasmids carrying the therapeutic genes are entrapped in lipid vesicles (liposomes). These liposomes act as vehicles that deliver the gene to the target cells where they are only transiently expressed. This is due to the fact that they do not incorporate into the host genome.[11] This approach is particularly promising in treatment of diseases that are manifested in the epithelial lining of various organs, making them accessible to surface delivery methods. Liposomes can also be introduced into internal organs via selective vasculature catheterization. This approach has been employed for selective delivery of recombinant genes (e.g., HLA-B7 plasmid DNA) to the lungs via the pulmonary vasculature in a patient with pulmonary metastases. The treatments were well tolerated and no adverse respiratory, cardiac, immunological or other organ toxicities were detected.[12]

Receptor-mediated endocytosis. Uptake of the therapeutic DNA by the specific target cells or tissue is a prerequisite for successful implementation of gene therapy. The physiological process of receptor-mediated endocytosis can be exploited to deliver genetic material to specific cell types. This approach uses antibodies or ligands with an affinity to a specific cell-membrane receptor (e.g., transferrin), and are known to undergo endocytosis. These are complexed with the therapeutic gene through a covalently bound polycationic linker molecule (e.g., poly-lysine). The complexes in turn bind to the cell surface receptor and are endocytosed into the cell's endosomal compartment. Certain steps must be taken to avoid degradation of the DNA, and to assist endosomal escape of the DNA into the cytosol where it is to be expressed.[13]

Gene targeting

Once introduced into the target cells, the therapeutic gene may be integrated into the host cell genome or remain as cytoplasmic episomes. Integration of novel DNA into the genome carries the potential of durable gene expression and propagation of the therapeutic gene into daughter cells. However, non-site-specific viral vectors integrate randomly into the host genome. This has the potential risk of disrupting functional genes and is known as insertional mutagenesis. This could result in a loss of gene function, defective regulation and gene expression, or an altered gene product. To overcome this problem, therapeutic genes may be designed in a manner that would ensure their integration into predetermined loci within the genome. This may be achieved by homologous recombination where the therapeutic gene is flanked by DNA sequences homologous to the genomic target locus. This approach takes advantage of the endogenous recombinational machinery of the cell which favors crossing-over between homologous sequences. This results in insertion of the therapeutic gene (if one crossover occurs) or replacement of the genomic sequence with the therapeutic gene (if two crossovers occur).[14] Another potentially effective technique (though still not widely used for gene therapy) is that of site-specific recombination. This approach employs exogenously supplied enzymes that induce recombinations (recombinases) at highly specific sites in the target DNA. Based on the number and orientation of these recombination sites, recombinase activity results in deletions, inversions or gene insertion.[15]

Experimental studies and clinical trials

Adenosine deaminase deficiency

Historically, the adenosine deaminase (ADA) gene was the first to be used in a gene therapy clinical trial aimed at achieving actual medical cure.[16] ADA deficiency is another form of fatal severe combined immunodeficiency disease with profound T-lymphocytopenia. Affected individuals have variable defects of both T- and B-lymphocyte function and greatly increased morbidity and mortality caused by frequent viral and bacterial infection, leading to death in early

childhood. Classical treatments include administration of the missing enzyme linked to polyethylene glycol (PEG–ADA), as well as bone marrow transplantation. Despite its severity, the disease is genetically simple, and restoration of a functional ADA gene into the patient's lymphocytes should theoretically result in clinical improvement. In 1990, a clinical trial was initiated using retroviral-mediated transfer of the ADA gene into the T-cells of two ADA-deficient children who did not respond to conventional PEG–ADA administration.[16] Peripheral blood lymphocytes were collected, cultured *ex vivo*, infected with a retroviral vector expressing the ADA complementary DNA (cDNA), and re-infused into the patients. This procedure was repeated monthly for 2 years. Subsequently, both children have been reported to have ADA-positive circulating lymphocytes. One patient had over 50% ADA-positive lymphocytes and a normal immune state. The other patient had only 0.1–1% ADA-positive lymphocytes, but a reportedly good clinical state. Gene treatment ended after 2 years, but integrated vector and ADA gene expression in T-cells persisted.[17,18] Several other teams have tried similar approaches for treating ADA deficiency by gene therapy with varying success.[19,20]

Cystic fibrosis

Cystic fibrosis is an autosomal recessive disease caused by a mutation of the cystic fibrosis transmembrane conductance regulator (CFTR) gene. The CFTR protein is a chloride-ion transporter, regulating transmembrane voltage. Reduced or absent cAMP-mediated chloride transport in epithelial-lined organs is responsible for the clinical manifestations. The disease is characterized mainly by accumulation of mucus in the lung, predisposing it to inflammation. Other affected organs include the gastrointestinal tract and the reproductive system. Studies with experimental animals demonstrate that the human CFTR cDNA could be transferred to the airway epithelium using an adenoviral vector (Ad-CFTR), with expression of the human CFTR gene lasting for at least 6 weeks.[21] The first human trial of gene therapy for cystic fibrosis was initiated in 1993. This clinical trial included four patients with cystic fibrosis who received the adenoviral vector (Ad-CFTR) by instillation to their nasal or bronchial epithelium.[22] Both the CFTR protein and mRNA, undetectable prior to treatment, were observed in about 14% of one patient's epithelium cells, and mRNA alone in another patient for 1 week. However, after 10 days, no expression was found.[22] Liposome-mediated treatment has also been attempted in cystic fibrosis patients. The restoration rate of CFTR activity was only 20%, peaking 3 days post-treatment, and reverting to pre-treatment levels after a week.[23] Hepatobiliary disease is the second most common cause of mortality in patients with cystic fibrosis. In the liver, only the intrahepatic biliary epithelial cells express the CFTR gene. To assess the feasibility of treating the hepatobiliary component of cystic fibrosis, intrahepatic biliary ephithelial cells were isolated from cystic fibrosis patients, immortalized *in vitro*, transfected with an Ad-CFTR vector, and assayed 2–31 days later for CFTR function. Transfected cells showed CFTR function for 31 days post-transfection although the number of responsive cells decreased with time.[24] Present gene-delivery methods do not appear to induce permanent CFTR gene expression, either in lung or in intrahepatic biliary epithelial cells. For gene therapy to be effective in cystic fibrosis, repeated administrations need to be performed. This would obviously limit the use of adenoviral vectors because of their potential to induce an immune response.

Inborn errors of metabolism

Numerous experimental studies have addressed the feasibility of gene therapy for a wide variety of metabolic disorders characterized by lack or complete deficiency of essential enzymes. Most of these studies are still in the early stages of animal model and *in vitro* human cell-culture studies.

Gaucher disease. A common inherited metabolic disorder, this is an excellent candidate for targeted gene therapy using hematopoietic stem cells. The feasibility of introducing the human glucocerebrosidase gene into hematopoietic progenitors with long-term expression using a variety of retroviral vectors has been demonstrated in animal models.[25] Subsequently, it was shown that glucocerebrosidase enzyme expression can be detected in peripheral blood lymphocytes more than 12 months post-transplantation, with a transduction efficiency of up to 95% in hematopoietic stem cells (CD34+).[26] This provides encouraging data for the future use of gene therapy for this disease.

Phenylketonuria. Classical phenylketonuria is caused by a deficiency of hepatic phenylalanine hydroxylase (PAH), resulting in mental retardation. A recombinant adenoviral vector containing the human PAH cDNA was constructed and administered to a phenylketonuria-animal model: PAH-deficient mice (strain PAHenu2).[27] The hyperphenylalaninemic phenotype was completely normalized within 1 week of treatment; however, the therapeutic effect did not persist. This study indicates that only 10–20% of normal enzymatic activity in the mouse liver is necessary to restore normal serum phenylalanine levels. These results indicate that phenylketonuria has the potential to be corrected by gene therapy once a vector system which allows long-term expression is developed.

Maple syrup urine disease. Maple syrup urine disease (MSUD) is an autosomal recessive disease caused by a deficiency of branched-chain keto acid dehydrogenase, a mitochondrial multienzyme complex responsible for the decarboxylation of leucine, isoleucine and valine.

The complex consists of three subunits (E1, E2 and E3) and mutations in any subunit result in MSUD. No satisfactory treatment for MSUD is currently available.[28] To assess the feasibility of gene therapy for this disease, a retroviral vector containing the human E2 cDNA was used to restore leucine decarboxylation activity in fibroblasts derived from a MSUD patient with a mutation in the E2 subunit. Decarboxylation activity in transduced cells was restored to 93% of the wild-type level. Correct targeting of the expressed wild-type E2 protein to mitochondria was demonstrated by comparing the immunofluorescent pattern of E2 and a mitochondrial marker protein. Stable expression of enzyme activity has been achieved for at least 7 weeks. These results demonstrate the capacity for phenotypic correction of a gene defect whose product is a part of a multienzyme complex.[28]

Metachromatic leukodystrophy. Metachromatic leukodystrophy is an autosomally recessive disease characterized by deficient activity of arylsulfatase A (ASA). This results in progressive accumulation of cerebroside sulfate in oligodendrocytes in the brain causing dysmyelination. An adenoviral vector with the ASA gene has been shown to achieve successful transduction with expression of ASA in primary fibroblasts from metachromatic leukodystrophy patients. In addition, the expressed ASA protein was correctly targeted to lysosomes and its resulting enzymatic activity was shown to be 2.3–5.0 times the activity of normal control cells.[29]

Hematological disorders

These disorders are, at least theoretically, more readily amenable to gene therapy since circulating blood cells can easily be reached for both *ex vivo* and *in vivo* gene therapy. Several studies have addressed hematological disorders as candidates for gene therapy. These include disorders of hemoglobin synthesis and coagulation defects. Mutations at the α-globin locus are a common class of mutations in humans resulting in the various forms of a-thalassemia. Deletion of all four adult α-globin genes results in the perinatal lethal condition manifested by hydrops fetalis. It has been demonstrated that introduction of a human α-globin transgene can ameliorate the severity of the disorder in a mouse thalassemia model, providing hope for gene therapy of this disorder.[30] To be relevant to the human disease, however, this treatment will have to occur prenatally with the affected fetus being treated *in utero*.

Coagulation disorders are also potential candidates for gene therapy. The need to replace deficient coagulation factors with blood-derived products that resulted in human immunodeficiency virus (HIV) infection further underlines the need for safe and effective treatments. Hemophilia B, a model of such coagulation disorders, is characterized by an X-linked deficiency of factor IX. It has previously been suggested that keratinocytes in the skin might provide a suitable target cell for delivery of factor IX to the systemic circulation in patients with hemophilia B. Experiments in transgenic mice demonstrated that human factor IX can be efficiently synthesized in the skin by keratinocytes and secreted across the epidermal basement membrane to reach the systemic circulation where significant levels can be attained.[31]

Neuromuscular disorders

Both muscle and the nervous system are affected by a myriad of genetic disorders that could potentially be treated by gene therapy. They are characterized by relatively inaccessible, non-dividing, terminally differentiated cells. This underscores the need to find efficient and safe gene delivery techniques for these cell types before any success can be achieved. The search for a gene therapy approach for Duchenne's muscular dystrophy and Parkinson's disease provides some insight into the difficulty of this task. Duchenne's muscular dystrophy, a lethal X-linked disorder, is caused by mutations in the dystrophin gene which is an exceptionally large gene (2300 kb, 79 exons) mapped to chromosome region Xp21. A lack of dystrophin results in muscle degeneration leading to progressive weakness and death by the second decade. Duchenne's muscular dystrophy demonstrates the problems associated with somatic gene therapy due to the enormous size of the gene and the large number of target cells that need to be treated. Myoblast transfer therapy and gene therapy have both been proposed as potential treatments for this disorder. Myoblast implantation has had some success in animal models but little, if any, effect on patients with Duchenne's muscular dystrophy.[32] Gene therapy based on the introduction of dystrophin gene-constructs by retroviral or adenoviral vectors has also been successful in animal models.[33] Adenoviral vectors may be a potentially effective delivery system for muscle disease, provided immature muscle cells are abundant in the muscle. This is due to the fact that myoblasts have an abundance of β3,β5-integrin, which is the main component of the internalization receptor for adenoviruses.[9] Unfortunately, the level of β3,β5-integrin is about three times lower in mature myotubes than in myoblast precursors. Another drawback of adenoviruses is that the maximal size of a gene insert is only about 7.5 kb. This is obviously not sufficient to accommodate the whole dystrophin gene, but may be enough to accommodate a dystrophin minigene (6.3 kb) that may confer partial dystrophin activity.[34] Although the minigene encodes a truncated protein, its expression has been shown in a mouse model to protect muscle fibers against the degeneration process that affects the dystrophin-deficient myofibers.[2]

Cancer

An area that sees some of the most concentrated effort towards the implementation of gene therapy is that of cancer. Insight into the mechanisms of cell development and growth regulation within cancer cells has

provided researchers with multiple pathways and potential methods for genetic intervention. Different approaches for employing genes and various gene delivery methods have been attempted. Although no ideal 'cure' gene has been identified, there are several potential therapeutic genes that may alter the biological behavior of malignant cells by decreasing their malignant potential or making them sensitive to chemotherapy. With regard to *in utero* gene therapy, there is a growing number of inherited genes that are responsible for familial cancer. An example of early expression of tumor-susceptibility genes is the retinoblastoma gene that may manifest in the first year of life. Potentially, such genes may be targeted *in utero* to prevent their expression by one of the approaches described above.

Ethical issues

Germ-line gene therapy has a sparked a lively ethical discussion concerning both the technical feasibility and the ethical acceptability of human germ-line modification for the prevention of serious disease. It may be argued by some that this is a slippery slope towards the Orwellian concept of 'human genetic engineering', viewing germ-line gene therapy as having a potential for misuse in trait enhancement and 'neo-eugenics', and feeling that this raises troubling ethical concerns.[35] Conversely, others view this as merely the concept of fetal gene therapy, taken a step further.[36] Some suggest that there is merit in continuing the discussion about human germ-line intervention, so that this technique can be carefully compared with alternative strategies for preventing genetic disease.[37] There is definitely a need for development of guidelines for research and clinical practice for the coming years in order to address the ethics, safety, accuracy, cost and overall merit of pre-implantation genetics.[38] This issue is becoming more than a hypothetical one since the advent of pre-implantation genetic diagnosis.

Fetal stem-cell therapy

In utero stem-cell therapy is an important new approach to the treatment of genetic disorders in the fetus. This approach poses several significant advantages over treatment of such conditions in the neonatal period:

(1) In early gestation, the fetal immunological system is immature, and during a critical 'window of opportunity' does not recognize foreign antigens, thus obviating the need for human leukocyte antigen (HLA)-matched donors:
(2) Institution of therapeutic stem cells at an early developmental stage may facilitate their incorporation into tissue-specific 'niches'; thus, immuno-ablative therapy associated with high morbidity and mortality is not necessary;
(3) Establishment of cellular therapy at an early stage may theoretically prevent the pathological processes that cause irreversible damage;
(4) The prenatal exposure to donor antigens induces tolerance, and their recognition as 'self', allowing postnatal cellular therapy from the same donor, if needed.[39]

Table 109.1 Some examples of genetic disorders that may potentially be treated by *in utero* stem-cell therapy

Hemoglobinopathies
Sickle cell anemia
Alpha and beta thalassemia major
Hemophilia
Immunodeficiency diseases
Severe combined immunodeficiency syndrome (SCID)
Chronic granulomatous disease
Agammaglobulinemia
Chediak–Higashi syndrome
Wiskott–Aldrich syndrome
Inborn errors of metabolism
Mucopolysaccharidoses
Krabbe's disease
Adrenal leukodystrophy
Metachromatic leukodystrophy
Niemann–Pick
Gaucher's disease
Neuromuscular disorders
Duchenne's muscular dystrophy
Becker's muscular dystrophy

The conceivable scope of disorders that may potentially be treated by such an approach is tremendous. Obviously, various hematological disorders may be treated with hematopoietic stem cell; defects in liver metabolism and protein production may be treated by hepatocytes; muscular disorders may be amenable to myoblast therapy. Table 109.1 provides a partial list of genetic disorders that may potentially be treated by *in utero* stem-cell therapy.

Hematopoietic fetal stem-cell therapy

Bone marrow transplantation, a well-established therapeutic mode, is based on the observation that engraftment and proliferation of a small number of normal hematopoietic stem cells are sufficient to sustain normal hematopoiesis for a lifetime. This mode of therapy has been used for the reconstitution of bone marrow in patients with hematological malignancies (i.e., leukemia) but also in the treatment of genetic

hematological conditions (thalassemias). Despite its widespread success, bone marrow transplantation has several significant limitations:

(1) Scarcity of HLA-compatible donors;
(2) The adverse effects of HLA-mismatch: graft failure and graft-vs.-host disease;
(3) The need for myeloablation to achieve successful engraftment into the bone marrow;
(4) Even with successful engraftment, some of the disease manifestation may have already caused some irreversible damage.

The lack of a suitable donor may mean choosing between two evils: postponing bone marrow transplantation, sometimes to the point where it may be too late, or choosing a partially matched donor, leading to engraftment failure or graft-vs.-host disease. The need for myeloablation requires strict isolation to prevent opportunistic infections.

Theoretically, at least, *in utero* stem-cell therapy overcomes these limitations: there is no need for a matched donor, because early in gestation, exogenous cells manifesting foreign antigens may induce immunological tolerance. Thus, multiple sources of potential donors open up. These may include fetal stem cells, cord-blood stem cells or adult-derived stem cells. With the latter, a designated donor such as an unaffected sibling or parent may be used. This allows postnatal bone marrow transplantation after tolerance to their antigens has been established, obviating the need for an HLA-matched donor. With the maturation of the T-cells, a process of negative selection takes place in the thymus. This results in deletion of T-cell clones that manifest affinity to self-antigens, and preservation of multiple T-cell clones that exhibit affinity to non-self-antigens. Introduction of foreign antigens prior to the period during which this critical process takes place will result in deletion of T-cell clones that display affinity to these foreign antigens. Eventually, the immune system will treat these antigens as 'self'. The critical 'window of opportunity' may be as early as 12–14 weeks of gestation.[40] In immunodeficiency states, however, this window of opportunity may extend even further particularly when T-cell function is abnormal.

Since the immature fetal immune system cannot mount an immune response against foreign antigens, there is a reduced likelihood of rejection. However, graft-vs.-host disease remains a significant problem that requires depleting the donor bone marrow of T-cells. There are likely more available 'niches' in the bone marrow during the fetal period; thus, myeloablation is not necessary for ensuring engraftment. This also prevents the need for isolation and, in any case, the uterine environment is an ideal sterile environment. With the current invasive diagnostic techniques such as amniocentesis and chorionic villus sampling, and the ever-expanding list of disease genes being discovered through the concerted efforts of the Human Genome Project, it is conceivable that many hematologic disorders may prove to be amenable to fetal hematopoietic stem-cell (HSC) therapy. This is further facilitated by recent technical advances in invasive fetal intervention. It is now realistic to perform chorionic villus sampling at 10 weeks' gestation, perform the necessary DNA analysis for diagnosis, and administer fetal HSC therapy at 12–14 weeks. This would allow engraftment and establishment of an adequate reconstitution of normal hematopoiesis during the period leading to delivery. This would also avoid such complications as recurrent infections, the need for multiple transfusions, and growth restriction that often accompany such disorders.

Source of donor cells

Fetal HSCs. Theoretically at least, fetal-derived HSCs may be the best source since they contain a small number of mature T-cells prior to 14 weeks' gestation. This fact eliminates the severe outcome of graft-vs.-host disease, and avoids the need for T-cell depletion, which is both cumbersome and may also adversely influence engraftment success. Other benefits of using fetal-derived HSCs may be attributed to ontologic differences in the capacity for both proliferation and differentiation of fetal vs. adult HSCs.[39] Animal studies have shown that adult-derived HSCs have a limited capacity for self-renewal compared to fetal liver-derived cells[41] and that umbilical cord blood-derived HSCs have increased replating potential compared to those derived from adult bone marrow. Furthermore, the proportion of responding cells decreases with age, when comparing HSCs purified from adult bone marrow, from umbilical cord blood and from fetal liver.[42] Fetal-derived cells appear to have a wider spectrum of lineages that they can express, when compared with adult-derived HSCs.[43] Finally, fetal cells may have better bone marrow homing ability that would improve engraftment success.

Unfortunately, the use of fetal HSCs poses great ethical and technical difficulties. Ethically, the use of normal fetuses through elective terminations of pregnancy as a potential source is likely to meet with widespread opposition. Even if the ethical obstacles were overcome, there is a serious concern regarding the sterility of fetal HSCs obtained through standard terminations of pregnancy.[44] Obviously, the contamination of transplanted HSCs with bacterial, viral or fungal pathogens may have grave consequences for the recipient fetus and/or the mother. Thus, alternative methods for obtaining contamination-free fetal HSCs need to be devised. Another technical problem has to do with the fact that the fetal liver, the rich source of HSCs, can only provide a limited supply of cells. Moreover, once this supply has been exhausted, it is not renewable. This undermines one of the alleged benefits of fetal HSC therapy, namely, the induction of tolerance to the donor cells.

Cord blood HSCs. The use of cord blood as a source for HSCs would certainly pose less of an ethical problem. Cord blood is relatively rich in circulating HSCs and cryopreservation of cord blood for autologous transfusion in the event of developing a hematopoietic malignancy is becoming widespread. Cord blood may be collected in a relatively sterile fashion, thus eliminating some of the concerns regarding possible transmission of infection. However, cord blood has a finite quantity of HSCs and it is not replenishable. Furthermore, unless the cord-blood donor is a known relative, who may become a postnatal bone marrow transplantation donor, there is no benefit gained by induction of tolerance.

Adult HSCs. Currently, adult-derived HSCs appear to be the most practical source for *in utero* fetal HSC therapy. This source would be ethically acceptable, infection-free, and most importantly, provide a readily renewable reservoir of donor cells. Thus, the induction of 'pre-immune' tolerance to donor antigens would allow the repeated administration of postnatal bone marrow transplantation from the same donor to whom tolerance has been obtained, such as a family member. There are, however, some significant limitations to the use of adult-derived HSCs. The presence of mature T-cells in adult bone marrow is responsible for graft-vs.-host disease. Unfortunately, complete depletion of T-cells often results in engraftment failure. Nonetheless, it is becoming technically possible to enrich adult bone marrow with hematogenic progenitors while reducing T-cell content to a level that would be tolerable with respect to graft-vs.-host disease, and still obtain engraftment.[45] Another concern stems from the use of a family member as a potential source of donor cells. In autosomal recessive disorders, the family member (parent or sibling) may be a heterozygous carrier, and the HSCs may not have the full therapeutic potential.

Future developments will most likely focus on the improvement of techniques for enrichment of adult bone marrow, and the discovery of ways in which HSCs can be propagated indefinitely in culture.

Diseases potentially amenable to fetal HSC therapy

The prerequisites for institution of fetal HSC therapy are:

(1) Understanding of the disease pathophysiology;
(2) The ability to perform first-trimester prenatal diagnosis;
(3) Incomplete amelioration by postnatal bone marrow transplantation.

The list of hematopoietic disorders potentially amenable to fetal HSC therapy can be divided into three general categories: hemoglobinopathies, immunodeficiency disorders and inborn errors of metabolism.

Hemoglobinopathies

The most common hemoglobinopathies are sickle cell disease and thalassemia syndromes (alpha and beta). These disorders may theoretically be diagnosed by DNA analysis in the first trimester, given previous knowledge of the specific gene mutations in the carrier parents. They can be ameliorated by postnatal bone marrow transplantation; however, some of the severe manifestations of the disorders may have already occurred by the time of delivery. Moreover, as time goes by in search of a suitable donor, additional organ damage may have occurred. Bone marrow transplantation also carries a risk of severe morbidity and mortality, and has yet to become standard treatment in these disorders. In thalassemias, the disease pathology is due to a lack of alpha or beta hemoglobin chains, and the ensuing anemia and extramedullary hematopoiesis. In sickle cell disease, the anemia is compounded by the tendency for sickling at low oxygen tension, leading to vaso-occlusive episodes. The addition of red blood cells with normal hemoglobin reduces the viscosity of the blood in a dose-dependent fashion. For successful HSC therapy of sickle cell disease, a sufficient amount of HSCs have to be transferred in order to overcome the anemia, but also to significantly alter the ratio of abnormal/normal red blood cells in order to reduce the risk of sickling. Maintaining a high proportion of red blood cells originating from transplanted HSCs may be possible in both disorders due to the longer half-life in the circulation of normal cells compared to abnormal ones.

Immunodeficiency diseases

These include a wide range of disorders with variable modes of inheritance and different molecular causes. Most of these disorders appear to be good candidates for *in utero* HSC therapy. However, those diseases in which a survival benefit exists for normal cells are likely to have the greatest likelihood of success. An example of such a disease is the severe combined immunodeficiency syndrome. More than 50% of these cases are caused by an X-linked recessive mutation of the gene encoding a common component, the cytokine receptor super-family.[46] Affected individuals suffer repeated infections due to T-cell dysfunction and diminished B-cell response. Bone marrow transplantation therapy for severe combined immunodeficiency disease with HLA-matched donors has been successful without myeloablation. This suggests that the normal HSCs have a survival advantage over the abnormal ones.[47] Even if no competitive advantage is expected for the donor HSCs, the partial reconstitution of a normal cell-line may be sufficient to ameliorate some of the clinical manifestations, and at least result in donor-specific tolerance. As predicted, immunodeficiency disorders were the first to be treated successfully with *in utero* HSC therapy, as will be outlined in the section about 'Clinical experience'.

Inborn errors of metabolism

The last group of disorders that may be treated by *in utero* HSCs are inborn errors of metabolism, that are caused by a specific defect of a lysosomal enzyme. This results in the inability to hydrolyze specific substrates, like glycogen, mucopolysaccharides or sphingolipids, which in turn accumulate and cause disease-specific tissue and organ damage. At least in some of these disorders, prenatal administration of HSCs may provide a source for normal mononuclear cells that may differentiate into tissue-specific phagocytes (Kupffer cells in the liver, macrophages in lymphatic organs, and microglia in the brain). The phagocytotic cells can theoretically dispose of the accumulating substances, thereby ameliorating some of the severe disease manifestations. The importance of initiating prenatal therapy is underlined in many of these disorders since severe and irreversible organ damage (especially in the central nervous system) may have already occurred at the time of birth in many of these disorders. In addition to early onset of central nervous system damage in some disorders such as metachromatic leukodystrophy, postnatal maturation of the blood–brain barrier may prevent the access of therapeutic HSCs into the central nervous system postnatally. It is still unclear, however, whether it is feasible to treat severe central nervous system-damaging disorders by supplying *in utero* HSCs for replacement of glial cells. More research using adequate animal models is required.

Animal models of fetal hematopoietic stem-cell therapy

The first evidence for *in utero* induction of immunological tolerance comes from well-known observations in cattle. Dizygotic cattle twins may share interplacental circulation, resulting in a state of hematopoietic chimerism. This leads to permanent tolerance for skin and organ transplantation between such siblings. Flake and coworkers demonstrated that pre-immune transplantation of allogenic fetal liver-derived hematopoietic cells results in long-term, multilineage hematopoietic chimerism in a sheep model.[48] They reported that the success of such treatments declined with increasing gestational age, supporting the concept of a 'window of opportunity' limited by immunological development for successful application of *in utero* HSC transplantation. Zanjani and colleagues also demonstrated that tolerance may be induced to xenogeneic transplantation. This was achieved by *in utero* transfer of human HSC into fetal sheep.[49] Multilineage engraftment was achieved and maintained for several years. Moreover, they were able to obtain multilineage repopulation after retransplantation into a second-generation recipient.[50] This was achieved by isolation of human HSC from a human–sheep hematopoietic chimera model, and performing *in utero* HSC transfer. However, only two of the six recipients demonstrated human HSC engraftment at birth. Nonetheless, this was taken as evidence for the engraftment of 'immortal' HSCs, confirming the potential of *in utero* HSC transplantation for lifelong reconstitution of fetuses with hematopoietic disease.

Clinical experience

There have been only a handful of reported clinical studies of *in utero* HSC therapy. Most cases, however, were unsuccessful either due to suboptimal timing, dose or source of donor cells, or due to graft-vs.-host disease.[51] Nonetheless, a few reports in the last few years have fuelled high expectations of this mode of therapy. The first successful experience has been reported by Touraine.[52] He reported successful treatment of a child with bare lymphocyte syndrome and a child with severe combined immunodeficiency disease using fetal liver-derived HSCs transfused into the umbilical cord. The child with bare lymphocyte syndrome had 10% donor lymphocytes at birth and as many as 26% at 1 year of age. More importantly, this child was free of infection. The child with severe combined immunodeficiency disease had received postnatal cell transplants, making the interpretation of the results of the prenatal treatment more difficult.

Flake and colleagues reported a successful *in utero* HSC treatment of a child diagnosed *in utero* with X-linked severe combined immunodeficiency disease. The source of the HSCs was the unaffected father's bone marrow. The donor bone marrow was enriched for CD34 + cells, and depleted of CD3 + cells. The fetus received three transplants at 16, 17.5 and 18.5 weeks' gestation, by ultrasound-guided intraperitoneal injection. Postnatal documentation of engraftment by several methods confirmed high levels of donor cell engraftment, with 100% of T lymphocytes of donor origin. Serial analyses confirmed persistence of the engraftment with progressive improvement in lymphocyte counts and humoral response, with evidence of specific response to vaccinations.[53]

Myoblast therapy

Another potential use of stem-cell therapy exists for muscular disorders with the transfer of myoblasts, which are the stem-cell precursors of muscle fibers. Duchenne's muscular dystrophy is a paradigm for such disorders. Theoretically, donor myoblasts injected into muscles of affected patients may fuse with host muscle fibers, thus contributing their nuclei, which are potentially capable of replacing the deficient dystrophin. There have been several attempts at postnatal myoblast transfer therapy for Duchenne's muscular dystrophy. Morandi and coworkers performed myoblast transplantation in three Duchenne's muscular dystrophy

patients from HLA-matched donors. However, 3 months later, biopsies from the injected muscles failed to demonstrate dystrophin expression by immunocytochemistry and reverse transcriptase-polymerase chain reaction (RT-PCR).[54] Mendell and associates injected donor myoblasts once a month for 6 months into the biceps brachii muscles in 12 boys with Duchenne's muscular dystrophy. Six months after the final myoblast transfer, the presence of dystrophin was assessed with the use of specific antibodies. No significant improvement in muscle strength was noted although in one patient, 10% of muscle fibers expressed donor-derived dystrophin, three other patients had less than 1% donor dystrophin, and the remaining eight patients had none.[55] Miller and co-workers evaluated myoblast implantation in ten boys (aged 5–10 years) with Duchenne's muscular dystrophy. Using RT-PCR, evidence of myoblast survival and dystrophin mRNA expression was obtained in three patients after 1 month and in one patient after 6 months.[56] The lack of success in treatment of Duchenne's muscular dystrophy by postnatal myoblast therapy underscores the value of *in utero* myoblast cell therapy.

Conclusions

Genetic approaches, once thought to be improbable and futuristic, are now reaching reality. Stem-cell therapies are more likely to be clinically applied in the next few years but direct injection of genes will probably have a place within the next decade. It will be incumbent upon the proponents of these therapies to ensure that the ethical arguments are well developed and espoused so that public opinion will welcome such developments.

110 Treatment of fetal arrhythmias

S. Maheshwari, J. A. Copel and C. S. Kleinman

Introduction

Technical advances have made it possible to diagnose both structural and functional heart disease prenatally. The developing fetus normally adapts to abnormal flow patterns, and is, therefore, rarely compromised by structural heart disease. In such cases, the major dilemma is whether to continue the pregnancy or not. However, in the case of fetal cardiac rhythm disturbances there are diagnostic, therapeutic and ethical dilemmas due to the potential for *in utero* therapy.

From the diagnostic point of view, in the absence of reliable transabdominal fetal electrocardiography, echocardiography and Doppler ultrasound are used to analyze cardiac rhythm by relating mechanical events to preceding electrical events. However, without an electrocardiogram some diagnoses are almost impossible to make (e.g. Wolff–Parkinson–White syndrome).

In terms of therapy, the pharmacological treatment of *in utero* arrhythmias involves the administration of potent cardiac medications to the mother. The treatment of this 'patient within a patient' therefore involves moral, ethical and even legal considerations. How much maternal risk is appropriate for a given fetal therapy? Can a mother provide informed consent that is free of subconscious coercion to provide potentially lifesaving treatment for her unborn child? Who should represent the unconsenting fetus in these deliberations?

The appropriate management of an arrhythmia requires an understanding of the precise nature, electrophysiologic mechanism and natural history of the arrhythmia, the pharmacology, pharmacokinetics and possible toxicity of the antiarrhythmic agents used in the maternal–fetal unit, and a detailed risk–benefit analysis.[1,2]

Although not all fetuses with sustained arrhythmias develop hydrops fetalis, the potential for this life-threatening complication is present for any fetus with such arrhythmias. Diastolic filling of the fetal ventricle is very dependent on atrial systole, probably due to limited compliance of the fetal myocardium compared to the ventricular myocardium of older children and adults.[3] This intrinsic 'stiffness' of fetal myocardium makes the fetal heart more prone to the deleterious effects of tachycardias, which foreshorten the diastolic filling period. The fetal heart, therefore, behaves as a heart with a limited reserve.[4] These properties of the myocardium and the unique fetal circulatory system, with the two ventricular cavities connected in parallel with one another, explains why hemodynamic compromise leads to elevated right atrial pressure, systemic venous hypertension and, ultimately, to systemic edema and hydrops fetalis.

The management of a fetus with a sustained arrhythmia begins with a risk–benefit analysis that considers whether the fetus has reached pulmonary maturity, and whether there is evidence of hydrops fetalis. If the fetus is mature, the best treatment option may be delivery and postnatal antiarrhythmic treatment, if necessary. If delivery is inadvisable due to prematurity, the presence or absence of hydrops dictates the urgency of treatment. As the mortality rate for severely hydropic infants is high (irrespective of the cause of the hydrops), vigorous attempts at *in utero* therapy are warranted.

In the fetus with sustained tachycardia but without evidence of hydrops, the therapeutic dilemma increases. In this setting, the decision regarding provision of therapy must depend on several considerations, including (1) the potential risk of developing hydrops fetalis, although determining the likelihood of this developing in a given patient may be difficult, or at times impossible; (2) the potential risks of antiarrhythmic therapy to mother and fetus and (3) individual considerations, including the wishes of the parents after an extensive discussion of benefits and risks. Such decisions must respect maternal autonomy and may be influenced by the gestational age of the fetus, and whether fetal viability imparts a limitation on maternal autonomy.

Fetal rhythm analysis and interpretation

When auscultation of the fetal heart reveals an abnormally rapid (> 160 bpm), slow (< 100 bpm) or irregular rate, the clinician is confronted with the task of accurately diagnosing the nature of the arrhythmia. The use of real-time-directed M-mode echocardiography has made this possible.[5,6] Fetal cardiac anatomy

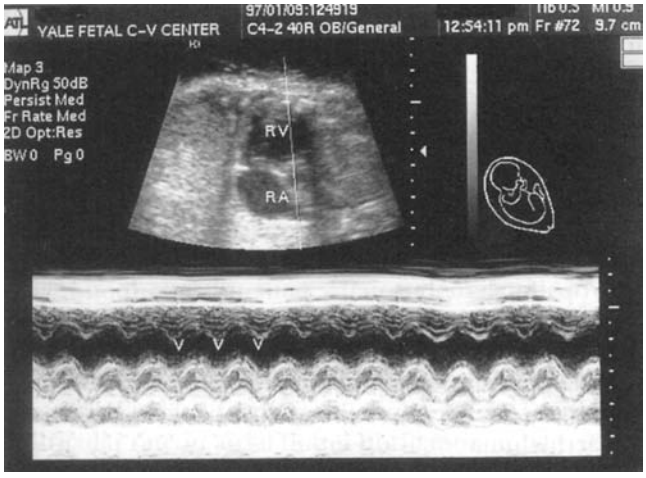

Figure 110.1 Normal M-mode recording. The M-mode cursor sweeps across the ventricle and the atrium. The ventricular wall contraction occurs at the same rate as the atrial wall motion, suggesting a normal 1:1 conduction. RV, right ventricle; RA, right atrium; V, ventricular wall; A, atrial wall.

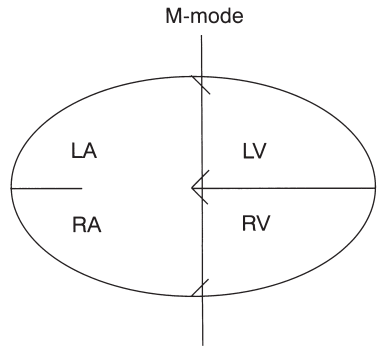

Figure 110.3 The M-mode cursor passing through the leaflets of the AV valves. The leaflets demonstrate an M-shaped motion during ventricular diastole, representing normal biphasic diastolic filling of the ventricles. Initial filling (E wave) is representative of passive early-diastolic filling, whereas atrial systole (active atrial contraction) is represented by the A wave. The onset of ventricular systole begins with inward motion of the ventricular wall. The atrial rate is the A–A interval and the ventricular rate is calculated from the V–V interval. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

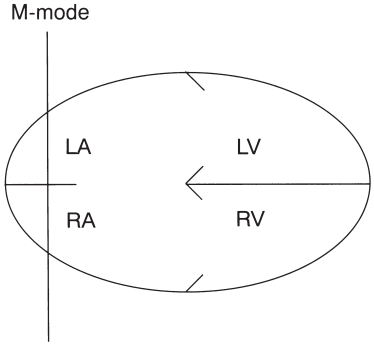

Figure 110.2 The M-mode cursor passing through both atria. Atrial systole is marked by the inward motion of the right and the left atrial walls and motion of the atrial septum primum within the left atrial cavity. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

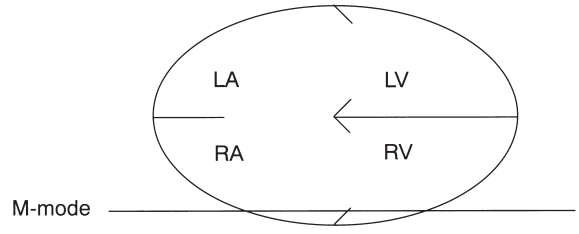

Figure 110.4 Atrial and ventricular systole is manifested by contraction of the atrial and ventricular walls, respectively. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

is first reviewed using two-dimensional imaging. The two-dimensional image is then used to orient the position of the M-mode sampling line. M-mode echocardiographic recordings of cardiac motion against time are made to time mechanical events in the cardiac cycle (Figure 110.1). The assumption is that mechanical events reflect preceding electrical stimulation of the atrium and ventricle. Alternatively, the sample volume of a pulsed Doppler scanner may be placed within the ventricles to provide further information concerning the timing of mechanical events and their influence on ventricular diastolic filling and systolic ejection.[7–10]

For rhythm analysis, atrial and ventricular wall motion may be visualized. Depending on the position of the fetal heart in relation to the ultrasound beam, the M-mode cursor can be directed through a plane that lies perpendicular, parallel or tangential to the interventricular septum (Figures 110.2–110.5).

Fetal antiarrhythmic agents

In this section, we will review the pharmacology and pharmacokinetics of the various medications used to treat *in utero* fetal arrhythmias via either maternal or direct fetal administration. We shall not discuss drug doses in detail because most doses are determined empirically, beginning with standard adult doses, recognizing that the metabolism of many drugs is altered in pregnancy by the changes in maternal blood volume and renal and hepatic metabolism. Doses can then be titrated upward, while closely monitoring the mother and fetus for toxic effects, or until a response is seen. We hospitalize all mothers for introduction of medications so that they can be monitored closely for any untoward effects. They are maintained on continuous telemetry until stable dosing is achieved. Each drug can be used for several different indications and

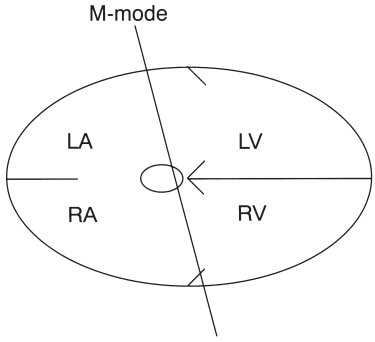

Figure 110.5 Aortic valve motion can be recorded. Ventricular systole is marked by opening of the aortic valve leaflets and/or ventricular wall contraction, whereas atrial activity is represented by atrial wall contraction. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

this will be further considered in the section on specific fetal arrhythmias.

The antiarrhythmic agents have traditionally been classified into four groups. Class I agents act chiefly by inhibiting the fast sodium channels: class IA agents include quinidine, procainamide and disopyramide; class IB agents include lidocaine and mexiletine and class IC agents include flecainide and propafenone. Class II agents act by β-blockade (e.g. propranolol). Class III agents act by a combination of electrophysiologic mechanisms and include amiodarone and sotalol. Class IV agents are the calcium-channel blockers, such as verapamil.

Digoxin

Although digoxin is not included in the preceding classification of antiarrhythmic agents, it is the mainstay of fetal therapy. It remains the drug of first choice in the treatment of *in utero* supraventricular tachycardia (SVT).

Mechanism of action

Digoxin inhibits the Na/K–ATPase pump. This leads to an increase in intracellular sodium, which in turn promotes calcium influx by the sodium–calcium exchange mechanism. The increased cytosolic calcium ion concentration leads to enhanced myocardial contractility. This effect may be useful in treating the congestive heart failure (CHF) presumed to occur secondary to the tachyarrhythmia.

Digoxin also causes parasympathetic activation, resulting in sinus slowing and atrioventricular (AV) nodal inhibition. This leads to a slowing in AV node conduction and a prolongation of the AV refractory period. This may serve to protect the ventricle against a rapid ventricular rate in the face of a SVT. It also has a potential role in breaking reentrant SVT involving the AV node as a part of the reentry circuit. Sympathetic inhibition via inhibition of sympathetic nerve discharge may play an additional important role in the effects of digoxin in CHF.

Pharmacokinetics

Most studies demonstrate that maternal and fetal serum levels of digoxin are similar, although the ratio of fetal to maternal levels may vary from 0.6 to 1.0. The major excretion of digoxin is via the kidneys, so maternal doses have to be decreased in the presence of renal failure. On the other hand, the increased glomerular filtration rate seen in normal pregnancies results in larger doses usually being required in pregnant women.

Clinical experience suggests that transplacental passage of this agent is impaired in the presence of hydrops fetalis,[11] but many patients do respond, with termination of the tachycardia and subsequent resolution of the hydrops. Direct administration of digoxin to the fetus by periodic intramuscular injections has been used when indirect therapy via the mother has failed to control the arrhythmia.[12,13]

A digoxin-like immunoreactive substance (DLIS) may be present in the serum of pregnant women and newborn infants who have not been treated with digoxin. This DLIS appears to be biologically inactive and does not increase the toxicity of digoxin, but its presence makes the maternal, fetal and neonatal digoxin concentrations measured by radioimmunoassay difficult to interpret.[14] During the administration of digoxin we therefore monitor the mother and fetus carefully for clinical evidence of digoxin toxicity, while striving to attain maternal digoxin levels toward the upper end of the therapeutic range (1.5–2 ng/ml). To attain these levels, we have used intravenous digoxin loading (total loading dose of 1 mg) followed by rather large oral maintenance doses (0.50–0.75 mg/day), which can be titrated upward or downward depending on response and toxicity.

Drug interactions

Quinidine, flecainide, verapamil and amiodarone may increase serum digoxin levels by decreasing the renal and non-renal clearance of digoxin. The dose of digoxin therefore needs to be adjusted when any of these medications are used concurrently. Procainamide and sotalol have no pharmacokinetic interactions with digoxin.

Features of digoxin toxicity

Features of toxicity include gastrointestinal problems (anorexia, nausea, vomiting and diarrhea), neurologic problems (malaise, fatigue, confusion, facial pain, insomnia, depression, vertigo and disturbed yellow–green color vision), and cardiac symptoms. These are largely explained by increased vagal tone and include AV block and sinus bradycardia. Digoxin also increases the automaticity of junctional and His–Purkinje tissue. Accelerated atrial, junctional or ventricular arrhythmias may therefore result, and when combined with AV nodal block are highly suggestive of digoxin

toxicity. Any 'new' arrhythmia appearing in a patient receiving digoxin should raise the suspicion of digoxin toxicity.

Quinidine

Quinidine is the prototype of class IA agents. It has a wide spectrum of activity against reentrant as well as ectopic atrial and ventricular tachyarrhythmias.

Mechanism of action

Quinidine, like all class I agents, blocks fast inward currents of sodium ions. It slows conduction and increases refractoriness in the retrograde limb of AV nodal tachycardias and over accessory pathways. It also has a vagolytic effect and inhibits muscarinic receptors. This can lead to sinus tachycardia or an increased ventricular rate in atrial flutter–fibrillation.

Pharmacokinetics

Quinidine is primarily metabolized by hydroxylation in the liver. Hepatic failure, therefore leads to higher blood levels. The transplacental passage of quinidine is variable. Traditionally, before quinidine is administered, a test dose of 0.2 g is given to check for drug-induced idiosyncratic reactions, including cardiovascular collapse.

Side effects

Quinidine may prolong the QT interval, which can lead to serious arrhythmias including ventricular tachycardia and torsades de pointes. This proarrhythmic effect of quinidine and of other agents in this class (e.g. procainamide and flecainide) must be discussed with parents when informed consent is sought for inclusion of this agent in the treatment regimen.

Quinidine excess is best prevented by serial measurements of QRS duration and QT interval on the electrocardiogram. If the maternal QRS duration widens by 50%, or if the total QRS duration exceeds 140 ms, or if QT or QTU prolongation occurs beyond 500 ms, the quinidine dose should either be reduced or its inclusion in therapy reassessed. Unfortunately, these parameters cannot be monitored in the fetus.

Non-cardiac side effects include diarrhea, nausea, headaches, dizziness, angioedema and tinnitus. Hypersensitivity reactions including fever, skin rash, agranulocytosis, thrombocytopenia, hepatitis, hemolytic anemia and lupus erythematosus have occurred. Neonatal thrombocytopenia has been reported with maternal use, and in view of anecdotal reports of retinal damage and intrauterine death with the use of maternal quinidine, we currently use quinidine very rarely.

Drug interactions

Concomitant use of quinidine and digoxin may lead to a twofold or a greater increase in serum digoxin levels. If quinidine is used along with other agents, such as amiodarone or sotalol, there is a much greater propensity for QT prolongation. Such combinations should, therefore, be avoided. Other agents that interact to prolong the QT interval include the macrolide antibiotics (e.g. erythromycin), the antihistamine terfenadine, certain antifungals (e.g. ketoconazole) and other type I antiarrhythmics.

Procainamide

This is another class IA agent, which is generally effective against a wide variety of supraventricular and ventricular arrhythmias, including ventricular tachycardia. Procainamide does not prolong the QT interval to the same extent as quinidine, and therefore has a relatively lower associated incidence of torsades de pointes.

Pharmacokinetics

There is rapid renal elimination (half-life 3.5 h with normal renal function). Unlike quinidine, there is no pharmacokinetic interaction with digoxin.

Side effects

Hypotension is a common side effect with intravenous administration of procainamide. In atrial fibrillation, the ventricular rate may increase as the atrial rate slows down, allowing more frequent AV nodal conduction, so that concomitant digitalization is advisable. Proarrhythmic effects, including torsades de pointes, can occur and may be dose-related, although the incidence is less than with quinidine.

Other side effects include fever and rash (early), and arthralgia, lupus and agranulocytosis (late toxicity).

Although procainamide is included here under medications used for *in utero* therapy, there have only been scattered reports of its use, with varying degrees of success. There have been reports of successful transplacental cardioversion of fetal SVT with procainamide,[15] while others have reported that procainamide is not effective in the treatment of fetal arrhythmias.[12]

Flecainide

Although flecainide continues to be used for life-threatening arrhythmias, it acquired a bad reputation because of its proarrhythmic effects in the Cardiac Arrhythmia Suppression Trial (CAST) study[16,17] of postmyocardial infarction patients.

Mechanism of action

Flecainide inhibits the fast sodium channel, and therefore depresses the upstroke of the cardiac action potential. It also has a marked inhibitory effect on His–Purkinje conduction with QRS widening.

Side effects

Cardiac side effects include aggravation of ventricular arrhythmias and the threat of sudden death (as shown in the CAST study). The proarrhythmic effect of flecainide has created controversy regarding its appropriate use.

When flecainide is used for the treatment of atrial flutter or fibrillation, it can cause a decrease in atrial

rate with accelerated AV conduction and ventricular arrhythmias. It should, therefore, be coadministered with digoxin, β-blockers or verapamil to avoid accelerated AV conduction.

Extracardiac side effects are related to the central nervous system (blurred vision, dizziness, headache, nausea, paresthesias, fatigue, tremor and nervousness).

Usage

This potent antiarrhythmic has been used in the treatment of life-threatening arrhythmias of both supraventricular (including Wolff–Parkinson–White syndrome, atrial flutter, atrial fibrillation) and ventricular origin in patients without structural heart disease.

The largest study on the use of maternal flecainide for fetal therapy was by Allan *et al.*,[18] who treated 14 patients with flecainide, of whom 12 responded with termination of the arrhythmia. There was one intrauterine death. The main advantage of flecainide was that the mean time to conversion was about 48 h, and quick control of the rhythm allowed resolution of the hydrops.

Although flecainide is effective in the treatment of fetal arrhythmias,[19] its proarrhythmic effect makes it unsuitable for routine use. Its use should be confined to high-risk patients with life-threatening arrhythmias, which are refractory to treatment with other agents. It should be emphasized that while certain fetal arrhythmias may be potentially life-threatening to the fetus they are not life-threatening to the mother. Therefore, exposing her to potentially toxic medication may not be justifiable.

Propranolol

β-Blocking agents, such as propranolol, have been utilized for the treatment of fetal SVTs. Propranolol is a non-selective β-adrenergic blocker, which slows down AV nodal conduction. It also inhibits atrial ectopic activity and, therefore is useful in the prophylaxis of macro-reentrant SVT by inhibiting the initiating atrial ectopic beats.

Pharmacokinetics

The half-life of propranolol ranges from 1 to 6 h. It is metabolized primarily in the liver. Propranolol readily crosses the placenta, although the degree of transfer is variable. As propranolol has a broad therapeutic index, the maternal dose can generally be increased without untoward maternal effects in efforts to attain therapeutic fetal levels. The starting dose is 60 mg orally every 6 h, with rapid titration to 180–240 mg orally every 6 h.

Side effects

A number of fetal/neonatal adverse effects have been reported following the use of propranolol in pregnancy. These include intrauterine growth retardation (IUGR) (although a confounding factor is that most pregnant women who are prescribed propranolol are hypertensive and this is a risk factor for IUGR), hypoglycemia, bradycardia, respiratory depression at birth (these are the most common side effects), hyperbilirubinemia, hyperirritability, hypocalcemia with convulsions, thrombocytopenia and polycythemia. If propranolol is used for *in utero* therapy, the newborn should be observed for 24–48 h after delivery for any evidence of bradycardia, hypoglycemia or other symptoms of β-blockade.

Amiodarone

Amiodarone is a unique wide-spectrum antiarrhythmic agent manifesting chiefly class III activity but also with powerful class I activity and ancillary class II and class IV activity.

Mechanism of action

Amiodarone lengthens the effective refractory period by prolonging the action potential duration in all cardiac tissues, including any bypass tract that may be present. It also has powerful class I (sodium channel inhibition), class II (β-blockade) and class IV (calcium antagonism) effects. Its class IV effects might explain the bradycardia and AV nodal inhibition associated with its use, and the relatively low incidence of torsades de pointes that is seen.

Pharmacokinetics

Amiodarone undergoes variable and slow gastrointestinal absorption. The main problem associated with its use for *in utero* therapy is its long half-life of 25–110 days, and the serious toxic effects that can occur. Amiodarone is excreted by the skin, the biliary tract and the lacrimal glands.

Side effects

In higher doses, there is an unusual spectrum of toxicity, the most serious being pneumonitis, potentially leading to fatal pulmonary fibrosis.

Amiodarone may inhibit the sinoatrial or AV node, but is generally regarded as a safe drug from the hemodynamic point of view. Although torsades de pointes is relatively rare, it can occur.

Central nervous system problems include proximal muscle weakness, peripheral neuropathy and neural symptoms (headaches, ataxia, tremors, impaired memory, insomnia, dreams).

Amiodarone has a complex effect on the metabolism of thyroid hormones. It contains iodine and shares a structural similarity to thyroxine. It can, therefore, inhibit the peripheral conversion of T4 to T3 with a rise in the serum level of T4 and a fall in the level of T3. In about 3–5% of patients hypo- or hyperthyroidism may develop.

Drug interactions

The most serious interaction is an additive proarrhythmic effect with other drugs prolonging the QT

interval, such as class I antiarrhythmic agents and class III agents, including sotalol. Amiodarone may increase quinidine and procainamide levels, and these combinations are therefore not advised.

Although amiodarone is a powerful antiarrhythmic agent and has been used with increasing frequency in children and adults, its appropriateness for *in utero* fetal therapy remains to be clarified. There have been several case reports documenting the successful use of amiodarone for fetal arrhythmias,[20,21] although hypothyroidism in the newborn has been reported and is of serious concern.[22]

Apart from maternal administration of amiodarone, there are reports in the literature of amiodarone injections into the umbilical vein, after maternal therapy with multiple antiarrhythmics, including amiodarone, failed to resolve the fetal arrhythmia.[21] As serious adverse effects attributable to amiodarone have been observed in the newborn, we continue to be cautious about advocating the use of amiodarone for fetal arrhythmias because of the limited data available. If it is used for refractory or life-threatening arrhythmias, it is mandatory to check thyroid function tests in the newborn period and to monitor the mother closely for any possible side effects.

Verapamil

Mechanism of action

Verapamil inhibits the action potential of the AV node, where depolarization is calcium-mediated. It thus inhibits one limb of the reentry circuit, which is believed to underlie most paroxysmal SVTs. Verapamil increases AV block and this explains the reduction in the ventricular rate in atrial flutter and fibrillation. Verapamil also has a negative inotropic effect on the heart and causes arterial dilatation, the combination of which can lead to hypotension and even cardiac arrest.

Drug interactions

Verapamil can interact with digoxin to increase serum digoxin levels. Digoxin doses should therefore be adjusted downward in order to avoid toxicity.

Side effects

Headache, facial flushing, dizziness and constipation can occur. Verapamil has a striking negative inotropic effect. Its use is contraindicated in ventricular tachycardia as it can cause myocardial depression, which may be lethal.

In infants, the use of verapamil is contraindicated as it can cause hypotension and cardiovascular collapse. It is believed that the immature myocardium, with its inherently limited systolic and diastolic reserve, is extremely calcium channel-dependent for contractile force. Administration of a profound calcium channel-blocking agent can have an extremely negative effect on the myocardium of the already stressed immature heart. Although verapamil is used for the treatment of fetal arrhythmias, it should therefore be used with caution, especially in the presence of cardiac failure and myocardial depression.

Adenosine

Adenosine is also a class IV agent that is a potassium channel opener and an indirect calcium antagonist. It inhibits the AV node and prevents reentry of electrical impulses through the AV node. The chief indication for its use is, therefore, narrow complex SVT [AV nodal reentrant tachycardia (AVNRT), AV reentrant tachycardia (AVRT) and Wolff–Parkinson–White syndrome]. Adenosine has no effect on ectopic atrial tachycardia or atrial flutter.

Adenosine is quite effective in breaking reentrant SVT, so it may be considered for inclusion early in the treatment protocol as a therapeutic/diagnostic trial. Should administration of this agent result in even a brief episode of sinus rhythm, one may be reassured regarding the accuracy of the initial electrophysiological diagnosis of the arrhythmia, and further therapy should be focused on the assumption that one is dealing with a reciprocating SVT. Adenosine may also be useful in breaking refractory SVT when transplacental therapy is unsuccessful. In that setting it should be followed by intraumbilical venous digoxin to load the fetus with a long-acting agent.

Pharmacokinetics

Adenosine has an extremely short half-life of 10–30 s. It must, therefore, be delivered directly to the fetal umbilical vein rather than to the mother for transplacental passage. The dosage should be approximately 100–200 μg/kg of estimated fetal dry weight.

Side effects

Side effects include headache, flushing, bronchoconstriction, chest pain and excess sinus or AV nodal inhibition. Since adenosine is given to the fetus rather than to the mother, none of these effects would be expected for the mother, although the electrophysiological side effects may occur in the fetus, especially with excessive dosing.

Tachyarrhythmias

Supraventricular tachycardia

The most common tachyarrhythmias identified in the fetus are SVTs. SVTs may be (1) reentrant (reciprocating), related to a 'circus' movement of electrical activity, (2) automatic (arising in an irritable ectopic focus above the bundle of His) or (3) a manifestation of atrial flutter or fibrillation.

Reentrant tachycardias

In the fetus and neonates, the most common electrical mechanism underlying SVT involves a reentrant or

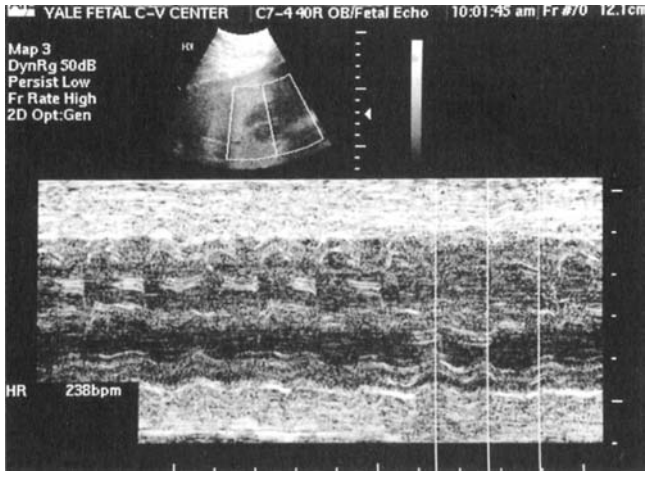

Figure 110.6 M-mode echocardiogram demonstrating a rapid atrial rate of 238 bpm secondary to SVT. The M-mode cursor is at the level of the atria.

reciprocating mechanism. An electrical impulse enters the atrium from the ventricle and develops a circular movement of repeated electrical stimulation that is faster than, and independent of, the normal sinus nodal pacemaker. Because the heart will beat at the rate of the fastest pacemaker, this electrical stimulus drives the heart at an abnormally fast and fixed rate.

The two common kinds of reentrant tachycardias are AVNRT and AVRT. In AVNRT there are two pathways with differing conduction velocities and refractory periods within the AV node itself. The usual inciting mechanism is an extra systole that encounters the fast conducting pathway (with a longer refractory period), while it is still refractory following the preceding normal sinus beat. AV conduction, therefore, occurs down the slow pathway. If the fast pathway has recovered by this point, ventriculo-atrial conduction may occur up the fast pathway to the atrium. This results in establishment of a circus movement of electrical activity.

In AV reentrant tachycardia, there is a discrete accessory conduction pathway that bypasses the usual delay within the AV node. This pathway directly connects atrial to ventricular muscle (as in the 'bundle of Kent' in the Wolff–Parkinson–White syndrome) and serves as the fast link in the reentrant pathway.

Reentrant tachycardia can be recognized by its sudden onset and sudden termination, with both events associated with precipitating extrasystoles. For fetal SVT, the typically encountered heart rate is in the 220–260-bpm range (Figure 110.6).

Therapy

As the AV node is generally a part of the reentrant circuit, any maneuver that slows down AV nodal conduction may abruptly terminate the reentrant tachycardia. An increased vagal tone caused by cord or head compression during uterine contractions has been reported to break SVT. Antiarrhythmic agents that depress conduction and prolong refractory periods in the AV node or accessory conduction tissue can disturb the reentrant circuit and may be useful for the termination of, as well as the prevention of, AVNRT or AVRT. These include the cardiac glycosides (digoxin), the class IA antiarrhythmics (quinidine, procainamide), class IC antiarrhythmics (flecainide), β-blockers (propranolol), the calcium channel-blocking agents (verapamil), and the class III antiarrhythmic agents (amiodarone).

We usually begin maternal therapy with digoxin and then add propranolol, flecainide or other agents, if necessary. It is important to note that the diagnosis of Wolff–Parkinson–White syndrome cannot be made prenatally, because its diagnosis depends on the analysis of an electrocardiogram. The use of digoxin remains controversial in the treatment of Wolff–Parkinson–White syndrome because it can increase conduction over the accessory pathway and lead to a rapid ventricular response in the presence of atrial flutter or fibrillation. Patients who are being considered for transplacental therapy of SVT with digoxin should, therefore, be informed about the potential risks associated with digoxin and the Wolff–Parkinson–White syndrome.

Atrial flutter and fibrillation

These arrhythmias are much rarer than SVT in fetal life. They can be associated with congenital cardiac malformations and can present with hydrops fetalis. In addition, therapeutic control is more difficult than with SVT. Atrial flutter results from a circuit movement of electrical energy within the body of the atrium itself. Although the typical flutter rate in the postnatal period is about 300 bpm, in the fetus monotonous atrial flutter rates of 400–500 bpm typically occur (Figure 110.7). Although postnatally, therapy aimed at decreasing the ventricular response is successful, this has unfortunately not been found to be the case prenatally. This is probably related to the relatively restrictive myocardium of the fetus, with a relatively volume-loaded right heart. Unless the atrial flutter is controlled, atrial contractions would continue against a closed AV valve, resulting in high atrial and systemic venous pressures contributing to the persistence of the hydrops. Thus, with *in utero* therapy of atrial flutter, it is imperative that the therapeutic endpoint be a resumption of 1:1 AV contraction.

Fetal therapy for atrial flutter involves (1) the control of the ventricular response rate with digoxin, verapamil or β-blockers that act at the level of the AV node and (2) the use of a class I antiarrhythmic agents, such as quinidine, procainamide or flecainide, to restore a normal atrial rhythm. Amiodarone may be used as an alternative if class I agents are ineffective or poorly tolerated.

Atrial fibrillation appears to be even rarer in the fetus than atrial flutter. Digoxin therapy can be attempted. If, however, the arrhythmia persists

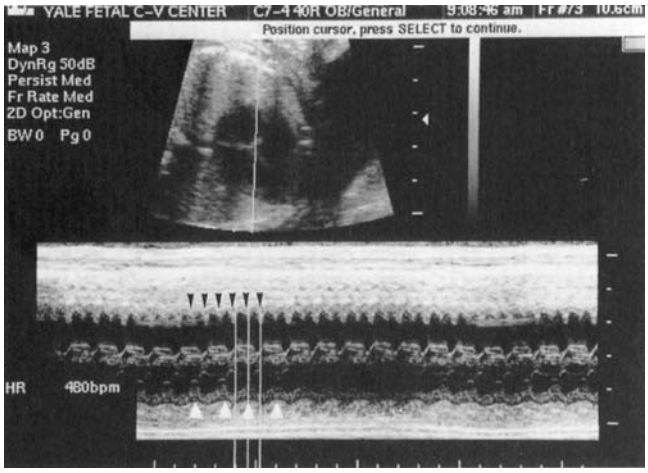

Figure 110.7 Atrial flutter with 2:1 block. Rapid and regular atrial contractions are being measured on the top panel (black arrows), while slower ventricular wall contractions are shown on the lower panel (white arrows). The atrial rate is around 480 bpm, with a ventricular response rate, which is half of that.

despite the control of the ventricular response rate, and if there is associated prematurity and/or hydrops fetalis, a class IA or IC antiarrhythmic agent is another option.

There is an increased mortality rate in patients with atrial flutter and fibrillation, which probably reflects the difficulty encountered in controlling this arrhythmia, in addition to its association with structural heart disease. It should be noted that the association of congenital heart disease with sustained fetal arrhythmias and hydrops fetalis appears to be ominous, imparting an extremely poor prognosis for survival with or without vigorous *in utero* and postnatal therapy.

Ventricular tachycardia

Fetal ventricular tachycardias are much less common than tachycardias of the supraventricular origin and they are also much more difficult to diagnose without an electrocardiogram. Many patients with this tachycardia are initially thought to have SVT. Careful examination of the M-mode echocardiographic tracings and recognition of the presence of AV dissociation (i.e. a lack of 1:1 relationship between atrial and ventricular contractions) are required to make this diagnosis. AV dissociation may also be found in junctional tachycardia, but is not found in AV reentrant tachycardias.

As fetal ventricular tachycardias are uncommon there, is not much literature available on *in utero* therapy. We have followed those fetuses with structurally normal hearts free of hydrops fetalis without any therapy. If there is evidence of right ventricular dilatation in the presence of a ventricular tachycardia and the fetus is previable, it would be reasonable to consider *in utero* therapy. Agents that could potentially be used after considering the risk–benefit ratio include β-blockers, flecainide, and perhaps, amiodarone. Although flecainide has been used with some success in the treatment of this arrhythmia, there are risks with this form of therapy, because *in utero* electrocardiograms are not available, and certain contraindications to the use of flecainide, such as a prolonged QT interval or a prolonged QRS duration, are not available for analysis before therapy is initiated. It is therefore important to inform the parents about possible risks and the limitations of *in utero* diagnosis and therapy for ventricular tachycardia, before treatment is initiated.

Bradydysrhythmias

The detection of a persistent fetal bradycardia (defined as a heart rate < 100 bpm) poses an infrequent but difficult management problem. In late pregnancy, the obstetrician's initial response is to suspect fetal distress. Inappropriate premature or operative delivery may follow. It is therefore important to be able to distinguish and diagnose the various causes of bradycardia in the fetus.

Sinus bradycardia is usually of no pathological significance, and implies immaturity of the fetal conduction system if it occurs in the presence of normal cardiac structure with normal heart rate responses to fetal activity. In the absence of hydrops fetalis, moderate sinus bradycardia (heart rates between 90 and 120 bpm) does not appear to be an ominous fetal arrhythmia. It requires no treatment and usually disappears spontaneously toward term.[23]

In atrial bigeminy with block, the bradycardia is related to coupled atrial ectopic beats. The ectopic beats follow too closely on the sinus beats to initiate ventricular contraction and the ventricular rate is thus halved. Electrophysiologically the ectopic beat is so closely coupled to the previous normal sinus beat that it encounters the AV node while it is still refractory, resulting in every second beat being blocked. This is a benign variant of premature atrial contractions and usually resolves quickly.

AV block implies that conduction of sinus or atrial impulses to the ventricle is delayed or interrupted. First-degree AV block is defined as prolongation of the PR interval and is impossible to identify in a fetus because of the absence of a reliable electrocardiogram. Second-degree AV block has been traditionally characterized as Mobitz type 1 or Mobitz type 2. Mobitz type 1 AV block, also referred to as Wenckebach conduction, is characterized by progressive PR prolongation with successive cycles prior to an eventual atrial impulse that fails to conduct to the ventricles. In contrast, Mobitz type 2 AV block refers to abrupt failure of AV conduction for one or more beats and is not preceded by progressive PR prolongation. During second-degree AV block multiple atrial impulses may be blocked for each impulse conducted. Conduction may occur in a regular or irregularly recurring pattern. Regular block can be characterized by the conduction ratio as 2:1, 3:1, 4:1, etc. Mobitz type 2 AV block has

Figure 110.8 Fetal hydrops in a fetus with complete heart block. The arrows indicate the abdominal wall edema.

been reported in fetuses. Some of these may progress to complete heart block. In the presence of Mobitz type 2 AV block, we recommend testing the mother for anti-Ro and anti-La antibodies. If these are positive one may hypothesize that the fetus is developing progressive damage to the AV node on an autoimmune basis, and the use of maternal steroids to ameliorate the inflammatory autoimmune response might be reasonable.[24]

Complete AV block

In third-degree heart block, no atrial impulses conduct to the ventricles. It is diagnosed when there is AV dissociation with a regular atrial rate exceeding a slow ventricular rate.

Etiology

Complete AV block occurs in two settings, characterized by the presence or absence of major congenital and anatomic cardiac defects. Certain forms of congenital heart disease have a high association with complete heart block, particularly AV septal defects and those involving abnormalities in bulboventricular looping, such as L-transposition of the great arteries or left atrial isomerism.[25] About 30% of the newborns with complete heart block have associated cardiac malformations.[26]

Congenital complete AV block in the absence of structural heart disease occurs in 1:15,000 to 1:20,000 live births.[27] An association between maternal connective tissue disease and congenital AV block was first demonstrated in 1977.[28] This has been demonstrated to be secondary to the transplacental passage of maternal IgG antibodies, termed anti-Ro (SSA) and anti-La (SSB). Several reports have demonstrated selective binding of immune complexes to His–Purkinje tissue and to fetal myocardium.[29,30] This has been associated with the presence of inflammatory infiltrates and fibrosis in the region of the AV node and bundle of His. The immune complex binding to fetal myocardium may also account for the clinical finding of myocarditis in some of these fetuses.

Prognosis

Clinical experience has shown that complete heart block in association with structural heart disease can be associated with the development of CHF and hydrops fetalis (Figure 110.8). On the other hand, fetal complete heart block without cardiac malformations only occasionally leads to hydrops fetalis, especially at higher atrial rates. In most cases, once complete AV block develops it is irreversible. The prognosis for the fetus with complete AV block, associated structural heart disease and hydrops fetalis, is very poor. On the other hand, the fetus with complete AV block, an adequate escape rate, and no evidence of CHF can usually be followed to term with serial ultrasounds to monitor for signs of cardiac decompensation. These fetuses tend to have a relatively good prognosis. In a multicenter study,[31] fetal or neonatal death was significantly related to the presence of associated structural heart defects, hydrops, an atrial rate less than 120 bpm and a ventricular rate less than 55 bpm.

In fetuses without CHF, vaginal delivery may be attempted. Assessment of the fetal atrial rate variability is a suitable form of intrapartum monitoring, which can be performed using external Doppler devices. Internal monitoring must not be used as it only reflects the ventricular rate that does not respond to changes in fetal oxygenation or acid–base status. If, however, hydrops fetalis is present, a cesarean section should always be performed since in these cases a vaginal delivery may result in a sudden and dramatic deterioration of the fetal condition.[26]

Management

Although several different therapies have been attempted in the treatment of a fetus with complete heart block with or without myocarditis, so far there has been no universally effective prenatal therapy. Maternal administration of β-agonists to increase fetal ventricular rate, such as ritodrine or terbutaline, has been attempted. This therapy may be associated with some increase in fetal heart rate, although in our experience this does not necessarily translate to an improvement in fetal edema because AV coordination has not been reestablished. In complete heart block, there is a lack of 1:1 AV contraction. This leads to an increase in atrial pressure with a consequent rise in systemic venous pressure causing the hydrops. Unless the 1:1 AV contraction sequence is restored, any therapy aimed at increasing the ventricular response rate may not be successful in helping resolve the hydropic state.

There have been several reports on the use of maternal steroid therapy in the presence of fetal hydrops and congenital complete heart block.[24,32,33] The rationale behind this treatment is that the anti-inflammatory effect of steroids could ameliorate the

fetal inflammatory reaction by reducing damage to the fetal conduction tissue and/or myocardial dysfunction caused by myocarditis. Dexamethasone has been used, as it is not metabolized by the placenta and is available to the fetus in an active form. Steroids also hasten lung maturity and their use may be associated with improved survival in premature infants. Although steroids have been shown to be effective in the treatment of the fetal myocarditis, with subsequent resolution of some of the fetal edema and improvement in the degree of block, the complete heart block itself may not necessarily be reversible.

Other prenatal therapies that are of interest, but which are not yet in standard use, include pacing of the fetal ventricle via a maternal transuterine–fetal transthoracic route.[34] At this point, we do not believe that such therapy is warranted unless studies on animal models demonstrate that ventricular pacing by itself may have a positive therapeutic effect.

Experimental therapeutic regimens, including the performance of plasmapheresis to diminish the quantity of maternal antibody that is transmitted to the fetus, have also been described.[35] Although congenital heart block persisted in the neonate described in this report, there were no signs of myocarditis at birth.

Conclusion

Fetal arrhythmias remain difficult, at times, to diagnose accurately and treat, because of the limitations of direct 'patient' accessibility. A close collaboration between obstetricians, perinatologists and pediatric cardiologists is essential to optimize patient management. Ideally, once a fetal arrhythmia is diagnosed, the mothers should be referred to tertiary care centers with specialized teams available for joint consultation and prenatal management of the problem. If the arrhythmia persists despite optimal medical therapy, delivery should preferably be at a center that has trained pediatric cardiologists experienced in dealing with arrhythmias in the neonatal period.

Although much progress has been made in the diagnosis and prenatal management of fetal arrhythmias, controversies persist. Hopefully, with time, our knowledge and experience will become more clearly defined.

111 Prenatal diagnosis and therapy: animal studies

J. L. Graf and M. R. Harrison

Introduction

During the past two decades, fetal surgery has become an option for some life-threatening and even non-lethal conditions. The advances in obstetric sonography, diagnostic imaging, and sampling techniques have allowed for the early prenatal diagnosis of some fetal anomalies. Serial prenatal ultrasounds have given us the opportunity to learn the natural history of these anomalies. This prenatal information may influence the timing, location and method of delivery, and, in highly selected cases, provides opportunity for *in utero* fetal surgery for the treatment of life-threatening anomalies.[1]

Fetal surgery is an option only if the following stringent criteria are met: (1) the natural history and pathophysiology of the disease are understood; (2) prenatal diagnosis is accurate and criteria exist to predict which fetuses have a poor enough prognosis to warrant fetal surgery; (3) maternal risk is acceptably low; and (4) in most cases, an animal model exists in which *in utero* therapy has demonstrated efficacy. Clinical studies may provide some of this information, but many of these vital questions cannot be answered without experimental studies.[2] This chapter will focus on animal studies that are used to study fetal therapy.

Animal studies

Since fetal therapy involves risk to both the mother and the fetus, before it can be offered to families the proposed fetal procedure must be technically feasible, safe, and effective in treating the anomaly. These requirements are best met through rigorous experimental animal studies. An animal model of the disease must simulate the natural history, pathophysiology and sequelae of the anomaly that is seen in human fetuses. The model must also allow for fetal intervention and provide objective criteria to determine the efficacy of the intervention. Animal models that have been used to study fetal disease processes and fetal interventions are listed in Table 111.1.

Table 111.1 Animal models for fetal studies

Sheep	Rabbit	Mouse	Monkey
Congenital diaphragmatic hernia	Esophageal ligation	Cleft lip	Congenital diaphragmatic hernia
Biliary atresia	Congenital diaphragmatic hernia	Cellular transplantation	Tocolysis
Cardiac defects	Craniosynostosis	Wound healing	Hydrocephalus
Hydrocephalus	Gastroschisis		Spina bifida
Urinary tract obstruction	Intrauterine growth retardation		Fetoscopy
Bladder exstrophy	Urinary tract obstruction		Fetal vascular access
Amniotic bands	Wound healing		Urinary tract obstruction
Myelomeningocele	Pulmonary hypoplasia		
Craniosynostosis			
Congenital cystic adenomatoid malformation			

In some instances, nature provides an animal model of a disease process that closely mimics that seen in humans. For example, intrauterine growth retardation is seen in fetal rabbits positioned in the middle of the uterine horn (a vascular 'watershed' area).[3] However, most of the disease processes that are seen in human fetuses must be created in the animal model prior to fetal intervention (e.g., creation in fetal lambs of a diaphragmatic hernia that is subsequently repaired later in gestation).[4]

The choice of an animal model takes into consideration several variables. The importance of each variable depends on the focus of the particular study. Variables include accurate time-dating of the pregnancy, seasonal availability, litter number, duration of gestation, fetal size, rate of spontaneous and intervention-induced miscarriage, susceptibility of the gravid uterus to preterm labor, operative considerations (i.e., anesthesia, instruments of appropriate size, venous access, etc.) and cost.

To demonstrate experimental fetal animal studies in different animal models, we shall discuss three models in greater depth:

(1) Congenital diaphragmatic hernia in sheep;
(2) Intrauterine growth retardation in rabbits;
(3) Hydrocephalus in monkeys.

Congenital diaphragmatic hernia in sheep

Congenital diaphragmatic hernia (CDH) is an anatomically simple defect that is correctable after birth by removing the herniated viscera from the chest and repairing the diaphragmatic defect. Unfortunately, the physiologic consequences of CDH are much more extensive and up to 60% of afflicted infants die of pulmonary insufficiency despite optimal postnatal care.[5] The pulmonary hypoplasia appears to be related to *in utero* lung compression by the herniated abdominal viscera. In theory, the *in utero* removal of abdominal viscera from the chest should allow pulmonary development to continue so that pulmonary function is adequate at birth.[6]

To test this theory, a model of CDH was developed in sheep.[7] The sheep has been used as a model for a wide variety of fetal anomalies and interventions. There are several advantages to using sheep as an animal model, including accurate time-dated pregnancies, a long gestation (gestational term 145 days), frequent twinning (provides a control fetus), a large animal to work on, reliable vascular access, stability during anesthesia, the ability to monitor the fetus non-invasively with ultrasound, and a quiescent uterus postintervention. Disadvantages include seasonal pregnancy, cost of long-term care, and a lower phylogenicity. Additionally, the quiescent postoperative uterus is not representative of a human uterus, which is exquisitely sensitive to preterm labor after intervention; therefore, one may not assume that a procedure which is technically feasible in a sheep will be so in a human.

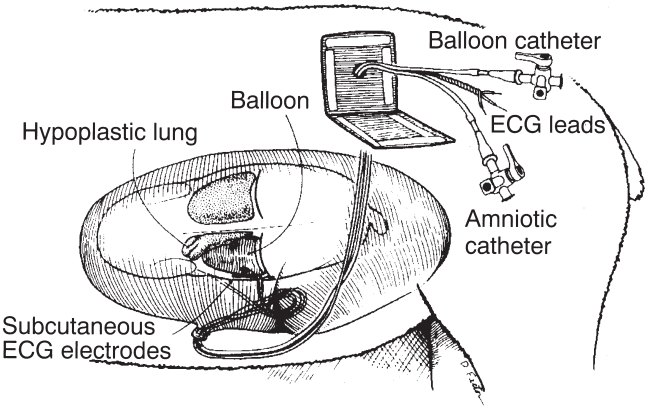

Figure 111.1 Fetal lamb model simulating congenital diaphragmatic hernia. A balloon placed in the left hemithorax is gradually inflated, simulating herniated abdominal viscera compressing the lung. ECG, electrocardiographic.

For the model of CDH the following characteristics were required: (1) a space-occupying lesion in the fetal thorax must enlarge through gestation and produce severe pulmonary hypoplasia incompatible with life after birth; (2) simulated postnatal diaphragmatic repair by removal of the space-occupying lesion; and (3) quantitative assessment of the effect of the simulated lesion and its removal on survival at birth and pulmonary vascular and parenchymal development.

All work performed at UCSF was under Institutional Review Board approval. Following 48 h of fasting, time-dated ewes at 100 days of gestation were induced with ketamine (Parke-Davis, Morris Plains, NJ, USA), intubated and maintained on a halothane–oxygen mixture on a Harvard ventilator. Antibiotics were given intravenously and into the amniotic fluid when the uterus was closed. Following a maternal midline laparotomy, a purse-string suture was placed through the uterine wall and hysterotomy performed inside the purse-string. A fetal left thoracotomy was performed and an inflatable silicone rubber balloon inserted into the left chest. Electrocardiographic (ECG) leads were tunneled subcutaneously on the fetus. The ECG leads and inflatable balloon catheter were brought out through the hysterotomy and maternal abdomen and were then tunneled to the ewe's left flank (Figure 111.1).

Twice a week the balloon had saline added for inflation while the fetal heart rate was observed. If fetal bradycardia was seen, the balloon was deflated until the heart rate stabilized, and the saline was then added more gradually and in smaller increments. The total balloon volume was 100 cm^3 at 120 days of gestation and 150 cm^3 at 140 days of gestation. This volume was calculated to be a little less than one half the total lung volume through the last trimester. After cesarean delivery, all lambs were intubated and ventilated. Frequent blood gas measurements were taken by a catheter placed in

the umbilical or femoral artery. Lambs underwent deflation of the balloon to simulate postnatal surgical repair. After 2 h support was withdrawn to determine viability. Control lambs were delivered by cesarean section and were not operated on, except for one twin, which had a balloon placed but never inflated. Analysis of the lungs included weight, construction of pressure–volume curves, fixation with barium–gelatin and gluteraldehyde, and microscopic examination.

The results of this study showed that lambs with the inflated balloon catheter had reduced lung weight, flattened pressure–volume loops, and reduction in air space volume and vascular bed volume. Blood gas analysis showed acidosis, hypoxia and hypercarbia. None of the experimental lambs were viable. Simulated postnatal repair by balloon deflation did not improve viability. The histologic studies did not show any striking difference between experimental and control lambs. All of these findings simulate the clinical and pathologic findings seen in human infants with CDH. This model provided valuable knowledge regarding compression as a causative factor of the pulmonary hypoplasia seen in infants with CDH. This knowledge led to refinements in the prenatal diagnosis and management of human fetal diaphragmatic hernia, including consideration of *in utero* correction.

Intrauterine growth retardation in rabbits

One-third of low birth weight babies are small for gestational age secondary to intrauterine growth retardation (IUGR). IUGR is believed to represent fetal undernutrition and in most cases this is because placental insufficiency prevents adequate nutrient and/or oxygen transfer from mother to fetus.[8] Nutritional supplementation of the mother will not benefit the fetus because of insufficient placental function. In theory, fetal enteral feeding could provide fetal nutrition. Amniotic fluid is swallowed and absorbed by the fetus, therefore instillation of nutrients into the amniotic fluid may provide a means to improve fetal nutrition, leading to improvement in IUGR.[9,10]

Rabbits provide a natural model for IUGR.[3] By virtue of the fetal position in the uterine horn, a 'runt' in the litter is usually present. The position of this fetus is in a vascular 'watershed' between the ovarian and vaginal artery, and is consistently the third fetus from the ovary. In contrast, the first fetus from the ovary is in a 'favored' position, having an excellent blood supply. The weight ratio of the runt to the favored fetus is consistently 0.85. For this study there were several advantages to working with rabbits in addition to the natural model of IUGR. These include accurate time-dated pregnancies, enough fetuses to provide littermate controls, uterine quiescence allowing fetal manipulation without inducing abortion, short gestation (gestational term 31 days), inexpensive animal costs, and relative tameness which allows chronic intervention. Disadvantages of working with rabbits include an exquisite sensitivity to anesthetics with a very narrow margin between anesthesia and respiratory arrest, cannibalism of young, and high rates of spontaneous abortion if the rabbit is stressed by the environment (noise, movement, handling, etc.).

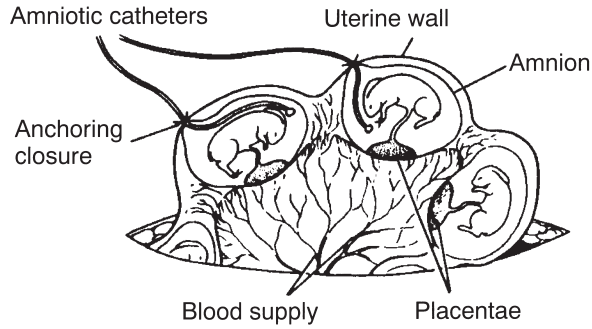

Figure 111.2 Fetal rabbit model of intra-amniotic nutrient infusion.

Time-mated rabbits were shipped to arrive 3–6 days before the planned procedure, to allow adaptation to their new environment. The does were not fasted preoperatively since they rarely vomit. At 23 days of gestation, the does received premedication with ketamine and acepromazine (Fort Dodge Laboratories Inc., Fort Dodge, IO, USA) followed by halothane–oxygen via a face mask. Preoperative antibiotics were given intramuscularly. For this relatively short procedure, intravenous access was not required. The rabbits were placed on a heating pad as they quickly become hypothermic during intra-abdominal procedures. Following a maternal midline laparotomy, the uterus was inspected to determine the litter size. The runt was identified by position in the uterine horn. A purse-string was placed through the uterine wall and a hysterotomy made using electrocautery. The fetus was marked for future identification by placing a silk stitch in the fetal foot. A polyethylene catheter was placed into the amniotic cavity and secured in place when the purse-string was tied (Figure 111.2). A second catheter was placed in the amniotic cavity of the fetus in the most favored position. The catheters were led out of the incision and were tunneled subcutaneously to an exit site near the ear where they were attached to a swivel harness that allowed the rabbit to move freely about the cage. The abdominal incision was closed in layers; a subcuticular suture was used to close the maternal skin because rabbits chew out external stitches or staples.

Amniotic 'feeding' was provided to the litter runt by infusion of dextrose, dextrose and amino acid, or a lipid solution. The fetus in the ovarian position had placement of a catheter and infusion of saline. Control animals were fetuses from the opposite horn who had catheters placed but no nutrient or saline infusion. The fetuses were delivered on gestational day 30, and fetal body, liver and brain weights were recorded.

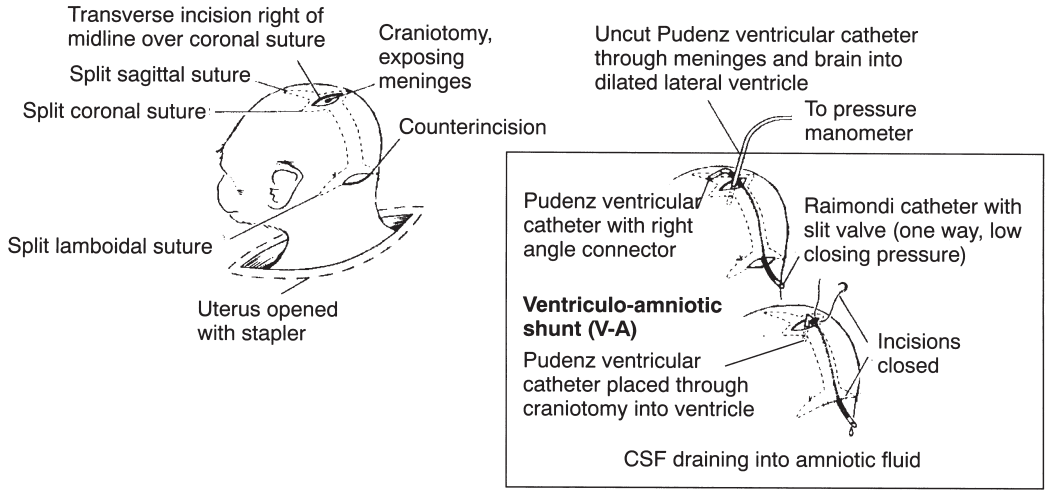

Figure 111.3 Fetal monkey model of ventriculo-amniotic shunting after subarachnoid kaolin injection. CSF, cerebrospinal fluid.

Interestingly, the results of this study showed that none of the nutrient amniotic infusions increased the weight ratio of the runt to the favored fetus. In fact, the fetus who received lipid infusion had a worsening of IUGR and lipid globules present in the fetal lungs. This study suggests that it is perhaps oxygen deficiency that leads to IUGR. The fact that nutrients did not enhance fetal growth suggests that oxygen may be the growth-limiting factor in this natural model of IUGR. Additional useful information was that substances placed into the amniotic fluid may be aspirated into the lungs. The results of this study did not support the use of transamniotic nutrient supplementation as a prenatal treatment for IUGR.[11]

Hydrocephalus in monkeys

Children born with significant hydrocephalus often have neurologic damage and a poor prognosis despite early postnatal treatment.[12] Fetal hydrocephalus may be detected by prenatal ultrasound. Given the poor prognosis after birth and the ability to detect the abnormality prenatally, the question arose as to whether prenatal treatment was possible. The consideration of fetal intervention was based on the assumptions that: (1) obstruction of cerebrospinal fluid (CSF) increases intraventricular pressure and leads to ventriculomegaly and has a deleterious effect on the developing brain; and (2) release of the obstructed CSF would allow for normal brain development. A model of hydrocephalus was developed in the monkey, based on obstruction of CSF flow and allowing for subsequent fetal intervention for CSF drainage.[13,14]

Monkeys are the most rigorous model used to test fetal surgical interventions. The gravid monkey uterus is very sensitive to preterm labor. Maintaining a pregnancy after fetal intervention has proved to be extremely challenging. Successful fetal intervention and maintenance of the pregnancy is perhaps more difficult in monkeys than in humans and thus provides an excellent and demanding model to use as a prerequisite for human fetal intervention.[15]

Rhesus monkeys with time-dated pregnancies received ketamine premedication and were then intubated, and anesthesia was maintained with halothane and nitrous oxide inhalation. In addition to providing anesthesia, halothane acts to relax the uterus. Ventilation was controlled or by hand. Intravenous access was obtained and antibiotics administered. The gravid uterus was exposed through a midline incision and the site of the placental disks determined. After a small hysterotomy was made with electrocautery, the uterus was opened using a stapling device. Kaolin (J.T. Baker Chemical Co., Phillipsburg, NJ, USA) was injected through the atlanto-occipital membrane into the subarachnoid space. The uterus was closed after removal of the uterine staples. Ultrasound was used to evaluate the fetuses postoperatively for the development of hydrocephalus. All fetuses with kaolin properly placed into the subarachnoid space developed ventriculomegaly. The fetuses were born with enlarged heads, diastasis of cranial sutures and bulging fontanels. Microscopic examination of the brains showed changes that closely parallel those seen in afflicted human neonates; there was thinning of the cortical mantle, primarily involving the white matter with preservation of the gray matter. This suggested that the structural changes induced by kaolin injection may be reversible.

The kaolin injection model of obstructive hydrocephalus in the monkey was used to evaluate the efficacy of *in utero* ventricular shunting. Kaolin was injected as described above and 14–21 days later, experimental fetuses underwent ventriculo-amniotic shunting. Non-shunted fetuses with kaolin-induced hydrocephalus served as controls. The shunting procedure is outlined in Figure 111.3. A shunt with a one-way flow valve was placed from the dilated lateral ventricle to the amniotic cavity. The results of this study were the following; ventriculo-amniotic shunting led to an increase in viability, a decrease in ventricular size to normal, and a decrease in head size.

Table 111.2 Life-threatening anomalies that may be amenable to *in utero* intervention

Anomaly	Effect on fetus	Natural history	*In utero* intervention	Animal model
Urinary obstruction	Hydronephrosis	Renal failure	Percutaneous catheter	Rabbit, sheep
	Lung hypoplasia	Pulmonary failure	Vesicostomy, open orfetoscopic	
Congenital cystic adenomatoid malformation	Lung hypoplasia, hydrops	Hydrops, death	Open pulmonary lobectomy	Sheep
Congenital diaphragmatic hernia	Lung hypoplasia	Pulmonary failure	Open complete repair, temporary endoscopic tracheal occlusion	Sheep, rabbit, monkey
Sacrococcygeal teratoma	High output cardiac failure	Hydrops, death	Tumor resection	None
Twin–twin transfusion syndrome	Vascular 'steal' through placenta	Hydrops, death	Fetectomy, cord ligation, laser ablation of communicating vessels	Sheep

However, histopathologic brain injury did not improve after shunting and there were problems with shunt occlusion. Based on these findings, we believe that knowledge of the pathophysiology of congenital hydrocephalus and the impact of fetal decompression on neurologic outcome, and improved efficacy of shunts are required before this procedure can be offered to humans. Of note, there is currently a self-imposed moratorium on fetal intervention for hydrocephalus.

Conclusion

During the past 15 years, with the availability of sophisticated prenatal diagnosis, the rationale and feasibility of prenatal intervention for a number of fetal anomalies has been investigated. Based on animal studies that have shown that *in utero* intervention may be justifiable, technically feasible and efficacious, human fetal intervention has been performed for some life-threatening conditions (Table 111.2). The use of animal studies in the field of fetal surgery has been crucial in our development of successful therapeutic strategies, and has also demonstrated strategies that were unsuccessful and need further investigation. With continuing research efforts and rigorous animal studies the applications for fetal surgical intervention should continue to expand and offer new hope for some life-threatening fetal anomalies.

112 Fetal cells in maternal blood: diagnostic and clinical aspects

W. Holzgreve, R. Zanetti-Dällenbach, C. De Geyter, P. Miny, S. Tercanli, O. Lapaire, I. Hösli and S. Hahn

Introduction

One of the great challenges facing obstetricians and medical geneticists in this century is how to meet the increased demand for prenatal counseling and diagnosis. Due to the inherent, albeit low, risks involved with current invasive procedures for prenatal diagnosis, such as amniocentesis or chorionic villus sampling, the need has been voiced for non-invasive alternatives.[1]

Hence, the past decade has witnessed many concerted, even multinational, efforts to establish a means of performing prenatal diagnosis using risk-free non-invasive methods. The main endeavor in this respect has been the attempt to enrich fetal cells from the circulation of pregnant women, and indeed great strides have been made both in the detection of fetal aneuploidies[2–4] and also in the diagnosis of single-gene disorders.[5,6] As with all major scientific enterprises, this research has also led to unexpected findings, which themselves have become the focus of further interesting scientific questions.

In this chapter, we will highlight the most important developments regarding the diagnostic potential of fetal cells gained from the maternal periphery and how these developments have recently altered our thinking with regard to certain disorders, such as pre-eclampsia[7] and even autoimmune diseases such as scleroderma.[8]

Eclampsia as the initial evidence for feto–maternal cell exchange

It is more than a century since Schmorl, in 1893, reported his finding that trophoblasts could be detected in the lungs of 14 out of 17 women who had died of eclampsia.[9] This finding should have alerted researchers to the concept of feto–maternal cell exchange, with its possible immunological consequences and the likelihood that the process can be altered under pathological conditions. However, these factors have only recently been appreciated once again. The problem that confronted pioneers in the field, and which needed to be resolved first, was to determine which fetal cell was most suited for genetic analysis.

Despite the confirmation of Schmorl's initial findings in the early 1960s by Attwood and Park,[10] who reported that trophoblasts were frequently found in the lungs of patients who had died from a variety of causes during pregnancy, or immediately thereafter, and were also found to be elevated under conditions of eclampsia, trophoblasts have been found to be unsuitable for fetal cell analysis in the blood of pregnant women. This was partially due to the irregularity of trophoblast transfer into the maternal circulation;[11] although trophoblasts were present in the uterine vein, they were detectable to a much lower extent in the inferior vena cava and not at all in the peripheral circulation. This phenomenon is probably largely due to the trapping and filtering-out of these large multinucleate cells from the circulation in the lungs of pregnant women.[10]

This scarcity has been exacerbated by the apparent inability to specifically enrich these cells due to the general lack of suitable antibodies.[12–14] Furthermore, their heterogeneous genetic nature, arising on the one hand from their multinucleate status, but also from the potential mosaicism existing in the placenta,[15,16] severely restricts their use in a genetic analysis based on fluorescent *in situ* hybridization (FISH). This limitation does not apply to diagnostic approaches based on polymerase chain reaction (PCR), and indeed it

was by this means that Hawes *et al.*[17] were able to correctly perform a diagnosis for paternally inherited β-thalassemias. The use of trophoblast cells may, however, be reinstituted in the semi-invasive method of cervical washings, a development that will have to await a thorough assessment of its efficacy and safety before it can be established as a possible alternative.[18]

Fetal lymphocytes and the problem of persistence

Although fetal lymphocytes have been readily identified[19] and enriched by fluorescence-activated cell sorting[20] in blood samples taken from pregnant women, the disadvantage of their use has been their potential longevity. They have been shown to persist for periods of up to 6 years postpartum in the mother's circulation.[21–25] This increases the risk of obtaining cells from previous pregnancies. These results again served to show that fetal cells migrate into the maternal periphery, where they can be enriched and identified, thereby providing the basis for a non-invasive prenatal diagnostic test. However, the results should have led researchers to raise the question of the possible immunological consequence of foreign immune effector cells persisting in a new host. As will be discussed later in this chapter, the answer to this question has recently become the focus of considerable scientific interest.

Evidence that the maternal immune system can react to the presence of semiallogeneic cells is provided by the observation that anti-human leukocyte antibodies (HLA) can be detected within the late-second/early-third trimester of a small percentage of primiparae, with a tendency that these are more frequent in multiparous women.[26,27] Although thought to be partially suppressed, or shifted to a less cytolytic TH2 phenotype,[28] maternal T-cells have been found to react to fetal cells.[29] This raises the question of how these fetal lymphocytes are able to persist for such long periods in a potentially aggressive host.

Prompted by the numerous observations that fetal lymphocytes can persist for several years after delivery in the maternal blood stream,[21,22] Bianchi *et al.*[25] re-addressed this question by the fluorescence-activated cell sorting of blood from women currently pregnant, and from those who had previously borne a son, for the presence of hemopoietic stem cells, lymphoid progenitor cells, T- and B-lymphocytes. In this examination, they tested for the presence of male cells by a Y-specific PCR analysis. In the CD34-positive stem-cell-enriched fraction obtained from blood samples of women who were currently pregnant (9.5–19 weeks of gestation and prior to any invasive procedure) this group found that male DNA was detectable in 4 out of the 13 cases where the fetus was female. As extensive precautions against the danger of contamination were taken, it could be concluded that this Y-chromosome-positive material could be the result of male fetal cells persisting from previous pregnancies where these women had borne sons or had terminations. On the other hand, male DNA was only detectable in 13 out of the 19 pregnancies bearing a male fetus. This implies that this population of fetal cells may not be present in the blood of all pregnant women, or if so, then they may sometimes be below the threshold of the detection method employed. When examining blood from women who had previously borne a son and who were not currently pregnant, the observation was made that male DNA was detectable in the samples that had been enriched for lymphoid progenitor cells (CD34+ CD38+) for periods of up to 27 years after the birth of the last son. In the same analysis, male fetal T-lymphocytes were found to persist for a period of up to 6 years. This study indicated that pregnancy might lead to the establishment of a long-term microchimeric state in the mother. One possible explanation for the extended survival of lymphocytic precursor cells, in contrast to mature T-lymphocytes, is the limited amounts of HLA molecules that these progenitors express.

Are feto–maternal microchimera implicated in disease?

If fetal cells can persist for several decades after birth in the blood stream of the mother, one can ask the justifiable question of whether these cells could be involved in the establishment, or at least progression, of diseases, in particular autoimmune disorders. The reasoning for this being that women are more prone to such diseases and that the fetal cells resulting from this microchimeric state would contain immune effector cells of the type proposed to be important for the eliciting of such disorders.[30]

This facet is currently being addressed by several groups, the first report of which was recently published by Nelson *et al.*[8] These studies have focused on the autoimmune disorder scleroderma, an invariably fatal graft vs. host disease, because of the higher predilection of this disease in women, especially in the postchildbearing years. Furthermore, graft vs. host disease has been observed in blood-transfusion patients in instances where the blood was obtained from a HLA homozygous donor,[31] which implies that the microchimerism that can result after such a transfusion may be implicated in the later development of the autoimmune disorder. Hence, it seems feasible that the microchimerism of fetal cells that occurs in women after birth may play a role in the etiology of autoimmune disorders. It was this hypothesis that Nelson *et al.*[8] set out to test. They examined peripheral blood samples that had been taken from a cohort of patients with scleroderma, and where possible, from their healthy sisters and normal controls. As all

of these recruited patients had borne at least one son, the authors examined the potential levels of male, and hence fetal, cells in the periphery of these women by a quantitative PCR method for Y-chromosome sequences.[32] In this study, they determined that the levels of male DNA equivalents per given blood sample were considerably higher in the instances of scleroderma than in either of the control populations (a maximum of 61 vs. 5, or a mean of 11.1 vs. 0.38 in 16 ml of whole blood). A further interesting point of this study was the observation that patients with scleroderma more frequently had a major histocompatibility complex (MHC) class II homozygous child than the controls. Although, in contrast, no such relationship was found for MHC class I alleles, these data do provide support for the proposal put forward by Artlett *et al.*,[33] whereby fetal–maternal HLA compatibility would confer susceptibility to scleroderma, by means of a graft vs. host reaction. Such HLA compatibility may also help explain the prolonged survival of potential immune effector cells in the new host, in that while maternal T-cells would normally register paternal alloantigens,[29] their clearing, at least in a murine system, is less rapid under syngeneic conditions.[34] Should this hypothesis be validated, it will be interesting to investigate the possible association of microchimeras with other autoimmune disorders such as systemic lupus erythematosus.

An interesting alternative speculation is that, although scleroderma is rare in males, microchimeras of maternal origin could be involved in the development of this disorder under similar instances of HLA compatibility. Since maternal cells can be found with significant frequency in cord blood samples,[35–37] indicating that the exchange of cells is not unilaterally restricted from fetus to mother, but is bidirectional, further supports this hypothesis.

Erythroblasts and the first successful detection of fetal aneuploidies

The conclusion gained by most researchers in the field to date from work on fetal lymphocytes is that fetal cells do traverse the placental barrier, but that care is needed to be taken to ensure that the cell chosen was of limited lifespan and self-replicative capacity. The cell that fulfills these criteria most effectively, by being easy to enrich and readily identifiable, is the erythroblast, also referred to as the nucleated red blood cell (NRBC). Consequently, most attention has been focused on this cell type.

Evidence for the presence of fetal erythrocytes in the circulation of pregnant women was first obtained by Kleihauer *et al.*,[38] who, by developing a staining procedure specific for fetal hemoglobin, were able to detect fetal erythrocytes under certain conditions such as rhesus incompatibility. These observations were confirmed by Clayton *et al.*[39] in the early 1960s, who also noted an increase in the number of these cells following terminations or amniocentesis. Since no direct genetic proof existed in these studies, such as by the identification of a Y chromosome, that the cells observed were indeed fetal, these reports were at best indicative but not conclusive: a fact that became all the more important when it emerged that the majority of erythroblasts detected in the circulation of pregnant women were not of fetal but rather of maternal origin.[7,40–42]

Evidence for fetal origin of some of these cells was first provided by Bianchi *et al.*[43] in 1990, when they enriched by fluorescence-activated cell sorting for fetal erythroblasts on the basis of their high expression of the transferrin receptor (CD71), and proved their fetal origin by the presence of male DNA. Our group was shortly thereafter able to successfully apply the then new magnetic cell sorting technology[44] to similarly enrich for fetal erythroblasts using micromagnetic beads.[45] The relative ease of these enrichment protocols no doubt facilitated the first correct determinations of fetal aneuploidies by the use of such cells, which were reported in close succession by Elias',[2] Bianchi's[3] and also our[4] groups.

These first optimistic results prompted the National Institute of Child Health and Human Development (NICHD) to extend its Fetal Cell Isolation Study (NIFTY) trial into a phase II clinical investigation. The aim of this trial is to assess the diagnostic efficacy of detecting aneuploid fetal cells in affected pregnancies.

For this study, a cohort of at least 3000 women were recruited who were considered to be at risk of bearing an aneuploid fetus: maternal age of greater than 35 years, indicative serum screening, sonographic abnormalities or previous instance of an aneuploid fetus. Furthermore, only those who were about to undergo an invasive diagnostic procedure were enrolled, as this permits a direct comparison to the experimental laboratory results obtained regarding fetal sex and ploidy. In all instances, informed consent was requested under the understanding that no experimental results were made available to the participants, nor that these results would in any way influence the lives of the mother or her baby. A further important aspect of this trial was a psychosocial study that investigated such relevant issues as social acceptance and coercion. The results of this study, following a rigorous statistical evaluation, were available in 2002.

A general observation made by the participants of this trial is that detection of fetal aneuploidies appeared to be easier than the determination of fetal sex, in that the number of aneuploid fetal cells appeared in greater numbers in the periphery of pregnant women than their normal counterparts. By the use of a quantitative PCR analysis, Bianchi *et al.*[32]

were recently able to confirm these findings, in that the quantity of male fetal DNA in maternal blood was higher in pregnancies with an aneuploid fetus, than in those with karyotypically normal fetuses. Furthermore, it has been found that the expression of CD71, the antigen commonly used for the enrichment of fetal erythroblasts, is also elevated under conditions involving an aneuploidy. It, hence, appears that the system favors the detection of fetal aneuploidies, which will be a major benefit for those wishing to develop this methodology for prenatal diagnostic purposes. Until then, however, several obstacles still need to be overcome, such as the need for automated image analysis and rapid fetal cell identification. This deficit has been noted by companies such as Applied Imaging, who are sponsoring a second similar trial that makes exclusive use of their image analysis equipment, proprietary enrichment protocols and antibodies for fetal erythroblast identification. The majority of those researchers desiring to use fetal erythroblasts for diagnostic purposes encounter the problem that, even after enrichment for fetal cells, the cells are hidden in the midst of a large population of co-enriched maternal cells. This problem is exacerbated by the fact that the majority of erythroblasts are of maternal and not of fetal origin.[7,40,42]

Ways in which this major problem may be surmounted include the use of new enrichment protocols,[47–50] more specific antibodies,[51,52] better fetal specific markers[53] and, as mentioned previously, automated scanning and detection systems.[54–58]

Recent success with the detection of single gene disorders

PCR was first used in the field, not for the detection of fetal genetic anomalies, but to provide additional evidence for the existence of fetal cells in maternal blood, a matter that had then still been the subject of considerable dispute. This was first achieved by Lo *et al.*[57,58] They were able to determine the sex of the fetus with considerable accuracy by performing a PCR analysis with primers specific for the Y chromosome directly on whole-blood samples taken from pregnant women. That such an allele-specific amplificatory approach, i.e. where the gene of interest was missing from the maternal genome, could be used diagnostically was shown by the subsequent detection of a paternally inherited hemoglobinopathy[59] and assessment of the fetal rhesus status.[60] The sensitivity of this technique for the non-invasive detection of the rhesus factor was shown to be enhanced by carrying out the examination on fetal RhD mRNA rather than on RhD DNA.[61] The rationale for this was that the number of mRNA copies is far in excess of the few fetal RhD DNA templates. This approach was followed by Al-Mufti *et al.*, who found a similar increment in sensitivity when examining RhD mRNA vs. DNA in fractions that had been enriched for fetal erythroblasts.[62]

As discussed, the main disadvantage of this method is that it is restricted to those instances where the gene of interest is absent from the maternal genome. In order to overcome this obstacle, researchers have resorted to techniques first pioneered in the examination of preimplantation embryos,[63] namely, by physically isolating single fetal cells under the microscope and then performing PCR on them. It is by these means that significant breakthroughs have been achieved, in the examination of both the fetal genotype for Duchenne's muscular dystrophy by Sekizawa *et al.*[5] and hemaglobinopathies in the laboratory of Kan.[6]

Enhanced transfer of fetal cells into the maternal periphery in pre-eclampsia

As mentioned above, the occurrence of fetal cells, in this instance trophoblasts, migrating into the maternal cell periphery was first described in patients who had died from eclampsia.[9] During our routine investigations we had previously observed a remarkable rise in the number of erythroblasts detectable in the periphery of women with pre-eclampsia.[64] Since, we at that time, were not able to determine whether these were fetal, and since, as discussed, the minority of these cells appeared to be fetal, we have recently readdressed this issue, by focusing exclusively on male singleton pregnancies.[7] In this case–control study, we examined an equal number of patients diagnosed with pre-eclampsia and an equal number of gestational-age-matched controls, who were similarly pregnant with a single male fetus, but who had not had any invasive procedure nor had the pregnancy been complicated by any hematological disorders.

With this approach, but now with the aid of FISH for the X and Y chromosomes, we were able to determine what proportion of enriched erythroblasts were male, and hence fetal, and how many were female, and therefore maternal. As before, our results indicated a clear significant increase in the number of morphologically identified erythroblasts in the pre-eclamptic patients when compared to the normal controls (a mean of 32 vs. 7). Interestingly, a comparative increase in the number of Y-chromosome-positive cells was also noted (a mean of 9 vs. 2). Although this increase in Y-chromosome-positive cells could not account for all the erythroblasts observed in the pre-eclamptic cases, this result did indicate that while not all of these erythroblasts were fetal, a significant proportion was. A further interesting feature of this examination was the linear correlation that we

observed between the maternal and fetal erythroblast populations. This implies that one and the same factor, which is able to traverse the placental barrier, is responsible for the same changes in both these pools. Erythropoietin is a likely candidate for such a factor, since hypoxic conditions that are known to occur in pre-eclampsia[65–67] are known to induce an expression of this gene.[68] However, it remains to be shown whether it is indeed involved, since the placenta is thought normally to be impervious to the transfusion of such cytokines.[69] This freer exchange of both cells and cytokines across the feto–maternal barrier could, however, be brought about by the gross morphological differences in the placenta found in pre-eclampsia,[67,70] whereby the fetal syncytiotrophoblast appears to be incapable of differentiating normally and, hence, is incapable of invading the maternal arterioles successfully.[71–73]

In this respect, it is unlikely that the increase in the feto–maternal cell exchange that we have observed to occur in pre-eclampsia is causal to the disease, but is probably a reflection upon the structural changes in this barrier. The increase in both maternal and fetal erythroblast pools is probably a reflection upon the generalized hypoxic state that occurs in these individuals.

One intriguing possibility is that while this alteration in feto–maternal cell transfer may not be involved in the etiology of pre-eclampsia, the increased flow of semi-allogenic cells into the maternal periphery may contribute to other disorders, such as the associated hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome, which bears certain hallmarks of an overt immune response.

Since the transfer across the placenta is bidirectional it will be interesting to observe whether the flow is also enhanced in the direction of mother to fetus. Our preliminary results do indeed indicate that a greater number of maternal cells are found in cord blood samples obtained from pregnancies affected by pre-eclampsia when compared to normal samples.

Conclusion

Great strides have been made in bringing us closer to the day when a non-invasive prenatal diagnosis using fetal cells from maternal blood will become part of the repertoire at the disposal of the modern obstetrician and geneticist. We doubt, however, that the advent of this will render current invasive practices obsolete, since other new methods, such as chorionic villus sampling with its inherent advantages of earlier gestational age, did not replace amniocentesis. It is more likely that it will become a complementary technique, with its own advantages and disadvantages. This is partially due to the current inability to obtain a full karyotype from fetal erythroblasts, and that even with the aid of five-color FISH, only the most common fetal aneuploidies are detected, namely those for chromosomes 13, 18, 21, X and Y. Although this may account for as much as 60–70% of all chromosomal aberrations routinely detected in our prenatal diagnostic facility,[1] in those instances where a full karyotype is required, it will be necessary to resort to using current invasive procedures.

An unexpected and scientifically interesting spin-off of the research carried out in this field is the new knowledge that has been gained concerning the transfer of both fetal and maternal cells across the placental barrier, and the possible roles this may have in the etiology or progression of certain disorders such as scleroderma and pre-eclampsia.

113 Ultrasonographic soft markers for chromosomal abnormalities

A. Antsaklis

Genetic sonography

Until the mid-80s, the main indication for second-trimester genetic amniocentesis was maternal age ≥ 35 years at the time of delivery. Maternal serum screening triple test, was introduced in the mid-80s and today is a standard practice, in order to reduce the loss of normal fetuses from amniocentesis, since it is important to identify methods that focus on a better group of candidates for invasive procedures. Women aged 35 years and older have traditionally been offered genetic amniocentesis, because at 35 the incidence of trisomy [e.g. Down's syndrome (DS)] starts to rapidly increase. Also at this time, the risk of any aneuploidy roughly equals the risk of amniocentesis-related pregnancy loss of 1 in 200, thus justifying the test.

Using maternal age to select women for an amniocentesis and make an antenatal diagnosis of DS is associated with a low detection rate. Maternal age is a poor method of screening.

Because younger women have the majority of pregnancies, younger women give birth to the majority (65%) of all DS children. In the 1980s, it was reported that alpha fetoprotein was unusually low in pregnancies complicated by DS. Elevated serum levels of chorionic gonadotropin and decreased unconjugated estriol have been identified in pregnancies with fetuses with DS. This combination of these three analytes is more predictive than any individual analyte alone. It is termed the *triple screen*, or *multiple marker screening test*, and has become the preferred DS screening test in many centers with a 5% screen-positive rate, the multiple marker screening test identifies approximately 60% of all DS pregnancies in women under the age of 35. In women over 35 years, it detects over 75% of DS pregnancies.

Genetic sonography has been established in the last decade as a very useful examination and offers the opportunity to better select candidates for invasive prenatal diagnosis by using a series of sonographic markers that are present more frequently in aneuploid than euploid fetuses. This permits the identification of 60–80% of the affected fetuses and this applies equally well to women whose fetuses are at high and at low risk for aneuploidy. Conversely, when these sonographic markers are absent, the age-specific risk of aneuploidy can be readjusted in women at increased risk of carrying an abnormal fetus because of age.

The second-trimester sonography includes evaluation of fetal biometry, and anatomy for detection of structural and non-structural anomalies (Figures 113.1 and 113.2). Examples of anomalies associated with DS are as congenital heart defects, duodenal atresia, ventriculomegaly, hypoplasia of the middle phalanx of the fifth digit with clinodactyly, flat face with maxillary hypoplasia, macroglossia, brachycephaly, hydrops and clubbed foot. Congenital heart disease (CHD) is the most common anomaly in infants with DS (44% of the infants with DS have CHD), with 45% of these defects being atrioventricular septal defects, 35% ventricular septal defects, 8% isolated secundum atrial septal defects, 7% persistent pattern ductus arteriosus and 4% isolated tetralogy of Fallot.[1] The prenatal diagnosis of CHD carries a significant risk of fetal aneuploidy. When prenatal diagnosis of CHD is found in association with other fetal structural malformations, the incidence of fetal chromosomal abnormalities is 60–70%, while when isolated CHD is found, the incidence of aneuploidy is 15–20%.

Ninety-nine percent of newborns with trisomy 18, 90% of newborns with trisomy 13 and 50% of newborns with trisomy 21 have CHD and, especially, ventricular septal defect.

Therefore, normal cardiac ultrasound examination theoretically decreases the prior risk of the birth of a child with trisomy 21 by 50% and almost eliminates the risk of trisomy 18 or 13.

Figure 113.1 Fetal omphalocele.

Figure 113.2 Duodenal atresia.

Non-structural markers (soft markers) included nuchal fold thickness of 6 mm or greater, renal pyelectasis (anterior–posterior diameter of renal pelvis greater than 4 mm), choroid plexus cyst (CPC), hyperechogenic bowel, echogenic intracardiac focus (EIF) and extremity shortening (humerus or femur). These markers are more common than the major structural abnormalities in fetuses with trisomy 21 and are non-specific. These markers are also present in fetuses without abnormalities, are often transient and can be readily detected during the second trimester.

Risk status is ascertained preferably by the patient's age and biochemical screening test results (triple or quadruple markers). Low risk is defined as anyone having a 'negative' biochemical screen or, in the absence of biochemical information, a maternal age younger than 35 years.

The soft markers for DS were originally described to help improve the sonographic detection of DS in high-risk women (predominantly pregnant women of advanced maternal age), who were attempting to gather more accurate risk information than that based on age alone before deciding whether to proceed to amniocentesis.

Major abnormalities are observed in fewer than 25% of affected fetuses, whereas one or more soft markers may be observed in 50% of the affected fetuses. This emphasizes the importance of soft markers for the detection of fetal trisomy 21 among high-risk women in whom high sensitivity is desirable. But the false-positive rate may be unacceptably high (13–17%) if any one of the soft markers is detected among low-risk women.

Sonographic markers are often associated with other markers or structural abnormalities and the risk of fetal DS increases with the number of markers present. Sonographic markers were considered isolated when they were not associated with the major or the other soft marker.

These sonographic markers are more common in fetuses with chromosomal defects, leading to the assumption that they might be useful in the prenatal identification of the fetus at risk of aneuploidy.

Echogenic intracardiac focus

EIF (golf ball) is defined as a small bright area within the fetal heart ventricles, generally in the left ventricle, but occasionally bilateral or right-sided located below the mitral or tricuspid valves with similar echogenicity to bone, and represents microcalcification in the papillary muscle or chordae tendinae of the fetal heart in the second trimester.[2] The majority of the cases of EIF are simple, but in some cases there is a multiple EIF in one or more chambers of the heart (Figure 113.3).

During the routine examination of the four-chamber view of the fetal heart, these foci are seen to move synchronously with the valve leaflets throughout the cardiac cycle.

Recently, it has been confirmed that EIF is caused by mineralization within the papillary muscle, but the cause of such changes remains unknown.

EIF is the most recent and the most controversial of the soft markers, because it is a subjective finding and its prevalence is influenced by a variety of factors, including the resolution of the sonographic equipment, the technique and the sonographer's experience and the maternal ethnic background.[3] The prevalence of second-trimester foci in fetuses with black mothers is 6%, in white mothers it is 10%, in Asian mothers, 30% and in mothers in whom the race is not identified, 11%.

Figure 113.3 Echogenic Intracardiac focus.

It has been shown that fetuses of Asian mothers have a three- and eightfold increased incidence of EIF over fetuses of white and black mothers, respectively, and because the incidence of EIF among fetuses of Asian mothers is actually higher than it is among fetuses with DS, this particular marker cannot be used accurately to predict the risk of DS in the Asian population.[4]

Fetal position is also important and EIF is best visualized when the cardiac apex is oriented toward the transducer. The association between aneuploidy and EIF was first seen in the early 1990s and is now well established.[5,6] The EIF is considered a soft marker for trisomies 21 and 13. This finding is neither sensitive nor specific and < 20% of aneuploid fetuses as well as 5–10% of normal fetuses display this sonographic marker.

EIF is not associated with congenital heart defects in chromosomally normal fetuses. The prevalence of EIF has been quoted to be as low as 0.46% and as high as 22% in the second and third trimesters of pregnancy. The prevalence of EIF may be affected by the timing of the ultrasound examination during pregnancy, as sometimes EIF resolves or develops late, and also whether the EIF was detected in pregnancies at high risk or low risk of aneuploidy. In high risk, the prevalence of isolated EIF in the second trimester is 3.5% and in low risk it lies between 0.4 and 7.4%.

In a period of 3 years, 10,769 women had a routine detailed anomaly scan, and there were 311 cases of isolated EIF. Among these, there was only one case of trisomy 21. In the same period, there were 14 cases with DS. The sensitivity of isolated EIF for detecting trisomy 21 was 7.1% and the specificity was 97.1%. They concluded that the isolated EIF is a normal ultrasonographic finding and should not be considered as a risk factor for trisomy 21 in an unselected low-risk population.[7]

Whether low-risk woman should undergo invasive testing because of the presence of a fetal EIF remains controversial.[5] Isolated EIF carries a relative risk of twice the prior risk of the presence of DS.[8,9]

The prevalence of this marker in high- and low-risk pregnancies is between 3% and 5%, making this finding the most commonly detected ultrasound marker. The prenatal detection of EIF might be potentially significant as a marker for aneuploidy.

Nyberge *et al.* confirmed that EIF is associated with an increased risk of trisomy 21, although as an isolated marker this association just reached statistical significance. These data support a large number of other studies suggesting an association between EIF and trisomy 21, whereas some studies have failed to show this association.[10]

Two independent studies in a high-risk population showed that the risk of aneuploidy in fetuses with isolated EIF is about four times greater than the risk in those with a normal scan.[11,12]

In a total of 5480 women undergoing amniocentesis, the prevalence of EIF was 4.6% (253 cases) and trisomy 21 was diagnosed in 23 cases (9.1%) of the 253 fetuses with EIF and in 69 (1.3%) of the 5227 without EIF.[5,11.13]

In a low-risk population, there is no such association. In 9263 low-risk pregnancies 153 fetuses had EIF and none of them had trisomy 21.[6]

On the contrary, Bromley *et al.* identified 290 fetuses with EIF of whom 165 were from a low population according to the maternal age and four (2.4%) had trisomy 21, concluding that the risk of aneuploidy is also increased in the low-risk population with EIF.[14]

On the basis of the current literature, there is strong evidence to support the fact that EIF is more prevalent in fetuses with chromosomal defects, specifically trisomy 13 and trisomy 21. In the high-risk population, an isolated EIF is associated with an increased risk of trisomy 21, whereas in the low-risk population the risk is considerably lower than the risk of fetal loss associated with amniocentesis.

When a EIF is identified, a detailed scan for other signs of aneuploidy must be undertaken.

Although this finding has been reported in association with fetal chromosome abnormalities, no other major or minor anomalies were identified in this fetus. In the absence of other risk factors, this is considered a normal variation and no further evaluation is recommended. When an EIF is identified, it is necessary to evaluate for other sonographic markers of trisomy 21, such as nuchal thickness. These additional efforts will help add to the certainty that the EIF is a normal variant in a low-risk woman.[15]

In the absence of associated sonographic findings suggestive of fetal DS in low-risk women, the risk of an affected fetus when an isolated EIF is found remains lower than the risk of fetal loss associated with an amniocentesis. In an otherwise unselected healthy pregnancy with a fetus at low risk of aneuploidy, the discovery of an isolated EIF on routine detailed anomaly scanning in the second trimester is

Figure 113.4 Increased nuchal thickness.

normal and should not be considered as a risk factor for trisomy 21.[7]

Nuchal fold

Nuchal thickness was the first sonographic marker associated with an increased risk of trisomy 21 in the fetus and is now accepted as the single most sensitive and specific marker for the detection of DS in the second trimester, in high- and low-risk pregnancies.

Sonographic measurements of nuchal thickness are obtained at the level of the posterior fossa on a modified transverse view of the fetal head, which includes the thalami, the cavum septi pellucidi, the cerebellum hemisphere the cicterna magna as well as the occipital bone (Figure 113.4). The soft tissue thickness posterior to the occiput is measured from the outside of the occipital bone to the outer skin edge and should be measured three times with the largest consistent measurement used for evaluation. Measurements ≥ 6 mm are considered abnormal and it has been suggested that a nuchal fold of > 6 mm was associated with a marked increase in the risk of DS.[16,17] Several investigators recommended that nuchal fold measurements become a part of every scan performed in this period of the second trimester.[18] It has been found using a 6-mm cutoff that there is an increase in sensitivity in older fetuses (19–24 weeks) vs. the fetuses between 14 and 18 weeks from 35% to 83% with a minimal corresponding decrease in specificity from 98.8% to 96.5%, and a high incidence (76%) of nuchal thickening among fetuses with DS between 14 and 18 weeks of gestation, and it has been suggested that for older fetuses, 6 mm should be used as a threshold between 19 and 24 weeks.[19] Several meta-analyses have studied the efficacy of the nuchal fold thickness measurements. Overall, Wald *et al.* in 1998 calculated a sensitivity of 38% for the efficacy of nuchal fold and a specificity of 98.7% for the diagnosis of trisomy 21.[20]

The gestational age at which the nuchal fold is measured is definitely an important issue. The nuchal fold is a transient finding, which may fluctuate even within the second trimester, and this marker does resolve over time. Nuchal fold measurements should only be used between 15 and 20 weeks. During this period, the normal measurements of nuchal fold remain remarkably constant at < 5 mm.

Furthermore, nuchal fold abnormalities can resolve on subsequent scans whether or not the fetus has DS. A thickened nuchal fold is also associated with other euploid syndromes, such as Noonan syndrome and heart defects.

A thickened nuchal fold can appear one week and be gone the next with normal follow-up measurements still resulting in a fetus with DS.

There are two recommendations. (1) Once a thickened nuchal fold is identified in the second trimester regardless of resolution in a subsequent scan, it places the patient at a high risk of fetal DS. (2) Measurements after 19 or 20 weeks are less reliable. Never use these measurements after 20 weeks in predicting the presence or the absence of DS.

Most of the nuchal thickening in fetuses with DS is thought to represent some form of lymphatic abnormality similar to cystic hygromata. Nuchal fold measurement is a useful marker for the detection of fetuses at risk of DS, and is a screening test that can alter the risk of a fetus having DS.

It has been shown that a normal nuchal fold in high-risk patients can decrease the risk of an affected fetus both in patients with abnormal triple test and in patients with advanced maternal age.[21,22]

The nuchal fold is the single most sensitive and specific finding leading the list for detecting fetuses at risk of DS, although the combination of several markers together has resulted in the most effective method for detecting affected fetuses.

Choroid plexus cyst

Cysts of the choroids plexus in the fetal brain usually are present in the second trimester as a solitary unilateral and simple round anechoic structure within the choroids plexus of the lateral ventricle (Figure 113.5). CPC is considered a marker predominantly for trisomy 18. Most of the cases are detected incidentally at routine second-trimester anomaly scan. Occasionally, they can be multiple, bilateral or complex. The prevalence of these cysts in the second trimester is approximately 1% and more than 25% disappear before 26 weeks.

The observation that most of the fetuses with CPC had trisomy 18 demonstrates that CPC can be the only marker in a trisomy 18 fetus.[23,24]

Despite the large number of cases of CPC reported, there is no consensus regarding the definitive role of this ultrasound marker in the prenatal detection of aneuploidy.[25]

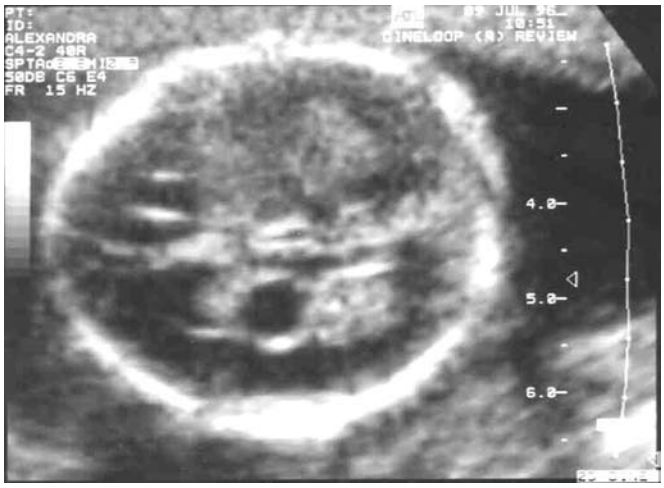

Figure 113.5 Unilateral choroid plexus cyst.

There is agreement that the ultrasound characteristics of CPC, such as bilaterality, size, number, complexity and resolution, are not related to the risk of aneuploidy. Once a CPC has been identified, a detailed fetal anatomical survey is needed including examination of the fetal hands, heart and central nervous system. Most of the controversy has been focused on whether an isolated CPC should be an indication of amniocentesis for trisomy 18.

Maternal age is an independent risk factor for trisomy 18 and in calculations of the risk of trisomy 18, this variable has to be taken into consideration.

Among fetuses with isolated CPC, the likelihood ratio for trisomy 18 is 0.03 and increases to 0.4 with one additional ultrasound finding and to 20.5 if there are two or more additional abnormalities detected by ultrasound. It was concluded that if the cyst is apparently isolated, the risk of trisomy 18 is marginally increased and maternal age should be the main factor in deciding whether or not to offer fetal karyotyping.[26] In a recently published meta-analysis, it was shown that the option of offering prenatal karyotyping to rule out trisomy 18 in cases with isolated CPC is only justified when the maternal age at delivery is 36 years or older.[27]

In a large review, 658 fetuses with CPC were identified in 101,600 births. Overall, 2.1% of these had a chromosomal abnormality. When only isolated findings of CPC were separately analyzed, 0.5% were chromosomally abnormal. If the analysis was stratified by age, 0.36% of mothers below the age of 36 years were aneuploid, whereas 2.4% were older.[28]

A review of 13 studies reporting more than 100 cases of isolated CPC revealed that the prevalence of trisomy 18, regardless of the maternal age or previous screening, was 0.6% or 1/176, which is above the population frequency of trisomy 18.[29]

It was concluded that the presence of isolated CPC, in an otherwise normal second-trimester fetus, carries an increased risk of trisomy 18. A detailed ultrasound examination of the fetus should be mandatory and if no abnormal findings are detected, maternal age and maternal serum screening results should be considered to determine whether the offering of karyotyping is advisable.[29] When a CPC is identified in a patient otherwise considered at low risk for fetal aneuploidy, it is necessary to exclude other sonographic markers of trisomy 18, such as 'clenched' hands. These efforts will help add to the certainty that CPC is a normal variant in low-risk women. Women confronted with the information that their fetus has a 'marker' for a chromosomal anomaly often have to endure a great deal of anxiety.

It has been suggested that the reporting of these two findings (the CPC and the EIF) causes more harm than good. It was recommended that when a CPC or an EIF is the only detected abnormality in a patient otherwise considered at low risk for fetal aneuploidy, it is considered a normal variant and not clinically significant and does not change her status from low to high risk and no further evaluation is needed.

Fetal echogenic bowel (FEB)

FEB is not a truly pathological condition, but rather a non-specific ultrasound feature associated with a number of fetal pathological conditions of which chromosomal defects and cystic fibrosis (CF) are the most well known (Figure 113.6).

FEB is defined as the fetal small bowel as echogenic as the surrounding bone in the second-trimester fetus.

Different pathological conditions, such as trisomy 21, CF, severe early onset of intrauterine growth restriction (IUGR), thalassemia, intramniotic bleeding, gastrointestinal obstruction, mesenteric ischemia, perinatal death and cytomegalovirus infections have been associated with second-trimester hyperchoid bowel.[19,30,31]

Poor perinatal outcome has been noted in one-third of pregnancies with FEB, including chromosomal defect in 9% of the cases, CF in 2%, congenital infection in 3% and IUGR in 8%.

The main limitation in the use of FEB as an ultrasound marker is the fact that the diagnosis is highly subjective and attempts to grade the echogenicity of fetal bowel have been abandoned due to the subjective nature of the findings.[32] The improved image resolution and the transducer frequency play a significant role in the diagnosis of this condition. The association between FEB and aneuploidy was established by Nyberg *et al.* in 1990, who reported increased bowel echogenicity in 5 (7%) of 68 second-trimester fetuses with trisomy 21. It has been estimated that the overall prevalence of chromosomal defects in cases of FEB was approximately 10% (79 out of 804) and the estimated risk of aneuploidy in cases of isolated FEB has been calculated to be between three- and fivefold greater than the background risk according to maternal age.[29,33]

Figure 113.6 Fetal echogenic bowel.

Figure 113.7 Mild ventriculomegaly.

Slotnik and Abuhamand in 1996 published a system that grades the relative echogenicity of the bowel when compared with the density of the adjacent fetal iliac crest. Of 7432 patients, 145 had fetuses with echogenic bowel. In 40 fetuses with bowel that was echogenic, but less echodense than the iliac crest, no cases of DS or CF were identified. In 81 cases where the bowel was equally echodense as the iliac crest, two cases of CF and two cases of DS were identified. When the bowel was more echodense than the fetal iliac crest, five cases of CF and six cases of DS were diagnosed out of 24 fetuses with echogenic bowel.[34]

Once the diagnosis of FEB is made, a detailed ultrasound examination of the fetus is warranted for other markers for aneuploidy to exclude intra-amniotic bleeding. If no associated findings are detected, the option of perinatal karyotyping should be discussed with the parents.[31]

Routine CF screening should also be considered, although in a low-risk population for this condition the chances seem to be low.[30]

If prenatal karyotyping is performed, fetal DNA testing for CF mutations should be considered. However, a serious limitation of CF testing is the small fraction of CF mutations currently available for screening. The diagnosis is only definitive in cases of homozygous fetuses.[35]

Routine screening for infection has not been advocated in view of the low yield and because most affected fetuses have additional findings suggestive of congenital infections. While this is not a particularly sensitive marker for DS, it is present in only 0.6% of the second-trimester fetal population; hence, the identification of this marker should lead to consideration of karyotyping, particularly if accompanied by any other sonographic findings.[2]

Mild ventriculomegaly

Mild ventriculomegaly (MV) is defined as a ventricular width of 10 mm or greater at the level of the atrium. A practical decision was made to include this as an anomaly rather than as a sonographic marker. The incidence of congenital ventriculomegaly ranges from 0.3 to 1.5 in 1000 births.

MV, including isolated MV (IMV), is the most common brain abnormality found on prenatal ultrasound (Figure 113.7). The most accepted definition of ventriculomegaly is the width of the atria of the lateral ventricles exceeding 10 mm.[36]

Progressive ventriculomegaly usually results from an excessive accumulation of cerebrospinal fluid, either because of obstructed flow or from loss of brain tissue, and is associated with CNS abnormalities, such as spina bifida, Dandy Walker complex, agenesis of the corpus callosum, congenital infections, chromosomal abnormalities and intracerebral hemorrhage.

The natural history and the etiology of MV remains unknown, much less well defined and does not appear to be associated with either obstruction or atrophy. The incidence of MV in a low-risk population is 1.48 per 1000 live births and increases to 22 per 1000 in high-risk patients. It usually involves both ventricles, but it may be unilateral or asymmetrical.[37,38]

In case of MV, a detailed genetic scan must include examination for markers of aneuploidy, fetal echocardiogram and serological tests for congenital infections should be taken, blood samples for platelet antigen typing and amniocentesis for karyotyping should be offered. IMV does not appear to be associated with raised intracranial pressure and appears to resolve in approximately 29% of the cases, remains stable in 57% and progresses in 14%.[39,40]

Figure 113.8 Mild dilatation of the fetal renal pelvis.

The incidence of chromosomal abnormalities varied from 3% to 12.6% (mean 9%) in cases with MV and 40% have other findings, while in cases with IMV the incidence decreased to 4%. It has been suggested that the majority of fetuses with MV and abnormal karyotyping will have additional sonographic abnormalities.[41]

The follow-up of fetuses with IMV in early childhood is good with 90% of the cases being normal. The quality of the outcome studies is poor with a small number of patients. Counseling should be based on the premise that IMV is a diagnosis of exclusion and outcome is generally good and further detailed studies are needed to document the significance of this finding.

Mild pyelectasis

Dilatation of the fetal renal pelvis (pyelectasis) was defined as an anteroposterior (AP) diameter ≥ 4 mm of fetal renal pelvis at 16–20 weeks, ≥ 5 mm at 20–30 weeks and ≥ 7 mm at 30–40 weeks of gestation[42] (Figure 113.8). An AP renal pelvis diameter of less than 7.0 mm was found to be predictive of a normal postnatal renal outcome. Pyelectasis may be unilateral or bilateral, but is more frequently reported as bilateral. There is also a marked sex difference with a male:female ratio of around 2:1.[43,44] The majority of cases of pyelectasis detected in the second trimester will resolve either before delivery or within the first year of postnatal life.[23] Mild pyelectasis is commonly detected in the second-trimester fetus and is associated with an increased risk of both chromosomal abnormalities and urinary tract pathologies. Thirty percent of cases with mild pyelectasis have persistent postnatal renal anomalies. The association with aneuploidy remains unclear, but it seems likely that mild pyelectasis is a marker that will alter prior risks.

Pyelectasis was described in association with trisomies 21, 13 and 18 and Benacerraf *et al.* reported seven fetuses (3.3%) with DS from a selected population of 211 fetuses with hydronephrosis. It also has been shown that the risk is higher when pyelectasis is associated with other abnormalities.[42]

In a recent study by Chudleigh *et al.* of 737 fetuses with mild pyelectasis from an unselected population of 101,600 births, it has been shown that when pyelectasis was present as an isolated finding, the risk of aneuploidy in women < 36 years of age was 0.33% and 2.2% in women > 36 years. Another approach has been to estimate the increased risk due to mild pyelectasis and adjust the prior risk by this factor.

It has been suggested that isolated mild pyelectasis confers a risk of trisomy 21 that is 1.5 times the background risk.[45]

Mild pyelectasis is a marker not sufficiently sensitive and specific to be used as an isolated finding for the detection of DS and the relative risk of DS is 1.5 times the prior risk. Mild pyelectasis is a soft marker to be used only in combination with other markers. Isolated pyelectasis in a low-risk patient should not warrant an amniocentesis.[8] The association between prenatal pyelectasis and postnatal pathologies (urinary tract obstruction and vesico-uretal reflux) is well established and 3–5% of cases of second-trimester pyelectasis may require urinary tract surgery. The sensitivity of second-trimester pyelectasis in identifying postnatal pathologies is improved by selecting those fetuses with persisting AP pelvis > 10 mm in the third trimester.

The detection of perinatal pyelectasis is an indication of detailed genetic sonogram looking for other markers of aneuploidy and for extra renal anomalies. The urogenital system should be examined carefully and care should be taken to exclude the duplex system, multicystic displastic kidney and to examine the bladder. Parents should be assured that this finding is common and the risk of serious sequelae is very small. Repeated scans should be performed early in the third trimester if the dilatation is still present or is increased; furthermore, postnatal scans and other investigations should be initiated as clinically indicated.[43]

Other sonographic markers

There are some other sonographic features of fetuses with DS. However, these may not be either sensitive or specific enough to be helpful for sonographic screening and they are difficult technically to evaluate accurately. Individuals with DS have short ears but the measurements are difficult to accomplish accurately and there is an overlap between normal and abnormal.

Hypoplastic or absence of the middle phalanx of the fifth digit is known as a finding among neonates with DS and together with clinodactyly can be

demonstrated in the early second trimester. This marker is difficult to measure and the false-positive rate is as high as 18%[46] for using this finding as a screening tool for DS.

Recently, there is evidence to suggest that delayed fusion of the amnion and the chorion is associated with an increased incidence of DS.[47] This finding is rare, occurring only occasionally in fetuses with DS and in normal fetuses.

The separation of the great toe (sandal gap toe) is a morphological feature seen in infants with trisomy 21, but occasionally detected *in utero* because of the rarity of this abnormality, and regarding its power as a marker is not useful in screening for fetal DS (Figure 113.9).

Some other fetal biometric parameters have been investigated as potential indicators of fetal trisomy 21. They do not have the same efficacy of detecting DS. The femur was considered shortened when the measured to expected ratio was 0.91 or less and the overall sensitivity and specificity for detecting DS was 29% and 92%, respectively.[48] The short humerus (measured to expected ratio 0.89 or less) has a sensitivity of 31% and a specificity of 95%, whereas when the short femur and short humerus are present, there is 33% sensitivity and 95% specificity for detecting DS.

Vintzileos *et al.*[49] measured four fetal long bones and compared their length with controls standardized on the basis of gestational age. Femur, humerus, tibia and fibula were measured in 493 normal fetuses and 22 with trisomy 21. The risk of having at least one of the four bones shortened had a sensitivity of 64% and a specificity of 78%.[49]

Scoring index

It is clear that the use of multiple sonographic markers is a more sensitive method and improves the detection of fetal aneuploidy over the use of any simple marker. Several authors have proposed grading or scoring systems to improve risk assessment. Benacerraf *et al.* proposed a scoring system based on the major and minor abnormalitites.[50] Major fetal abnormalities and the thickened nuchal fold both have a score of 2 and even if isolated, there is a strong indication for amniocentesis. Soft markers are often present in normal fetuses and each one receives a score of 1 (short femur and humerus, pyelectasis, echogenic fetal bowel, EIF and CPC) (Table 113.1).

It has been demonstrated, that the sonographic scoring index can achieve a sensitivity of 81% for trisomy 21 and 85% for trisomy 18 with a false-positive rate of 4%, when a score ≥ 2 is used for amniocentesis.

The use of ultrasound-adjusted risks of fetal trisomy 21 is expected to decrease the number of amniocenteses in women over the age of 35 when a genetic ultrasound examination does not demonstrate any abnormal ultrasound markers, while still identifying the majority of fetuses with DS. By applying Bayes' theorem to the risk of trisomy at a given maternal age in a fetus with a sonographic score of 0, a modified risk was calculated.

In women over 35 years of age, a threshold of 1 was used as a positive criterion to optimize the identification of the affected fetuses. This results in a sensitivity of 83% and a false-positive rate of 13%, respectively. The same scoring system can be used to decrease the risk of trisomy 21 in patients at risk of having an affected fetus, either because of advanced maternal age or because of abnormal triple screening test.

Women of 40 years of age or older, with a genetic sonogram score of 0, were advised to undergo amniocentesis since the score 0 could not reduce the patient's age-specific risk below the commonly accepted threshold for offering amniocentesis. Women between the

Figure 113.9 Seperation of the great toe (sandal gap toe).

Table 113.1 Proposed sonographic score for the detection of DS

	Score	Likelihood ratio
Major structural anomalies	2	25
Nuchal fold	2	18.6
Short femur	1	2.5
Mild pyelectasis	1	2.2
FEB	1	1.5
Echogenic indracardiac focus EIF	1	5.5
CPC	1	2.0

From Benacerraf *et al.*[51]
If amniocentesis is performed for fetuses scoring > 2, 73% of fetuses with trisomy 21 and 85% of fetuses with trisomy 18 can be identified with a false positive of 4%. Each likelihood ratio can be multiplied by the maternal age-based risk

age of 35 and 39 years, however, can benefit from the genetic sonography.[52]

It has been suggested that a genetic sonogram be offered as an option for women who are at increased risk of having fetuses with aneuploidy, but who do not wish to undergo invasive testing without additional information.

Nyberg *et al.* have developed the genetic sonogram via the age-adjusted ultrasound risk assessment for DS, based on maternal age and the likelihood ratios of the various sonographic markers.[4] Major structural anomalies, nuchal thickening, echogene bowel, short humerus, short femur, EIF and pyelectasis have likelihood ratios of 25, 18.6, 5.5, 2.5, 2.2, 2.0 and 1.5, respectively. Each likelihood ratio can be multiplied by the maternal age-based risk to revise the individual risk of the woman. They found that using one or more sonographic markers allowed identification of 68% of fetuses with DS with a false-positive rate of 12.5%.[8]

Vintzileos *et al.*[49] determined that the best combination of sonographic markers for detecting affected fetuses was the thickened nuchal fold, pyelectasis and short humerus, resulting in a sensitivity of 89% with a false-positive rate of 6.7%. It also has been demonstrated that a normal ultrasound could reduce the risk of DS by a likelihood ratio of 0.4.[49]

They reported that the yearly utilization of the genetic sonogram rather than amniocentesis was 0.4% in 1993, 16.6% in 1994, 48% in 1995 and 55% in 1996. They showed that women are accepting the genetic sonogram more and over half of the women presenting to the ultrasound laboratory, because of advanced maternal age or abnormal triple test screen, choose to have the genetic sonogram before they decide whether or not to have amniocentesis.[2,22,49]

In addition to the combination of sonographic markers with maternal age, the triple biochemical screen may also add information to the specific risk that a woman has a fetus with DS, before a woman makes a decision to undergo amniocentesis.

In a study by Yagel *et al.* evaluating women less than 35 years of age with abnormal triple screen results, the sensitivity for detection of DS using sonographic markers was 80%.[53] The use of ultrasound-adjusted risks of fetal trisomy 21 is expected to decrease the number of amniocenteses in older women when a genetic ultrasound examination does not demonstrate any abnormal ultrasound markers, while still identifying the majority of fetuses with DS.

A multicenter study was undertaken to evaluate the diagnostic efficacy of the genetic sonogram. Of a total of 176 fetuses with DS, 125 (71%) had an abnormal long bone length (femur, humerus) or a major structural abnormality or a sonographic soft marker for DS. The combined diagnostic sensitivity was 71.6%. The sensitivity of individual markers varies between 3% (sandal gap) and 46.5% (nuchal fold thickness). In this eight-center study, it was concluded that the genetic sonogram can be used to better adjust the DS risk for high-risk patients.[54]

In conclusion, multivariate analysis of sonographic markers of trisomy 21 has resulted in a detection rate of DS between 75% and 90% and presents a reasonable alternative to high-risk women considering invasive testing. Multivariate analysis permits more accurate counseling and allows identification of the optional components of a genetic sonogram. This may lead to a standardization of the contents, a shorter duration of the examination with no loss of sensitivity and a decrease in the false-positive rate.[55]

114 Fetal anatomy in the first trimester of pregnancy

A. Antsaklis and A. Souka

Introduction

First-trimester ultrasound scan was initially used to date the pregnancy. In the last 15 years, technological progress and, in particular, the introduction of the transvaginal approach made possible the detailed examination of the fetal anatomy in the first trimester for the diagnosis of structural defects.

In this decade, a number of studies have shown that nuchal translucency (NT) (the accumulation of fluid in the nuchal area, Figure 114.1) can be measured by ultrasound at 11–14 weeks. NT measurement is a sensitive and accurate screening test for the diagnosis of chromosomal abnormalities yielding a sensitivity of about 75% for a 5% screen positive rate.[1] The introduction of first-trimester biochemical markers free beta-human chorionic gonadotropin (beta-hCG) and pregnancy associated plasma protein A (PAPP-A) has increased the sensitivity to about 90% for the same screen positive rate.[2]

Increased NT at 11–14 weeks has been associated with structural defects and in particular cardiac defects and a wide range of genetic syndromes.[3] Possible pathophysiological mechanisms include cardiac dysfunction, venous stasis, anomalous or delayed development of the lymphatic vessels of the neck, abnormal collagen biosynthesis, fetal anemia and congenital infections.

The majority of the fetal organs can be visualized in the first trimester and transvaginal scanning has greatly increased our ability to examine the first-trimester fetus.

Using ultrasound scanning in the first trimester, we can accurately date the pregnancy, establish fetal viability and ascertain chorionicity in multiple pregnancies. At 11–14 weeks, we can estimate the risk of chromosomal defect by NT measurement and examine fetal anatomy.

The normal first-trimester fetus

Several ultrasound studies[4–28] using mainly the transvaginal approach at 4–12 weeks of gestation describe the development of the normal fetus as follows.

The fourth week

The gestational sac is visible from about 4 weeks and 3 days as a hypoechoic, ring-like 2–3 mm structure surrounded by a hyperechoic rim. Further details within the sac cannot yet be defined. The sac represents the chorionic cavity and is typically located in the upper part of the decidualized endometrium in an eccentric position.

The fifth week

The yolk sac becomes visible as the first structure within the sac at about 5 weeks and is always present at 5 weeks and 4 days. At the end of the fifth week the fetal pole measuring 2–3 mm can be seen beside the yolk sac and heart motion may be identified. At this stage the fetal heart rate is about 100 beats/min.

The sixth week

At 6 weeks, the embryo measures (crown–rump length, CRL) 4–8 mm. The fetal pole, the yolk sac and the heart motion are always visible. Heart activity should always be seen in embryos of 5 mm (6 weeks and 4 days) or more. The gestational sac contains two

Figure 114.1 Nuchal translucency in an 11-week fetus.

fluid-filled cavities: the coelomic (chorionic) cavity with the yolk sac and the considerably smaller amniotic cavity with the fetal pole. The two cavities are separated by a thin membrane surrounding the embryo, the amniotic membrane. At the end of the sixth week the cavity of the rhombencephalon becomes visible as a small hypoechogenic area at the cephalic part of the fetal pole.

The seventh week

At 7 weeks the CRL is 9–14 mm and the mean heart rate is about 130 beats/min. The amniotic cavity starts expanding rapidly. The head can be distinguished from the body and hypoechogenic areas (brain vesicles, Figure 114.2) appear in the developing brain at the cephalic end of the embryo. The cavity of the rhombencephalon that will eventually form the pons and the cerebellum can always be identified at 7 weeks as a rhomboid, hypoechoic area at the cranial pole of the embryo. At this stage the rhombencephalon is larger than the developing hemispheres. The small cavities of the hemispheres originating from the dividing Y-shaped telencephalon, the diencephalon (that will form the thalami, hypothalamus and the third ventricle) and the mesencephalon (that will later form the nuclei and the aqueduct of Sylvius) may be identifiable.

The umbilical cord is short and appears wider and hyperechogenic at the point of the insertion in the abdomen; this is the first sign of bowel herniation into the cord. The lower limb buds can vaguely be depicted.

The eighth week

At 8 weeks, the CRL is 15–22 mm, the brain vesicles are more prominent and the choroid plexuses can be visualized as small hyperechogenic areas. The rhombencephalon is still the largest cavity lying on top of the brain. There is a broad connection between the lateral ventricles, the diencephalon and the mesencephalon. Fetal heart rate is about 160 beats/min and the heart occupies more than 50% of the thoracic cavity. Atria and ventricles are sometimes visible at the end of the eighth week. The abdominal cavity is fully occupied by the liver anteriorly and the stomach dorsally while the intestine is herniated into the umbilical cord. Fluid in the stomach can occasionally be seen toward the end of the eighth week probably as a product of the gastric epithelium, since swallowing movements only start at 11 weeks. The outlines of the skull, spine and ribs can vaguely be seen. The limbs appear as short echogenic outgrowths and the first body movements become visible during the eighth week.

The ninth week

At 9 weeks, the CRL is 23–31 mm. The amniotic cavity is now larger than the coelomic cavity and occupies most of the sac volume. The fetal body becomes ellipsoid with the head being disproportionately big and the soles of the feet touch in the midline. The choroid plexuses are obvious and occupy almost fully the lateral ventricles. The cortex is thin and hypoechoic. The cerebral hemispheres become visible and are clearly separated. The connection between the mesencephalon and the third ventricle becomes narrower. The fetal heart rate reaches a peak of about 175 beats/min. Bowel herniation is visible in all fetuses. The first ossification centers can be seen at the mandible and clavicle. Limb movements can be identified.

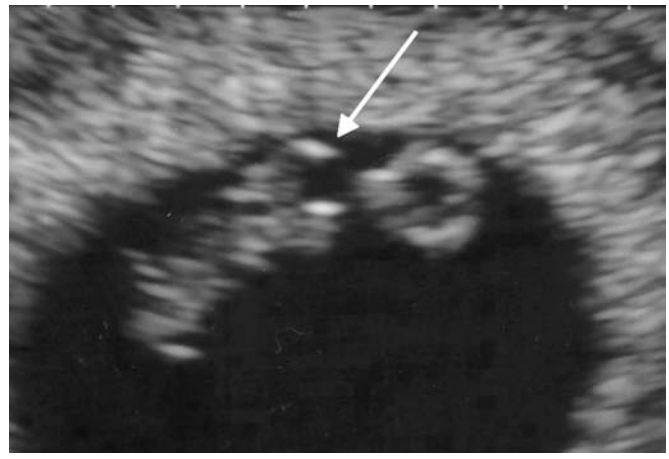

Figure 114.2 A 7-week fetus. The arrow points to the cavity of the rhombencephalon.

The postembryonic period (10–11 weeks)

During the postembryonic period, the CRL is 32–54 mm. The fetus acquires human shape and the fetal body becomes longer although the head is still disproportionately large with a prominent forehead and a flat occiput. The cerebral hemispheres start being detectable during the ninth week. Ossification starts from the occipital bone at 10 weeks. The cortex is about 1 mm thick at the end of the first trimester. The lateral ventricles occupy completely the anterior part of the head and cover the diencephalon. The mesencephalon gradually moves toward the middle of the brain, the third ventricle, after a transient increase, becomes narrow and the cerebral hemispheres fuse in the midline at 11–12 weeks. Fetal heart rate drops to about 165 beats/min at the end of the 11th week. The motion of the atrioventricular valves and the atrial and ventricular septa may be visible at 10 weeks. All cardiac structures can be visualized at the end of the 11th week. Starting from the end of the eighth week the small bowel herniates into the umbilical cord and gives the sonographic appearance of a hyperechogenic mass at the insertion of the cord. Maximum herniation of the

Figure 114.3 Fetal skull and brain.

Figure 114.4 Fetal face.

bowel is detectable at the beginning of the 10th week, whereas the return of the bowel in the abdominal cavity begins at 10 weeks and 4 days and is usually completed at 11 weeks and 5 days. In 75% of embryos the stomach is visible before the 10th week. The ossification centers of the spine and the long bones start being visible at 10 weeks. The ossification of the spine begins at the level of the cervical vertebrae and spreads caudally to the thoracic and lumbosacral areas during weeks 12–13. Ossification of the metacarpals and metatarsals can be identified at 12 weeks. The digits and sometimes the toes become visible from 11 weeks.

Figure 114.5 Fetal profile.

Fetal anatomy at 11–14 weeks

Although in the general population structural defects are relatively common (3–5%) and cardiac defects the commonest amongst them, few studies have addressed the issue of fetal anatomy in low-risk populations as part of the 11–14 weeks' scan.[20,29–34] Visualization of the cardiac anatomy at this gestational period has been reported from specialists in fetal echocardiography and has been mainly limited to high-risk pregnancies.[35–45]

Two studies[20,46] examining fetal anatomy at 11–14 weeks have used the following protocol:

(1) Skull and brain: examination of the completeness of the skull, the presence of the midline in the brain and the butterfly shape of the choroid plexuses (Figure 114.3).
(2) Face: examination of the orbits and lenses and the view of the fetal profile (Figures 114.4 and 114.5).
(3) Spine: examination of the alignment of the vertebrae and the skin covering the spine (Figure 114.6).
(4) Heart: examination of the four-chamber view and the great vessels (three-vessel view, Figures 114.7 and 114.8).
(5) Stomach: visualization of the stomach as a hypoechoic structure at the left upper abdomen (Figure 114.9).
(6) Abdomen: examination of the umbilical cord insertion into the abdominal wall (Figure 114.10).
(7) Kidneys: visualization of the kidneys as hyperechoic structures with a hypoechoic center lateral to the spine (Figure 114.11).
(8) Bladder: visualization of the bladder as a hypoechoic structure in the fetal pelvis (Figure 114.12).
(9) Extremities: examination of the long bones, fingers, toes and the movement and posture of the joints (Figures 114.13 and 114.14).

Figure 114.6 Fetal spine.

Figure 114.8 Fetal heart. The three-vessel view.

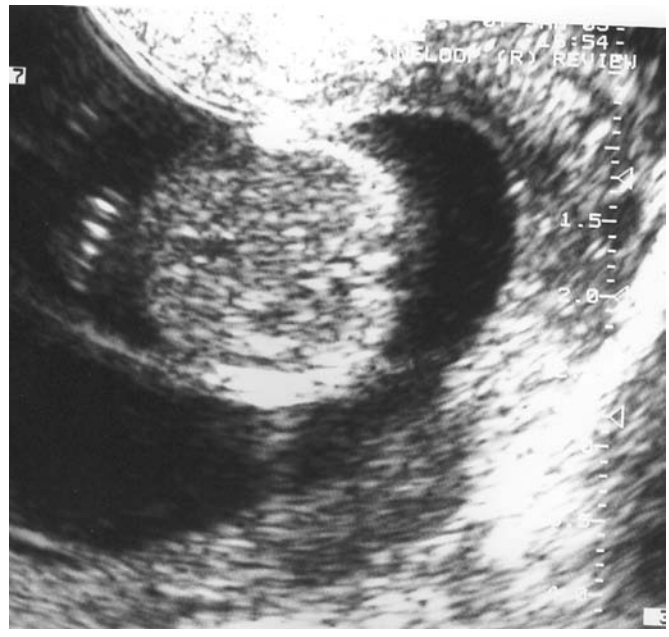

Figure 114.9 Transverse section of the abdomen (the stomach).

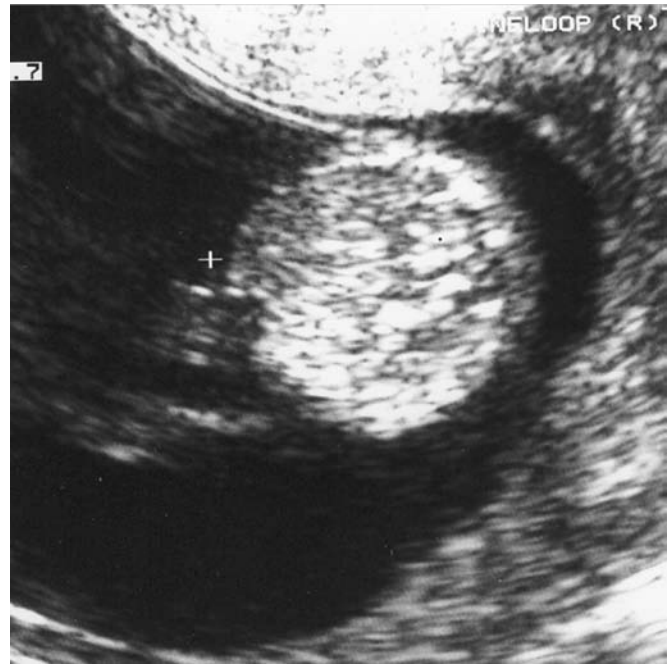

Figure 114.10 Umbilical cord insertion.

In a study of 1144 fetuses examined at 11–14 weeks with a combination of the transabdominal and transvaginal route full check of the fetal anatomy was achieved in 48% of the fetuses, whereas non-cardiac anatomy was visualized in 86% of the fetuses.[46] Successful visualization of the fetal organs depended on CRL (Table 114.1). The use of the transvaginal approach increased successful examination of the

Figure 114.11 Fetal kidneys.

Figure 114.12 Fetal bladder.

Figure 114.13 Fetal lower extremity.

Figure 114.14 Fetal hand.

fetal anatomy from 72% to 86% of the fetuses (Table 114.2). Transvaginal scanning was particularly helpful in examining the face, kidneys and bladder.

In a screening study for structural abnormalities at 11–14 weeks using transvaginal ultrasound, fetal anatomy (not including face and heart) was seen in 94% of the cases.[30] Similarly in an anatomical survey of 298 fetuses at 12+0 to 13+6 weeks of gestation, Braithwaite *et al.* were able to complete the examination of the fetal anatomy, including the four-chamber view, in 95% of the fetuses.[20] With the combination of the transabdominal and transvaginal route the four-chamber view of the heart was seen in 97% of the fetuses, the bladder in 98%, the head, brain and kidneys in 99% and the remaining organs (diaphragm, stomach, abdominal wall, spine and extremities) in 100% of the fetuses. The use of the transvaginal approach increased successful examination of the fetal anatomy from 72% to 95%.[20] In both studies the factors influencing visualization of the fetal organs were gestation, maternal habitus and uterine position and the authors stress the contribution of the transvaginal ultrasound in completing the examination of the fetus.

A few studies have addressed the issue of visualizing the four-chamber view and the outflow tracts at 11–14 weeks (Tables 114.3 and 114.4).[36–39,44,46,47] Examination of the fetal heart at this early gestation is still mainly restricted to high-risk patients and performed in specialized centers by experts in fetal echocardiography. Visualization rates of the four-chamber view improved with gestation, remaining poor before 11 weeks and increasing to more than 90% during the 12th and 13th weeks (Table 114.3). Similarly, visualization of the outflow tracts was achieved in the majority of the fetuses examined between 12+0 and 13+6 weeks of gestation. Only two studies have examined cardiac anatomy as part of

Table 114.1 Visualization of fetal anatomic structures according to crown–rump length. Anatomy Check I = includes all other organs except of the heart, Anatomy Check II = all organs including heart anatomy[46]

CRL (mm)	N	Anatomy Check I	Anatomy Check II	Head/ Brain	Face	Spine	Heart	Abdomen	Stomach	Kidneys	Bladder	Extremities

the routine 11–14 weeks' scan.[20,46] In the first study on 298 women, examination was performed at 12 + 0 to 13 + 6 weeks and the four-chamber view was seen in 76% of fetuses transabdominally, 95% transvaginally and 97% using a combined approach. Outflow tracts were not examined.[20] In the second study, 1144 women were examined at 11 – (13 + 6) weeks of gestation (CRL 45–82 mm). Complete cardiac anatomy was seen in 50% of fetuses, with visualization of the four-chamber view in 87% of cases and of the three-vessel view in 50% of cases.

Studies on screening for structural defects by first-trimester ultrasound

Three studies on a total of 12,327 pregnancies have examined the impact of assessing fetal anatomy in the first trimester on the detection rate of structural defects (Table 114.5). The differences in the detection rates can mainly be attributed to differences in protocols, definition and postnatal ascertainment of anomalies. The study with the lowest detection rate reports on all (major and minor) anomalies; if only major anomalies were included, the first-trimester scan sensitivity would be 50.8% and the overall ultrasound scan sensitivity 78.8%.[34] Detection rates in the two other studies have been calculated excluding nuchal anomalies. The majority of abnormalities diagnosed in the second and third trimester would not be detectable in the first trimester including central nervous system defects (microcephaly, ventriculomegaly, brain atrophy, Dandy–Walker malformation, cerebellar asymmetry), cardiac defects (tetralogy of Fallot, hypoplastic left heart, ventricular septal defects), renal defects (hydronephrosis, multicystic dysplastic kidneys) and gastrointestinal defects (bowel obstruction). However, it is likely that at least some of the cases of neural tube defects and cardiac defects and probably all cases of abdominal wall defects and limb reduction defects will in the future be diagnosed in the first trimester. These studies have shown that the first-trimester scan can detect more than one-third of the major structural anomalies, including lethal anomalies or those leading to severe handicap (anencephaly, holoprosencephaly, body stalk anomaly).

In conclusion, examination of the fetal anatomy is feasible during the routine 11–14 weeks scan and the completeness of the examination mainly depends on maternal habits and gestational age. It is clear that the optimal gestation for examining both cardiac and non-cardiac anatomy starts from the beginning of the 12th week to the end of the 13th week of gestation. Access to the transvaginal approach is important in completing the examination.

With the modern trend of shifting prenatal diagnosis at the earliest possible gestation and the advancing technology, it is not difficult to see the 11–14 weeks' scan becoming the first minianomaly scan with the aim of diagnosing the severest structural anomalies, thus giving the parents earlier reassurance about the well-being of their fetus.

Structural defects at 11–14 weeks

Central nervous system defects

Acrania/anencephaly (birth prevalence 1 in 1000)

The diagnosis of anencephaly in the second and third trimesters of the pregnancy is based on the absence of cranium and cerebral hemispheres. Animal studies have shown that the absence of the skull leads to progressive degeneration and destruction of the brain tissue. Similarly, ultrasound studies have shown that in human embryo acrania progresses to exencephaly and anencephaly.[48–56] Acrania, meaning the absence of the skull (cranium), is the hallmark of anencephaly in the first trimester. The brain may show signs of degeneration or even appear normal. Several authors have described cases of anencephaly from as early as 9 weeks; the appearance of the brain varies from echogenic and disorganized with abnormal shape of the skull and head circumference smaller than the abdominal circumference to completely normal.[48,49,53–55] In the four screening studies for structural defects by first-trimester ultrasound, all cases of anencephaly were diagnosed in the first trimester.[30,32,34,57] In two screening studies for chromosomal abnormalities by NT measurement on a total of 6861 pregnancies, all seven anencephalic fetuses were correctly identified in the first trimester.[50,56] In another screening study of about 54,000 pregnancies there were 47 cases of anencephaly.[51] In the first phase of the study the sensitivity of the first-trimester scan for diagnosing anencephaly was 74% (23 of 31 cases) but this increased to 100% (16 of 16 cases) in the second phase when sonographers were instructed to look for the specific signs of anencephaly at this early gestation.

Holoprosencephaly (birth prevalence 1 in 5000)

This rare but severe defect covers a spectrum of conditions where there is a defect in the division of the prosencephalon, the frontal part of the brain. There are three types (lobar, semilobar, and alobar holoprosencephaly) depending on the degree of fusion of the prosencephalon. In the lobar type, the ventricles and thalami are divided but the cavum septum pellucidum is absent. In the semilobar type the lateral ventricles and thalami are only partially separated and in the alobar type there is complete fusion of the ventricles with a large monoventricle and fused thalami. The defect is strongly related to chromosomal abnormalities (particularly trisomies 13 and 18) and other structural defects (mainly facial clefts). Holoprosencephaly was present in 24% of the 46 fetuses with trisomy 13 at 10–14 weeks, as described by Snidjers *et al.*[58] The diagnosis of the alobar type has been reported in the first trimester based on the visualization of a single ventricle and the fusion of the thalami.[59–67] In the earliest report of alobar holoprosencephaly Blaas *et al.* diagnosed the defect at 9 weeks and 2 days (CRL 22 mm).[66] There was a small monoventricular endbrain behind the forehead and a proboscis. The diagnosis was confirmed a week later. In four screening studies for structural defects by first-trimester ultrasound on a total of about 9500 fetuses, there were four cases of holoprosencephaly and three were diagnosed in the first trimester.[30,33,34,46] Spina bifida (birth prevalence 1 in 1000) is the result of failed closure of the neural tube normally occurring during the sixth week, whereas the ossification of the spine begins at 10 weeks. The hallmarks of the diagnosis of spina bifida in the second trimester are the scalloping of the frontal bones of the skull (lemon sign) and the displacement of the cerebellum (Arnold–Chiari malformation, banana sign).

Figure 114.15 Spina bifida in a 13-week fetus.

The diagnosis of spina bifida has been reported in the first trimester from as early as 9 weeks.[68–72] Blaas *et al.* identified the defects in three embryos from high-risk pregnancies at 9 weeks of gestation (CRL 22–28 mm).[71] The authors used a combination of two- and three-dimensional transvaginal ultrasound to examine the spine. They note that the scalloping of the frontal bones and the Arnold–Chiari malformation did not occur before 12 weeks (Figure 114.15).

In four screening studies for structural defects by first-trimester ultrasound, there were 12 cases of spina bifida on a total of about 9500 fetuses and six were diagnosed in the first trimester.[30,33,34,46] It is of interest that at least in some cases the lemon sign and banana sign are present in the first trimester (Figures 114.16 and 114.17).

Heart defects

Congenital heart defects are amongst the commonest structural defects with a birth prevalence of 5–10 per 1000 births. Approximately, one half of those will need medical or surgical treatment (major defects) and the other half will be asymptomatic (minor defects). First-trimester diagnosis of several cardiac abnormalities has been reported in the first trimester, such as ectopia cordis, common truncus arteriosus, dextrocardia, monoventricular heart, Uhl disease, atrioventricular septal defect and ventricular septal defect.[73–77]

Figure 114.16 Lemon sign in a 13-week fetus.

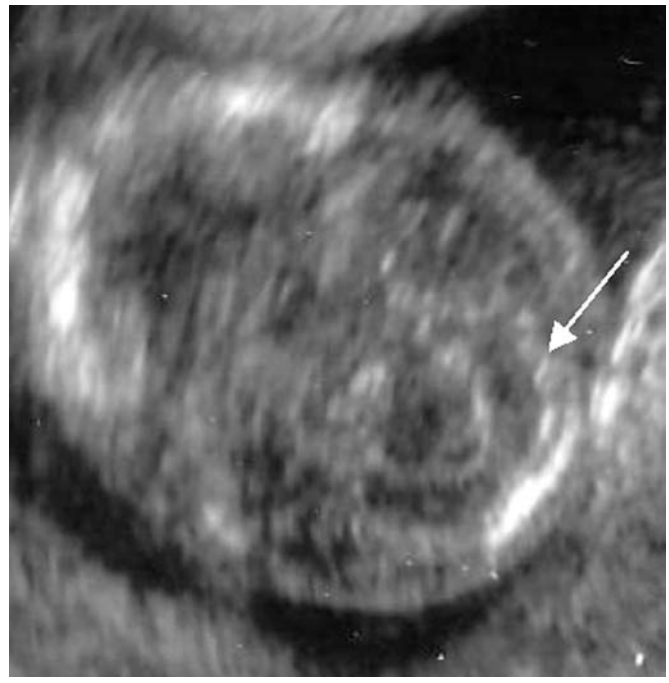

Figure 114.17 Banana sign in a 13-week fetus.

In a screening study of 114 pregnancies at risk for cardiac defects by transvaginal ultrasound at 11–16 weeks of gestation, there were six abnormal fetuses scanned at 11–14 weeks and the defect was diagnosed in five (sensitivity 83%).[78] Nuchal fluid was increased in four fetuses. In another small study of 15 high-risk fetuses scanned at 12 – (13 + 6) weeks,[79] the first-trimester scans were normal in 10 cases and inconclusive in four cases; one of the two cardiac anomalies (left isomerism) was identified at 12 weeks and a muscular ventricular septal defect was diagnosed postnatally (sensitivity 83%). Haak *et al.* performed first-trimester transvaginal fetal echocardiography in 54 fetuses with increased NT and reported sensitivity and specificity of 88% and 97%, respectively.[43] Another study on 241 fetuses with increased NT at 11–14 weeks (CRL 40–85 mm) identified 28 of the 37 cardiac anomalies in the first trimester (sensitivity 76%).[80]

Screening studies for heart defects have so far been limited to high-risk pregnancies defined by family history, maternal disease (diabetes, epilepsy) or increased nuchal thickness and performed in the setting of fetal echocardiography units by experts in cardiac scanning, thus explaining the high sensitivities reported. There is a strong association of increased NT with cardiac defects. A meta-analysis of screening studies reported that the detection rates for heart abnormalities were about 37% and 31% for NT cutoffs of 95th and 99th percentiles, respectively.[81] Fetal echocardiography, during the first trimester if possible, should be included in the routine follow-up of the fetuses with increased nuchal fluid.

Abdominal wall defects

Exomphalos (omphalocele, birth prevalence 1 in 4000)

In exomphalos there is midline defect of the abdominal wall through which intra-abdominal viscera herniated into a sac. The umbilical cord inserts at the apex of the sac. Herniation of the small bowel only is a normal step of the embryonic development and occurs between 8 and 10 weeks. The diagnosis of exomphalos is made if the bowel fails to return into the abdominal cavity by 11 weeks or if other viscera are herniated at any gestation.

Exomphalos is commonly associated with chromosomal abnormalities and syndromes. Chromosomal abnormalities, usually trisomy 18, are present in about half of the fetuses with exomphalos in the first trimester, one-third of cases in the second trimester and about 15% at birth. Exomphalos may be part of an extended defect in the abdominal wall development. If the abnormality involves the cephalic fold it results in pentalogy of Cantrell (exomphalos, ectopia cordis, cardiac defects, diaphragmatic hernia, sternal cleft). If it involves the caudal fold it results in bladder or cloacal exstrophy, bowel atresia and vertebral defects.

Many cases with exomphalos have been diagnosed in the first trimester, the earliest case being at 11 weeks for exomphalos containing liver.[82–87] Van Zalen-Sprock *et al.* reported on 14 cases with exomphalos at 11–14 weeks.[86] Nuchal fluid was increased in eight fetuses and seven of those were chromosomally abnormal. Exomphalos contained bowel only in fetuses

with chromosomal abnormality. Liver was often present in the contents of the sac as well as bowel in the chromosomally normal ones.

In a study of 622 high-risk patients there were two cases of exomphalos diagnosed in the first trimester.[31] In four screening studies on a total of about 9500 patients there were two cases with exomphalos correctly identified in the first trimester.[30,33,34,46]

In a study screening for chromosomal defects at 10–14 weeks by NT measurement in about 1500 patients, the diagnosis of exomphalos was made at this early gestation.[56] Finally, in another screening study for chromosomal defects at 11–14 weeks by NT measurement, 15,726 fetuses were examined and there were 18 cases of exomphalos.[87] The karyotype was normal in seven fetuses; the remaining 11 fetuses had trisomies 18, 13 or triploidy. This study showed that the prevalence of exomphalos and the risk of chromosomal defects in affected fetuses is increased in the first trimester because of the strong association with lethal chromosomal anomalies.[87]

Gastroschisis (birth prevalence 1 in 4000)

In gastroschisis there is a small defect of the abdominal wall laterally and usually on the right of the umbilical cord insertion through which herniation of the viscera (usually small bowel) occurs. Although gastroschisis is as common at birth as exomphalos, there are few cases reported in the first timester.[88,89] Prenatal diagnosis is based on the visualization of loops of bowel floating in the amniotic fluid. Gastroschisis is rarely associated with chromosomal abnormalities.

Defects of the urinary tract

Megacystis

Dilatation of the urinary bladder in first-trimester fetuses has been reported in association with obstructive uropathy (usually with posterior urethral valves or urethral atresia), severe renal abnormalities and prune belly syndrome.[90–97]

Liao *et al.* studied 145 fetuses with bladder diameter more than or equal to 7 mm at 10–14 weeks of gestation.[98] Fetuses with mild and moderate megacystis (bladder diameter 7–15 mm) were chromosomally abnormal in 24% of cases; in the ones with normal karyotype spontaneous resolution occurred in 90% of cases but in 10% there was progressive evolution to obstructive uropathy and/or echogenic kidneys. Fetuses with severe bladder dilatation (more than 15 mm) were chromosomally abnormal in 11% of cases but progression to obstructive uropathy was observed in all of the remaining chromosomally normal cases.

In a study of 622 high-risk patients there were two cases of megacystis diagnosed in the first trimester.[31] In four screening studies on a total of about 9500 patients there were two cases with megacystis correctly identified in the first trimester.[30,33,34,46]

Meckel–Gruber syndrome (birth prevalence 1 in 10,000)

This is a lethal, autosomal recessive condition with variable phenotypic expression. The typical features include encephalocele, bilateral polycystic kidneys and polydactyly. Other features may be present such as growth deficiency of prenatal origin, microcephaly, cerebral and cerebellar hypoplasia, anencephaly, Dandy–Walker malformation, absence of the corpus callosum, cleft lip and palate, renal agenesis, hypoplastic bladder, obstructive uropathy, syndactyly of the fingers and toes. Phenotype may vary from isolated polydactyly, which may represent the mild expression of the heterozygote state, to the full clinical manifestation of the disease. The diagnosis is based on ultrasound examination demonstrating encephalocele, usually occipital, enlarged, dysplastic, echogenic kidneys and polydactyly.

In three studies on a total of 15 pregnancies from high-risk families all eight affected fetuses were correctly diagnosed in the first trimester.[99–101] Another case of the syndrome from a low-risk couple was identified at 13 weeks in a study screening for chromosomal abnormalities by NT measurement.[100] In four screening studies on a total of about 9500 patients there were two cases with Meckel–Gruber syndrome diagnosed in the first trimester.[30,33,34,46] These studies have shown that the phenotype of Meckel–Gruber syndrome is present from the first trimester and it is likely that the diagnosis is actually easier at this early gestation when amniotic fluid volume is still within the normal range rather than in the second trimester when oligohydramnios hinders detailed ultrasound examination.

Skeletal defects

Caudal regression syndrome (sirenomelia, birth prevalence 1 in 500,000)

This is a rare sporadic defect involving vertebral abnormalities varying from partial sacral agenesis to complete absence of the lumbosacral part of the spine. Sirenomelia, the extreme form of the syndrome presents with variable degrees of hypoplasia and fusion of the lower limbs and is associated with genitourinary, gastrointestinal and central nervous system defects. Sirenomelia is about 250 times more common in mothers with poorly controlled diabetes.

There are five cases of first-trimester diagnosis of sirenomelia, the earliest being at 9 weeks of gestation.[102–105] In one case the mother was a diabetic presenting with ketoacidotic coma.[102] Features of the syndrome identifiable in the first trimester are CRL shorter than expected for the gestation, inability to visualize independently the lower limbs and abnormal movement of the lower limbs, intra-abdominal cyst and increased nuchal tanslucecny.

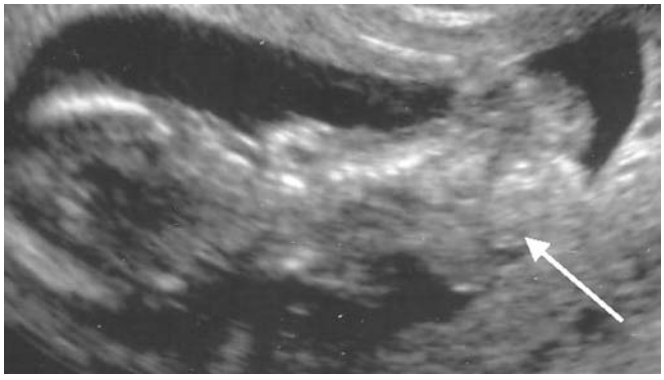

Figure 114.18 Body stalk anomaly in a 12-week fetus. The arrow points to the large abdominal wall defect. Part of the fetal body lies outside the amniotic cavity and is stuck to the uterine wall.

Figure 114.19 Kyphoscoliosis in a 14-week fetus.

Body stalk anomaly (birth prevalence 1 in 15,000)

This is a rare sporadic anomaly characterized by anterior wall defect, kyphoscoliosis, limb reduction and a rudimentary umbilical cord (Figure 114.19). Possible pathogenetic mechanisms included abnormal folding of the trilaminar embryo in the first 4 weeks of gestation, early rupture of the amniotic membrane and abnormal embryonic blood supply. In a study of about 106,000 pregnancies for chromosomal abnormalities by NT measurement there were 14 cases of body stalk anomaly and all were diagnosed in the first trimester.[106] In all fetuses the lower part of the body was outside the amniotic sac, in the coelomic cavity, which is possible because of early rupture of the amniotic membrane (Figure 114.17). NT was increased in about 70% of cases and the karyotype was normal in all cases. Contrary to this theory, Paul *et al.* presented a fetus with body stalk anomaly at 10 weeks of gestation (CRL 35 mm).[107] There were multiple anomalies including clefting defect of the cranium and brain, anterior wall defect, severe kyphoscoliosis and deformity of the lower limbs. The fetus was inside the amniotic sac, which appeared intact with no sonographic features of rupture. The earliest diagnosis of the defect is at 9 weeks of gestation; the fetus was partly outside the amniotic cavity, there was an abdominal wall defect and the lower limbs could not be seen.[108] In four screening studies on a total of about 9500 patients there was one fetus with body stalk anomaly diagnosed in the first trimester.[30,33,34,46]

Skeletal dysplasias

Skeletal dysplasias present with a prevalence of about 1 in 4000 (Figure 114.19). Although in some skeletal syndromes the clinical picture does not become obvious until the second or even the third trimester, there are skeletal defects that have been diagnosed in the first trimester and the commonest ultrasound features include limb shortening and bowing, limb fractures and hypomineralization of the skull and the spine and increased NT.

Achondrogenesis (birth prevalence 1 in 40,000)

Achondrogenesis type II is a lethal, autosomal recessive skeletal dysplasia usually presenting with hydrops, severe shortening of the limbs, narrow thorax, and hypomineralization of the vertebral bodies but normal mineralization of the skull. In the rarer type I of the disease there is hypomineralization of the skull and rib fractures.

There are two case reports on the first-trimester sonographic diagnosis of achondrogenesis type II in high-risk pregnancies; both fetuses had increased NT and short limbs that were abnormally positioned, with lack of movement.[109,110] There is also a report of a fetus with achondrogenesis type I presenting at 13 weeks with increased NT, short limbs, small thorax and deficient ossification of the skull, vertebral bodies and pelvic bones.[111]

Hypophosphatasia (birth prevalence 1 in 100,000)

Hypophosphatasia is a rare skeletal disease, which is clinically classified according to the age of onset of symptoms. The most severe type is perinatal hypophosphatasia, which has an autosomal recessive mode of inheritance. The perinatal form of the disease is due to abnormalities in the tissue-non-specific isoenzyme of alkaline phosphatase.

Souka *et al.*[112] reported on three pregnancies of a high-risk family. In the two affected pregnancies the diagnosis was made at 12 and 14 weeks and the features were marked hypomineralization of the skull and spine, narrowing of the chest with short ribs, shortening of all the long bones, bilateral talipes and increased NT.

Osteogenesis imperfecta type II (birth prevalence 1 in 60,000)

This is a lethal skeletal dysplasia where the majority of cases are new mutations of the genes encoding collagen type I. Recurrence (6–7%) is usually due to parental

mosaicism (somatic or germ-line), although, in a small number of families, autosomal recessive inheritance has been observed. In the second trimester, the characteristic sonographic features are short limbs and ribs with multiple fractures and hypomineralization of the skull.

Makrydimas *et al.* reported on an affected fetus presenting at 11 weeks with obvious shortening of all long bones and ribs and increased NT.[113]

Roberts syndrome

This is a rare, autosomal recessive condition characterized by symmetrical limb defects of variable severity (tetraphocomelia), facial cleft, hypertelorism, microcephaly and growth retardation.

In a fetus with Roberts syndrome, from a high-risk family, the sonographic findings at 11 weeks were increased NT and tetraphocomelia.[114]

Short-rib polydactyly syndrome

This is a rare, autosomal recessive, lethal skeletal dysplasia, characterized by short limbs, narrow thorax and postaxial polydactyly.

In a fetus with short-rib polydactyly syndrome type I, from a high-risk family, the sonographic findings at 13 weeks were increased NT, narrow chest, short limbs and polydactyly.[115]

SECTION XIII

Intrauterine growth

Section Editors: **J. M. Carrera and G. P. Mandruzzato**

115 Fetal growth characteristics

J. M. Carrera, B. Serra and R. Devesa

Introduction

'Growth' is generally defined as the process whereby the body mass of a living being increases in size as a result of the increase in the number (hyperplasia) and size (hypertrophy) of its cells and intercellular matrix. 'Development', on the other hand, should be understood as the process by which organs and their regulatory mechanisms gradually assume their functions. Broadly speaking, the term 'growth' is preferred when referring to measurable anatomic changes, while 'development' is used to refer to the gradual acquisition of specific physiological functions.

From the time of conception, embryonic and fetal growth does not happen in a disorganized manner, but is governed by still poorly defined physical and chemical mechanisms, which are responsible for a perfectly modulated cellular multiplication and differentiation. Gestation is a biological process that normally develops according to a predetermined sequence from its beginning. Duration of pregnancy is also pre-established and varies in different species (in humans 266 days or 38 weeks from the time of fertilization). Major intrauterine changes take place: a 130-μm zygote weighing 10 μg multiplies its length 4000 times and its weight 200 million times. During the embryonic stage (the first 8 weeks of development), the embryo does not look like a human being, although his or her appearance and proportions change during the remaining period of gestation: the head to body length ratio increases from 1:2 at 3 months to 2:5 at 5 months and 1:3 at 9 months.

It is surprising that fetal growth has been of little interest to physicians for almost the entire history of medicine. There is no mention of the birth weight of a child in the Bible, ancient Greek, or in the writings of Roman and Arabic physicians. Cone[1] reviewed the history of weighing the newborn infant and found the earliest mention of birth weight in the fourth edition (1964) of the celebrated textbook of Françoise Mauriceau, the great French obstetrician of the 17th century. According to Mauriceau, one fetus of 9 months ordinarily weighs 13 lb (about 6 kg). However, this excessively high birth weight was, amazingly, quoted by Smellie, a Scottish obstetrician, and Lobb, an English surgeon. In 1747, Lobb stated that the mean birth weight of neonates was approximately 16 lb. The first birth weights with scientific value were provided by the German physician Roederer in 1753, who reported average weights of 6 lb 12 oz (3038 g) in male infants and 6 lb 5 oz (2841 g) in females. In 1786, Clarke published the following estimations: 7 lb 5 oz (3291 g) in males and 6 lb 11 oz (3009 g) in females. Nevertheless, scientific and systematic studies on birth weight appeared in 1835, when Quetelet, trained in statistics and mathematics, reported mean values of 3200 and 2900 g for male and female neonates, respectively.

Anatomical studies of fetal growth were initiated by Streeter[2] and Scammon and Calkins[3], who provided useful information on intrauterine growth as estimated from weights at postmortem examinations. In 1951, Thomson[4] was the first author to construct growth curves derived from fetal crown–rump length and fetal weight and in 1963, Lubchenco and colleagues[5] presented weight curves in the form of percentiles.

Nowadays, the interest of Perinatal Medicine is not only focused on clarifying the characteristics of the fetal growth and its possible anomalies, but also in the consequences that they can have all through the life. In some way, these discoveries have changed the image of obstetrics as a discipline.[6]

Mechanisms of fetal growth

A series of processes occurring simultaneously during fetal growth, i.e. organic differentiation, weight gain and development of bodily function, prepare the fetus for an extrauterine life in optimal conditions. 'Timing' in each system may be different: formation of the ear, tactile sense, urine production or circulatory changes may occur much earlier than thermoregulation, endocrine adaptations or pulmonary maturation. At present, fetuses weighing less than 500 g cannot be maintained alive. In neonates weighing more than 1000 g, current advances in technology allow us to overcome functional immaturity-related complications and to achieve excellent survival rates.

Cellular processes characteristic of fetal growth (mass growth, protein synthesis and differentiation) are still poorly understood.

Cell mass growth

Cell mass growth involves three mechanisms (i.e. an increase in the number of cells, an increase in the size of cells and an increase in the intercellular matrix) interacting with each other, especially the increase in cell number and size of cells. Cell division or multiplication (hyperplasia) is usually followed by an increase in the size of individual cells secondary to the uptake of nutrients from the outside. After a determined cell size is attained, a subsequent cell division resumes. Sinclair[7] estimated at 10^{14} the total number of cells of an adult human being that are accomplished after 45 cell generations derived from the fertilized ovum. Immediately after fertilization of the ovum, growth of the fertilized egg is characterized by simple cell division until a certain stage is reached, after which cell multiplication is accompanied by an increase in the cytoplasm. While at the beginning of the embryonic period, divisions of cells occur simultaneously (synchronism), at more advanced stages of development, cell divisions are asynchronous, i.e. in each tissue of different organs only a few cells undergo division at the same time.

It is well known that DNA forms the primary genetic material. Martell and Bertolini[8] established the following: (a) the DNA content of a determined cell lineage remains constant, whatever variations in the environmental and nutritional conditions occur; (b) the DNA content of each cell lineage is related to its functional complexity; (c) the organism as a whole shows greater DNA content and consequently more total genetic information as complexity increases and (d) all cells of different tissues in the same species show an identical composition of DNA bases, which remains unaffected by changes in the environmental or nutritional conditions.

The human haploid genome has approximately 3×10^9 base pairs, forming between 50,000 and 100,000 genes of 1000 to 200,000 base pairs each. Functionally, the genome is involved not only in the genetic code system, but also in DNA regulation and replication, as well as chromosome alignment and recombination.

The intercellular matrix, mainly composed of hyaluronic acid and water-retaining complex polysaccharides, is poorly developed in the embryonic stage, but as the fetus grows, collagen and elastic fibers become prominent (collagen fibers account for a third of the proteins of the organism).[8]

Protein synthesis

Of all substances synthesized by cells during the process of growth and development (nucleic acids, glycogen, fat, steroids, etc.), proteins are undoubtedly the most important. Briefly, transcription refers to the process by which a base sequence of messenger RNA (mRNA) is synthesized (by an RNA polymerase) on a complementary strand of DNA and translation is the rather complex process by which mRNA, transfer RNA (tRNA) and ribosomes effect the production of protein from amino acids. A set of three consecutive nucleotides (triplet or codon) provides the genetic information to code for a specific amino acid that will be incorporated into a protein chain or serves as a termination signal.

Cellular differentiation

Although all cells of the organism have the same chromosomal content, the fact that they differ in functional differentiation continues to be a mystery. It has been suggested that cellular differentiation is a process of repression and derepression.[8] However, it is highly improbable that such a large amount of repressor substances could exist, for example, to repress indefinitely the multiplication capacity of neurons. In any case, permanent inhibition of a series of cell function capacities to open the way to the development of other functions may be based on specific immunological responses and may occur through methylation of some DNA or histone bases.

Numerous studies support the concept that 'embryonic induction' is essential for the development of tissue diversity. Embryonic induction refers to the stimulation of a specific developmental pattern in specific cell groups (responding or target tissue) by other close groups (stimulating or inductor tissue). For example, vertebral bodies are formed from the notochord, whereas the halves of the vertebral arch derive from the neural tube, so that anomalies in the development of one component will produce anomalies in the other. However, the molecular basis of these interactions is poorly understood.

The diversity of substances required for each process of cellular differentiation may be simplified by the action of 'organizing substances' (molecular inductors) whose presence would only be required at a given time of development (e.g. in a particular cell lineage); from this moment on, cell division would proceed normally. This is currently the subject of extensive research. Among these molecules, growth factors have been identified in almost all animals including humans and constitute a group of proteins with primarily stimulating activity. Growth factors are also involved in tissue differentiation, e.g. transforming growth factor-β is associated with differentiation of the ectodermal layer into the mesodermal layer. Genes with the function of activating cell differentiation have also been identified (e.g. homeobox genes).

General characteristics of fetal growth

Fetal growth is primarily genetically controlled (differentiation from other species, racial differences, gender, etc.) but also considerably modified by more intangible environmental factors. Genetic factors are

involved in the control of embryonic development, rate of cell division, number of cells forming each organ and tissue and 'potential' growth of fetal weight and height. The human fetus may be considered to be the result of the interaction of its genetic potential and the environment, i.e. fetal and maternal factors that limit or favor growth. This explains the high rate of variability among individuals of the same species, which is genetically and biologically necessary.

According to Elejalde and de Elejalde[9], normal fetal growth and development is proportional, symmetrical, global, temporal and controlled. Proportional growth refers to the development of different parts of the body as expected to give rise to an infant of normal weight and appearance at the end of gestation. Double organs show the appropriate symmetry. The mechanisms by which right/left and cranial/caudal symmetry and asymmetry axes are established have not been fully identified, although it seems that a genetic alteration would produce protein anomalies[10] resulting in true morphogenetic substances, the effects of which would be related to their function, spatial disposition, or simply to their gradient or concentration (right, left, cranial or caudal). Theoretically, for example, an elevated concentration on the left would place the heart in the correct site or would determine an anatomical differentiation in the formation of the right and left bronchial tree. Moreover, all organs grow following a determined rate and up to a determined time to maintain the expected proportions and symmetry. Each organ and system has its own 'timing' – a particular growth rate – although the rate of fetal growth and development during the first trimester of gestation is much faster than during the second and third trimesters. Finally, cellular growth of each organ at each moment of intrauterine life is perfectly established (with minimal and maximal ranges) in relation to the gestational age.

All these features determine that fetal growth, in reference to weight and height gain, is a dependent, constant and linear function and although all organs and tissues have different growth rates and capacities, the overall proportion of the fetus is preserved.

116 Regulating factors

J. M. Carrera, B. Serra, E. Scazzochio and M. Carrera

Introduction

Fetal growth can be divided into two stages, consisting of two phases each; a first stage of exponential fetal growth, in which differentiation of organs and systems occurs simultaneously, and a second stage of linear fetal growth that continues until birth, in which maturation processes predominate. Although some specific endocrinological actions can be related to certain aspects of fetal growth, in general terms the mechanisms responsible for general coordination or development of particular organs are still to be elucidated (Figure 116.1).

Fetal growth rate is primarily governed by an intrinsic fetal growth potential, which is essentially genetic in nature ('genetic regulating factor'). Genetic control of fetal growth, however, is largely modified by two superimposed intrauterine growth regulating factors: 'hormone regulating factor' (of fetal origin and of a stimulating nature) and 'environmental regulating factor' (of maternal origin and mostly restrictive in nature). Thus, the slope of the fetal growth curve throughout pregnancy, and consequently the birth weight, results from the interaction of inhibiting and stimulating factors on the fetal genotype. The human fetus may be considered as the interaction between genetic potential (its chance of 'being') and incidental factors associated with the accomplishment of this goal (the 'environment'), which may act to limit or favor this purpose.[1–7]

Whilst the genetic regulating factor predominates during the first half of pregnancy, determining a narrow range of fetal growth variability, hormone and environmental regulating factors have a marked effect during the second half of gestation, inducing a wide range of variability in fetal growth and development. In addition, other factors play a main role in fetal growth regulation, such as the bioavailability of substrates for the fetus, the nature of fetoplacental interaction, and the organization of progressive fetal maturation.

Genetic regulation of fetal growth

The mechanisms through which genetic information in the fertilized ovum controls cellular multiplication and differentiation until giving rise to a human being are purely speculative.[8] Biochemical aspects of fetal growth are also poorly defined. It is well known, however, that two cell genomes (paternal and maternal) are required for normal embryonic growth and development. Surani and colleagues[9] and Solter[10] found that parthenogenetic embryonic cells with male genome produced primarily embryonic tissues, whereas parthenogenetic embryonic cells with only genetic contribution from the female could initiate preimplantational development and even placentation, but were unable to differentiate extra-embryonic tissues properly. It has been suggested that these differences related to genetic contribution from the male and female arise from 'imprinting' during gametogenesis. Although the molecular nature of these phenomena has not been reliably demonstrated, there is

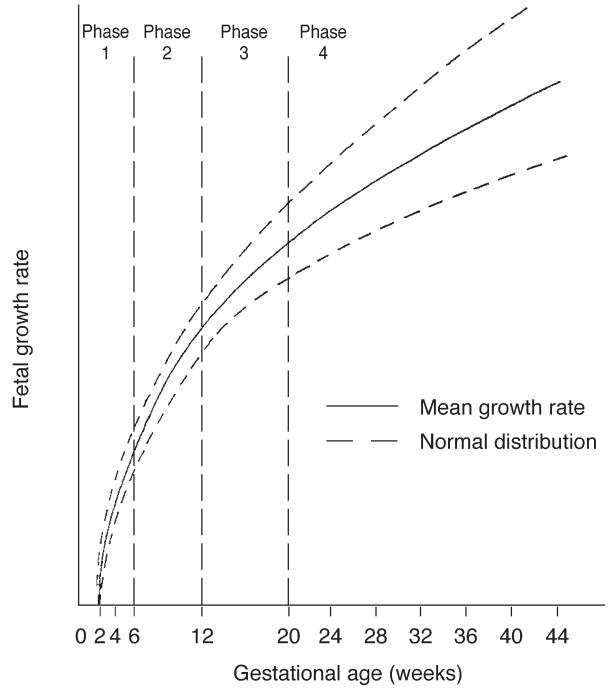

Figure 116.1 Fetal growth rate in relation to physical parameters. There is exponential growth in the first two phases (until 12 weeks' gestation) and linear growth thereafter. The normal range becomes wider as the fetal growth rate decreases, so that the accuracy of a single measurement to estimate gestational age is inversely proportional to age.

evidence that locus-specific methylation patterns are probably inherited according to predetermined paternal/maternal patterns.[11]

Holliday and Pugh[12] postulated that developing fetal cells would probably be subjected to genetic control, resembling in nature the 'modifying enzymes' of some bacteria. These enzymes would allow a precise number of cell divisions. Differentiation would be attained until a certain stage of development, by means of changing the position of some sequences of DNA bases in each cell division, inducing activation of a particular gene or genes, which, in turn, would initiate cell differentiation. Accordingly, the following issues may be explained:

(1) In the full-term fetus, the total number of cells is the result of 42 successive divisions of the fertilized ovum. The importance of this precise number is appreciated by the fact that only five more cell divisions are required to achieve the adult size. In this case, the genetic chronometer 'counts' exactly the number of cell divisions and decides, according to an established program, after which cell division, differentiation of a particular cell lineage is going to be started.
(2) A given developmental process occurs at a given gestational age. It is evident that the program is 'written' in basic sequences of DNA, which, after consecutive replications, activate particular genetic 'commutators' to induce these events.
(3) There is a time order in the formation of fetal structures. This order is obviously related to the number of cell divisions, carefully counted by the 'genetic chronometer' in the developing cells.
(4) Although cell differentiation may be induced by activation of a single gene, codification and an active enzymatic system at different genomic sites with identical control sequences are required.
(5) Differential characteristics of genetic code and DNA changes would be responsible for preserving the stability of each cell lineage.

The effect of the genetic regulating factor on fetal growth and development has been demonstrated in studies carried out in monozygotic twins whose final heights were highly correlated ($r = 0.95$), as opposed to the definitive heights of dizygotic twins.

However, fetal genotype accounts for about 15% of variations in birth weight due to certain inherited traits. These include fetal sex, racial and ethnic characteristics, and paternal and maternal genetic contributions.

Approximately 2% of variations in birth weight can be attributed to sex chromosomes.[13] The birth weight of a full-term male infant is on average 150–200 g higher than that of a female. This increase may be due to the effect of testicular hormones or to a more marked antigenic difference between the male fetus and his mother.[14] Placentas from male neonates also weigh more than those from females (2% higher at 40 weeks).

Generally speaking, Black neonates have a tendency to be smaller than Caucasian babies, although they have a faster maturation thereafter. Asian newborns are smaller than both Caucasian and Black neonates. As an example, the mean birth weight of Cheyenne newborns – tribe of North American Indians – is 3800 g, compared with 2400 g for newborns from the Luni tribe in New Guinea.[15] However, it is important to take the influence of socioeconomic conditions into consideration when comparisons between different ethnic groups are made.

Paternal influence on fetal weight is exclusively exerted through autosomal genes and sex chromosomes. From an anthropometric perspective, for each centimeter by which paternal height exceeds normal values, fetal weight at birth is increased by 9 g.[16] The maternal contribution is more complex and not only expressed through genetic material; in fact, the effect of maternal genotype on fetal growth and development is probably as important as the fetal genotype-derived influence.[17] Anthropometric data indicate that maternal weight prior to pregnancy has a greater influence than maternal height.[18]

It is therefore evident that several factors, which are considered physiological but have a genetic basis, determine the weight of a newborn child.[19] However, the majority of these factors (height and weight of the mother and the father, ethnicity, parity, etc.) are regrettably not considered in the population models used currently. The exception is the gestational age.[7] The consequence of this omission is the adoption of an inadequate classification of the newborn children. So the newborn babies, whose mothers are low weight and short height and therefore belong to an ethnic group of normally small newborn babies, are misclassified as babies subject to a growth restriction.[20]

Hormonal regulation of fetal growth

In addition to a genetic chronometer, there is no doubt that other 'endocrine chronometers', inducing hormonal secretion, must be present. The genetic chronometer is virtually immutable, whereas the endocrine chronometer(s) are theoretically susceptible to pharmacological modification.

Maternal hormones

The placenta is impermeable to many maternal hormones, especially to protein hormones and growth factors (for that reason, the fetus is substantially autonomous from an endocrinological point of view). With regard to other hormones, thyroxine and cortisol can pass through the placenta, but in practice they do not reach fetal blood because increased concentrations of thyroxine and hydrocortisone in the maternal circulation are not accompanied by significant increases in fetal blood levels of these hormones.

Although maternal hormones are not directly implicated in fetal growth, they are indirectly involved by ensuring adequate concentrations of glucose and nutrients in fetal blood. Some disorders of fetal development and endocrinological function may be explained by changes in blood glucose levels. In maternal diabetes, for example, pancreatic function of the fetus may be affected as a result of fetal hyperglycemia secondary to maternal hyperglycemia. During the first half of pregnancy, there is a noticeable maternal hyperinsulinism (due to an increase in the number and function of pancreatic cells) resulting from progestational and estrogenic stimuli, that promotes maternal anabolism but does not increase the energy supply to the fetus. By contrast, fetal anabolism predominates during the latter half of pregnancy due to an increase in a series of anti-insulin factors (an increase in insulin clearance, an increase in insulin receptor resistance and insulin antagonists of endocrine nature), resulting in a partial catabolism of maternal reserves that are directed to the fetus.

On the other hand, catecholamines, angiotensin II, aldosterone and prostaglandins play an important role in maintaining maternal cardiovascular homeostasis and uteroplacental blood flow. According to Speroff,[21] by analogy with the kidney, prostaglandins and the renin–angiotensin system would be involved in the regulation of uterine blood flow.

Placental growth factors

The placental growth is determined by the proliferation, differentiation and migration of the cytotrophoblast. The proliferation of the trophoblastic cells is closely related to the placental growth. For this reason, the progressive reduction of this proliferation, after its time of maximal activity between the eighth and ninth week of gestation, suggests that the placental invasion has been successful.[22,23] On the contrary, an increase of the proliferation rate during the last period of gestation must lead to think that there are some problems of implantation that can be associated with hypoxia conditions.

The fetal growth depends basically on the placental function. The placenta is an organ specialized in providing an appropriate fetal nutrition, but it also acts as an endocrine organ. In this sense, the specialized cells of the trophoblast produce peptide growth factors, whose function is to serve as modulators of the fetal growth.

One of these growth factors is the insulin-like growth factor (IGF), which has a fundamental role in the control of the placental and fetal growth.[24,25] Nowadays we know that it not only stimulates the production of glucose and amino acids, but also acts in the proliferation and differentiation by producing several hormones.[26] It has been shown that growth hormone-induced growth stimulation is mediated by IGFs,[27] in particular IGF-1.

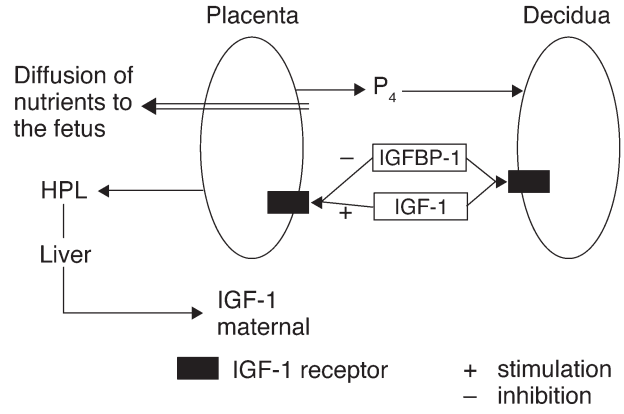

Figure 116.2 Paracrine and autocrine regulation of insulin-like growth factor-1 (IGF-1) and IGF-binding protein (IGFBP-1) in the placenta and decidua. HPL, human placental lactogen; P_4, progesterone.

For this reason, human fetal IGF levels have been associated with birth weight.[28,29] Recent studies have confirmed IGF secretion in a large variety of fetal tissue, mainly the connective tissue and mesenchymal cells, and the paracrine effects of this factor.[30] Fetal IGF-1 levels have been shown to be significantly lower in cases of growth restriction.[31] There is a statistically significant increase in maternal IGF-1 levels in the third trimester of pregnancy, which stimulates the transplacental passage of nutrients. IGF-1 action seems to be modulated by placental lactogen. On the other hand, this mechanism may be inhibited by IGF binding proteins (IGFBP-1), which bind to placental IGF receptors. Apparently, progesterone may in turn modulate this effect by regulating decidual secretion of IGFBP-1 (Figure 116.2).[32] However, further studies are warranted to define the role of growth hormone in fetal weight regulation.

On the other hand, low levels of serum IGF-1 in IUGR and preterm infants appear to predict an increased risk of retinopathy of prematurity (ROP).[33]

IGF bioavailability is modulated by specific binding proteins. Among these, IGFBP-1 is present in the decidua and at the decidua–trophoblast interface[34] and may act as a local modulator of IGF action on fetal growth. Increased IGFBP-1 has been implicated in poor placentation, potentially by reducing trophoblast invasion of the spiral arteries in early pregnancy,[35] raised serum maternal IGFBP-1 concentrations occur in pregnancies that are complicated by IUGR or pre-eclampsia.[35–37]

There is a robust relationship among the rate of increase in individual maternal IGF-1 levels after 16 weeks, placental mass, and neonatal fat mass. This does not imply causality but does indicate that mid-pregnancy changes in IGF-1 levels may be a valuable marker for anomalous fetal growth.[38]

Human placental development combines elements of tumorigenesis and vasculogenesis. The dysfunction

of the vascular endothelium is now thought to be the primary factor responsible for growth anomalies.[39]

Besides IGF, also other growth factors as the vascular endothelial growth factor (VEGF) can be important. VEGF is a specific mitogen and survival factor for endothelial cells, and a crucial promoter of angiogenesis in physiological and pathophysiological conditions.[40,41] During pregnancy, VEGF is essential to the proliferation of trophoblasts, the development of embyonic vasculature, and the growth of maternal and fetal blood vessels in the uterus.[42]

Fetal vasculogenesis and angiogenesis, and vascular adaptation of the uterine circulation, are unique.[43] VEGF is a protein with antiapoptotic, mitogenic, and permeability-increasing activities specific for the vascular endothelium.

Other factors of vasculogenesis

Ashworth *et al.*[44] showed that myometrial arteries from women with pre-eclampsia have an attenuated response to the endothelium-dependent vasodilator, bradykinin. However, Ashworth *et al.* used vasopressin as a vasoconstrictor, a substance that has no known role in the myometrial vascular bed[45] and only assumes a physiological role in cases of profound shock.[46,47] Other more physiological agents, such as noradrenaline, 5-hydroxytryptamine, angiotensin II, prostaglandin F2 α and endothelin-1, do not provide such a contraction on myometrial arteries[45] and therefore cannot be used.

Ong *et al.* confirmed that myometrial arteries from women with pre-eclampsia or intrauterine growth restriction, exhibit an attenuated endothelium-dependent vasodilatory response.[48]

Fetal hormones

Recent studies also suggest that the underlying mechanisms that regulate feto-placental growth responses to changes in substrate availability involve the endocrine, paracrine, and autocrine effects of placental growth hormone, placental lactogen, insulin, the family of IGFs, and their binding proteins.

Fetal growth hormone

Fetal growth hormone concentrations are substantially higher than those found after birth (resembling growth hormone levels in patients with acromegalia) and show a peak at 20–24 weeks' of gestation.[49] However, the influence of growth hormone on the regulation of fetal growth is negligible.[50] This is probably related to the absence of growth hormone receptors in the fetal liver.[51] For example, mean growth hormone levels in anencephalic fetuses are 80% lower than those found in normal conditions, but fetal weight is not significantly reduced.[52] In cases of growth hormone familial deficiency, weight at birth is practically normal, height may be somewhat lower,[53] and there are no clinical signs of growth hormone deficiency. In animal studies, fetal growth rate was not affected by hypophysectomy[54] or decapitation.[55]

Despite this evidence, results of different studies suggest that growth hormone possibly contributes to fetal growth to some extent. Hoet[56] considered that growth hormone can increase the sensitivity of β-cells of the pancreas to plasma glucose levels. Thus, the well-known increase in the number of fetal β-cells and insulin levels that is observed in maternal diabetes does not appear in anencephalic fetuses from diabetic mothers. Fetal weight may be conditioned by insulin–growth hormone balance. In fact, the relationship between growth hormone and insulin is shown by the intrauterine diabetogenic effect of growth hormone[57] and by an inhibiting action on fetal hypoglycemia secondary to endogenous hyperinsulinism, acting as an antagonist of insulin. Some functional similarities between growth hormone and placental lactogen may be expected given that 85% of their amino acids are identical. Growth hormone promotes lipolysis and glycogen deposits in the fetal liver,[58] and exerts a direct stimulation of the adrenal glands[59] and possibly of the epiphyses of long bones.[30]

An 80% decrease in neonatal growth hormone secretion after childbirth has also been demonstrated. The fact that growth hormone levels increase in fetal plasma by the same relative proportion that growth hormone levels decrease in the hypophysis has remained unclear for many years. These findings suggest a 'defect' in the regulation of growth hormone secretion, probably due to immaturity of the fetal hypothalamus–portal system and absence of IGFs. At the end of gestation, however, this situation is reversed by maturation of the portal system and functioning of the hypothalamic negative feedback regulating system.[60]

Thyroxine

Despite the essential role attributed to thyroxine in cell metabolism, the thyroid gland does not seem to be implicated as a regulating factor of intrauterine growth. Thyroid hormones, however, are involved in antenatal maturation of the fetal lungs and skeleton. It has been shown that birth weights of hypothyroid fetuses are even higher than the average.[61] The excess of thyroxine in thyrotoxic fetuses does not accelerate fetal growth rate, and they are even susceptible to intrauterine growth retardation.[62] Fetuses from thyroidectomized rats and rabbits did not exhibit growth retardation.[8]

However, thyroxine may be involved in fetal growth as shown by results of experimental studies. Sheep fetuses undergoing thyroidectomy 7 weeks prior to delivery showed marked growth restriction.[63] This indicates that a period of time is required for thyroxine-related effects to become evident. Inconsistencies

Table 116.1 Effect of experimental manipulation of fetal insulin levels on fetal weight at term in different animal species[78]

Insulin level	Procedure	Species	Fetal weight
High	Maternal diabetes	Monkey, pig	Unchanged
		Sheep, rat	Unchanged
High	Insulin infusion	Pig, sheep	Unchanged
		Monkey, rat	↑10–25%
High	Glucose infusion	Sheep, rat	↑10–20%
Low	Pancreatectomy	Sheep, rat	→ 20–30%
	Diabetogenic drugs	Sheep, rat	→ 20–40%
		Monkey	→ 10–20%

between these results and those mentioned above may be explained by ovine placenta not being permeable to thyroxine and tri-iodothyronine,[64] whereas in humans, rats and rabbits, the placenta is slightly permeable to maternal thyroxine. It seems that small amounts of maternal hormone are sufficient to maintain normal fetal growth rates. In the absence of both maternal and fetal thyroid hormones, fetal growth restriction occurs. In rhesus monkeys, ablation of maternal and fetal thyroid tissue by means of radioactive iodine was followed by a decrease in protein synthesis, with decreased levels of total RNA, total proteins, ATPase activity, and carbonate dehydratase activity.[65] Studies on the growth of fetal guinea pigs showed decreased plasma levels of thyroxine and triiodothyronine in cases of intrauterine growth restriction.[66] Information based on these experiences may be relevant in humans.

Insulin

Insulin is the only fetal hormone related to intrauterine growth. Macrosomia is frequently observed in pregnancies complicated by diabetes mellitus. Given that maternal insulin cannot diffuse through the placental membrane, insulin is exclusively of fetal origin. It has been suggested that maternal hyperglycemia would induce fetal hyperglycemia, which would stimulate fetal pancreatic islet cells with an increase in the secretion of insulin.[67] Fetal hyperinsulinism mobilizes glucose deposits, increasing fetal growth. Other authors[68] have also shown that an increase in maternal amino acids causes a similar stimulating effect on fetal insulin secretion.

Clinical and experimental evidence indicates that insulin can be considered as the true 'fetal growth hormone'. High insulin levels are found in neonates of diabetic mothers.[69] There is a positive correlation between plasma insulin levels and fetal weight in a high number of animal species. A positive correlation between insulin cord levels and excessive birth weight in newborns of diabetic mothers has also been reported.[70] Low insulin levels have been consistently associated with low weight fetuses (Table 116.1).[71,72] Fetal injections of insulin in rat[73] and sheep models[74] produced an increase in birth weight with an increase in fat tissue and nitrogen content. Growth restriction was reported in fetuses of rhesus monkeys and sheep which were rendered insulin-dependent by chemical ablation of pancreatic β-cells after uterine injection of streptozocin,[75,76] and despite the induction of hyperglycemia, use and oxidation of glucose in fetal tissues was impaired. Intrauterine growth restriction has also been documented in full-term neonates with pancreatic agenesis[77] whose development seemed to be interrupted at 30–32 weeks' gestation (the time at which excessive fetal growth in maternal diabetes is documented).[76] Pancreatectomy-induced growth retardation has also been confirmed in experimental studies. In sheep fetuses,[78] pancreatectomy was followed by a 40–50% decrease of the growth index (Figures 116.3 and 116.4) that returned to normal after insulin therapy.[79] Fetal insulin concentration varied in parallel with glucose levels.[78]

Insulin effects in the antenatal and postnatal periods are substantially different. Maternal plasma glucose levels are maintained within a narrow range by maternal insulin, so that there is a relatively constant and uniform glucose perfusion to the fetus. The absence of sudden fluctuations in glucose levels is the reason for a fetal lack of requirement of pancreatic β-cells, resulting in a fetal pancreas insensitive to acute increases in glucose concentrations (to some extent a situation similar to that found in diabetics).[80] Amino acids show an even greater stimulating effect on insulin secretion than glucose. However, in cases of sustained hyperglycemia (e.g., maternal diabetes) the fetal pancreas ultimately

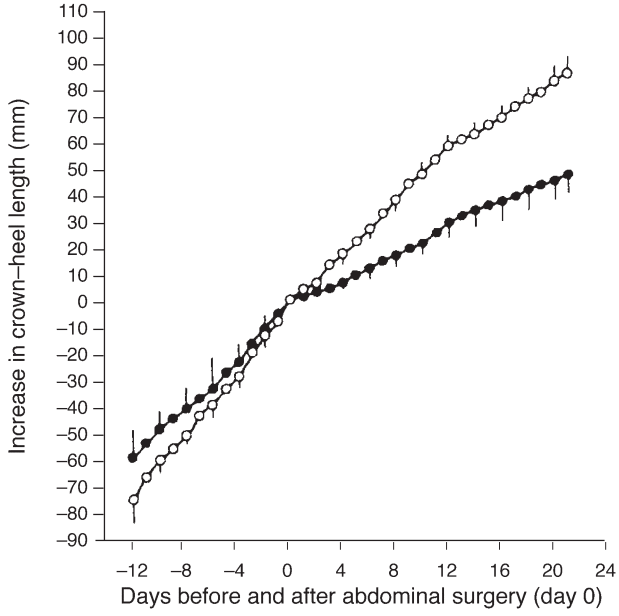

Figure 116.3 Mean ± SD crown–rump length (crown–heel) in sheep fetuses before and after pancreatectomy on day 0 (•, $n=6$) and before and after a sham operation on day 0 (∘, $n=5$).[78]

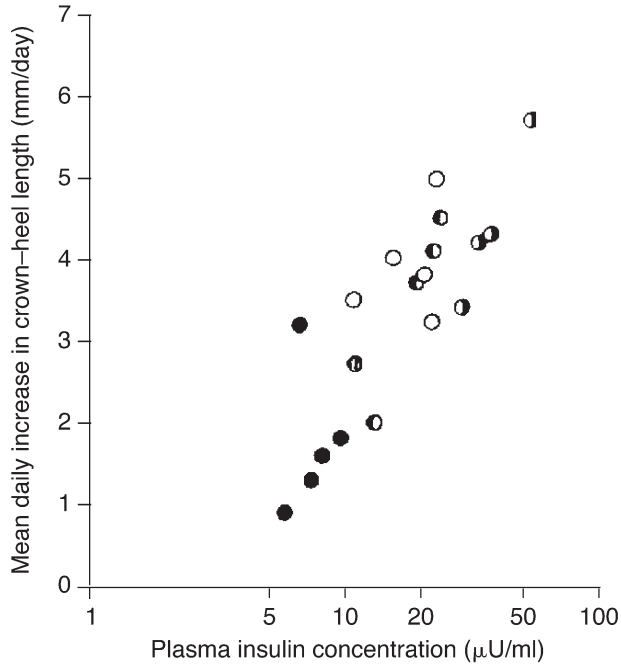

Figure 116.4 Relationship between plasma insulin concentration and daily increase in crown–rump length in sheep fetuses after a sham operation (∘) or pancreatectomy and insulin replacement (•) ($y=3.97$, log $x+1.50$; $n=19$; $r=0.847$; $p<0.001$).[78]

shows a response with hyperplasia of β-cells and an increase in insulin secretion.

An adequate supply of nutrients and uteroplacental blood flow are necessary for fetal growth stimulation by insulin. In maternal diabetes with progressive uteroplacental vascular insufficiency due to microangiopathy of villi arterioles, fetal hyperinsulinism due to β-cell hyperplasia is followed, on the contrary, by chronic hypoglycemia and growth restriction.

No insulin receptors are found during the first stages of fetal growth, so that there is a lack of response to insulin at this stage.[81] On the other hand, it seems that these receptors are not insulin-specific, as they also respond to somatomedins.[82]

In rats, plasma insulin levels decrease suddenly after birth and remain low despite proper postnatal development of the animal. Plasma levels of growth hormone also decrease. These findings may be explained by glucose being the only intrauterine fetal nutrient. After birth, insulin loses its role as a growth hormone since a nutrient (milk) poor in carbohydrates but rich in fat is supplied. The stimulating action of insulin on fetal growth is due in part to its direct anabolic effect on fetal metabolism and to an indirect stimulating effect on other growth factors, such as somatomedins (IGF-1 and IGF-2). It has been shown that the higher the fetal weight, the higher the IGF-1 levels are.[83]

Placental hormones

Human placental lactogen

Human chorionic somatomammotropin (HCS), also known as human placental lactogen (HPL) or human chorionic growth prolactin (HCGP), is the only placental hormone significantly related to fetal growth. This hormone, secreted by the placental syncytiotrophoblast, diffuses exclusively to the maternal circulation. Maternal plasma levels of HPL increase exponentially according to placental growth. HPL represents 5–10% of the total proteins synthesized and released by the placenta. The levels of HPL are closely related to placental weight, i.e., to functional trophoblastic tissue mass.[84]

Human placental lactogen is detectable in maternal plasma from weeks 6–8 of pregnancy. In normal conditions, HPL levels show an exponential increase up to a plateau of 6 ± 1 mg/ml at week 35, which is 1000-fold higher than baseline growth hormone levels. As stated above, HPL replaces growth hormone in some of its functions.

Physiological actions of HPL include a series of maternal changes (Figure 116.5).[85,86] In relation to the lipolytic activity of this hormone, HPL mobilizes fat deposits with a subsequent increase in plasma free fatty acids and triglycerides which would be therefore available to fetal needs. On the other hand, there is an increase in insulin resistance due to a peripheral antagonist effect of HPL on glycolytic activity but not on lipogenic or glycogenetic activities. HPL induces a decrease in maternal glucose consumption, thus ensuring adequate nutrients to the fetus, stimulates amino acid incorporation to proteins (an action probably synergistic with insulin), and increases circulating levels of insulin as a response to glucose overload.

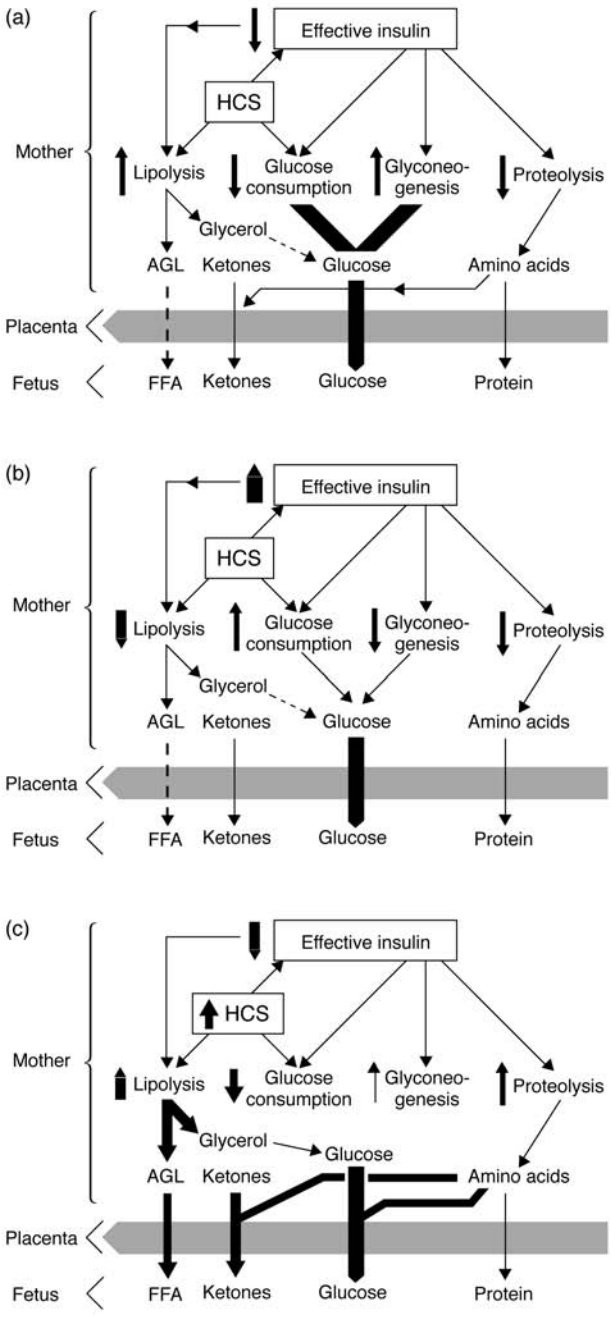

Figure 116.5 Role of human chorionic somatomammotropin (HCS) in (a) the provision of maternofetal substrate,[86] (b) the provision of maternofetal substrate and nutritional status,[86] and (c) maternofetal provision in fasting conditions.[86] FFA, free fatty acids.

Based on the knowledge of these partial functions, it may be assumed that the metabolic role of HPL in relation to fetal development consists mainly in ensuring an adequate supply of carbohydrates by inhibiting insulin glycolysis in maternal tissue, facilitating the conversion of fat into metabolic nutrients, and protecting the maternal protein supply by its synergistic effect on the protein-anabolic activity of insulin, so that lipids rather than carbohydrates are more extensively used for maternal nutrition. Since transplacental diffusion of large amounts of lipids is not possible, and given that fetal nutrients are mainly carbohydrates, this maternal metabolic condition favors fetal nutrition. This pathway is particularly important in cases of maternal malnutrition; in fact, fasting is the main stimulus for HPL secretion in pregnancy. The anti-insulin effects of HPL are only counteracted in the immediate postprandial state by peak plasma levels of insulin, which, on the other hand, allow maternal hepatic stores of glycogen and fat to be replaced. Increased insulin and HPL levels activate protein synthesis. Therefore, insulin constitutes a fluctuating modulator of HPL effects on the maternal organism.[87] Food intake increases 'effective insulin' and restores maternal substrates, whereas fasting induces a decrease in 'effective insulin', and the catabolic effects of HPL guarantee an adequate supply of nutrients to the fetus.

Sex steroids

Progesterone has catabolic and insulinogenic effects, and estrogens are antagonists of HPL effects on bone growth. It is likely that both sex steroids and hydrocortisone would also have a modulating effect on physiological actions of HPL and that HPL, in turn, may regulate the effects of some growth factors, such as IGF-1 and IGFBP-1.[32]

Eicosanoids

Recent studies have considered prostaglandin E_2 of placental origin as responsible for a reduction of fetal breathing movements occurring in hypoglycemic conditions.[88] Accordingly, the fetus would 'save' glucose to be used by other more essential processes.

Placental proteins

During the last years, several research works have linked the low levels of pregnancy-associated plasma protein A (PAPP-A) and free beta-subunit of human chorionic gonadotrophin (FβhCG) to fetal growth anomalies. However, there are still some doubts about the consistency of this association.

One study found a positive correlation between PAPP-A at 8–14 weeks and eventual birth weight[89] and an analysis of 60 *in vitro* fertilization pregnancies described lower concentrations of PAPP-A in the first trimester among eight women who eventually delivered preterm.[90] A further study of 5297 women showed lower PAPP-A and FβhCG levels at 10–14 weeks' gestation among women who miscarried, delivered babies small for gestational age and developed pre-eclampsia.[91]

The association between first-trimester biochemistry and later pregnancy complications has been examined in such a multicenter, prospective, non-interventional cohort study among a subgroup of 8839 women with singleton, karyotypically normal babies, where outcome data had been retrieved. This analysis showed strong and highly statistically significant

Table 116.2 Adjusted odds ratios for adverse perinatal outcomes associated with first-trimester PAPP-A and free hCG in the lowest 5th percentile (from Smith *et al.*[92])

	PAPP-A < 5th percentile		Free hCG < 5th percentile	
Outcome	**Adjusted odds ratio (95% CI)**	**P**	**Adjusted odds ratio (95% CI)**	**P**
Birth weight < 5th percentile	2.9 (2.0–4.1)	< 0.001	1.3 (0.9–2.0)	0.15
Delivery 24–32 weeks	2.9 (1.6–5.5)	0.001	1.1 (0.5–2.7)	0.77
Delivery 33–36 weeks	2.4 (1.7–3.5)	< 0.001	0.5 (0.3–1.0)	0.04
Pre-eclampsia	2.3 (1.6–3.3)	< 0.001	1.1 (0.7–1.8)	0.64
Stillbirth	3.6 (1.2–11.0)	0.02	2.3 (0.7–8.2)	0.18

Odds ratios adjusted for BMI, height, smoking status, ethnicity, parity, maternal age, gestational age at the time of sampling, PAPP-A and free hCG
Odds ratio for delivery week 33–36 also adjusted for interaction between age, ≥35 years and height

associations between levels of PAPP-A at 8–14 weeks and the risk of fetal growth anomalies.[92]

The association persisted in multivariate adjusting for body mass index (BMI), height, smoking status, ethnicity, parity, maternal age, gestational age at the time of sampling (Table 116.2). There was also an association between FβhCG and growth restriction across the range of deciles. However, the association between FβhCG and later outcome did not persist in multivariate analysis including the PAPP-A level.

Other studies also reflect a defect in early pregnancy placentation and later adverse outcome. For this reason, low first-trimester maternal circulation of PAPP-A, is associated with an increased risk of growth restriction.[93–97]

However, some researchers consider that this so-called association cannot be considered as proven, since some epidemiological,[98] diagnostic and methodological variables have not been taken into account (errors in dating).[99]

PAPP-A has been found to be part of the system controlling the IGFs in trophoblast. PAPP-A has been identified as a protease for IGFBP-4.[100] IGFBPs bind IGF-I and IGF-II, inhibiting their interaction with cell surface receptors and have, therefore, a key role in modulating IGF activity.[101] Because PAPP-A breaks down IGFBI[100] low levels of PAPP-A would be expected to be associated with high levels of IGFBP and, therefore, low levels of free IGF.

Environmental regulation of fetal growth

Reduction of the free rate of fetal growth due to its environment is a common and normal occurrence. In the absence of these environmental conditioning factors, it is possible that the weight at birth would be doubled. It has been postulated that fetal growth restriction may be exerted by the activation of a predetermined maternal regulating factor[102] ('environmental chronometer'), which may be triggered by the maternal genotype and by the degree to which maternal fetal growth was restricted during its own development. Therefore, it is possible that fetal weight variations may be transmitted through successive generations without forming part of the genotype. This hypothetical regulating factor would act on the 'intrauterine environment' and through the external environment where the mother lives. With regard to the intrauterine environment, it seems logical that the first mechanism of action would be related to a limiting effect on the trophoblastic activity resulting in a decrease in the exchange surface of the placenta.

On the other hand, if maternal support to fetal growth is unlimited, fetal growth rate would be linear not only until week 38, but also until the time of delivery. Gruenwald[103] considered that from week 38 onwards there is a physiological placental insufficiency due to a lack of maternal support, which limits fetal growth potential. This has been definitely confirmed by the postnatal increase in growth rate once the newborn is free from intrauterine restriction, thus achieving again the growth rate present before 38 weeks' gestation. Gruenwald[103] observed that in countries with the highest neonatal birth weights, such as Sweden, there was a delay in the flattening of the fetal growth curve (with respect to the potential fetal growth curve) as compared with communities with a worse degree of nourishment.

On the other hand, as commented on in the description of factors affecting fetal growth, the ability of the uterus to retain the fetus until maturity, and the ability to nourish the fetus properly (adequate uteroplacental blood flow, etc.) vary according to

multiple factors, such as parity, maternal weight, maternal height, fetal gender, etc.

In respect of the 'external environment', the mother herself seems to act as a buffer protecting the fetus from an adverse environment. Until recently, it was considered that only substantial changes in the diet,[104] percentage of oxygen[72] or socioeconomic factors would be able to induce minor modifications of birth weight. Recent studies,[105] however, have suggested that fetal availability of macronutrients (particularly carbohydrates and amino acids), mainly during the last weeks of pregnancy, plays an important role on fetal weight at birth. An inadequate maternal nutrition during pregnancy has been associated with small fetuses.[106] In animal studies, a decrease in oxygen supply also induced fetal growth retardation.[107]

117 Dynamics of fetal growth

J. M. Carrera, F. Figueras, B. Serra and M. Carrera

Introduction

Fetal growth has been evaluated by obstetricians by observing maternal abdomen enlargement, and for many years measurement of the uterine height was practically the only method to estimate intrauterine growth. Although, after the introduction of antenatal ultrasound imaging many studies were reexamined, the only reliable method to measure the product was to do so after delivery. Neonatal anthropometry was developed under these circumstances in an attempt to measure systematically multiple variables related to gestational age of the neonate (after a pregnancy considered normal), and growth tables in relation to weight, height, head circumference, volume of different organs, etc. were developed.

Ultrasound examination has allowed the assessment of not only fetal growth as a whole but also the individual growth of all visible structures. At present, virtually all parts of the fetus have been measured cross-sectionally and longitudinally from its initial vestiges until birth, so that normal ranges of practically all fetal structures throughout the gestational period have been established. Fetal growth is a dynamic process, the evaluation of which requires at least a comparison of two measurements taken at different intervals to obtain more reliable information on how fetal growth develops.

Dynamics of fetal growth

Fetal growth has been studied by means of biochemical methods and anthropometric methods.

Biochemical methods

Biochemical studies carried out in experimental animals and in necropsy specimens from human fetuses have focused on cellular biochemical aspects, and assessment of changes in fetal biochemical composition and in the chemical composition of some individual organs.

Cellular biochemical studies

Biochemical methods for measuring the number and volume of cells were introduced by Winick.[1] Since DNA is almost exclusively limited to the nucleus, and the DNA content of a diploid nucleus in a given species is constant, the total DNA content of an organ reflects exactly the number of diploid nuclei; therefore, dividing the total DNA of an organ by the fixed DNA content of the diploid nucleus results in the actual number of cells. Similarly, weight, proteins, or RNA content of a cell can be determined by dividing total weight, total proteins, or total RNA content of an organ by the number of cells. These values, however, are not valid for organs with a high number of non-diploid nuclei (e.g. liver, testis), or multinucleated cells (e.g. pancreas). Although the time-course of fetal and placental cellular growth in pregnancy has been studied with this method, in practice, weight/DNA and protein/DNA ratios are used to estimate cell volume, and the RNA/DNA ratio is used to assess the mean RNA content of each cell.

According to data reported by Winick,[1] three growth stages are identified: a first stage consisting of proportional increases in weight, proteins, and DNA content (hyperplasia) (DNA increase occurs both in the fetus and in the different organs); a second stage, characterized by a slower increase in DNA content as compared with proteins and weight; and a third stage, in which there is an increase in neat proteins and weight, but not in DNA content (hypertrophy). This different behavior is related to a decrease in the rate of DNA synthesis.

During the first half and a large part of the second half of gestation, growth is based on cell hyperplasia, whereas by the end of pregnancy, hyperplasia is combined with hypertrophy. Therefore, malnutrition during the stage of hyperplasia causes inhibition of the cell division index, resulting in irreversible size reduction and a decrease in the number of cells of an organ. Malnutrition during the stage of cell hypertrophy causes growth deceleration, with recovery taking place once the adverse factor has been corrected, resulting in an organ of normal volume. This pattern of cellular growth is valid for organs in which regeneration is not possible. The time at which the process of cell division is interrupted, however, varies in different organs.

Changes in fetal biochemical composition

In terms of relative fetal body composition, fetal growth means constant adjustment of proportions.

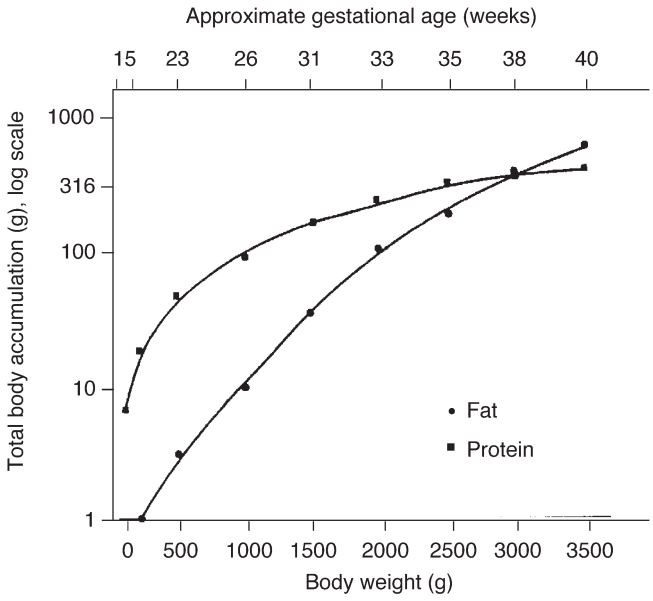

Figure 117.1 Protein and fat accumulation curve (data from Southgate and Hey[5]).

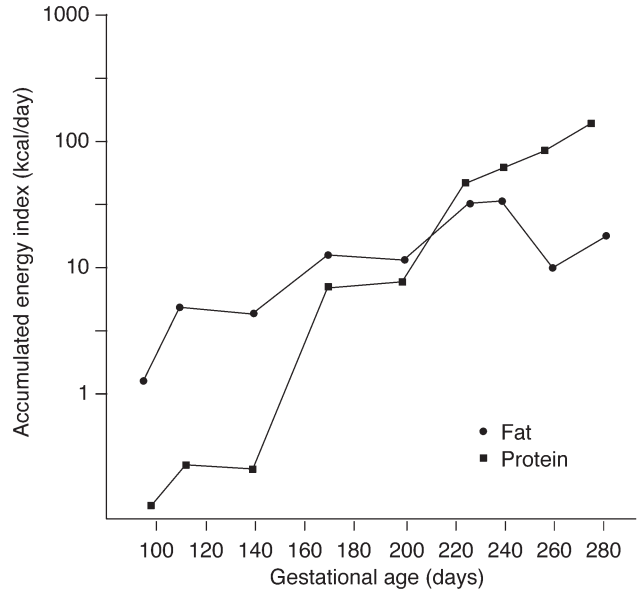

Figure 117.2 Energy stored in fetal proteins and fat (graph constructed according to calculations from Widdowson[3] and data from Southgate and Hey[5]).

Water content is about 94% in an embryo at 10 weeks and 70–80% in a full-term fetus. The percentages of extra- and intracellular water change from 65% and 15–20% during the first weeks of pregnancy to 40% and 38%, respectively, at the end of gestation, due to a progressive increase in the cellular mass by storage of substances (especially proteins) and water. High levels of hyaluronic acid, acting as a gelatinous matrix, probably play an important role in preserving the structure of fetal tissues.

The curve of protein accumulation shows a rapid increase until 26 weeks' gestation (fetal weight 1 kg), followed by slow weekly decreases and steady values starting from 35 weeks' gestation (Figure 117.1).

The rate of fat synthesis early in pregnancy is very low and probably limited to synthesis of structural lipids of cellular membranes and other structures. During the second half of gestation, fat synthesis and storage rates increase exponentially[2] and from 38 weeks' of gestation fat levels are higher than those of proteins.

Figure 117.2 shows energy rates stored in fetal proteins and fat according to the calculations of Widdowson.[3] Maximal protein-derived energy rates are found between days 220 and 260 of pregnancy (about 30 kcal/day). Storage of fat-derived energy is very low until day 140 of pregnancy (< 6 kcal/day). However, starting from day 200 and coinciding with an increase in fat synthesis, there is a marked increase in energy as strong as (100 kcal/day). Therefore, requirements of metabolizable energy are almost totally fulfilled at the end of pregnancy. This fact is very important since fetal weight decreases in cases of intrauterine growth restriction are mainly related to fat loss.[4] Fetal lipid composition remains unchanged from 6 to 32 weeks' of gestation, given that lipid metabolism is perfectly developed early in pregnancy. In relation to fat distribution, Southgate and Hey[5] reported increases in body fat of 10–80 g between day 200 and birth, whereas subcutaneous fat showed an exponential increase, from 20 to 350 g during the same period. Subcutaneous fat wasting characterizes fetal growth restriction.

Changes in chemical composition in fetal organs

Liver. Southgate and Hey[5] described that from day 100 of pregnancy, the curve of fetal liver weight is similar to that of total body weight. Fetal liver composition (Table 117.1) also remained unchanged from the second trimester.[4,5] Widdowson and colleagues[6] studied liver cell growth by measuring DNA and protein content, and found a rapid increase in DNA from week 15 to the end of gestation, while the protein/DNA ratio showed no variations between weeks 15 and 25. This suggests that in the early stages, liver growth occurs by an increase in the number of cells rather than by an increase in the volume of these.

Heart. Functional development of the heart is completed by day 31. Cardiac development is initially very fast, but from day 100 of pregnancy, the heart weight curve is similar to that of total fetal body weight. The chemical composition of this organ remains stable during the last two trimesters of pregnancy (Table 117.2). Widdowson and Dickerson[7] reported an increase in sodium concentration and a decrease in potassium concentration from week 20 to the end of gestation, apparently related to interstitial fluid loss of the cardiac muscle.

Table 117.1 Fetal liver composition (from day 100 to full term),[5] for fetuses with normal and small weights for gestational age

Kidney. The kidney grows and develops rapidly during the fetal period (the fetal kidney becomes functional from the ninth week). Kidney weight is variable during the first trimester of pregnancy, but from day 100 of pregnancy its growth curve is similar to that of total fetal body weight (Table 117.3). Nitrogen concentration in renal tissue increases throughout pregnancy.[7] It should be noted that small-for-dates babies have a higher renal fat content than appropriate-for-gestational age newborns.

Anthropometric methods

Neonatal anthropometry

The distinction between the constitutionally small and the growth-restricted infant is being increasingly accepted, the former being considered the low extreme of the distribution of normal neonates weight, which is not considered a pathologic condition by itself. Thus, birth weight alone has been observed to be poorly correlated with perinatal outcome.[8] On the contrary, abnormalities of neonatal constitution are believed to reflect impaired fetal nutrition and have been found to be more useful indicators of adverse perinatal and long-term outcomes.[9] The skin-fold thickness at different sites, the mid-arm circumference to occipitofrontal circumference ratio, and the ponderal index (weight (g)/height (cm)^3) have been suggested as useful parameters to identify growth-restricted fetuses.

Fetal anthropometry

Theoretically, fetal anthropometric studies can be carried out in the framework of different designs, which can be categorized in cross-sectional (each fetus is measured once) and longitudinally (measurements are made in the same fetus at different gestational age).[10,11] Since growth is a dynamic process, it seems biologically plausible that its quantification requires the evaluation of serial measurements. Nevertheless, longitudinal studies are more likely to result in biased estimates (e.g. high-risk fetuses and/or pregnancies are more likely to be intensively scanned). On the other hand, the high correlation between measurements on the same fetus means that the effective sample size

will be nearer to the number of fetuses than to the total number of measurements. In addition, longitudinal designs require more complex statistical models than cross-sectional studies. Among the methods described to construct longitudinal curves, the most straightforward ones, as pairwise means, do not account for the regression toward the mean phenomena, which is essential to analyze growth 'velocities'. More complex methods, as multilevel models, appear to be the most appropriate methodology to derive conditional centiles, which take into account the fetus' size earlier in gestation. Software applications (packages ML-3 and ML-n) for these methods have been developed in recent years.[12–14] Although, there are preliminary clinical data suggesting that conditional centiles better predict infants with low ponderal index than unconditional centiles,[15] further studies are needed before the introduction of these reference ranges in clinical practice.

Other design drawbacks could hamper the validity of fetal anthropometric standards. Among them, inappropriate selection of cases, unclear inclusion and exclusion criteria, small sample size and unreliable gestational ages are considerably frequent.[10,11]

Fetal weight. All authors agree that fetal weight is the most sensitive indicator of fetal nutrition and growth, since fetal weight is the earliest parameter to be affected by adverse intrauterine circumstances. For this reason, however, and because of the high variability in birth weight among different population groups,[16–18] it is difficult to obtain a pattern of fetal growth exclusively based on fetal weight, particularly because there is a linear relationship between weight at birth and duration of gestation. On the other hand, the construction of tables or curves of normal fetal weight at different weeks of gestation faces several difficulties. These include the fact that data obtained in longitudinal studies are not reliable (a fetus or a neonate may be weighed only once, and previous weight variations are unknown), weights of fetuses born prematurely cannot be included in the range of normality, and comparison of different tables and curves is further complicated by the lack of uniformity in the entry of data.

In 1963, Lubchenco and coworkers[19] presented weight curves in the form of percentiles as estimated from the birth weights of 5635 liveborn Caucasian infants at 24–42 weeks of gestation. One year later, Gruenwald[20,21] estimated intrauterine growth in the form of standard deviations (Figures 117.3 and 117.4). Many other curves representing intrauterine growth have been reported thereafter. These curves, however, cannot be superimposed due to sample-inherent limitations, such as differences in socioeconomic conditions, altitude, racial features, etc. For example, fetal weight curves constructed for singleton fetuses in Spain, France, Italy, Czechoslovakia, and other countries showed fetal weights higher than the median weights of Colorado babies in the study of Lubchenco and coworkers[19] (Denver is 1584 m above sea level) which, in turn, were lower than those given by Swedish authors.[22,23] Fetal weight curves used by the authors of this chapter[24] are depicted in the form of percentiles (Figure 117.5) and standard deviations (Figure 117.6).

Most fetal weight curves can be divided into four areas of different fetal growth rates (Figure 117.7), i.e. low rate (up to 16 weeks' gestation, mean weight gain $\leq$10 g/week); accelerated rate (between 16 and 26–27 weeks' gestation, 85 g/week); maximal rate (between 28 and 38 weeks' gestation, 200 g/week); and decelerated rate (around 37–38 weeks' gestation, 70 g/week). Beyond 42 weeks' gestation, fetal weight shows no variation or negligible increases. A remarkable fact is that 10% of the weight at term is exclusively reached during the first half of pregnancy, and it is only after the first two trimesters of pregnancy that the fetus acquires one-third of its weight at birth. During the first half of pregnancy, however, organogenesis and progressive development and refinement of fetal structures are taking place. The most crucial period of fetal life starts at about 28 weeks of gestation, coinciding with the maximal slope of fetal weight gain (mean 200 g/week).

Fetal weight curves are somewhat different when constructed according to sex or multiple pregnancies. Values obtained in females are lower than in males, with differences of up to 300 g in some sections. In multiple pregnancies, McKeown and Record[25,26] reported that maternoplacental supply can ensure normal growth of fetuses until achievement of a determined overall weight, so that earliness of weight deficit is inversely related to the number of fetuses.

Differences in fetal weight curves. Fetal weight curves derived from data reported by different authors may be substantially different. After an extensive review of the literature, Gruenwald[27] proposed a classification of fetal weight curves into four groups (Figure 117.8). Group 1 included data on intrauterine growth as estimated from weights of dead fetuses.[28,29] These estimations were clearly beneath weight curves of the remaining groups for most weeks of gestation, given that they were based on postmortem examination of abnormal fetuses. Group 2 consisted of fetal weight curves made with corrected data of liveborn neonates. In these cases, dead fetuses, inaccurate menstrual data, liveborn neonates with anomalies, etc. have been excluded.[19,27,30] Most published fetal weight curves based on adequately corrected material are included in this group. Group 3 was formed by fetal weight curves somewhat above group 2, since, in general, uncorrected[27] or partially corrected data[28,29] were used. Group 4 included fetal weight curves based on uncorrected material or representing populations with particular racial or social characteristics[33–35] (Kaltreider, personal communication).

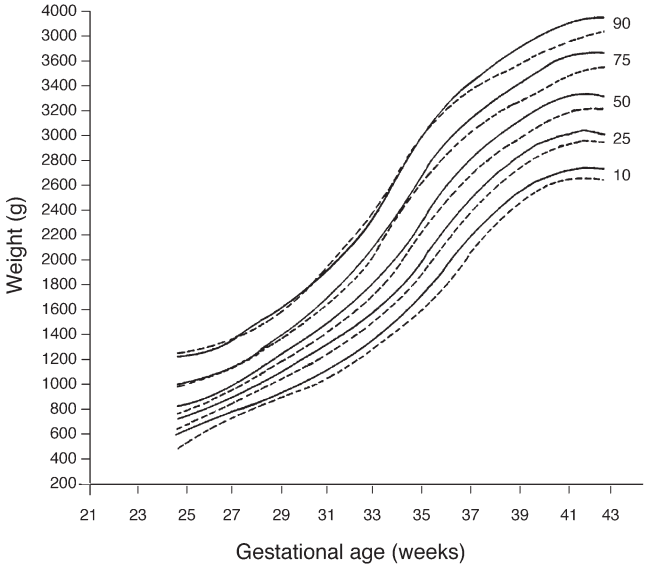

Figure 117.3 Fetal weight curves (percentiles) for males (solid lines) and females (dotted lines) (data from Clavero Salvador *et al.*[16]).

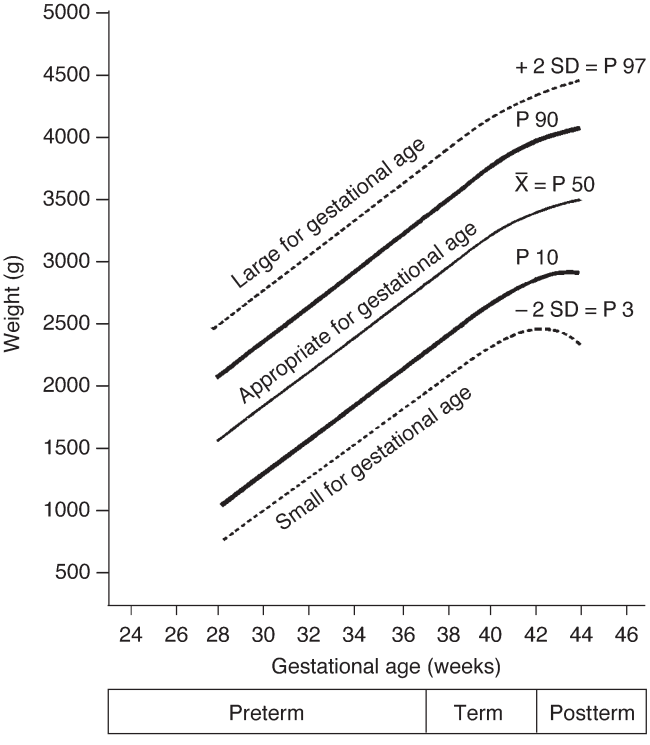

Figure 117.4 Relationship between fetal growth curves in percentiles (from Clavero Salvador *et al.*[16]), and curves constructed with standard deviations (from Alonso and Arizcun[17] and Meredith[18]).

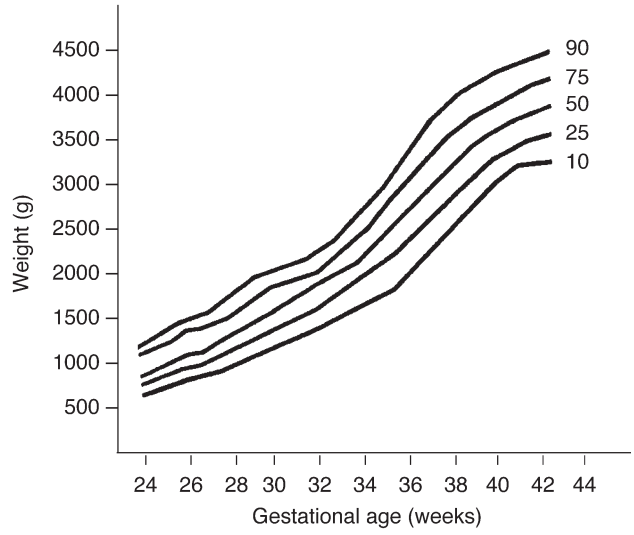

Figure 117.5 Overall fetal growth curve in percentiles.[21]

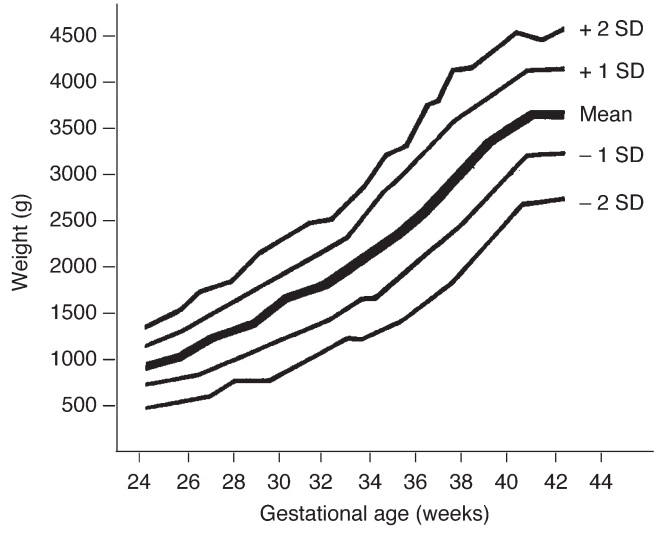

Figure 117.6 Overall fetal growth curve with standard deviations.[21]

As noted by Gruenwald,[27] all types of fetal weight curves except those based on deadborn neonates, coincide at 38 weeks of gestation because at this time the likelihood of an error in gestational age is very rare. Before this time, outstanding differences found in some cases may be attributed to information bias or inadequate correction. From 38 weeks' gestation to birth, fetal weight curves diverge again due to changes in the supply line (maternal and placental) among different population groups on which curves are based.[27] In fact, although all types of fetal weight curves stabilize at 41 weeks' gestation, heights are different according to the socioeconomic conditions of the sample. Thus, a difference of more than 500 g is found between the curve of Kaltreider, based on data from the indigent black population in Baltimore, USA (personal communication), and that of Lindell,[23] based on Swedish neonates (a tall population with high living standards). The fact that the estimations of Lubchenco and colleagues[19] were lower than those given by other authors may be attributed to the altitude of Denver.

Human fetal weight would presumably follow a straight line after term if there were no limitations to provision of nutrients, that is, if maternal and placental supply provide endless support to fetal growth.[20,21]

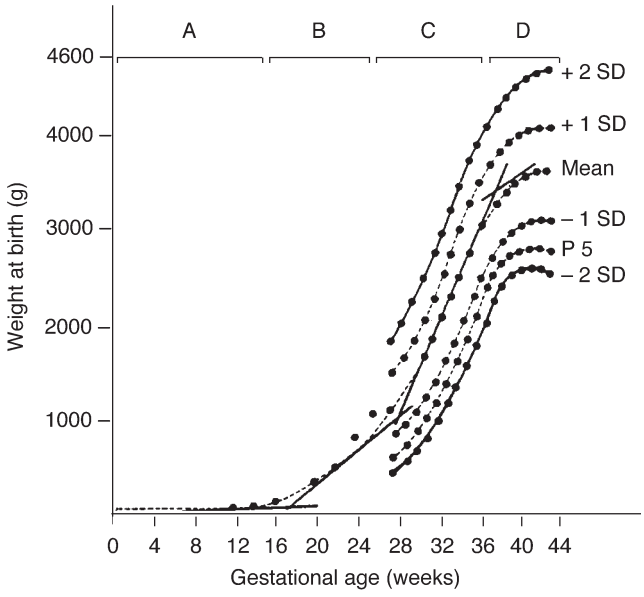

Figure 117.7 Fetal weight curve (with standard deviations) divided into four areas of low (A), accelerated (B), maximal (C), and decelerated (D) fetal growth rates.

Therefore, deviations from the ideal extrapolated curve are less evident as nutritional supply decreases.

Customized birth weight standards. Due to the fact that several maternal (height, weight, race, age, parity, etc.) and fetal (number, gender, etc.) variables play a significant role in fetal growth both in low-[36] and high-risk[37] pregnancies, population-based birth weight standards result in misclassification of a large proportion of cases.[38] Individually adjusted or customized growth charts aim to optimize the assessment of fetal growth by taking individual variation into account, and by projecting an optimal curve, which delineates the potential weight gain in each pregnancy. Customized birth weight standards increase the possibility of identification of fetuses at risk of stillbirth, neonatal death, and low Apgar score, probably due to improved identification of growth restriction.[39] Moreover, customized curves are better correlated with neonatal morphometry than population-based standards.[40] The evidence of their usefulness as well as the fact that customized charts could be used in clinical setting in a very flexible way, make customized birth weight references the current standard for evaluation of fetal growth.

Fetal height. As in the case of fetal weight, fetal height curves show a moderately sigmoid shape with an ascending trend as gestational age increases. Fetal

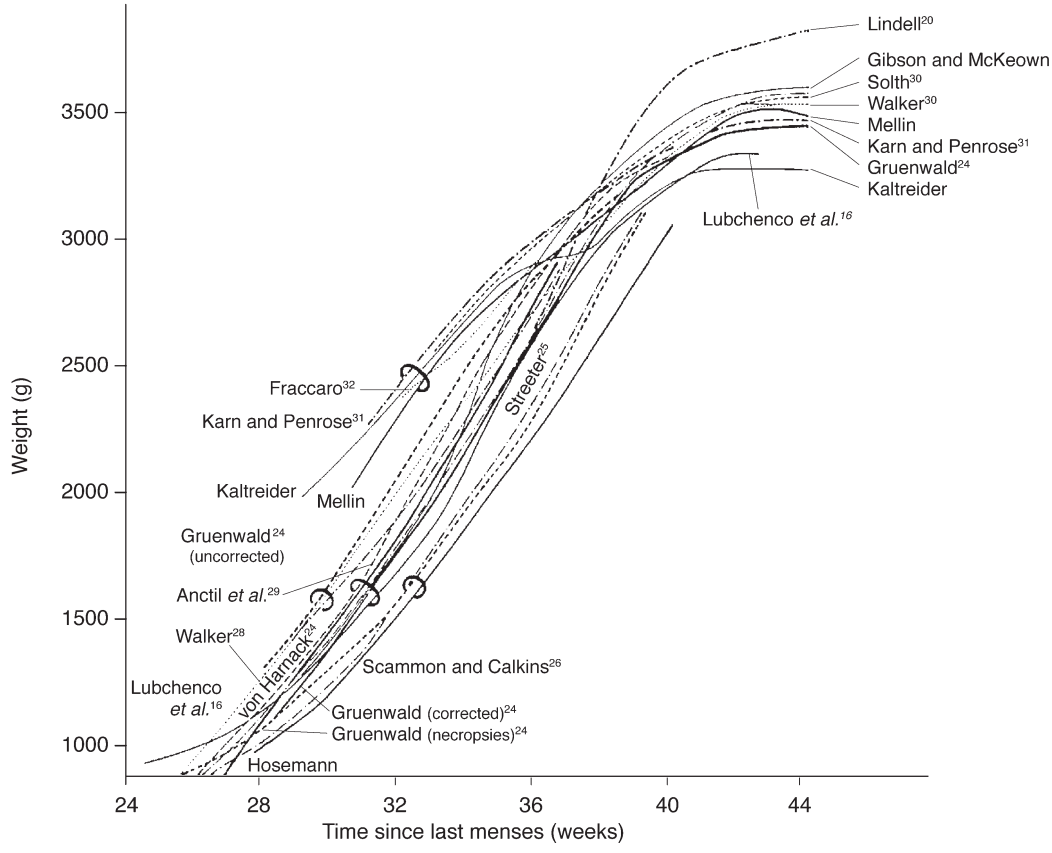

Figure 117.8 Fetal growth curves classified into four groups by Gruenwald.[24]

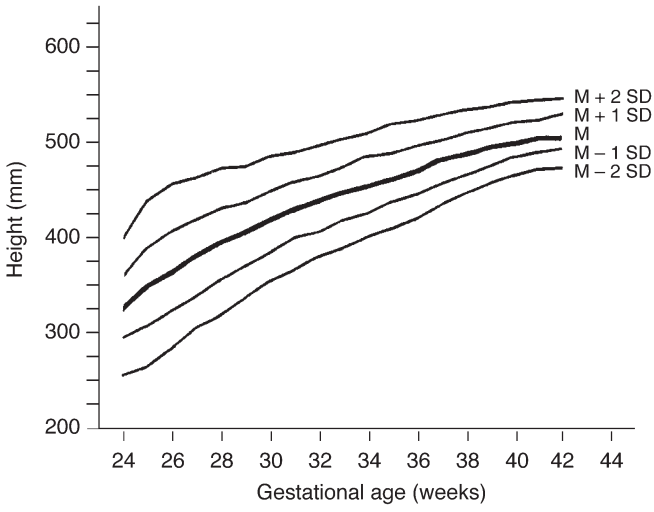

Figure 117.9 Overall fetal height curve with standard deviations.[21]

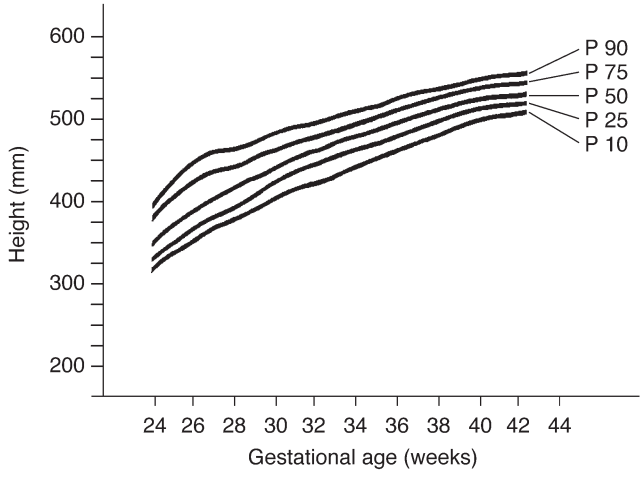

Figure 117.10 Overall fetal height curve in percentiles.

height curves from our institution (Figures 117.9 and 117.10) were based on a depurated sample of 8876 liveborn neonates at 22–42 weeks of gestation.

After fetal weight, fetal height is the second parameter that is rapidly affected by fetal macro- and microenvironmental conditions. While fetal heights recorded in Sweden[22] and in some areas of the USA[41] were taller than in Spain, our figures are, in turn, higher than those reported by others.[19,42] Fetal height has rarely been used in the past for assessing fetal growth. The anthropometric value of this parameter in association with fetal weight and head circumference to identify some fetal growth patterns has been recently established.[27,41]

Head circumference. Given that fetal brain weight is the parameter least affected by an adverse intrauterine environment (malnutrition), the importance of this measurement is considerable. Although head

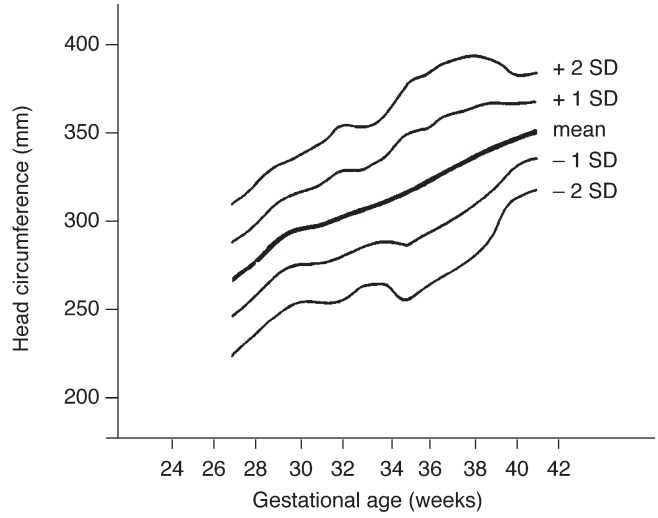

Figure 117.11 Fetal head circumference curve with standard deviations.

circumference is not a highly reliable index of fetal growth and nutritional conditions, it is a sensitive indicator of gestational age, which may be useful for comparison with the remaining parameters. Therefore, as may be expected, head-circumference curves do show large variations throughout the gestational period. The curve is almost linear with a more accentuated slope than the fetal-height curve (Figure 117.11). Interestingly, Ferrazzi *et al.*[43] found that normalization of the umbilical vein flow provided the most sensitive parameter for growth-restricted fetuses, suggesting that due to the brain-sparing effect, head circumference is preserved in placental insufficiency. Differences in the individual curves by sex were smaller than those observed in fetal height curves, and values of the fetal head circumference in twins are lower than the overall fetal growth curve. Comparatively, our values for fetal head circumference are higher than those reported by Lubchenco and colleagues,[19] but lower than those presented by Miller and Hassanein[41] and Usher and McLean.[44]

Three-dimensional fetal growth assessment. The advent of three-dimensional sonography has allowed a new insight into fetal growth. Calculation of organ volumes could be made reliably and in a non-invasive way using this new technology. Brain volume has been found[45] to increase from 34 ml at 18 weeks to 316 ml at 34 weeks of gestation. At the same time, brain growth demonstrates a marked slow down as expressed by a weekly increment in brain volume at 34 weeks of only one-third of the weekly increment at 19 weeks of gestation. Fetal liver is very important in determining the status of fetal growth. In uncomplicated pregnancies, mean fetal hepatic volume was 9.7 ml ± 4.4 at 20 weeks and 96.4 ml ± 8.2 at 36 weeks of gestation.[46–48] Interestingly, the fetal brain/liver volume

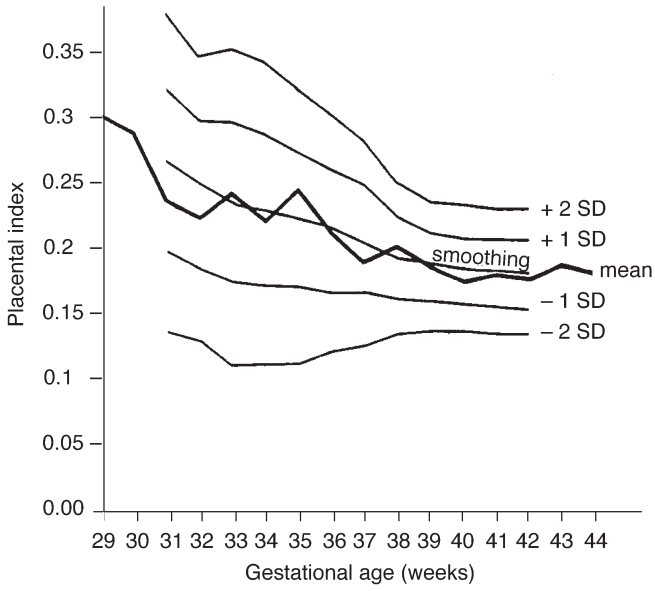

Figure 117.12 Placental index curve (fetoplacental relationship) throughout gestation (from Gruenwald[21]).

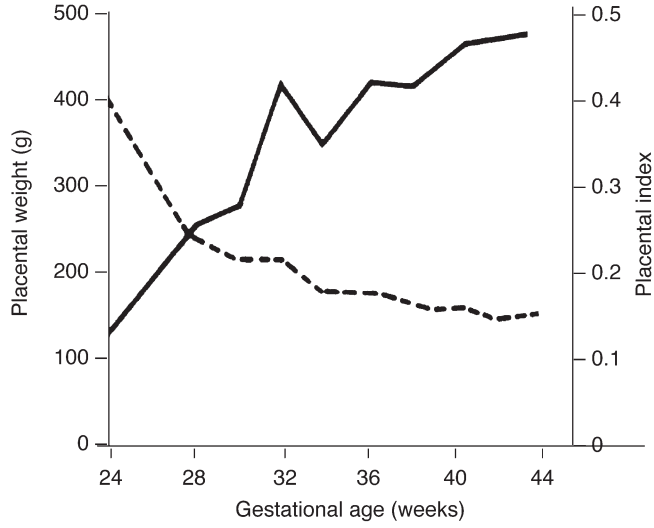

Figure 117.13 Relationship between placental index and fetal growth throughout gestation.

ratio has been described as a predictor of fetal outcome in the growth-restricted fetus. An inverse relationship exists in small-for-gestational-age fetuses between brain/liver volume ratio and fetal weight-related umbilical venous blood flow. Fetal lung volume ranged from 1.18 ml at 18 weeks to 56.26 ml at 37 weeks for the left lung, and from 1.69 ml at 17 weeks to 60.2 ml at 39 weeks for the right lung.[49–50] Fetal kidneys volume has been observed to increase linearly through the second and third trimester, ranging from 1.5 ml at 20 to 16.3 ml at 40 weeks for the right kidney, and from 1.8 ml at 20 to 17 ml at 40 weeks for the left one.[51]

Relationship between fetal anthropometry and placental biometry

The interest elicited by placental weight and its relationship with fetal weight is fully justified by the crucial role played by this organ in fetal growth and nutrition. For this reason, it is surprising that this question has been poorly addressed in studies on fetal growth published in the literature.

Analysis of placental weight at different gestational ages shows different periods similar to the evolution of fetal weight. Until 16 weeks' of gestation, placental weight is greater than fetal weight because of a more rapid growth of the placenta early in pregnancy. Placental and fetal weights are similar by 16–28 weeks' gestation. At week 27, however, the placenta has already achieved 50% of its weight at term (because of its rapid initial weight gain), whereas the fetus has only gained 30% of the weight at birth. During the period of maximal fetal growth (28–38 weeks' of gestation), placental growth rate is much lower than fetal growth rate (in relative terms placental growth is restricted with respect to fetal growth). From 38 weeks' of gestation, placental growth rate shows an accentuated deceleration as compared to fetal weight gain, which is even more apparent from week 40. Curves of the relationship between fetal and placental weights expressed as percentages of normal fetal weight at birth are particularly illustrative of this finding.

The inter-relationship between fetal and placental weights can be studied by the so-called 'fetoplacental relationship' (fetal weight/placental weight ratio), the 'placentofetal relationship' (placental weight/fetal weight ratio), also named the placental index, which is the most usual method (Figures 117.12 and 117.13). The fetoplacental relationship increases as pregnancy advances, whereas the placental index decreases. At 24 weeks' of gestation, the value of the fetoplacental relationship is 3; at week 35 it varies between 4 and 5; at term it varies between 5 and 6; and from 40 weeks' of gestation, there is no change. The placental volume is the parameter that correlates better with fetal weight.[16] In contrast, there is a poor correlation with the number of cotyledons, suggesting that by the fourth month structural development of the placenta has been completed, so that potential adverse factors acting later on in pregnancy have no effect on the number of cotyledons.

118 Intrauterine growth restriction: concept and epidemiology

E. Fabre, R. González de Agüero, J. L. de Agustín and A. Ezquerra

Concepts related to growth restriction

It is clear that there exists an optimal range of size at birth, within which complications are rare. The incidence of morbidity and mortality increases when there is a deviation from this optimal range. In order to specify this clinical impression we need a standard reference with which to be able to define terms like 'too small', as well as to relate to dependent variables such as mortality and morbidity rates. Considering intrauterine growth, it is important to recognize several remarkable concepts and definitions.

Growth and maturity

In any consideration about development, one may arbitrarily distinguish maturation, meaning change of structure and function, from growth in the sense of increase in mass, while realizing that the two of them are not entirely independent of each other. Growth is measured in terms of change in weight and size in relation to age. Maturation determines the functional capabilities of the organism and its parts, and thus controls such aspects as the ability of a neonate to adjust itself to extrauterine life; it is largely independent of the effects of deprivation.

Low birth weight

The term low birth weight (LBW) describes infants with a weight of less than 2500 g, regardless of gestational age[1]. To avoid confusion, the word preterm is used for infants born under 37 weeks' gestation, regardless of the birth weight. Further subdivisions of LBW have been commonly used: very low birth weight (VLBW) and extremely low birth weight (ELBW) describe infants with weights less than 1500 and 1000 g, respectively (Figure 118.1). From this point of view, LBW at first glance seems to be a simple concept: any baby below a certain threshold of weight is an LBW baby. But what is threshold? And should it be the same for babies of all types and from all populations? Are there different kinds of LBW babies?

Populations vary considerably in the size of their babies at birth. The median birth weight among infants born in India is lower than in Ireland, while the median gestational age at birth is very similar, and the percentage of LBW infants is higher in India than in Ireland (Table 118.1). The differences in the birth weight could reflect either the diversity of the human biology or the social differences among the studied populations. The election of a universal threshold below which LBW is defined will mistakenly define the Indian population of newborns as having a high incidence of a pathological condition. For a really valid comparison we therefore need a specific reference standard for the individual population under study.

A method has been suggested to adjust the differences in mean birth weight among different populations. It is based on the observation that many distributions tend to be approximately 'normal' in shape in their central portion. The effect of a shift in the mean birth weight in different populations can then be eliminated by using the percentage of births below the estimate (mean −2 SD). The result is an 'adjusted' rate for (relative) LBW occurrence, which is applicable regardless of the mean birth weight for the population (Table 118.2).[2] This procedure yields a much greater degree of uniformity for the 'adjusted' LBW percentages as compared to the unadjusted percentages. This simple technique is only applicable if the birth-weight distribution is known to be Gaussian.

Mathematically oriented studies[3] have argued that the roughly normal birth-weight curve in any population is really a mixture of two distributions, one of the normal population and the other of a pathological group of babies (referred to as the 'residual' distribution) in whom small size is a reflection of some unhealthy maternal or fetal condition. The comparison between Japanese babies and African-American

Table 118.1 Comparison of birth weight and gestational age at delivery in different countries (based on data from Rooth[2])

Country	Infants weighing ≤2500g at birth (%)	Median birth weight (g)	Median gestational age at birth (weeks)
Ireland	5.9	3478	40.5
Poland	6.8	3380	40.1
Venezuela	7.9	3206	39.7
Greece	9.5	3287	39.8
Taiwan	11.3	3106	40.0
Japan	11.3	3029	40.2
Iran	14.2	3024	39.4
Philippines	14.2	2889	39.6
Malaysia	17.3	3057	40.2
India	29.0	2771	40.6

Table 118.2 Low-birth-weight percentages before and after adjustment for differences in mean birth weight (based on data from Rooth[2])

Country	Mean birth weight (g)	Mean –2 SD (g)	Low birth weight (%)	
			Unadjusted	Adjusted
Austria	3150	2200	5.7	5.5
Cuba	2900	1850	10.8	3.5
Hungary	2900	1900	10.8	5.6
Japan	2950	2150	5.3	3.3
New Zealand	3150	2200	5.2	4.0
Sweden	3205	2250	3.9	3.8
USA (six states)	3100	2100	6.0	3.5

babies illustrates this fact.[4] The mean birth weight in Japanese babies is about the same as that for American blacks, at about 3200 g. But these two populations differ markedly in the proportion of births in the residual distribution, 1.3% in Osaka and 4.3% in American black babies, who are small for presumably pathological reasons. This difference, because it is composed of infants at very high risk of death, explains why mortality is so much higher among African-American infants than among Japanese infants, even though both populations have relatively equal mean birth weights. The important point to note is that it is the pathological conditions that lead to an excess of small babies in the residual distribution that should stimulate public health action, not that part of the variation in birth weight which appears to be irrelevant to human health.

The use of a single cutoff point for birth weight when applied to a range of gestational ages will automatically result in heterogenous data. Children born with low birth weight include both the ones born preterm as well as those born at term gestation but subnormal in weight. For this reason a classification frequently used in epidemiological surveys is to take all LBW babies and to divide them arbitrarily into preterm-LBW (< 37 weeks) and term-LBW (37 weeks or

more); fetuses with retarded growth would fall into the second group and preterm babies into the first. This classification does not differentiate the fetus with delay of growth and born before 37 weeks' gestation, which is identified as born preterm; therefore it ignores a substantial number of growth-retarded fetuses.

Preterm delivery and fetal growth appear to have distinct determinants, and one of the most important and little-appreciated observations about the state of our knowledge in this area is that, while we have considerable understanding of the causes of impaired fetal growth, we know next to nothing about the causes of preterm delivery. For term-LBW infants, most underlying causes (e.g. maternal smoking, weight at conception and gestational weight gain) have been identified, for preterm-LBW infants, the etiology largely remains unexplained.[5] Both concepts differ in another important way. Preterm delivery is much more important as a cause of infant mortality in developed nations. Fetal growth impairment, though not rare, does not cause the same rate of mortality as does early delivery. The long-term impact of fetal growth restriction on neurodevelopment, though more important than its effect on the newborn, is also not as pronounced as the effect of preterm birth.

For public policy purposes, a single cutoff value for low birth weight in all populations must therefore be treated with a certain amount of skepticism. It is a crude indicator, useful for making a quick and rough assessment, but one that needs more refinement if public policy initiatives are to be appropriately targeted. However, this approach has several advantages, considering that it is easy to use and offers a practical means to compare incidences worldwide and among populations of different ethnic origin and socioeconomic status, taking into account their own restrictions.

Small-for-gestational age fetuses

Intrauterine growth of the human fetus can be charted by plotting birth weight, or other birth dimensions, against the gestational age. Starting from fetal growth curves, distributions of birth weight at each gestational age, intrauterine growth anomalies have been quantitatively defined, in terms of absolute values of weight for gestational age, or standard deviations from a mean, or percentile ranking. A deficit of birth weight in relation to gestational age is evidence of fetal growth restriction. The LBW concept underestimates the magnitude of the problem since it does not include those infants whose weight at birth falls below the cutoff of weight for gestational age but who weigh more than 2500 g; these infants also have intrauterine growth restriction (IUGR).

Neonates can be categorized as appropriate (in weight) for gestational age (AGA), small for gestational age (SGA) or large for gestational age (LGA). In general, the term SGA refers to those infants below the 10th percentile of birth weight relative to a specific gestational age in representative distributions[6] (Figure 118.1). However, there is no general agreement as to what constitutes an SGA fetus. Some studies have used the third or fifth percentiles,[7,8] whereas others have used 2SD below the mean birth weight[9,10] as the cutoff point. Birth-weight distributions are affected by factors other than intrauterine nutrition, including maternal height, weight, race, parity, ethnic background and sex of the newborn. It is obvious that the use of different birth-weight percentiles, or correction of the standard for the mentioned factors have a major effect on the birth weights that define SGA fetuses. Even when the same statistical criteria are used, the limits often vary among different populations,[11–14] and hence are not always comparable (Table 118.3). For this reason infants of certain weights will be diagnosed as being small for gestational age in some studies but not others. In consequence, many of the SGA-related risk factor and infant outcome studies are not comparable, which often leads to conflicting results.[15] Although at present it remains universally accepted as the best and most standardized method for examining fetal growth and its restriction, we should look closely at its limitations.

SGA is not synonymous with fetal malnutrition; one may occur without the other. Fetal malnutrition is a clinical diagnosis and is independent of birth weight at a given gestational age, and may be present at almost any birth weight. An infant who is classified as SGA may or may not have malnutrition. Fetal malnutrition is characterized by obvious intrauterine weight loss or failure to acquire normal amounts of subcutaneous fat and muscle.[16] Weight, length and head circumference may or may not be affected. In fetal malnutrition, the subcutaneous tissue and underlying muscle are diminished and the skin of arms, legs, elbows, knees and interscapular regions is very loose. Perinatal problems and/or central nervous system sequelae occur primarily in malnourished babies, whether AGA or SGA, but not those who were simply SGA and not malnourished.

The clinical manifestations of fetal malnutrition depend, in part, on when it began during gestation. Babies whose length, head circumference and weight are significantly reduced were probably exposed to malnutrition beginning early in the second trimester. Those whose length and head circumference are less affected but are small and underweight with some loss of subcutaneous tissues and muscle probably became malnourished early in the third trimester. For babies who are significantly underweight for gestational age with obvious loss of subcutaneous tissues, but with length and head circumference within the normal range, an insufficient or unbalanced nutrient supply most likely occurred in the late third trimester. For the last two categories, weight may be above the 10th percentile for gestational age; however, signs of malnutrition may be obvious.

Intrauterine growth restriction

The phrase IUGR describes the fetus who has failed to reach its own theoretical normal growth potential.[17]

Table 118.3 Differences between definitions of small-for-gestational age neonates based on a birth weight below the 10th percentile for gestational age

Gestational age (weeks)	Birth weight (g)				
	Lubchenco *et al.*[6]	Babson *et al.*[11]	Brenner *et al.*[12]	Naeye and Dixon[13]	Williams *et al.*[14]
28	860	695	770	967	727
32	1290	1351	1310	1534	1301

40	2630	2880	2750	2776	2848
42	2720	3039	2830	2778	2965

Currently, most investigators accept the SGA infant as a marker for IUGR and, in everyday usage, the term IUGR is often used synonymously with SGA, although there is little doubt that the two are not identical. The National Institute of Child Health and Human Development in the USA[18] recommends that, both for clinical and research purposes, IUGR birth should be defined as resulting in birth weight less than the 10th percentile for gestational age, using criteria appropriate to the populations under study. However, IUGR is used to denote a pathophysiological process resulting in restriction of fetal growth, while SGA refers to a statistical grouping of infants below the 10th percentile. From a practical standpoint, there may be considerable overlap of these groups, although at a conceptual level the distinction may be important.[19] Statistically, 10% of infants should fall below the 10th percentile regardless of medical intervention and this group may reflect both biological diversity as well as restriction of growth. Small infants may be constitutionally small, small secondary due to infections, toxic or congenital growth limitations, or small due to deprivation or placental insufficiency.[20] The biological variation of birth weight implies that not all SGA infants are growth-retarded and that some infants classified as AGA can be growth-retarded. A fetus that has stopped growing but is delivered before the weight crosses the 10th percentile should still be considered an infant subjected to a growth-restricting process even if the birth weight is appropriate for gestational age.

LBW and SGA are pediatric terms that refer only to the anthropometry of the newborn and mainly to birth weight. These concepts have a notable disadvantage: they are limited to the recognition at birth of an event that has already occurred, while the most important time for identification of whether or not there is growth restriction is during the antenatal period. Currently, only ultrasound is capable of providing data sufficiently accurate for assessing the fetal growth rate. IUGR may be indicated by insufficient growth rates of several fetal measures that are easily observed *in utero* regardless of birth weight. The growth restriction describes a dynamic event in which the fetus deviates progressively from a normal growth line, and hence diagnosis of true IUGR requires at least two measurements of size.[21] A single measurement will not be able to differentiate between size and growth. The observation of a fetus with small dimensions at a determined date does not confirm that there has been a change in the rhythm of growth. Although ultrasound allows the longitudinal study of fetal growth, it has not been utilized by epidemiologists to study IUGR. On the contrary, the concept and definition of SGA are still utilized in order to evaluate the utility of the ultrasonic measures. This is a paradoxical situation in which the value of a technique that studies the longitudinal growth of the fetus is mistakenly judged by a unique observation and measurement at birth.

In fetuses with IUGR, two different patterns of growth can be demonstrated by using ultrasound.[22] In the first case, growth decreases from early in pregnancy, with a sustained low rate; these infants are usually small, presenting a reduction of all of their external measures. This symmetry has important prognostic implications as it relates to whatever primary process is limiting fetal growth and the potential functional damage that may follow. Symmetric IUGR is seen with extrinsic conditions (intrauterine infections and exposure to drugs) that are active early in a pregnancy, or alternatively with intrinsic embryonic conditions (genetic causes and congenital anomalies) that act to diminish the growth potential of an affected fetus. Symmetric IUGR may be considered to represent a wide variety of conditions with a large range of prognoses. In most cases, the small size of the newborn is constitutional and not associated with abnormality. However, in many others the risk of perinatal asphyxia, serious permanent disability or nonsurvival accompanies the subnormal growth. In the second case, growth may be normal until early in the third trimester but then flattens. The infant is small, with the head circumference and length being relatively normal in size for gestational age, but with a reduced abdominal circumference, weight/length ratio and ponderal index. Head growth assessed sonographically by biparietal diameter or head circumference often remains normal throughout the pregnancy

or only drops below the normal growth curve later. Trunk growth, conversely, as indicated by abdominal circumference, decreases earlier. The overall pattern of fetal growth in these cases is typically normal until late in the second or early in the third trimester, when the limit of the uteroplacental capacity to sustain a normal fetal growth rate is reached. Asymmetrical IUGR is mainly a result of uteroplacental insufficiency secondary to extrinsic factors like hypertension, diabetes mellitus, etc. The asymmetry is perhaps the result of predictable adaptation of the fetus to sequential deprivation, and fetal asphyxia is often the terminal event. The long-term prognosis for the infant with asymmetric IUGR is usually better than that for the infant with non-constitutional symmetric IUGR.

In summary, IUGR is defined as a pathological decrease of the fetal growth rhythm. The result is a fetus that does not reach its growth potential and has a high risk of perinatal complications. The diagnosis is difficult considering that it is not always easy to define accurately the fetal growth rhythm. In spite of this inconvenience, the definition of IUGR should be based on fetal growth and not on the birth weight or other birth dimensions. The condition of IUGR is not homogenous and similar presentations may have different etiologies and implications. IUGR does not define a homogenous population that necessarily shares a common fate, nor does it mean that those infants of similar birth weight share a common prognosis.

Epidemiology

The use of many different standards in order to define the anomalies of fetal growth is leading to statistical anarchy. Since the LBW concept was accepted as an international definition, one might think that a standard reference percentile should serve equally well as the basis of an international definition of SGA babies, thereby enabling direct comparisons to be made of data from different sources. But we seem to be a long way from any such agreement, and a locally produced standard is usually thought to be more appropriate than any general standard. Most studies on perinatal epidemiology are based on classification by birth weight because this measurement is generally readily available. Likewise, risk factors and perinatal mortality are chiefly reported in terms of birth weight. In only a few reports are populations defined in terms of birth weight and gestational age.

Epidemiological factors

Epidemiologic investigations have revealed that in developed countries, the predominant risk factors in order of importance are: (1) cigarette smoking (2) low maternal weight gain and (3) low prepregnancy weight. These three risk factors account for nearly two-thirds of growth-retarded infants.[23] Other risk factors for LBW include black race, first births, female sex, short maternal stature, maternal low birth weight, prior LBW birth, maternal illnesses, fetal infections and a variety of metabolic and genetic disorders.

Age and parity

It has become axiomatic that the age of the mother is a determinant factor that determines her reproductive efficiency. Rates of LBW are significantly higher among young mothers.[24] At the other end of the spectrum, older women are beginning to show the effects of the aging process. Consequently, the pattern of LBW related to age is a U-shaped curve, with incidence elevated below 20 and over 35 years of age. However, it is not clear if the risk of teenage childbearing is due to young maternal age or to the low socioeconomic status that often accompanies teenage pregnancy.

Socioeconomic status

LBW is closely related to socioeconomic disadvantage. Socioeconomic status is usually determined by income, occupation and education. Low educational attainment is associated with higher rates of LBW. Women with a lower education level are 50% more likely to have VLBW babies and more than twice as likely to have moderately LBW babies (between 1500 and 2500 g) than women who have graduated from college.[25] It appears unlikely that income and education by themselves account for the differences in birth weight. Rather, it is the social and physical environment that these factors represent that is exerting an effect.

Race and ethnic background

In the United States, the prevalence of LBW varies according to the ethnic background. African–American infants (13.5%) are twice as likely to be born LBW than whites (5.8%), Hispanic origin (6.2%) or Asian–American infants (6.5%).[26] Epidemiological research has shown that these ethnic group differences are not wholly explained by ethnic differences in the occurrence of various medical illness, in smoking or use of other drugs, or in the use of prenatal care, or by demographic characteristics and other lifestyle differences. This provides some evidence that poverty may not be the sole reason for the high rates of LBW births among African–Americans. While it is valuable to know what does not cause the racial group differences in LBW, more emphasis needs to be placed on studying the basic biological differences between the racial groups, which may be responsible for these disparities.

Maternal weight gain and prepregnancy weight

Maternal weight gain during pregnancy results from a variety of factors, including maternal dietary intake, prepregnancy weight and height, length of gestation and the size of the fetus. Epidemiological evidence has demonstrated a nearly linear association between maternal weight gain during pregnancy and birth weight, and an inverse relationship to the rate of LBW.[27] A meta-analysis of nine studies found that weight gain during pregnancy has a significant effect on birth weight when prepregnancy weight is low.[23] Investigators who have examined the effect of a given gestational weight gain in

women with different prepregnancy weight for height status have been virtually unanimous in concluding that the two factors strongly interact. A clear tendency exists toward increasing rates of IUGR with decreasing prepregnancy weight for height among women with low gestational weight gain. The effect of gestational weight gain on fetal growth is weak, or perhaps even absent, in obese women.[28] The evidence for other effect modifiers is not nearly as strong as that for prepregnancy weight for height.

Lifestyle choices

The bulk of evidence shows a clear and consistent association between LBW (primarily due to IUGR and not preterm birth) and smoking during pregnancy. Cigarette smoking is unequivocally the largest and most important known modifiable risk factor for LBW. It accounts for up to 20% of all LBW births.[25] The result holds among women of different ages, gravidities, geographic regions, social classes and ethnic groups. It has been consistently reported that, even after controlling for other factors, women who smoke are about twice as likely to deliver an LBW baby as are women who do not smoke.[29,30] Other behaviors, such as the abuse of alcohol and other drugs, while important, do not have nearly the same impact on overall rates of LBW births as cigarette smoking. The effects of alcohol intake during pregnancy upon birth weight have also been widely studied. A prospective study of 900 pregnant women adjusted for social class and smoking demonstrated that drinking more than 100 g of alcohol per week (10 standard measures) is associated with a risk of IUGR twice as high as for those drinking less than 50 g per week. The effects of alcohol and smoking are synergistic, although it is probable that smoking is a greater risk factor for IUGR than is drinking.[31]

Prenatal care

It is unclear whether or not the observed decreased rates of LBW among women who receive prenatal care are due to its effectiveness in preventing LBW or to other differences between women who receive prenatal care and those who do not. Women who receive prenatal care are a heterogenous group, but are generally healthier, more educated, and more advantaged than women who do not receive prenatal care. Rather than preventing LBW, prenatal care may be another indication of the many health-enhancing behaviors that characterize healthy, insured women who have healthy children. Although prenatal care provides a variety of valuable medical services to pregnant women and their fetuses (for example, management of normal birth, maternal hypertension and maternal diabetes, and/or detection of congenital malformations and genetic diseases in the fetus), evidence suggests that prenatal care may not provide significant benefits with respect to LBW.

Previous LBW infants

Several studies have shown that a maternal history of previous preterm or LBW infants increases the risk of giving birth to a subsequent preterm or LBW infant. LBW is known to repeat itself in 25% of cases where no maternal high-risk factor exists,[32] although many of them are born of a low-risk pregnancy and might be constitutionally small. Bakketeig and colleagues[33] showed that birth weight and not length of gestation is the best predictor of birth weight in subsequent pregnancies, just as length of gestation is the better predictor for subsequent gestational length. Mothers whose first-born infants were LBW have a two- to three-times higher risk of having an LBW second infant than the total population of secundiparae; the tendency to repeat births of lower weight is not markedly affected by a tendency to repeat medical complications that predispose to LBW.

Assisted reproductive technology (ART)

In the last few years, the number of births after the use of ART has increased steadily around the world, especially in developed countries. However, ART has been associated with an increased number of adverse perinatal outcomes, multiple pregnancies, preterm birth, low birth weight (LBW), very low birth weight (VLBW) and perinatal death.[34] Some studies suggest that the high incidence of multiple births after the use of ART is responsible for the majority of adverse perinatal outcomes, such as preterm delivery and LBW. Schieve found that ART singletons were 2.6 times more likely to be term-LBW compared with the general population.[35] Wang found that the observed number of preterm births and LBW was 2.4 and 2.1 times higher respectively than the expected number when applying general population birth rates. The comparison between ART singletons and general population singletons suggests that ART infants have a higher risk for preterm birth and LBW. This increased risk persists even when comparing ART singletons conceived with the transfer of only one embryo with singletons in the general population.[36]

Incidence and mortality

The incidence of LBW by region ranges from 31.1% in Middle South Asia and 19.7% for Asia as a whole to 14.0% in Africa, 10.1% in Latin America, 6.8% in North America and 6.5% in Europe.[37] The LBW rate is lower in many Western European nations, while in underdeveloped countries the LBW rates are often over 10% and the incidence of LBW is four times higher than that of developed countries. The LBW rate in Europe varies from 4.1% in Finland to 9.5% in Romania (Table 118.4).[38]

The general opinion is that the incidence of LBW in developed countries is diminishing. However, researchers using time series data have observed that the LBW rate has increased in the past few years. In European Union (EU) the incidence of LBW has increased from 5.97% in 1982 to 6.87% in 2002 (Table 118.5).[38] The Spanish Perinatal Mortality Survey of the Perinatal Medicine Section of the Spanish Obstetrical and Gynecological Society recorded data

Table 118.4 Incidence of low-birth-weight (LWB) and perinatal mortality rates in European countries in 2003 (based on data from WHO Regional Office for Europe)

from 597,585 births, with known birth weight and gestational age, at hospitals in different Spanish regions from 1980 to 1992.[39] During the period surveyed the total incidence of LBW increased from 4.8% in 1980 to 7.1% in 1992 (Table 118.6).

The contribution of LBW to perinatal deaths is very important. In the Spanish Perinatal Mortality Survey, LBW represents 66.4% of fetal deaths, 69.6% of early neonatal deaths, and 67.7% of overall perinatal deaths. The high percentage of perinatal deaths generated from a relatively low number of LBW infants

(*)Finland and Romania have been selected because they are the countries in which the incidence of LBW is the highest and the lowest in Europe respectively.

should call attention to the importance of this problem. Table 118.6 shows mortality rates during the perinatal period in LBW births. In the overall period surveyed, the fetal mortality rate was 31 times higher in LBW fetuses than in those born weighing $\geq$2500 g (87.0 vs. 2.8/1000 births), the early neonatal mortality rate was 40 times higher (64.8 vs. 1.6/1000 live births) and the perinatal mortality rate was 33 times higher (146.1 vs. 4.4/1000 births) (Table 118.6).

Medical scientists have focused on two major strategies to find ways to reduce the number of perinatal deaths: improving the survival of infants, and preventing births in groups of lower weight that have a higher risk of death. In European Union (EU), during the last two decades, the overall perinatal mortality rates have declined substantially (14.86 in 1980 vs. 6.42/1000 births in 2004), while rates of LBW have increased (from 5.97% in 1982 to 6.92% in 2003).[38] How can these very highly correlated outcomes, perinatal mortality and LBW rates, have shown such different tendencies? The seemingly contradictory decline in perinatal mortality without parallel declines in LBW birth is attributed to the increasing survival of LBW infants (Table 118.7). From an epidemiologist's point of view, in a given population, the overall perinatal mortality rate depends as much on the birth-weight distribution as on the birth-weight-specific mortality rates. In European Union, the recent decrease in perinatal mortality can be attributed solely to specific mortality improvements for each birth-weight group, since the incidence of LBW has increased. This mortality pattern indicates that our response to LBW has been effective at the level of treatment but not at the level of prevention. Every year many LBW infants are now added to the population who would not previously have survived. Although the vast majority of these infants are healthy, some of them have such severe handicaps as to make their impact on the population prevalence of cerebral palsy noticeable.

An examination of the epidemiology of LBW children must therefore include consideration of whether the children were born preterm or at term gestation.

Table 118.6 Trends in the incidence of low birth weight, fetal mortality, early neonatal mortality and perinatal mortality from 1980 to 1992 (mortality rates per 1000)

Spanish Perinatal Mortality Survey of the Perinatal Medicine Section of the Spanish Obstetrical and Gynecological Society

In developed countries, the major contributor to LBW is preterm birth, while in underdeveloped countries it is IUGR.[40] In the Spanish Perinatal Mortality Survey, when the analysis is carried out differentiating the preterm LBW births from the term LBW births, it is observed that the preterm LBW rate has increased by 37%, from 3.0% in 1980 to 4.1% in 1992, and the term LBW rate has also increased by 53%, from 1.9 to 2.9% (Table 118.7). Compared to term LBW infants, preterm LBW infants are four to five times more likely to die

within the perinatal period. The perinatal mortality rate in preterm LBW infants in the overall period was 220.1/1000 births, compared to 46.3/1000 births in term LBW infants (Table 118.7). In the United States the incidence of increase in LBW from 1981 to 1991 (6.6 vs. 7.1%) resulted from the increase in preterm LBW infants (3.8 vs. 4.4%), while the term LBW rate decreased from 2.9 to 2.7% in the same period.[39] In the United States, the increased incidence of preterm LBW infants during 1981–1991 partly reflects changes in the distribution of selected maternal and infant characteristics. In particular, the percentage of births to unmarried women and women receiving no prenatal care may be markers of psychosocial and environmental risk factors for preterm deliveries.

There is evidence that the growth restriction process is associated with significant consequences to the infant. The likelihood of stillbirth or death during the first week of life is several times higher in SGA than in AGA babies, considering the corresponding gestational age (Figure 118.2). It is obvious that babies weighing less than about 1000 g are very likely to die, regardless of gestational age. The group with birth weight 1000–2000 g also has a rather high perinatal mortality rate, especially at early gestations. At all gestational ages, mortality falls steeply when birth weight increases up to about 4000 g, while the influence of gestational age at any given weight is comparatively much smaller.

119 Etiology and pathogenesis of intrauterine growth restriction

J. M. Carrera, B. Serra and J. Mallafré

Introduction

Agents or factors supposedly associated with intrauterine growth restriction (IUGR) can be divided into intrinsic (endogenous) and extrinsic (exogenous) factors. The subject, however, is further complicated because these factors can be studied with regard to the fetus and/or the placenta, and because there are doubts about how some of these mechanisms should be classified. Therefore, we prefer to consider maternal, fetal and placental factors, although their endogenous or exogenous condition will be mentioned when describing the pathogenesis of IUGR.

Maternal factors

General and constitutional factors

Age

Evidence seems to confirm that at maternal age between 21 and 29 years, conditions for the development of normal newborns are the best, with the lowest rates of abortion, prematurity, perinatal mortality and growth restriction. At these ages, metabolic, homeostatic, nutritional, and psychological mechanisms reach a prime. Butler and Alberman[1] have shown that for equal parities, there is a significant effect of maternal age on fetal weight, i.e., the rate of growth restriction increases before and after this decade. In our experience, the incidence of infants with a birth weight < 1500 g related to both, prematurity and IUGR, in women under the age of 20 years is twofold higher than in women aged between 25 and 30 years. On the other hand, there is a higher rate of congenital defects in mothers under 15 years, especially of those (anencephalia) that are sometimes associated with IUGR. Older women experience a larger number of metabolic and vascular disorders (hypertension, diabetes mellitus) that favor poor implantation and uteroplacental insufficiency. The greater relative risk of fetal chromosomal abnormalities, frequently associated with IUGR, in women over 35 years of age is well known.

Maternal height

Some authors[2] consider that for each centimeter by which maternal height exceeds normal values, fetal weight at birth is increased by 16 g, while others[3,4] affirm that when the weight factor is corrected, maternal height has little effect on the weight of the fetus. In the opinion of Fabre and colleagues,[5] shorter women, usually with a lower weight before pregnancy, have more low birth weight infants. Other investigators, such as Abdul-Karim and Beydoum[6] found that the influence of paternal height on fetal weight is more closely correlated than maternal height. It has been argued that infants born of short-stature fathers have a mean decrease of 183 g in birth weight as compared with those born of high-stature fathers.[7] Lechtig *et al.*[8,9] and Junis *et al.*[10] observed a statistically significant association between short maternal height and the incidence of fetuses with low weight at birth (Figure 119.1). A positive association between paternal adult height and fetal growth has been described after controlling for confounding factors.[11]

Maternal weight at birth

Ounsted and Ounsted[12] have shown a statistically significant relationship between neonatal birth weight and maternal birth weight, and have suggested a potent hereditary influence on fetal variables. Many mothers of infants with IUGR have been small-for-dates themselves.[13–15] Moreover, it has been reported that women who were themselves low birth weight infants as a result of IUGR are more likely to deliver an IUGR fetus than those mothers who were low birth weight secondary to prematurity.

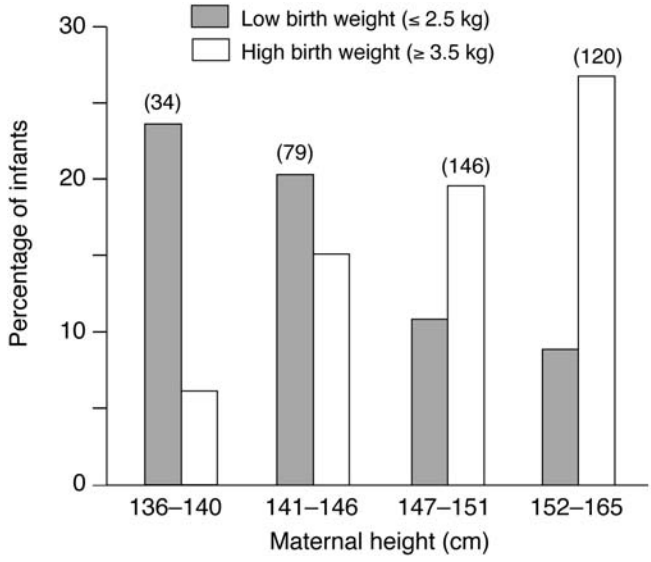

Figure 119.1 Relationship between short maternal height and percentage of infants with low birth weight.[8]

Table 119.1 Relationship between pre-pregnancy weight and neonatal weight in Caucasian and Black women[11]

Maternal pre-pregnancy weight (kg)	*n*		Mean neonatal birth weight (g)	
	Caucasians	Blacks	Caucasians	Blacks
<45	1293	122	3066	3057
45–53	8851	618	3215	3132
54–62	9733	806	3332	3176
63–70	3198	369	3419	3262
71–80	854	144	3431	3282
≥80	406	72	3444	3410
Total	24335		2133	

Maternal weight prior to pregnancy

Simpson and associates[16] have shown a clear association between maternal and fetal weight. Fetal growth restriction is particularly associated with mothers weighing less than 54 kg (Table 119.1). Fabre and colleagues[5] found a positive correlation between maternal body mass index and neonatal birth weight. According to the statistical analysis in this study, maternal weight prior to pregnancy would account for 11.02% of differences in birth weight. Similar results have been documented in other reports.[17–21]

Maternal weight gain during pregnancy

Low maternal weight gain in pregnancy,[22,23] in particular prior to 12 weeks' gestation,[24] may be considered an index of possible fetal malnutrition. Weight gains < 3 kg until 20 weeks' gestation or an increase < 1 kg/month in the second half of pregnancy[5] should alert to the risk of IUGR.

Maternal heart volume

Lehmann and coworkers[18] demonstrated a clear association between neonatal birth weight and maternal heart volume, with heart volumes < 600 ml in mothers of newborns with birth weights < 3000 g (Table 119.2). In cases of IUGR, Duvekot and colleagues[25] reported poor cardiovascular adaptation at the beginning of pregnancy with hypovolemia and reduced maternal heart volume.

Race

It is very difficult to find strictly comparable studies of different ethnic groups matched for social and economic status, as well as to isolate the effects of genetic factors from those related to unfavorable nutritional, socioeconomic and environmental conditions.[26] As stated by Gruenwald,[27] the actual influence of ethnic factors on fetal weight will remain unknown until diverse ethnic groups have been living under comparable conditions for a period of time, perhaps two generations. However, there is extensive information which provides evidence of ethnic differences. Thus, Indian infants are constantly smaller in different circumstances: in India as compared with general registries, in South Africa as compared with other ethnic groups, in Malaysia as compared with Chinese, and in Kenya as compared with Caucasians and Blacks. Even taking into account socioeconomic and environmental differences, it seems that there are differences in birth weight between Caucasian and Black neonates, which can be attributed in half of the cases to purely racial influences.[28] At 40 weeks' gestation, weights of White fetuses are 156 g greater on average than those of Blacks, even when the weight factor is corrected for economic level and parity (Figure 119.2).[29] Jans[30] offers a clear example of the role played by ethnic factors, finding that Bambuti pygmy babies from the Itu tropical forest have a very low mean birth weight (2635 g) with an extremely low weight variation as compared with that usually found in Caucasians. But other sudies[31] have not found statistically significant differences between White and Aboriginal population in Australia. They concluded that there is no reason to use separate fetal growth curves when examining Aboriginal fetuses.

Genetic and familial factors

Epidemiological studies have demonstrated a possible role of genetic and familial factors in determining birth weight.[32,33] Klebanov[34] found that delivery of small for gestational age infants and preterm delivery were significantly more common among women who were themselves small for gestational age and who were delivered preterm, respectively. In addition,

Table 119.2 Relationship between maternal heart volume, maternal height and weight, placental weight, and weight and height of neonates[2]

Fetal age or weight at birth	Maternal weight at birth (kg)	Maternal height (cm)	Placental weight (g)	Neonatal weight (g)	Neonatal height (cm)	Maternal heart volume (ml)	*n*
3400–3600 g	62.3	163	560	3552	50	647	15
≥4000 g	74.7	165	737	4270	53	671	25
40–41 weeks	60.6	163	475	2746	47	568	29
38–39 weeks	60.6	161	480	2632	46	597	17
36–37 weeks	61.7	162	442	2497	46	597	18

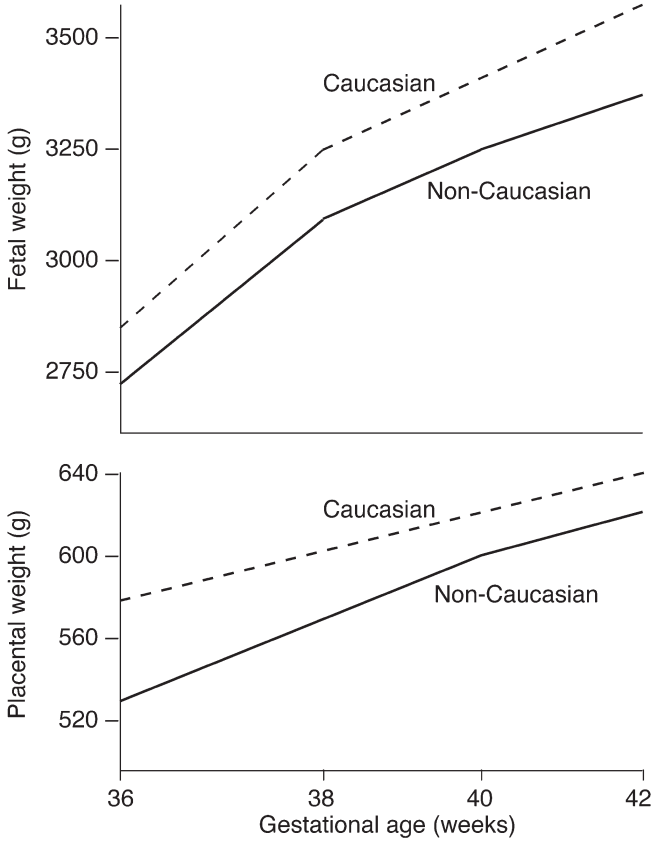

Figure 119.2 Relationship between racial group and fetal and placental weights.[29]

several studies have found that infants are more likely to have low birth weight if their mother's sisters had delivered small for gestational age infants.[35] Bakketeig[32] found that mothers whose fetus was small for gestational age are two to three times more likely to produce a small for gestational age second infant compared to the total population of mothers who had delivered their first and second infants without IUGR. These observations support the importance of genetic or environmental factors in the genesis of an infant of low birth weight. Although it is difficult to exclude familial aggregation of certain specific environmental factors such as dietary habits with any certainty, it is unlikely that in developed countries these factors have a large impact on birth weight.

Ghezzi[36] assessed the familial pattern of the IUGR condition through a detailed pedigree analysis of a selected population of women with more than one affected child, and he identified a subset of families in which the IUGR condition demonstrated vertical transmission, suggesting an autosomal pattern of inheritance. Some fetuses from different families showed an abnormal chromosome constitution and severe IUGR, indicating that more than one genetic cause may contribute to the low birth weight.

Chromosome abnormalities have been cited by several investigators as the possible genetic cause of IUGR. Moreover, placental chromosome mosaicism, favoring an abnormal segregation of imprinted regions in the fetus, has been widely described in IUGR fetuses. Ghezzi[36] postulated two further conditions where an inherited genetic cause can be identified: first, a dominant or recessive inheritance of gene mutations may disturb the correct fetal growth; second, a parental carrier of balanced chromosome abnormalities may confer a risk not only for unbalanced malformed fetuses, but also for IUGR conditions due to the anomalous segregation of the imprinted regions.

Several authors believe that the identification of the inheritance pattern of IUGR has an important clinical value because a knowledge of the family history and of the parental karyotypes may be helpful in preventing both fetal malformations and adverse neonatal morbidity in subsequent low birth weight infants.

Socioeconomic conditions

Unfavorable socioeconomic conditions markedly increase the incidence of fetuses with low weight at birth in relation to the following factors: diet, family and social environment, education and intellectual level, type of work, teenage pregnancies and marital status, among others. Women of low socioeconomic class are prone to a larger extent than their counterparts to early, frequent and numerous pregnancies, which continue to a more advanced maternal age. It

Table 119.3 Maternal education level and rate of intrauterine growth restriction (IUGR)

Maternal education	IUGR group	Control group	Total
University degree	10	19	29
Secondary education	12	61	73
Primary education	78	20	98
Total	100	100	200

has been largely recognized that fetal and neonatal risks increase significantly at the limits of age and parity, as well as in cases of repeated gestations at short intervals.[8,9,37,38]

Role of sense of control

There is limited earlier literature on the role of sense of control and pregnancy outcomes, especially IUGR. Several authors have looked at how sense of control might affect health outcomes. Taylor and Seeman[39] concluded that sense of control might act as a mediator of the effects of socioeconomic status on health, while other authors think that sense of control may have an impact on how one copes with stress, perhaps modulating how stress affects health outcomes. Literature also suggest that other measures of control may have an impact on access to health care services, health behaviors and participation on screening activities.[40–43] Durousseau[44] found no statistically significant association between IUGR and maternal pregnancy intendedness, initial happiness about becoming pregnant, and maternal sense of control.

Deficient maternal schooling

Deficient maternal schooling is associated with illiteracy and ignorance, with unawareness of the physiology of reproduction and the possibilities of contraception, and as a result, high natality rates, poor hygiene, and scarce or absent medical control of pregnancies are found among these social groups (Table 119.3).[45]

Marital status

In the study by Norska,[46] the percentage of single mothers was 1.2% in the control group vs. 6.9% in the group with IUGR.

Psychosocial factors

Few studies have examined the association between psychosocial factors and the risk of IUGR, probably due to the difficulty to separate the impact of these factors (pregnancy intendedness, initial happiness about becoming pregnant, stress, etc.) from that of other sociodemographic variables. Several limitations should be considered when assessing the results of these studies.[47–50]

Inappropriate physical work

Inappropriate or excessive physical work can exert an unfavorable effect on fetal nutrition, particularly when found in association with other factors related to a precarious economic condition. Some types of work can cause poor intrauterine fetal growth, such as those which implicate heavy physical work; jobs requiring long periods of time spent in forced or uncomfortable positions which, in addition, impair renal or uterine circulation; jobs with chemical products or accompanied by mechanical vibrations; stressful working places, causing risk of nerve-induced uterine contractions; work in the open air under unfavorable meteorological conditions, or work in poorly ventilated and highly contaminated closed spaces; or work in places far from home that require travel of several kilometers each day. In these cases, a decrease in neonatal weight may be expected.[51,52]

Maternal malnutrition

On a worldwide scale, maternal malnutrition is the most frequent cause of IUGR. One should distinguish, however, between transient nutritional deficits (of different causes, either forced or voluntary) and chronic undernutrition.

Transient malnutrition. There is evidence that when a normally well-nourished woman suffers from severe starvation for a period of time, gestation is not substantially affected. Studies carried out in The Netherlands[53,54] during wartime (1944–45), when for 27 weeks daily food intake was lower than 1000 kcal and 40 g of protein, a marked decrease in fetal weight (< 240 g) was not documented. Perinatal mortality did not increase either, and intellectual or somatic deficits did not occur in the long term. Placental abnormalities were not seen. Hammond[55] postulates that, in these cases, fetuses are able to compete with the mother for the use of nutrients due to their high metabolic rate.

Chronic malnutrition. In these cases, there is prepregnancy and pregnancy malnutrition. Gruenwald[56,57] compared the birth weight of Japanese neonates born in different decades: in a period of severe food deprivation (1945–46), birth weight was significantly lower than that of North American infants, whereas some years later (1963–64), when nutritional problems disappeared, differences between both populations were almost inappreciable (Figure 119.3). In a rural Guatemalan population, Lechtig[68] reported a higher incidence (40%) of low birth weight neonates, with a four-fold mortality rate during the first year of life among women who had been severely undernourished since childhood. After nutritional intervention, a progressive reduction in the incidence of low birth weight was observed. According to others,[59] establishment of a balanced diet during the last trimester of pregnancy could even compensate the effects of malnutrition in the first months of gestation on fetal weight.

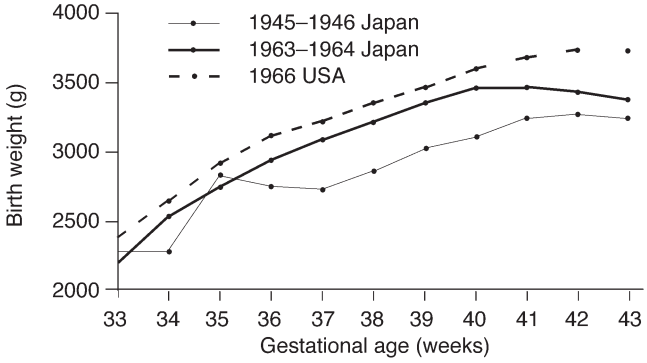

Figure 119.3 Fetal growth curves in Japanese neonates born in two different periods: 1945–46 (wartime) and 1963–64 (economic recovery), as compared with American neonates.[57]

Pathogenetic mechanisms involved in poor intrauterine fetal growth include: (a) a low nutrient supply to the placenta, which, in turn, causes a deficient turnover of amino acids and other substances in the major organs, such as the fetal liver[60]; and (b) placental abnormalities, with a marked decrease in placental weight and in the number of chorionic villi.[61,62] This indicates that the placenta is highly sensitive to the effects of malnutrition.[63]

Nutritional deficits. Long-standing unbalanced diets can be harmful for fetal growth.[64,65] Papiernik and associates[66] assessed the influence of maternal diet on fetal growth in a middle-class Parisian community. The mean caloric intake was 1689 ± 123 kcal in the study group and 1944 ± 155 kcal in the control group. In general, subjects included in the study group consumed less fat and significantly lower amounts of carbohydrates than controls. The study showed that IUGR in women with no apparent cause was associated with a lower caloric intake (300 kcal) than controls. Since protein consumption was similar in both groups, a decrease in the ingestion of carbohydrates was the presumed reason for fetal growth restriction. On the contrary, Bender and Nuñez[67] found that after adjusting for other known maternal risk factors, caloric intake did not present a direct effect on IUGR. Lechtig[9] found that protein supplementation had no effect on fetal weight, in contrast to carbohydrate supplementation, which had a positive effect on fetal weight gain. Abnormalities in blood composition caused by selective nutritional deficits (folic acid, magnesium, riboflavin and other vitamins, iron, etc.) should be included in this subgroup as well as, in a broad sense, some hypoxic states (high altitude) or disorders preventing adequate maternal nutrition. Riboflavin deficiencies in the last trimester of pregnancy cause a delay in the appearance of rapid isoenzymes of alkaline phosphatase, which, in turn, determines fetal hypotrophy. In these cases, placental alkaline phosphatase activity is dramatically reduced.

Micronutrients and fetal growth

Observational studies, recently reviewed by Ramakrishnan *et al.*[68] and Fall *et al.*[69] show for almost every vitamin and mineral, associations between poor maternal micronutrient status and IUGR or other adverse pregnancy outcomes, but most studies should be considered with caution because of methodology problems. Nevertheless, we will review available information regarding different micronutrients and its relation with fetal growth.

Fat-soluble vitamins. Trials among HIV-positive mothers in Tanzania[70] and South Africa[71] showed no effect of vitamin A alone on fetal growth. Regarding vitamin D, two studies of adequate quality have not found significant differences in fetal growth in newborns from mothers that received vitamin D supplementation during pregnancy. There is a trial of vitamin E supplementation in pregnancy focused on hypertensive disorders.[72] Women with a previous history of pre-eclampsia or with abnormal uterine artery Doppler waveforms were randomly assigned to receive vitamins C and E or placebo. The supplement was associated with a significant decrease in the incidence of pre-eclampsia and a lower number of small-for-gestational-age infants, but showed no effect on mean birth weight.

Water-soluble vitamins. Vitamin B-1 (thiamin), B-2 (riboflavin) and B-3 (niacin) are essential cofactors for energy metabolism, and therefore its deficiency might be expected to result in impaired fetal growth, but despite evidence that deficiency in pregnancy is common, there are only observational studies that focus this issue and with contradictory results.[73,74] Vitamin B-12 is derived mainly from animal sources and its deficiency is therefore more common in vegetarians, but there is no literature available regarding its relation with pregnancy. On the other hand there is a large body of literature on folic acid in pregnancy. A recent Cochrane review[75] concluded that despite a significant reduction in maternal anemia, there was only a small and non-significant effect on the incidence of low birth weight. Finally, several observational studies showed positive correlations between maternal vitamin C status and birth weight.[76,77]

Minerals. Iron. Several large studies in developed countries have shown a U-shaped relationship between maternal hemoglobin concentration and birth weight, with higher birth weights at both ends of the distribution.[78,79] This fact may be explained by maternal plasma volume expansion, which although producing anemia, probably acts as a compensatory mechanism to improve uteroplacental perfusion. Evidence from developing countries shows that maternal iron deficiency is associated with low birth weight and poor obstetric outcome,[78,79] but the previous Cochrane review[80] reveals that data from

these countries are not sufficient for drawing conclusions.

Zinc deficiency states are characterized by impaired growth, and although there are numerous observational studies, most of them have an inadequate size or methodological problems.[81] Although a large, well conducted study on 580 women with low serum zinc concentrations in a developed country showed a significant increase in birth weight, recent large trials of zinc in low-income women of developing countries showed no effects on birth weight.[82,83]

Iodine. Levels of iodine in soil and therefore in plant foods are highly variable, with several deficiency areas. A non-randomized trial in Algeria[84] showed a significantly higher birth weight in iodine-supplemented mothers.

Calcium. Most trials of calcium supplementation couldn't find any effect on birth weight,[85,86] although the Cochrane metaanalysis,[87] showed a significant effect on low birth weight, probably because of prolongation of gestation rather than enhanced fetal growth.

Magnesium. The Cochrane review[88] showed a beneficial effect on low birth weight.

Other trace elements. The role of copper, selenium, chromium, manganese and molybdenum in human pregnancy remains unknown.

Geographical and climatic factors

Although in poverty-stricken areas it is difficult to differentiate geographical factors from socioeconomic conditions, there is enough evidence of the influence of altitude and temperature on birth weight of neonates.

Altitude

Chronic maternal hypoxia caused by living at high altitudes may be a restrictive factor of placental and fetal growth,[89,90] although pregnancy increases maternal ventilation and raises arterial O_2 saturation, which helps to protect against altitude-associated IUGR. On equal terms of socioeconomic status, it seems that there are differences in the weight of babies born at sea-level and at high altitudes,[91] that Moore quantifies in 100 g fall per 1000 m elevation gain.[92] Adaptations in multigenerational high-altitude populations seem to permit higher uterine artery blood flows and protect against altitude-associated IUGR.

Climatic conditions

Although an inverse correlation between mean fetal weight and mean annual temperature has been reported, these data should be interpreted with caution since many other variables (race, socioeconomic status, etc.) are associated with the effect. Toverud[93] found that babies born in summer had a greater birth weight than babies born in winter, and he explained these differences by changes in maternal energy production and tissue regeneration stimulated by rest when the weather is cold. In contrast, Prasaad[94] reported that birth weights of Indian babies were systematically lower in summer and the rainy season than in winter.

Air pollution

The association between air pollution and adverse pregnancy outcomes, among them IUGR, has been studied in several countries,[95–97] but a recent review of 12 epidemiologic studies conducted by Maisonat concluded that current scientific knowledge on the impact of air pollution on fetal growth is still limited.[98]

Toxic habits

Smoking

Cigarette smoking has been unequivocally associated with low birth weight. The first report on the reduction of fetal weight by the effect of maternal smoking was published by Simpson and Linda,[99] and thereafter extensively documented by others.[1,100,101] Different studies[102,103] have demonstrated that after excluding other variables, the weight at birth is reduced by an average of 170–200 g in infants born to mothers who smoke more than 10 cigarettes a day. The distribution curves of birth weights according to weeks of gestation confirms a displacement to the right in the curve corresponding to smoking women (Figure 119.4).[104] This factor accounts for 5% of variations in weight at birth.[5]

There is no agreement regarding the mechanism by which cigarette smoking decreases fetal weight, but some of the following have been postulated[105–111]: (a) increased fetal levels of carboxyhemoglobin[105,106]; (b) left-shift of the hemoglobin dissociation curve; (c) nicotine-related uteroplacental vasoconstriction; (d) moderate anorexia and deficient maternal nutrition, preventing fetal compensation of the high rate of fetal carboxyhemoglobin by means of an increase of hematocrit; (e) reduced plasma volume; and (f) increase in requirements for vitamin B_{12} and some amino acids which are necessary for tobacco-supplied cyanide detoxification. Given the variety of factors involved, it is not possible to establish a common pathogenetic mechanism for the effects of maternal smoking. This is the reason for which, in some cases, fetal weight is the only parameter affected, while in others fetal height and head circumference are also reduced.[101,112]

Despite this information, a lot of controversy was aroused in the 1970s, with most authors[107,108] in favor of the causative role played by cigarette smoking, and others[109] believing that maternal constitutional differences between smokers and non-smokers could be responsible for the depressant effect on fetal weight. Recently, a relationship between IUGR and an alteration of epidermal growth factor receptor in placental membranes of smokers has been suggested.[113]

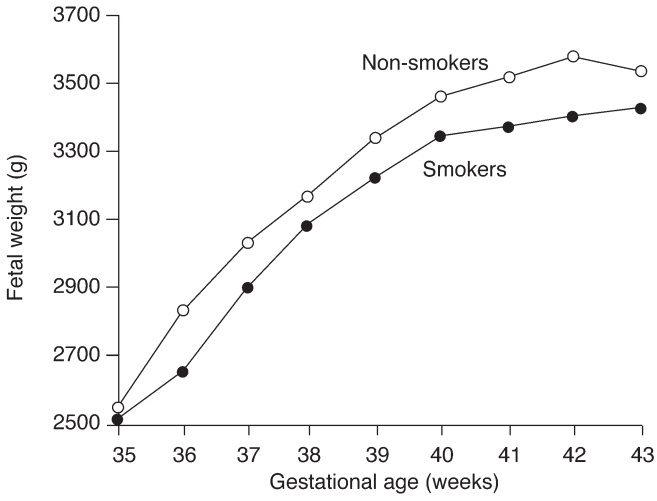

Figure 119.4 Influence of smoking habit on fetal weight.[1]

Recently, it has been discovered that offspring of mothers who smoked during pregnancy are more likely to develop type II diabetes.[114]

Zaren[115] found that the negative effect on fetal growth from maternal smoking curiously affected male fetuses proportionally more than female ones. A different hormonal milieu is suggested as possible explanation for the greater male susceptibility.

Alcohol use

Ulleland[116] reported for the first time that IUGR was particularly common among children born to alcoholic mothers. In addition to evidence of the adverse effects of alcohol on fetal weight in animal models,[117,118] there are multiple reports in humans.[119] The weight at birth is reduced by an average of 160–190 g in infants born to mothers with daily alcohol consumption > 200 g. Different authors[120,121] described the characteristics of these children and established the concept of 'fetal alcoholic syndrome', in which weight, height, and head circumference of the neonates are below the 3rd percentile. Moreover, different abnormalities (skeletal, cardiac, neurological, etc.) and craniofacial stigmata are frequently observed. Frequently, alcohol consumption is accompanied by elevated caffeine, tobacco and/or cannabis consumption, complicating the epidemiological analysis of the effect of each of these substances.[122]

Caffeine

Methylxanthines, especially caffeine and theophylline, are found in numerous food products, beverages and medicines. Although a clear deceleration effect of caffeine on fetal growth has been reported in experimental animals,[123] data in pregnant women are controversial. Risks associated with maternal caffeine consumption during pregnancy and perinatal outcomes have been proved difficult to estimate. Caffeine is consumed by most of pregnant women, and small risks influence large numbers of pregnancies. The ingestion of more than seven or eight cups of coffee a day (600 mg of caffeine) apparently increases the rates of both fetal growth restriction and prematurity.[124–127] These findings, however, have not been confirmed in other studies.[128–130] It is possible that caffeine consumption and smoking interact to reduce fetal growth, but the involved mechanisms remain unclear.

Some earlier studies[131] provide reassurance that moderate caffeine consumption during pregnancy does not meaningfully influence fetal growth, but large quantities of caffeine should be avoided.

Illicit drug addiction

Babies born to heroin-addicted mothers weigh significantly less than do those born to mothers who do not consume opioids,[132–134] independently of maternal nutrition and drug use withdrawal during gestation. Low fetal weight is related both to prematurity and IUGR. An increase in fetal weight has been shown in pregnant women giving maintaining doses of methadone, although similar fetal weights than in controls were not reached.[135]

At early stages of gestation, opioids have a critical influence on fetal growth. Different mechanisms have been proposed to explain the effect of drug abuse on fetal growth, such as a significant decrease in the number of cells of different organs and in the size of the brain[132] (methadone antagonizes cell reduction by an unknown mechanism), impairment of carbohydrate fetal metabolism (methadone seems to have a hyperglycemic action), and a decrease in plasma concentrations of corticosteroids[136] (methadone may reverse a relative adrenal hypofunction, acting indirectly on carbohydrate metabolism).

With respect to the effect of cocaine on fetal weight, no conclusive evidence is available.[137,138] A recent multicenter study, however, failed to demonstrate an increased incidence of low birth weight and preterm birth among cocaine consumers, although there was a significantly higher rate of abruptio placenta.

Drug treatment

Some teratogenic drugs also have an important effect on fetal growth. Adverse effects of tetracyclines include fetal growth restriction secondary to skeletal hypoplasia when this antibiotic is administered during the first trimester of pregnancy, and permanent staining of the teeth in the second trimester. Untoward effects of anticoagulation drugs (warfarin), especially when given between 6 and 9 weeks' gestation,[139] comprise mental restriction, dysmorphisms (nasal hypoplasia), and evident IUGR. Folic acid antagonists (aminopterin and derivatives) are potentially lethal drugs for the embryo when given within 40 days before conception. The administration of these compounds during the first trimester of pregnancy can cause severe structural defects (neural tube defects, abnormalities of the

limbs, ophthalmic hypoplasia, etc.) and fetal growth restriction that persists in postnatal life.[140] Hydantoin anticonvulsants are responsible for the 'fetal hydantoin syndrome' characterized by mental restriction, a number of craniofacial defects, and fetal growth restriction.[141] The 'fetal trimethadione syndrome' consists of characteristic craniofacial and cardiac defects which are almost always associated with mental and fetal growth restriction.[141] Lithium causes a number of cardiac defects (Ebstein's disease) and IUGR.

Maternal diseases

A large number of maternal disorders have been related to fetal growth restriction.

Poor adaptation of maternal circulation

There is growing evidence for poor pregestational preparation of maternal circulation (with or without uterine vascular insufficiency) as a cause of very early recurrent miscarriages and IUGR.[142] Current research is focused on color Doppler examination of the uterine arteries to detect defective placentation. Results of these studies will probably provide some keys for establishing an early prognosis of pregnancies in which this condition occurs. Immunologic aspects may also be involved in poor adaptation of maternal circulation.[143] This seems particularly plausible in very early IUGR with positive antiphospholipid antibodies (lupus anticoagulant and anticardiolipin antibodies), in which the cause may lie in an early inhibition of the production of prostacyclin at the vascular endothelium.[144]

Chronic renal disease

Chronic renal diseases most frequently associated with IUGR include chronic pyelonephritis, glomerulosclerosis, chronic glomerular disease, and lupus glomerulonephritis.[145,146] Fetal growth restriction in maternal renal disease is largely secondary to protein loss.[145] Chronic renal disease should always be suspected in patients with a history of IUGR associated with 'toxemias' and persistent proteinuria and hypertension after childbirth.

In patients with blood urea nitrogen > 60 mg/dl, fetal mortality is 80–100%. In fact, Parbooshing and Cochburn[147] reported an IUGR incidence of 100% in patients with plasma urea levels upon 60 mg/dl and/or creatinine clearance values below 60 ml/min.

Pre-eclampsia and chronic hypertension

Hypertensive disorders of pregnancy and chronic hypertension exert an unfavorable effect on fetal growth.[148–150] In patients with hypertension and proteinuria, fetal weight is decreased by 300–400 g.[151] In our experience, fetal growth restriction is initiated from 35–36 weeks of gestation, so that the birth weight of preterm infants is lower than that expected for the gestational age. It is likely that severe pre-eclampsia or serious chronic hypertension need to be present to substantially affect fetal weight.[152]

Several studies support the hypothesis that pre-eclampsia is an etiologically heterogeneous disorder that occurs in at least two separate subsets, one with normal or enhanced placental function and another involving placental dysfunction.[153–155] In the subset with placental dysfunction, IUGR fetuses often have asymmetric fetal body proportion and reduced fetal length, which is consistent with placental hypoperfusion.

Uteroplacental ischemia has been considered for many years to be the most important factor of fetal distress and hypotrophy. Vasoconstriction would account for most cases of sudden intrauterine fetal death. It seems equally proven that placental oxygen consumption is decreased in hypertensive pregnancies with hypertrophic fetuses. The involvement of coagulation disorders has been recently hypothesized based on the identification of extensive infarctions and intervillous and perivillous fibrin deposits in placentas of some small-for-date neonates from hypertensive mothers. Intervillous fibrin deposits could be explained by activation of coagulation pathways.[156,157] There is evidence of platelet activation in many cases of IUGR occurring in normotensive and hypertensive pregnancies.[158] Trudinger[159] reported depletion of platelets in maternal blood in IUGR associated with pre-eclampsia as a result of intravascular coagulation in the placenta with local deposition of fibrin and platelets. An abnormal increase in the thromboxane/prostacyclin index at the intervillous level and in the peripheral blood due to a deficient production of prostacyclins of trophoblastic origin is currently accepted as the cause of altered vascular reactivity.[160]

Elevated homocisteine is an independent risk factor for peripheral vascular thrombosis, found in 20–30% of pre-eclamptic women, that seems to act through similar mechanisms.[161] Recent reports have related elevated homocysteine plasma levels in the early second trimester with the subsequent development of pre-eclampsia,[162–164] but other studies have not observed this relation.[165]

Placental growth factor (PlGF) and vascular endothelial growth factor (VEGF) are involved in placental angiogenesis through interactions with the VEGFR-1 and VEGFR-2 receptors, and placentas of pregnancies with fetal growth restriction are characterized by abnormal angiogenic development, classically associated with hypoxia.[166] Tsatsaris[167] suggested that there are two different pathophysiological mechanisms associated with pre-eclampsia. The first one is related to an overproduction of competitive VEGFR-1 that may lead to suppression of VEGF and PlGF effects. The second one is the downregulation of its membrane bound form (VEGFR-1) in the placental bed, which may result in the defective uteroplacental development.

Maternal hyperinsulinemia

There is evidence for interrelationships between glucose, insulin and human placental lactogen (HPL) in fetal growth. Fragmentary data were obtained by three research groups. Abell and coworkers[168] found that low estriol levels and hypotrophic fetuses were associated with a higher incidence of abnormal glucose tolerance, particularly hypoglycemia, but also hyperglycemia. Frydman[169] demonstrated that insulin levels were clearly increased in many pregnant women with growth-restricted fetuses, especially in the postprandial phase, as a result of which less substrates are offered to the fetus due to excessive dispersion to maternal deposits. Grumbach[170,171] described the anti-insulin activity of HPL, and Spellacy[172] confirmed the lipolytic properties of this agent. Accordingly, postprandial maternal hyperinsulinemia due to high hormonal secretion, low tissue resistance to insulin, or impaired insulin removal by the placenta (low HPL levels) would enhance anabolism and decrease transplacental passage of carbohydrate substrates. In a group of pregnant women with IUGR, Frydman and colleagues[169] found that glucose ingestion was followed by an increase in the maximal peak of insulin, marked inhibition of HPL, and prominent reduction of free fatty acids and amino acids. This situation may be further complicated by deficient fetal insulin production. The hypothesis of the 'selfish mother' is depicted in Figure 119.5.

Long-standing, poorly controlled insulin-dependent diabetes associated with diabetic retinopathy, hypertension and nephritis may cause placental microvascular disorders that give rise to an increase in IUGR.[173] Low fetal weight is accompanied by low weight of all other fetal organs.

In pregnancies complicated by insulin-dependent diabetes, treatment with insulin and caloric restriction results in a decreased incidence of macrosomia and perinatal mortality, although fetal growth restriction may increase significantly (19.1% vs. 10.8% in the control group).[174] Fetal weight decrease may be explained by iatrogenic hyperinsulinemia and/or excessive caloric restriction with marked consumption of carbohydrate substrates, especially in the postprandial phase.[175] For this reason, there is a high percentage of newborns above the 90th percentile when maternal serum glucose levels are maintained between 100 and 150 mg/100 ml, while low birth weights are frequent when glucose concentrations are < 100 or > 150 mg/100 ml.[176]

Pregnant women with a family history of diabetes mellitus should have a glucose tolerance test, since a marked decrease in the K_1 coefficient is consequently associated with fetal weight alterations. Abnormal glucose tolerance (hyperglycemia) is especially found in old and obese women of high parity with history of miscarriages, fetal death, and newborns of unusual birth weights (low or high).[177]

Impairment of fetal growth in cases of maternal hypoglycemia secondary to unbalanced diets or relative hyperinsulinemia is related to enhanced maternal lipolysis and ketonemia[178] or catecholamine release.

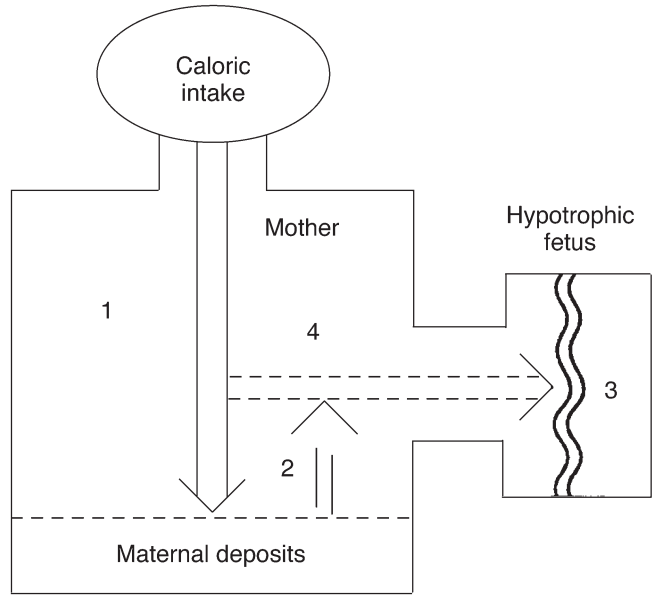

Figure 119.5 Hypothesis of the 'selfish mother' according to Frydman and colleagues.[169] Possible causes: 1, excessive insulin anabolism; 2, low tissue insulin resistance; 3, deficient fetal insulin production; 4, others.

Chronic cardiopulmonary disease

Fetal growth restriction has been reported in patients with heart or lung disease causing hypoxemia, such as coarctation of the aorta, pulmonary atresia, reduced cardiac output, bronchial asthma, bronchiectasis, etc.

Anemia

Whilst low levels of hemoglobin (<6 g/dl) are associated with an increase in perinatal mortality, moderate anemia (6–10 g/dl) is associated with a significant decrease in fetal weight.[179] This may be due to a decrease in oxygen transport (sickle cell anemia, etc.) or it may simply be related to poor maternal nutrition.

Urinary tract infection

It has been generally accepted that pyelonephritis during pregnancy causes IUGR.[145]

Autoimmune diseases

The association between systemic lupus erythematosus and IUGR is well known, although it is usually difficult to distinguish between the effects of high doses of glucocorticoids and azathioprine, and vasculitis caused by the disease.[180] On the other hand antiphospholipid (lupus-like) syndrome has been associated with an increase in the incidence of miscarriages, IUGR and intrauterine death.[144,181,182] Serum concentrations of insulin-like growth factor I (IGF-I) and insulin-like growth factor binding protein I (IGFBP-I) are abnormal in the antiphospholipid syndrome.

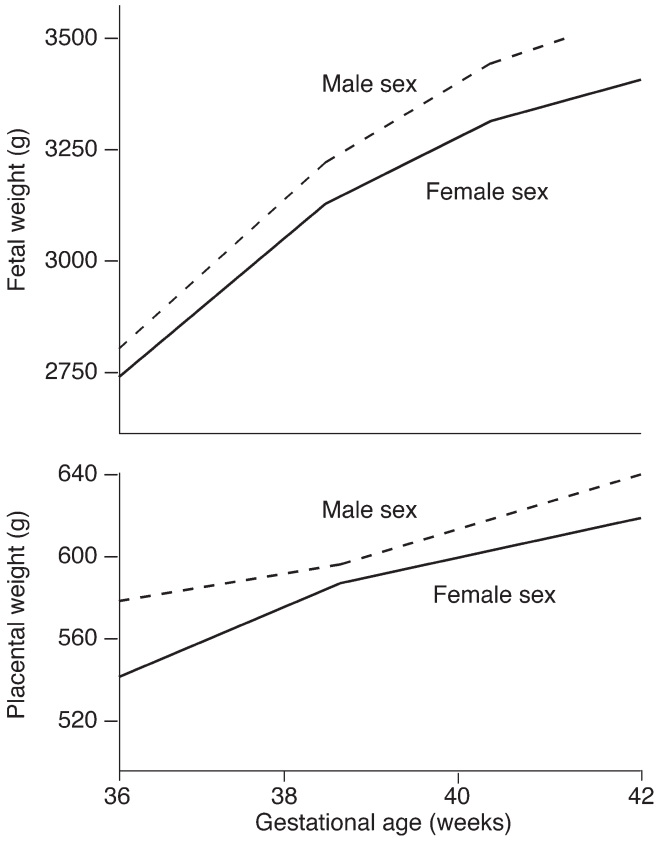

Figure 119.6 Relationship between sex of the neonate and birth weight and placental weight.[29]

Angiotensinogen mutation

Angiotensinogen is the precursor of the vasoactive hormone angiotensin II, which plays an important role in blood pressure regulation, body fluid volume, and vascular remodeling. It has been shown that mutations affecting its gene lead to failed pregnancy volume expansion and fetal growth impairment.[183–185]

Vaginal hemorrhage

North[186] reported an increase in perinatal mortality and in the incidence of small-for-dates neonates in pregnancies complicated by vaginal hemorrhage during the second trimester.

Fetal factors

Fetal sex

It is well known that the birth weight of full-term male infants is an average of 140–150 g higher than that of females (about 4% difference). Consequently, the incidence of IUGR may be higher among females if birth weight curves are not differentiated by sex (Figure 119.6).

Chromosomal abnormalities

Chromosomal abnormalities are accompanied by a high incidence of IUGR.[187,188] Chromosomal defects are identified in approximately 15% of cases of IUGR.

Autosomal abnormalities

Down's syndrome (trisomy 21). Various studies[189,190] have demonstrated that, as compared with normal babies, newborns with trisomy 21 have lower birth weights (about 450 g) and are shorter. The mean birth weight of infants with trisomy 21 is 2725 g.[187] Although the length of gestation is reduced by 7–10 days, this fact cannot account for such a large difference in fetal weight. Because in these cases placental morphology is normal, it may be concluded that IUGR in fetuses with trisomy 21 is related to a decrease in intrinsic fetal growth potential.

Edward's syndrome (trisomy 18). Fetal growth restriction is an outstanding characteristic of this syndrome, and most fetuses are below the 10th percentile at any time of gestation. The mean birth weight of neonates with trisomy 18 is 2333 g.[187]

Patau's syndrome (trisomy 13). Fetal weight is less severely affected than in trisomy 18. The mean birth weight of babies with trisomy 13 is 2400 g.[187]

Segmental chromosome imbalances

All these syndromes are accompanied by a significantly higher incidence of IUGR. Seventy percent of neonates with 5p-cri-du-chat syndrome have a birth weight below the 10th percentile. Fetal growth restriction also occurs in other syndromes, such as monosomy 21, 18p-short arm, and ring chromosome-related abnormalities.[191] Disorders caused by autosomal ruptures, such as Fanconi's anemia and Bloom's syndrome are also associated with fetal growth restriction.

Abnormalities of sex chromosomes

Turner's syndrome (45,X). About one-third of neonates with this defect weigh less than 2500 g at birth.[192] A mean birth weight of 2800 g has been reported in babies with Turner's syndrome.[193] The occurrence of IUGR apparently depends on the presence of mosaicisms in other cell lines and on the abnormal structure of the X chromosome.[194] This karyotype is found in 20% of miscarriages in the first trimester of pregnancy, and it is estimated that 90% of fetuses with Turner's syndrome are not viable.

Multiple X syndromes.

Multiple X syndromes are more frequent than monosomies, i.e., the XXX karyotype is found in 1:1125 female babies born alive, and XYY in 1:700 male infants born alive. Barlow[195] reported that for every extra X chromosome, fetal weight loss is equivalent to 300 g, and that for every extra Y chromosome, fetal weight loss is equivalent to 100 g.

Other chromosomal abnormalities that have been associated with fetal growth restriction are shown in Table 119.4.

Table 119.4 Cytogenetic anomalies that may be associated with intrauterine growth restriction

Ring 1	Ring 9
1q partial trisomy	Ring 18
4p trisomy	18p-
Ap–	18q-
5p–	Ring 21
5q–	Trisomy 22

Inherited syndromes

A variety of diseases of bone dysplasias, e.g., dwarfism (achondroplasia, hypochondroplasia, Russell–Silver syndrome etc.) and chondrodystrophies, osteogenesis imperfecta, etc. have been associated with IUGR. Placental sulfatase deficiency has also been cited in connection with IUGR. With regard to neural tube defects, most studies report low mean weight at birth in cases of both anencephalia (2117 g) and spina bifida cystica (200 to 240 g less than in the control group).[196,197]

Maternofetal radiation

Fetal pathology depends on the x-ray dose and the time of exposure. Radiation effects on fetal weight are related to a large extent to placental damage. Although there are no data for calculating the risk of fetal complications due to unintentional radiation therapy during the first trimester of pregnancy, it seems that the risk increases when the dose exceeds 10 rads. Radiation-induced IUGR may be due to chromosome ruptures, congenital malformations of the central nervous system, inhibition of cell replication, etc.

Intrauterine infection

Embryopathic infectious processes may influence intrinsic fetal growth potential in several ways, either by first affecting the mother, thereby directly affecting the fetus, or by negatively affecting both. When they directly affect the fetus during the stages of organ differentiation, they are capable of causing permanent reductions in the number of cells, thereby causing more or less severe damage to most of the fetal organs (Figure 119.7). According to Knox,[198] 10% of IUGR cases are due to transplacental infection of the fetus. Rubella and cytomegalovirus infection are the most significant, followed by herpes simplex, toxoplasmosis, paludism, congenital syphilis, and other acute bacterial infections.

Rubella infection illustrates the pathogenesis of IUGR. During primary viremia the virus affects at the placenta, causing villous placentitis and lesion of the vascular endothelium. Continued viral replication with secondary viremia may then follow.[199] Viral fetal invasion determines direct inhibition of cell replication, obliterans angiopathy, chromosomal ruptures and cytolysis. These abnormalities together with chronic ischemia derived from vascular placental lesions would explain IUGR. Sixty percent of neonates with congenital rubella have a birth weight below the 10th percentile.[200] Viral replication also affects postnatal growth. In these cases, continued viral secretion after childbirth has been documented. With regard to cytomegalovirus infection, IUGR is found in 35% of cases.[201] It seems that there is a relationship between severity of infection and frequency of fetal growth restriction.

On the contrary chlamydia pneumonia infection is unlikely to play a role in the pathogenesis of IUGR.[202]

Twin pregnancies

This is one of the most frequent causes of IUGR. In all series of IUGR, twin pregnancies account for 20% of cases.[203] The intrauterine growth curve of twin pregnancies is similar to that of singleton pregnancies until week 33 of gestation; from then on, the curve for monozygotic twins diverges whilst that of dizygotic twins does so between weeks 35 and 36. Weight discrepancy in twin pregnancies may be due to twin-to-twin transfusion (severe anemia in the 'donor' twin), but most frequently to placental problems (unequal nutritional supply due to a smaller placenta, marginal insertion of the cord, etc.). Poor perinatal outcome has been reported for the 'smaller' twin.[204,205]

Immunological factors

In 1953, Medawar,[206] a specialist in transplantation, considered for the first time the product of conception as a 'grafted' tissue and argued that a mechanism preventing rejection of the placenta by the maternal immune system has to exist to allow viviparity. The lack of normal HLA antigenic expression in the trophoblast is probably the principal mechanism. HLA-G expression protects trophoblastic cells from maternal recognition and immunological response to incompatibility.[207] From an immunological point of view, it is currently accepted that there is active signaling between embryonic and maternal tissue even before implantation of the fertilized egg. An embryonic secretion product, presumably platelet activating factor, induces the release of early pregnancy factor (a sign of immunosuppression),[208] which, in turn, stimulates the secretion of leukocytic molecules responsible for the suppression of T cell function.

In animal models, 'dwarf's syndrome' or Runt's syndrome refers to weight restriction as a result of an exacerbated host-vs.-graft reaction. In human beings it is also possible that immunological mechanisms could play an important role in some forms of IUGR. Some findings include weight restriction found in fetuses undergoing intrauterine transfusion, an

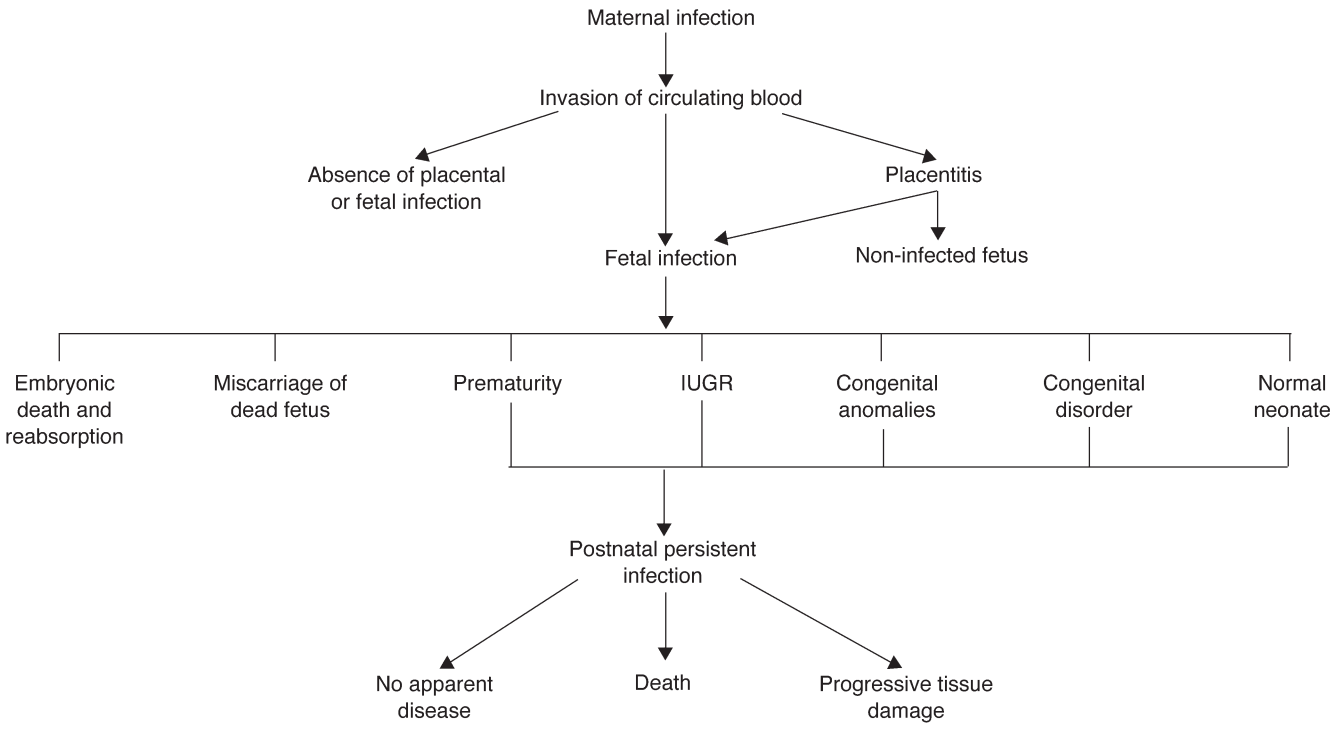

Figure 119.7 Pathogenesis and outcome of fetal infection. IUGR, intrauterine growth restriction.

increase in congenital anomalies in gestations with incompatibility against human leukocyte antigen (HL-A), and the similarity of placental histological features in some case of IUGR with those seen in animals with the dwarf's syndrome.[209]

Some findings suggest that reproduction efficacy may be affected by maternofetal 'genetic disparity'. Jones[210] indicated that mean placental weight was lower in gestations with probable genetic disparity regarding the fetus, and found a higher incidence of low weight fetuses in patients with leukoagglutinins. In contrast, larger placentas are found in male fetuses from primiparas in cases of ABO incompatibility. Billington[211] demonstrated in mice that genetic disparity in hybrid animals caused significantly larger placentas than in pure lineage animals. Findings in humans also indicate that genetic similarity may be an etiological factor of IUGR; newborns of incestuous unions and of first cousins weigh 200–300 g less than normal. The fact of a lower weight of female fetuses as compared with males has been attributed by Ounsted and Ounsted[212] to a certain antigenicity of the Y chromosome.

Based on these data, the concept originally proposed by Walton and Hammond[213] has been broadened, suggesting that intrauterine growth is mainly controlled by two variables; that is, genetic disparity between mother and fetus, and predetermined stimulus of maternal regulator. Independently of the immunological mechanism involved, signs of immune depression that may persist up to 9 months after childbirth are found in many small-for-gestational age neonates.[214,215]

Interval between pregnancies

There is a decrease in both, duration of gestation and fetal weight, when the time passed between the last delivery and the new pregnancy is less than 2 years or more than 6 years.[216] The incidence of infants with low weight at birth is higher in women with short intervals between gestations.

Fetal order at birth

Fetal growth restriction occurs more often in first-born neonates, particularly when the mother is very young or old. The second or third child of the same mother usually weighs more than the first child. Mean fetal and placental weights in multiparas are significantly higher than in primiparas (at 40 weeks, 3.4% and 2.5%, respectively). The first pregnancy may well determine a true maturation of uterine structures, especially the vessels, which become more sensitive to gestational stimuli resulting in improved local conditions in subsequent gestations. On the other hand, and according to data of Scott and Usher,[217] the probability of fetuses with IUGR increases in relation to the number of previous gestations with low birth weight neonates (Figure 119.8).

Uteroplacental factors

Uterine anomalies

Congenital uterine anomalies, in particular uterus bicornuate and septate uterus, are consistently associated

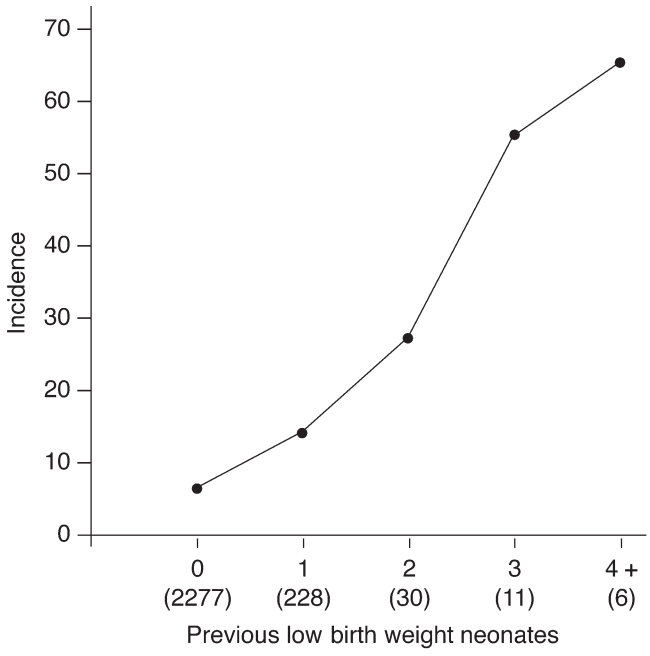

Figure 119.8 Incidence of fetal growth restriction in the current pregnancy according to number of previous gestations with low birth weight neonates. The total number of current gestations studied in each group is given in parentheses.[218]

with IUGR,[218] accounting for approximately 1–3% of cases.[219] Although Scott and Usher[217] did not find statistically significant differences in neonatal birth weight between pregnant women with and without uterine fibromyoma, other authors[219] reported uterine fibromas in 1–5% of cases of IUGR. Uterine synechiae have not been related to IUGR.[218]

Placental anomalies

Anomalous cord insertion

Sotelo-Avila and Shanklin[220,221] studied the relationship between the site of cord insertion and IUGR. The incidence of full-term small-for-dates neonates was significantly higher in cases of anomalous cord insertion. Velamentous insertion of the cord is a well-defined pathologic entity, with an 1% estimated frequency. This anomaly accounts for approximately 12% of cases of IUGR. Fetal growth restriction has also been associated with marginal and markedly eccentric insertions of the cord.

Abnormalities of placental form

The girdle placenta is the only abnormality of placental form associated with a high incidence of small-for-gestational age birth. A phenomenon of secondary placental growth to compensate for an early placental insufficiency seems to be confirmed by the observation by Shanklin and Sotelo-Avila[221] of a decreased superficial cord vasculature.

Abnormalities of placental site

It is well known that placenta previa, especially total and partial placenta previa, is associated with a higher frequency of IUGR.[222]

Tumors

Vascular tumors originating from extra-embryonic primitive mesenchyma, mainly hemangiomas and hamartomas, have been associated with an increased incidence of growth restriction.[56,220] It has been suggested that the effect on fetal growth is exerted through placental insufficiency[56,223] resulting from a considerable portion of fetal blood flow passing through the tumor rather than through functional placental tissue. However, arteriovenous shunting as a cause of IUGR and even fetal death has been proposed by other authors.[220,221,224] Although it has been insisted that there is a frequent association between these tumors and growth restriction and also with congenital anomalies, Fox[225] considered the latter improbable. In large tumors, cardiomegaly and cardiovascular insufficiency is a prominent complication in neonates due to increased peripheral resistance of the placental vasculature.

Single umbilical artery

The absence of one umbilical artery has an incidence of 1% in singleton pregnancies and up to 7–14% in twin pregnancies. Malformations are present in about 15–20% of fetuses with a single umbilical artery syndrome and can affect any organ system. They are accompanied by IUGR,[226] particularly when they are associated with trisomies. Growth restriction is caused by reduced fetoplacental blood flow.

Parabiotic syndrome

Monochorionic multiple gestations place the fetuses at risk of twin transfusion syndrome. In such cases an arteriovenous shunt is present at the placental level between the two members of the set. Under those conditions, one fetus, the donor, provides the major share of the blood supply to its co-twin. As pregnancy progresses, this major physiopathologic change in the fetal blood volume causes the donor fetus to become anemic and growth-restricted, whilst the recipient twin becomes fluid-overloaded, polycythemic and cardiomegalic.

Placental mosaicism

Numerous cases of placental aneuploidies have been described, particularly trisomies 2, 7, 9, 10, 12, 13, 15, 16 and 18,[227–230] that have been associated with miscarriages, growth restriction and fetal death, despite the fact that fetuses were chromosomally normal. Kalousek and Dill[227] have suggested that the occurrence of non-disjunction at random in the very early

stages after conception could give rise to mosaicism in the placenta or in the fetus.

There is a high correlation between the number of aneuploid cells found in cultured villi and the number confirmed in studies of the placenta at term. These data are also relevant for fetal outcome. Thus, growth restriction (80% of cases) and fetal death (20–30% of cases) normally need only be feared in cases of high levels of mosaicism (more than 35% of cells involved).[231,232] For this reason, it has been suggested that, at least in part, the length of gestation and fetal survival depends upon the ratio of euploid cells to aneuploid cells in the placenta. Many other conceptions are, however, aborted before 22 weeks of gestation. There are nevertheless case reports of normal fetuses.[233,234] Fetal outcome may be related to the effect of uniparental dysomy. Some authors[235,236] have shown a threefold increase in mosaicism confined to the placenta in growth-restricted fetuses (25%) as compared with neonates with normal birth weight (8%). Placental molecular reports support the concept of a clear biological effect of chromosome mosaicism on fetal growth.[236,237]

Pathogenesis

All different etiological factors related to IUGR act through common pathogenetic mechanisms. Based on studies in animal models,[238–240] three basic etiopathogenic mechanisms are currently recognized: (a) decrease in intrinsic fetal growth potential, (b) uteroplacental vascular insufficiency, and (c) fetal malnutrition secondary to maternal malnutrition.

Decrease in intrinsic fetal growth potential

Intrinsic fetal growth potential relies upon genetic material, sex and anatomy of the fetus, and length of gestation. Different etiological factors, such as those of genetic or chromosomal origin, embryopathic infectious processes (rubella, cytomegalovirus, toxoplasmosis, syphilis, paludism, etc.), and toxic habits or radioactive agents begin to exert their influence from the time of conception, or at least from the embryonic stage, acting on fetal metabolism and organogenesis. In these circumstances, although the placental maternal blood supply remains unaffected, the fetus is unable to progress. However, genetic potential accounts for about 35–40% of variations in fetal weight.

Growth restriction may result from a single genetic defect (e.g., cystic fibrosis, phenylketonuria) or a polygenic multifactorial action, which would explain the majority of height and weight variations of 'hereditary' type. The influence of chromosomal-related factors on fetal weight is probably exerted by affecting the duration of some periods (G_1 or G_2) of the cell cycle. Studies in rats have shown that chromosomal antigenic inequality (Y trophoblast and XX decidua) would apparently explain greater trophoblastic plugs in male eggs and greater development subsequently.

Abnormalities of placental nutrients and oxygen supply

Etiopathogenic mechanisms that cause a deficient supply of oxygen and/or nutrients through the placenta are included in this section. In addition to chronic hypoxia and fetal malnutrition secondary to maternal malnutrition already mentioned, uteroplacental insufficiency deserves particular attention.

Uteroplacental insufficiency

This includes those factors capable of affecting maternal–fetal–placental exchange as a result of (a) impaired uterine perfusion due to anomalies of the terminal uterine branches, and (b) a deficient exchange surface due to villous microcirculatory anomalies.

Impaired uterine perfusion due to physiological changes. Uterine vasculature undergoes a series of modifications, that is, an increase in uterine circulation with arterial and venous hypertrophy and hyperplasia, in order to increase blood flow from 50 ml/min at 10 weeks of gestation to 600 ml/min at term. Main changes after implantation consist in the formation of the intervillous space and trophoblastic infiltration of the spiral arteries.

Trophoblastic infiltration produces fibrinoid degeneration with disruption of the musculoelastic wall,[241] and adrenergic denervation of uterine vessels with a marked decrease in sympathetic neurotransmitters.[242] These changes are accompanied by vasodilation and inhibition of platelet aggregation in relation to the effects of prostacyclin[243,244] released by placental vascular endothelial cells (Figure 119.9). Local decrease of the thromboxane/prostacyclin index as an adaptative mechanism prevents spiral artery thrombosis and subsequent placental infarction. As a consequence of trophoblastic activity, the spiral arteries are converted into a low-resistance, high-flow vascular bed. Prostacyclin also favors a phenomenon of vascular insensitivity.[245]

Partial or total replacement of the normal musculoelastic wall by fibrinoid material has the following effects: (a) widening of spiral arteries (30-fold as compared with non-pregnant women) which confers greater capacity and an infundibuliform aspect to these vessels; (b) reduced vascular resistance of the placental bed, which therefore determines a higher adaptation capacity of spiral arteries for increasing blood flow; and (c) decrease or abolition of the vasoconstriction response to stimuli of adrenergic agents (catecholamines, etc.) or to stimuli of the autonomic nervous system. Control of uteroplacental circulation is mainly exerted on radial rather than on spiral arteries.

Impaired uterine perfusion due to pathological changes. Uteroplacental insufficiency takes place during the last weeks of gestation (because of a deprived supply line according to Gruenwald[246]) that justifies a decrease in fetal growth rate around the 37th gestational week. This 'physiological' insufficiency is

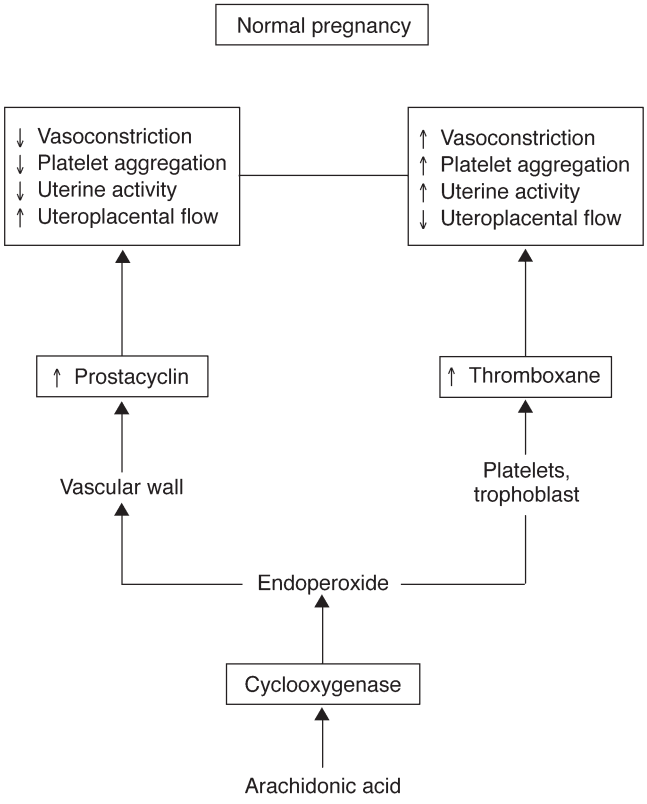

Figure 119.9 Normal gestation. A balanced thromboxane/prostacyclin index guarantees an adequate uteroplacental blood flow. As compared with pregestational status, there is a decrease of this index in the systemic circulation with a clear enhancement of prostacyclin-related vasodilation and inhibition of platelet aggregation.

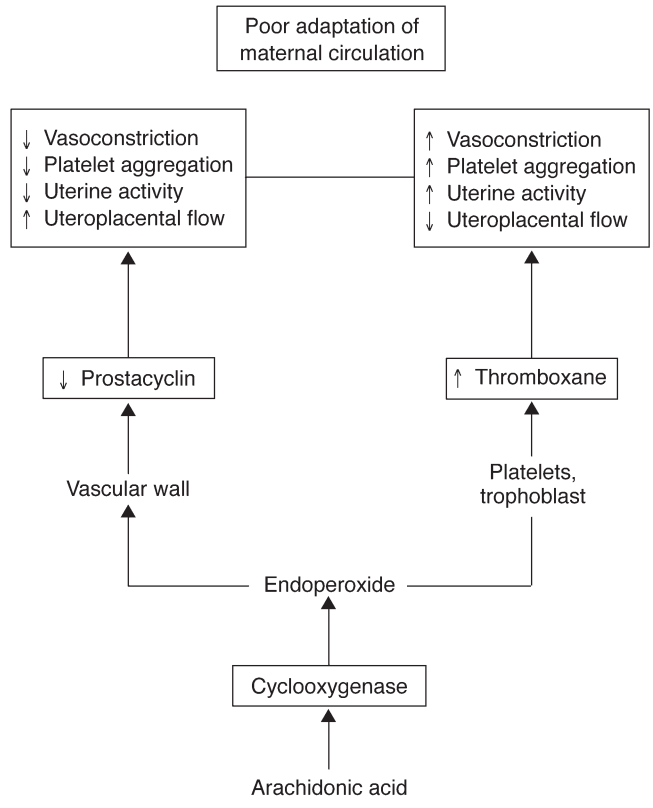

Figure 119.10 In gestations with 'poor adaptation of maternal circulation', there is a pathological increase in the thromboxane/prostacyclin index leading to an increase in systemic resistance, platelet aggregation and uterine activity, all of which cause a decrease in uteroplacental blood flow.

related to inability of the maternal environment to satisfy fetal needs despite the fetal capacity to maintain growth rate. Early or enhanced 'physiological' uteroplacental insufficiency accounts for about 35% of cases of growth restriction.[247]

The sequence of events leading to impaired uterine perfusion is probably initiated by a pathologic increase in the thromboxane/prostacyclin index in the intervillous space secondary to reduced prostacyclin production,[243] resulting in discontinuation of trophoblastic infiltration of the spiral arteries[248] and preservation of their vasomotor activity.[241,249] As a consequence of impaired trophoblastic activity there is an early reduction of uteroplacental blood flow.

Moreover, alterations in systemic maternal circulation include a decrease in prostacyclin levels and a relative increase in thromboxane (TX_2). An unbalanced thromboxane/prostacyclin index leads to an increase in vascular resistance and vasopressor sensitivity, and a reduction of plasma volume. This cascade (Figure 119.10) seems to be precipitated by a reduced prostacyclin production,[250–252] which is further supported by the finding of statistically significant decreases (50%) of prostaglandin I_2 in pre-eclampsia.[253] In addition, there is an activation of coagulation with increased platelet aggregability, thrombopenia etc., as well as general and local vasoconstriction (vasospasm, hypertension, etc.) leading to decreased systemic blood flow and, in short, to a reduction in uteroplacental blood flow and IUGR.[250,254] At the level of the uteroplacental circulation, there is also a specific decrease in prostacyclins, probably mediated by a local paracrine mechanism resulting from high epinephrine and norepinephrine concentrations in the maternal portion of the placenta.

On the other hand, specific changes in the vascular endothelium resulting from insufficient trophoblastic activity include alterations of permeability (responsible for fibrin and lipid deposits) and a decrease in the local synthesis of prostacyclin and other factors, such as endothelial-derived relaxing factor, nitric acid and C-protein (anticoagulant), with a simultaneous increase in vascular endothelial growth factor (VEGF), asymmetric dimethylargine (ADMA), an endogenous inhibitor of endothelial nitric oxide synthase,[255,256] and platelet-derived growth factor. All these factors will favor acute atherosis, vasoconstriction, and activation of coagulation. Lipid deposits are frequently accompanied by IgG, IgM and complement deposits and perivascular lymphomonocytic infiltration resulting from a maternal immunitary reaction against antigens from the endovascular trophoblastic cells (Figure 119.11).

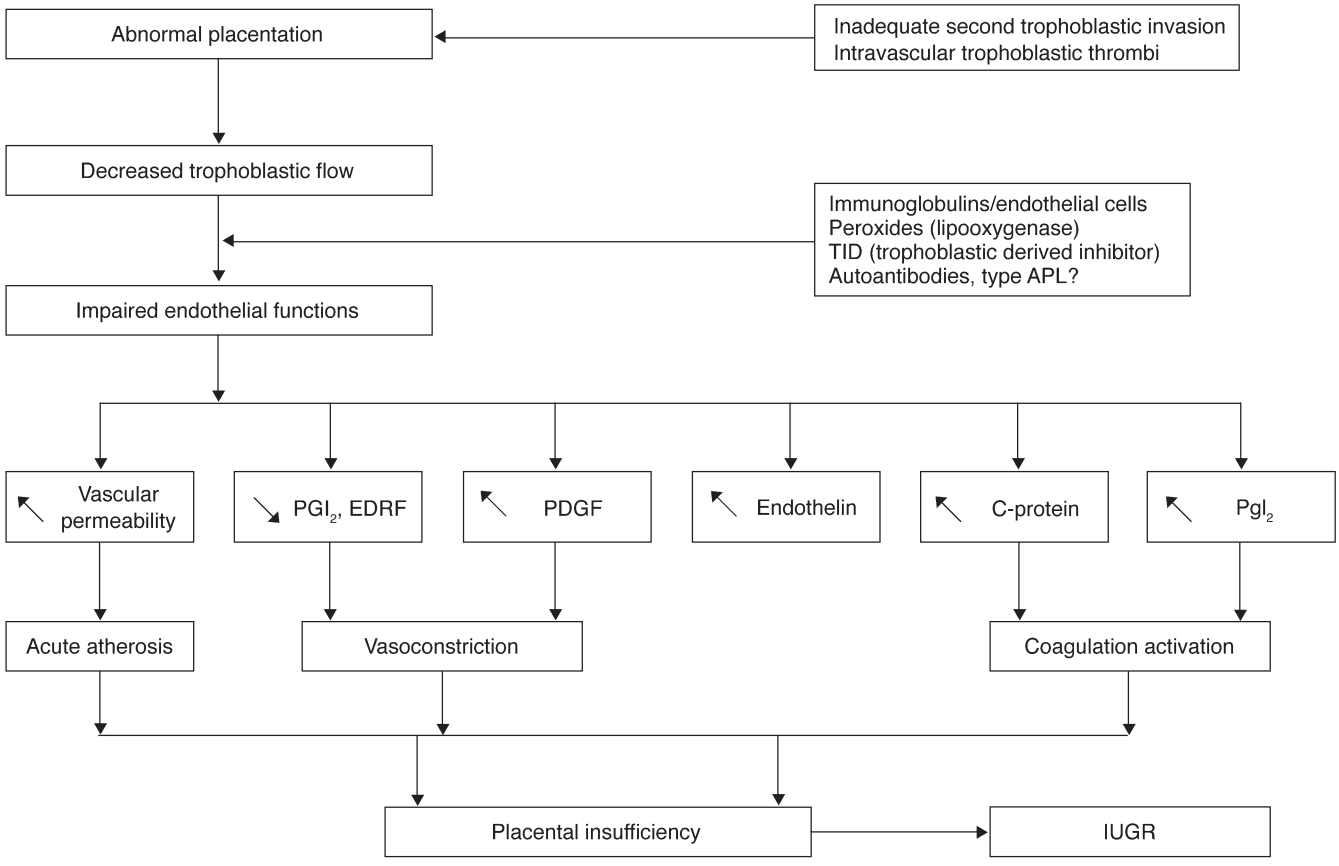

Figure 119.11 Summary of the physiopathologic hypothesis of intrauterine growth restriction (IUGR) of vascular cause. APL, antiphospholipid antibody; PGI_2, prostaglandin I_2; EDRF, endothelial-derived relaxing factor; PGDF, platelet-derived growth factor; VEGF, vascular endothelial growth; ADMA, asymmetric dimethylargine.

In cases of pre-eclampsia with or without IUGR, an immunologically mediated deficiency in trophoblast invasion of the spiral arteries of the placental bed leads to a poorly perfused fetoplacental unit. The subsequent secretion of VEGF into the maternal circulation leads to activation of the vascular endothelium. Galatzios[257] observed a correlation between raised umbilical cord serum VEGF levels and the development of pre-eclampsia, and in some circumstances of IUGR and preterm delivery. On the other hand, Sawidon[258] observed a correlation between elevated concentrations of ADMA and the same pathologies.

Subclinical placental infection may cause the release of inflammatory cytokines,[259] which, in turn, cause an overproduction of VEGF in the placenta, which may lead to IUGR.

The correlation between serum levels of antiphospholipid antibodies and fetal morbidity including IUGR has been demonstrated in different studies.[260–262] From a biological point of view, antiphospholipid antibodies increase the risk of venous and arterial thrombosis, and inhibit local synthesis of prostacyclins.

Impaired uterine perfusion finally causes hypoxic ischemia in the intervillous space, with secondary vasoconstriction of villi arterioles. In this case, changes in uterine blood flow velocity waveforms may be detected in Doppler studies before changes are detected in umbilical velocity waveforms, as occurs for example in patients with pre-eclampsia.

Deficient transplacental transport of amino acids. The level of most amino acids is higher in the fetal circulation than in maternal plasma, reflecting that there are transportation systems of amino acids through the trophoblastic cells. IUGR is associated with reduced plasma concentrations of a number of amino acids despite normal or higher maternal concentrations than in normal pregnancies.[263] Whether this is a cause or a consequence of the IUGR remains unclear, but some evidence shows that hypoxia can downregulate amino acid transporter expression and activity in cultured human trophoblastic cells.[264]

Deficient exchange surface. The main pathologic finding is a significant decrease in the number of arterioles of the tertiary villi,[265] which may be the result of two basic pathogenetic mechanisms: (a) lack of formation of arterioles, due to interference in the process of placental maturational angiogenesis,[266] or (b) obliteration, secondary to a thromboembolic or vasospastic phenomenon.[267,268] In both cases, the cause of these changes may ultimately lie in a decrease in uterine perfusion, or in the fetus itself through changes in vascular resistance mediated by poorly understood

biochemical or reflex mechanisms.[267,269,270] In these cases, changes in umbilical velocity waveforms may be detected in Doppler studies whilst uterine blood flow velocity waveforms are unaffected.[271–274] The current theory is that prolonged reduction in maternal intervillus flow, and hence oxygen delivery, would result in prolonged vasoconstriction with secondary reduction in stem villus luminal diameter, increased flow resistance and vascular medial hypertrophy.[268,275–277]

Fetal malnutrition secondary to maternal malnutrition

This is one of the main causes of IUGR. Deprivation of adequate fetal nutrition alters cellular homeostasis. Limited bioavailability of amino acids for protein synthesis is the origin of a series of modifications. Nucleotides are subtracted from DNA synthesis and diverted to RNA synthesis, which is manifested by high and low activities of the enzymes RNA-polymerase and DNA-polymerase, respectively. However, despite increased RNA synthesis, total cellular concentration is low due to an increase in RNA hydrolysis, manifested by an increase in alkaline RNAase.

Because each organ has a different growth pattern, acme of cell division indexes are not synchronized, giving rise to different periods of vulnerability for each organ or system. When data obtained in rats are extrapolated to human beings, considering that human growth is mostly hyperplastic, the consequences of growth restriction appear especially discouraging, in particular for brain development. However, some differences between growth in rats and human fetuses should be mentioned. In humans, the speed of cell division is lower, so that the effects of malnutrition would be less severe during the same period of time. Neuroblastic proliferation also occurs in a highly protected period (prior to 20 weeks' gestation) when factors affecting fetal growth are not usually present. Injury late in pregnancy is associated with underdevelopment of the cerebellum, nerve cell synapses, and dendritic arborization, which may be as important as a reduction in the number of neurons.

Specific effects of malnutrition on cell growth and fetal development depend on the stage at which the adverse factor begins to affect the fetus (Figure 119.12) and the mechanisms involved. Malnutrition early in pregnancy during the stage of cell proliferation or hyperplasia causes inhibition of the cell division index. This results in irreversible size reduction and a decrease in the number of cells of an organ. Malnutrition during the stage of cell hypertrophy causes growth deceleration, with recovery taking place once the adverse factor has been corrected, resulting in an organ of normal volume. In general terms, there is an association between a high rate of cell division and the intensity of effects of the growth-limiting factor.

With regard to the mechanisms involved, evidence is based on experimental studies. Severe protein

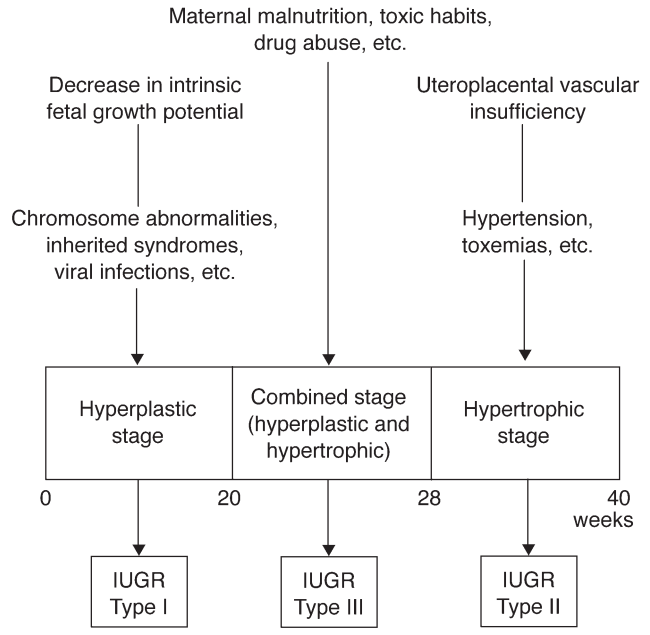

Figure 119.12 Pathogenesis and classification of intrauterine growth restriction (IUGR) (stage at which the adverse factor begins to affect the fetus, affected stages, and types of IUGR).

restriction in rats[278,279] produced symmetrical and harmonious growth restriction (all organs were affected, including the brain). There was a 20% decrease in the animals' weights, and a number of biochemical changes were found. These included a decrease in protein, DNA and RNA concentrations in all organs, which was proportional to the decrease in the animals' weights. A decrease in DNA-polymerase activity was followed by an increase in alkaline RNAase activity. In all brain specimens examined, there was a reduced number of neuroglial elements and neurons,[280] as well as decreased DNA concentrations. The magnitude of these biochemical and cellular changes was related to the degree of protein deprivation and the stage at which restriction began.

In studies of selectively induced uteroplacental vascular insufficiency, ligation of the uterine artery providing blood supply to the rat uterine horn produced growth restriction of fetuses implanted in that horn.[281,282] In these animals, IUGR was asymmetrical or disharmonious (not all organs were equally affected). Whilst the liver only reached half of the normal size and showed an almost complete glycogen depletion, the brain was practically unaffected. Biochemical abnormalities included marked decrease in DNA, RNA and proteins in the fetal liver, high RNAase activity both in the liver and the brain, and almost unchanged RNA concentration and negligible and transiently increased RNase activity in the brain.

Extrapolation of findings of cell growth reduction in animal models to human beings should be carried out with caution. As a matter of fact, weights of neonates (3500 g) born to women with a mean weight of 60 kg accounts for 5.8% of the maternal weight,

whereas rats weighing 200 g give birth to 10 animals of 5 g each, which is 25% of the rat maternal weight. On the other hand, the length of gestation in experimental animals is significantly shorter, and the intensity of nutritional and vascular restrictions is unusual in human beings.

Two aspects, however, should be commented on. Biochemical and cellular changes found in rats with intense protein restriction and subsequent IUGR can be due to a decrease in primary fetal growth and/or caused by maternal nutritional deficiency. Since causative factors act early during the whole gestational period, symmetrical and harmonious growth restriction occur in both cases, that is, all organs are similarly affected. Differences in the intensity and course of injury would also explain moderate anthropomorphic variations between the two types of growth restriction.

Studies in humans are consistent with this interpretation. Naeye[283] reported significantly lower weights of brains from fetuses born after 33 weeks in a group of low maternal weight and poor weight gain during pregnancy as compared with a group of normal or high maternal weight and marked weight gain. By contrast, biochemical and cellular changes found in different organs in cases of IUGR derived from uteroplacental insufficiency are very similar to those described in rats undergoing ligation of the uterine artery. In these circumstances, in which the causative factor acts late in pregnancy beyond the hyperplastic stage of growth, IUGR is asymmetrical and disharmonious, and the brain is practically unaffected.

Differences in postnatal behavior between both groups are in agreement with this pathogenetic assumption. Campbell[284] found that the earlier fetal growth restriction occurred, the more affected were cephalometric parameters recorded during ultrasound scanning. At follow-up, a higher percentage of children had heights, head circumferences and weights below the 10th percentile throughout childhood as compared with normal children. When growth restriction began prior to week 26, not only was somatic growth impaired, but also in many cases intellectual development was affected, whereas in late IUGR with almost normal cephalometric profiles, postnatal somatic and intellectual development was usually normal.

120 Classification of intrauterine growth restriction

J. M. Carrera, B. Serra and P. Prats

Introduction

Several researchers who have investigated intrauterine growth restriction (IUGR) over the years have suggested a whole host of classifications for this phenomenon. Now, available data regarding the physiopathology of fetal growth and the etiopathogenesis of IUGR, and the modern methods for diagnosing it, are very different from those of 20 years ago. On the other hand, the terminology and classifications used in the past have caused confusion. For example, 'fetal size' has been confused with 'fetal growth', and 'intrauterine growth restriction' has been confused with small-for-gestational age birth weights.[1] The classification of fetuses with growth restriction therefore not only implicates an attempt to understand the etiopathogenesis of the process, but also, more specifically, a way of approaching each case and establishing the appropriate prognosis and obstetric management strategy.

Attempts to classify IUGR

The first classification of IUGR which was generally used was that proposed by Winick *et al.*[2–6] This group based their research on rats (vascular ligatures, restriction of nutrients, etc.) and reached the conclusion that there are two basic types of growth restriction: (a) intrinsic IUGR, principally derived from the fetus itself and (b) extrinsic IUGR, caused either by placental vascular insufficiency (asymmetrical IUGR) or by maternal protein restriction (symmetrical IUGR). Symmetrical IUGR seems to be caused by an impairment of cellular hyperplasia, whereas the asymmetrical one would be the result of an abnormal cellular hypertrophia. This classification was adopted with slight variations by the majority of English-speaking authors.[7,8]

Campbell *et al.*[9,10] proposed a classification based on the profile of the fetal biparietal diameter (BPD) curve. These authors distinguished between: (a) restrictions with an 'early low profile' in the cephalometric curve and (b) restrictions with a downturn or 'late flattening' of this curve. This classification, which was used by most ultrasonographists, was subsequently expanded by Levi *et al.*,[11–13] who also recognized the value of the head circumference/ abdominal circumference (HC/AC) index. IUGR was thus classified as: (a) harmonious (normal HC/AC ratio) or (b) disharmonious (HC > AC). Experience went on to show that harmonious IUGR was generally intrinsic with an early low cephalometric profile, and disharmonious IUGR was, in contrast, extrinsic and characterized by a late flattening of the BPD curve.

The majority of English-speaking specialists[14] went on to adopt the classification of symmetrical and asymmetrical IUGR, with some of them adding a third type called symmetrical IUGR with 'femur sparing', characterized by a femur length appropriate for the gestational age, but disproportionate to the rest of the biometrical parameters.[15]

Several classifications have been suggested for the neonate, based on its specific characteristics (presence or absence of malformations, corporal biometry, trophism, etc.). Rosso and Winick[16] established two groups: (a) with congenital malformations and (b) without congenital malformations; the latter was subdivided into type I (extrinsic symmetrical) and type II (extrinsic asymmetrical). In 1977, Sieroszewski[17] and Holtorff[18] proposed, independently of each other, two very similar classifications. The former divided fetuses that are small-for-gestational age (SGA) into hypoplastic and hypotrophic, and the latter grouped them as eutrophic (genetically small), hypoplastic, hypotrophic or with multiple congenital malformations.

In practice, most pediatric units classify growth restriction as (a) proportionate (symmetrical), or (b) disproportionate (asymmetrical), by simply calculating the ponderal index of Rohrer. This index is obtained by dividing the neonatal weight by the cube of the neonatal length (crown–heel) and then multiplying by 100. If this index is normal (=2.20), IUGR is

Table 120.1 Integrated classification of intrauterine growth restriction (IUGR) (from Carrera[26])

	IUGR		
Parameter	**Type I**	**Type II**	**Type III**
Biometry	Alterations in weight, length and head circumference	Alterations in weight	Alterations in weight and length
Etiology	Intrinsic	Pathological extrinsic	Deficient extrinsic
Onset	Early	Late	Semiearly
Morphology	Symmetrical harmonic	Asymmetrical disharmonic	Semiharmonic
Trophism	Eutrophic	Undernourished dystrophic	Malnourished hypotrophic

symmetrical, and if it proves to be abnormally low, IUGR is considered asymmetrical.[19–23]

On behalf of the evolution of fetal growth over time, Salvadori[24] identified three theoretical types of restriction: (a) 'primary', or constant throughout gestation; (b) 'secondary', which may be early or late depending on the moment in which the factor that causes the growth restriction begins to affect the fetus and (c) 'transitory', when recovery occurs after a deceleration in fetal growth.

Gruenwald[25] and other authors have classified growth restriction as either slight, moderate or serious/severe according to the severity of the syndrome.

Integrated classification of IUGR

We first proposed this classification in 1976,[26–37] taking into account all basic features of growth restriction: onset (early or late), etiology (intrinsic, abnormal), anthropometry of the neonate (weight, length and HC), general morphology (harmonious, disharmonious or semiharmonious) and trophism (eutrophic, hypotrophic, dystrophic) (see Table 120.1). Depending on these characteristics, we differentiate three types of growth restriction: type I: intrinsic–harmonious; type II: extrinsic–disharmonious and type III: extrinsic–semiharmonious.

Type I: intrinsic–harmonious

This type is also known as 'symmetrical' or 'early'. The noxa still acts from the beginning of gestation, or at least since the embryonic phase. Due to this precocity, all three parameters usually assessed to judge fetal growth are affected: weight, length and HC. There are references in the literature to microsomatic and hypoplastic fetuses, and also to fetal hypogrowth.

The most outstanding characteristics of this group are:

(1) Neonates do not have a dystrophic appearance and their bodies are well-proportioned;
(2) There is normally no fetal hypoxia;
(3) Metabolic insufficiency is not intense and
(4) The placenta is small and usually histologically normal except in cases of infectious embryopathy.

There are basically three causes:

(1) Genetic or chromosomic causes, that include three possibilities: genetically small but 'normal' fetuses; fetuses with chromosomic alterations (e.g. trisomies) and malformed fetuses;
(2) Infectious causes: viral embryopathies (particularly rubella and cytomegalovirus), toxoplasmosis, etc. and
(3) Toxic causes or ionizing radiations, which are very uncommon.

These fetuses present some characteristics that can be identified prenatally by ultrasound:

(1) Growth restriction is early;
(2) Growth pattern is symmetrical and
(3) There are usually no signs of fetal hypoxia (Doppler studies are normal).

Neonates have sharply defined characteristics, which enable to establish the diagnosis of intrinsic IUGR at birth (Figure 120.1):

(1) Eutrophic appearance;
(2) Harmonious and well-proportioned development;
(3) HC corresponds to weight at birth, but not to gestational age;
(4) Differentiation and maturity of the organs corresponds to gestational age;
(5) The number of cells of the different organs is low (hypoplasia);
(6) Nearly 50% of the cases have serious alterations or congenital malformations, which make life difficult. The prospects for cerebral evolution are very bleak (small cerebral weight, incomplete neuronal capacity, delay in myelinization). Apart from the group of 'normal' neonates, which should be considered as a variant of normality, postnatal development is usually bad.

Figure 120.1 Small-for-gestational age neonate who has experienced type I intrauterine growth restriction.

From the pathogenic point of view, the primary growth potential of the fetus is inhibited or modified in these cases by the above-mentioned factors, which produce a decrease in the rate of the use of nutrients per weight unit and a permanent reduction in the number of cells (hypoplasia), by acting on the fetal metabolism and the organogenic process. Even if there is an adequate maternal diet and a satisfactory placental transfer of nutrients, the fetus is, under these circumstances, incapable of taking complete advantage of them, and this logically results in an alteration or restriction of its growth.

Type II: extrinsic–disharmonious

This type is also known as 'asymmetrical', 'late' or 'placental'. As the related factors only occur in the last trimester, only the weight is affected, while the length and HC remain normal or near normal. Its pathogeny is similar to those of IUGR produced artificially in rats by vascular deprivation (failure of nutritive supply).[38]

There are also references in the literature to prenatal dystrophy, fetoplacentary malfunctioning, preterm hypermaturity, chronic fetal distress, prenatal immaturity and placentary insufficiency.

The characteristics of this group are:

(1) Dystrophic or hypermature appearance;
(2) There is usually fetal hypoxia;
(3) The metabolic insufficiency is constant and
(4) The placenta is pathological but not small, and has an almost normal DNA content.

The basic cause lies in an insufficiency of the malfunctioning placenta determined by:

(1) A deficit in uterine perfusion or
(2) A deficit in the vascular surface area (alteration in the villous microcirculation).

Some factors are usually considered enhancing (advanced age of mother, uterine circulatory disorders, anomalies in placental insertion), while others are considered determining (pre-eclampsia, high blood pressure, diabetes, postmaturity). These factors do not usually come into play until the rapidly developing fetus needs the placental reserves (weeks 35–36). If there is a failure in the 'supply line' at this point,[39] the weight curve declines and the fetus becomes more vulnerable. Fetuses generally exhibit the following characteristics:

(1) Late growth restriction;
(2) Asymmetrical growth pattern and
(3) There are usually signs of hypoxia or fetal distress.

Neonates with extrinsic IUGR reveal the following characteristics (Figure 120.2):

(1) Dystrophic appearance; they seem to have lost weight and have an excess of skin;
(2) Disharmonious, disproportionate development;
(3) HC and length correspond better to gestational age than to weight;
(4) The number of cells in their organs is normal, although the cellular mass is reduced (especially in the liver);
(5) They frequently develop postnatal hypoglucemias and
(6) A considerable proportion suffer from neurological disorders caused by perinatal hypoxia.

Type III: extrinsic–semiharmonious or extrinsic symmetrical

This type is somewhat mixed compared with the previous two types; while the operative factor is extrinsic (malnutrition or maternal nutrient deficiency) its consequences resemble those of an intrinsic IUGR, since the noxa is usually active throughout the gestation.

The characteristics of this group are:

(1) Harmonious but undernourished appearance;
(2) Constant metabolic insufficiency;

Figure 120.2 Small-for-gestational age neonate who has experienced type II intrauterine growth restriction.

Figure 120.3 Small-for-gestational age neonate who has experienced type III intrauterine growth restriction.

(3) Respiratory insufficiency is uncommon and
(4) A small placenta, with few morphological anomalies, but with clear biochemical changes (DNA reduction).

The cause lies in a severe alteration in maternal nutrition, due to the lack of particularly important factors, such as folic acid, amino acids or other nutrients.

Babies delivered by ill-nourished mothers have been the subject of extensive anthropomorphic, biochemical and cellular studies, which have shown that (Figure 120.3):

(1) Weight, length and HC are reduced, although the reduction in the latter seems less than in intrinsic symmetrical IUGR;
(2) Although all organs are smaller, some of them, specially the liver and the spleen, are particularly small;
(3) Both the number (15–20%) and individual volume of the cells are reduced and
(4) If malnutrition continues postnatally during the cellular division period, the reduction in the number of brain cells can reach up to 60%.[6]

The pathogenesis of this group has been described in detail elsewhere in this chapter.

Factors leading to a modification of the classification

The information that has emerged in recent years has made certain modifications necessary, particularly in the characterization of type I IUGR.

Biometrical studies on SGA neonates with associated congenital defects (chromosomopathies or malformations) observed that these fetuses frequently present an asymmetrical pattern instead of an symmetrical one. Several pediatric studies have shown that a high proportion of malformed neonates and virtually all of those with chromosomopathies associated with growth restriction have a disproportionate disharmonious morphology, so that we include them in the group of asymmetrical growth restriction[19,21,23] and not in that of symmetrical growth restriction.[40] According to several authors, fetuses with symmetrical and asymmetrical IUGR show similar rates of congenital defects[41,42] and a similar degree of acid–base

impairment.[43] The ponderal index of Rohrer is abnormally low in the majority of cases. However, necropsic studies on trisomic fetuses (particularly trisomies 18 and 21) reveal a significant reduction in the size and weight of the majority of organs and viscera, apart from the spleen,[44] even after making the appropriate correction for weight.[45] The exception is trisomy 13, where the weight and size of organs are normal.[46] Regarding malformed fetuses, growth restriction may have three origins:[47] (a) the nature of the malformation itself (e.g. cardiopathy) determines the growth restriction by means of hemodynamic alterations;[48] (b) the restriction creates circumstances suiting the emergence of the malformation (early growth restriction represents a state of heightened susceptibility to malformations[49] and (c) the growth restriction and the malformation are the consequence of a common etiological factor (e.g. prenatal infections such as rubella and cytomegalovirus).[48]

A decrease in umbilical perfusion has been observed in a significant proportion of IUGR fetuses with associated congenital defects (chromosomopathies and major malformations). The absence of fetal hypoxia in a type I IUGR is therefore not always true. Several researchers[50–57] have observed a pathological increase in umbilical artery resistance indexes, which could not, however, be confirmed in the uteroplacental arteries. It is still not well known why this increase in umbilical resistance, which in many cases will finally cause an asymmetrical growth restriction, appears in fetuses with congenital defects. There are, at least in theory, two possible explanations: (a) there is a process that obliterates the arteries of the placental tertiary villi,[51] secondary to a thromboembolic or angiospastic phenomenon mediated by the fetus and (b) the placental maturing process does not occur or is delayed, with the logical consequence of placental immaturity.[58] In both cases, there could be a secondary effect on the potential for fetal growth.

A significant number of fetuses with early intrinsic growth restriction and congenital defects present biochemical signs of hypoxia or acidemia. The chance to obtain fetal blood by means of funiculocentesis[59] has enabled us to assess different biochemical parameters (oxygenation, acid–base balance), which give us information on the real state of the fetus.[60] These studies have confirmed that fetuses with late extrinsic IUGR often present hypoxia and acidemia,[61–64] but also that a significant number of fetuses with early restriction, especially those with concomitant congenital defects, present biochemical parameters compatible with chronic hypoxia and even with episodes of severe hypoxia.[65] On the other hand, the mean body weight and degree of karyocytosis is higher in fetuses with triploidies than in SGA fetuses that are chromosomically normal. This makes us think that there is a general delay in hematological maturation in triploidies.[65]

Anatomopathological studies of placentas in trisomic fetuses are both histologically and functionally abnormal,[45,66–68] with a reduced vascular capacity in the tertiary villi,[67] which probably accounts for the decrease in the umbilical conduction indexes and the frequent episodes of distress observed in this type of fetuses.

Early defects in circulatory adaptation can give rise to highly precocious growth restrictions, the majority of which end in pregnancy interruptions. There is increasing evidence that poor pregestational circulatory preparation, with or without uterine vascular deficits, can cause repeated abortions, with associated growth restriction.[69] An inadequate vascular backup, either anatomically or functionally, prevents an adequate implantation, and so a defective circulatory anchorage is established. This 'poor maternal circulatory adaptation' can also have an immunological cause.[70]

Cytogenetic studies of placentas of apparently idiopathic growth restrictions reveal the presence of mosaicisms restricted to the placenta.[71]

Fetuses affected by an infectious embryopathy (rubella, cytomegalovirus) develop a mixed IUGR type.

Echographic follow-ups on some very early onset restrictions demonstrate that some fetuses with a symmetrical morphology during the first half of gestation go on to develop a clearly asymmetrical IUGR. Most of these fetuses are carriers of a congenital defect. In the past, early restrictions with congenital defects were classified as morphologically symmetrical IUGR;[29,32,33,40,72] only in recent years several researchers have refuted this view.[45,65,73] Our opinion, which is endorsed by Droste,[45] is that these cases are probably symmetrical growth restrictions with a superimposed asymmetrical IUGR. An asymmetrical IUGR, accompanied by histological and functional placental alterations, with a reduction in umbilical–placental perfusion and eventual fetal hypoxia, can thus be found in many congenital defects, whether fetal (chromosomopathies, major malformations), and/or placental (mosaicisms restricted to the placenta). However, we should probably not consider it a primary asymmetrical growth restriction, but rather a secondary asymmetrical IUGR, added or superimposed on a symmetrical IUGR due to a reduction of the intrinsic growth potential. This could explain why early echographic studies on these fetuses generally reveal a generalized delay in symmetrical growth, with the asymmetrical or disharmonious nature of fetal growth only becoming apparent later on.

For all these reasons, in recent years we have abandoned classifications based on rigid anthropometric criteria and have adopted another one that strikes us as more useful in practice and pays special attention to the etiopathogenic features of the process.

Modified integrated classification

Considering the large amount of new morphological (cytogenetic and anthropometric), echographic (biometric and Doppler studies) and hematologic (oxygenation, acid–base balance) data obtained by research, we should now adopt the following classification (Table 120.2).

Table 120.2 Modified integrated classification of intrauterine growth restriction (IUGR) (from Carrera and Serra[37])

Type I IUGR	Type II IUGR	Type III IUGR
'Normal' SGA oligohydramnios	Without embryopathies	Infectious
SGA with congenital defects	With oligohydramnios	Toxic embryopathies

SGA, small-for-gestational age

Type I IUGR

This growth restriction is brought on by a reduction in the intrinsic growth potential. The causal agent or agents act during the blastemic and/or embryonic stages. Two subtypes must be distinguished.

Normal small neonates

These neonates are characterized by early reduction in fetal growth (that could be assessed before weeks 30–32), accompanied by harmonious (symmetrical or proportionate) fetal growth and a normal trophism. The well-proportioned fetus presents a HC that corresponds to the weight at birth but not to the gestational age. These neonates are absolutely normal, apart from their delayed growth (maximum 2–3 weeks), and do not show any of the neonatal complications normally associated with IUGR. This condition must be considered as a normality variant due to a genetically low growth potential, which may run in the family.[74]

Neonates with congenital anomalies

These neonates show a very early (or ultraearly) reduction in embryonic or fetal growth with a progressively disharmonious morphology. All these cases present congenital anomalies, either chromosomic or genetic. The delayed growth can always be diagnosed before 22 weeks of gestation, but the fetal corporal asymmetry becomes more apparent as pregnancy advances. A significant number of these gestations abort. The surviving fetuses present a considerable number of deficits as a consequence of the frequent reduction in the number of brain cells.[74] At least 25% of fetuses with severe early growth restriction, which can be diagnosed with echography, are aneuploid.[73]

Type II IUGR

This is defined as delayed growth resulting from an alteration in the supply line, clinically apparent at a late stage (from 30 to 32 weeks), generally through an asymmetrical and disharmonious development of the fetus. It represents 55–75% of all growth restrictions.[9] In fact, the only confirmed reduction in weight in most of these neonates is biometrically restricted to the trunk. Length and HC correspond both more to the gestational age than to the weight. Fetuses have a markedly dystrophic appearance. The number of cells of the different organs is generally normal, although the cellular mass is reduced (especially in the liver), and a reduction in functional elements is sometimes appreciable in some organs. A substantial reduction in the number of nephrons has been demonstrated when the neonate is below the third percentile, and this could not be compensated postnatally.[75] It seems that this type of restriction could cause some pathological processes in adult life, such as cardiovascular diseases,[76] diabetes,[77–81] altered time of onset of puberty,[82] reduced size of the uterus,[83] delayed follicular development,[84] earlier menopause,[85] obesity,[86,87] arterial stiffness[88] and abnormal retinal vascular morphology.[89] This association could be explained with Barker's theory: intrauterine malnutrition leads to a reduction of energy destined to growth in order to allow survival and development of vital organs as the brain. If the availability of nutrients is insufficient to determine critical moments of fetal life, this could lead to an impaired development of the endocrine system and its posterior function.

Even when the data in the literature are contradictory, there seems to be a statistically significant association between the degree of hypoxemia and fetal acidemia and the data obtained by Doppler velocimetry from umbilical, aortic, common carotid and mean cerebral readings.[90–94]

Some authors, given that the velocimetrical data are inherently uncertain for determining the degree of asphyxia, perform a funiculocentesis when the fluxometrical study suggests a centralization of the flow.[95]

Three basic types of clinical–pathogenic processes are accepted in this group:

(1) Chronic hypoxia, particularly as a result of cardiorespiratory diseases, which may induce, on a permanent basis, a low partial saturation of oxygen in the blood of the uterine artery.
(2) Maternal malnutrition, which can be due to maternal undernourishment (rare in our society) or an unbalanced maternal diet (sometimes associated with smoking). IUGR can also be caused by maternal hyperinsulinism, with an exaggerated postprandial anabolism and a dispersal of nutrients to the maternal reserves and away from the fetus. This is the so-called 'selfish mother' hypothesis of Frydman *et al.*[96] All pregnant women with baseline or postprandial hypoglucemias are suspects for this group.
(3) Uteroplacental vascular insufficiency, whether through a deficit in uterine perfusion or through a deficit in the vascular exchange surface area, due generally to an insufficient villous microcirculation.

Clinically, it is useful to classify two subgroups.

Table 120.3 Frequency of the three types of intrauterine growth restriction (IUGR) in case histories (from Carrera and Serra[37])

Type of IUGR	Frequency (%)
I	19.7
II	53.9
III	9.2
Non-classified	17.1

Type II IUGR without oligohydramnios

It is to be supposed, in these cases, that the fetal hypoxia is still moderate, since the extreme mechanisms of fetal adaptation have still not been established.

Type II IUGR with oligohydramnios

The gestation must be closely watched in these cases, since there is a fetal adaptation mechanism, which can lead to an acute decompensation.

In the past, it was thought that this kind of IUGR fetuses have an accelerated maturation due to intrauterine stress. This would make them more resistant to neonatal respiratory distress, especially if they were prematurely delivered. But Bernstein[97] has shown that this is not true. He compared the rate of respiratory distress, intraventricular hemorrhage and neonatal mortality between type II IUGR fetuses and controls of the same gestational age, and he found that all these complications were more frequent in the growth-restricted fetuses, independent of the prenatal administration of corticosteroids. Other authors have recently confirmed this observation.[98]

Type III IUGR

This is characterized by delayed growth due to mixed mechanisms, which generally act during a relatively early phase of gestation. For this reason, the fetus usually presents a semiharmonious growth with a hypotrophic appearance. Many fetuses present specific alterations related to the noxa that has produced the growth restriction. The Doppler study is generally normal, and there are no alterations in the hemodynamic parameters of fetal asphyxia. From the etiopathogenic point of view, two types can be identified:

(1) *Infectious embryopathies*: the cause usually lies in rubella, cytomegalovirus or toxoplasmosis infections.
(2) *Toxic embryopathies*: caused by medication, drugs or toxins, although it is not always possible to identify the origin.

In our recent case histories, the distribution of the different types of IUGR is as follows: 19.7% type I, 53.9% type II, 9.2% type III and 17.1% of cases that we have been unable to classify for lack of consistent data (Table 120.3).

121 Natural history of fetal compromise in intrauterine growth retardation

J. M. Carrera, C. Comas, M. Torrents, A. Muñoz, C. Mortera and B. Serra

There are a number of causes of fetal compromise in intrauterine growth retardation (IUGR), ranging from inadequate uteroplacental perfusion to compression of the umbilical cord due to oligohydramnios, insufficient placental microcirculation or a deterioration in maternal oxygenation. These phenomena can occur singly or in combination, and sooner or later they lead to hypoxemia, which triggers the fetal defense mechanisms designed to limit as far as possible the extent of asphyxia and, above all, to avoid brain damage and fetal death – sometimes, regrettably, to no avail.

Some of these mechanisms are hemodynamic, and aim to adapt the fetal circulation to the changed circumstances, but others are biochemical and seek to supply energy to the fetus under anaerobic conditions, and reduce its need for oxygen. A healthy fetus is equipped with a significant number of mechanisms and strategies for reducing the impact of asphyxia. Severe and possibly irreversible damage occurs only when the gravity of the anoxia exceeds the system's capacity to maintain the cellular mechanism within acceptable limits in specially vulnerable organs, such as the brain or the heart. On the other hand, fetal responses against such asphyxic aggression are not uniform. While some fetuses or neonates emerge neurologically undamaged from an episode of asphyxia, others acquire serious neurological and mental deficits. It goes without saying that the circumstances prior to the asphyxic accident must be evaluated with sufficient attention to explain why some are more vulnerable than others. It is therefore a mistake to consider that perinatal asphyxia causes brain damage and/or cerebral palsy in every case.[1–3]

However, although the incidence of hypoxic encephalopathy as a result of IUGR has declined considerably as a consequence of obstetric practice, which places an even greater emphasis on the interests of the fetus, it cannot by any means be considered a thing of the past. It is true that the great obstetric traumas generated by brain damage have practically disappeared, and many encephalopathies are now recognized as being secondary to genetic, infectious or metabolic processes unrelated to asphyxia, but even so a certain number of handicaps clearly do have this origin. The cerebral palsy rate in neonates at term is still 1–2 per 1000 in industrial countries.[1] According to the calculations of the American Academy of Pediatrics and the American Association of Obstetricians and Gynecologists,[4] at least 10% of these are associated with perinatal asphyxia.[5] Finally, prolonged follow-up studies[6] warn that neonates with hypoxic encephalopathy who survive the postnatal period show handicap figures at the age of 8 years between 15% and 18%, depending on whether the hypoxic encephalopathy is moderate or severe.

All this indicates the importance of studying the biophysical and biochemical mechanisms of fetal compromise and, if possible, establishing markers that allow us to identify cases of growth retardation with a poor neurological prognosis.

We shall distinguish between, on the one hand, the possibility of performing hemodynamic studies (with the use of Doppler technology) in those cases with a physiopathology primarily based on uteroplacental deterioration, and, on the other hand, fetal defensive biochemical mechanisms against hypoxia and their intrauterine study.

Hemodynamic study of fetal deterioration

The reduction in the number of functional arterioles in the tertiary villi, through the mechanisms already described in the explanation of the pathogenesis of IUGR, progressively increases the circulatory resistance in the umbilical artery, and gives rise to a

decrease in the pO_2 in the umbilical vein. Both these events set into motion a phenomenon of circulatory redistribution principally characterized by the centralization of blood flow. The better-oxygenated blood goes toward the most vital organs (brain, heart, adrenals), while vasoconstriction limits the blood's arrival at the organs considered less indispensable (digestive system, lungs, skin, skeleton, etc.).

The redistribution or centralization of blood flow has been studied in animal experimentation by various researchers,[7–9] and the above-mentioned mechanical pattern has been confirmed. However, it should be stressed that when fetal hypoxemia was induced by maternal hypoxemia, not only was there an increase in cardiac and cerebral perfusion, but there was also a significant increase in the umbilical blood flow, and this was not the case when the fetal asphyxia originated from microembolization of the umbilical arteries, thus creating conditions similar to those of a human fetus with a placental lesion.[10,11]

Thanks to the Doppler technique, it is possible to recognize four periods with relatively well-defined hemodynamic, biophysical and biochemical patterns. These are (1) a silent period of increase in resistance; (2) a period with reduction in umbilical blood flow; (3) a period with centralization of the blood flow and (4) a period with decentralization of blood flow.

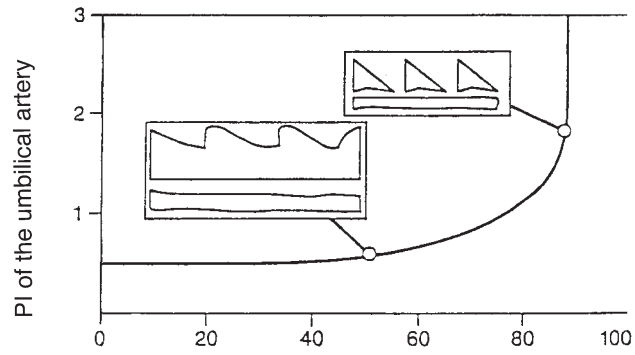

Figure 121.1 Trudinger's mathematical model,[12] relating the morphology of the flow velocity waveform of the umbilical artery (Doppler) with the resistance in the villous arteriolar system (percentage of obstructed villous arterioles). PI, pulsatility index.

Silent period of increase in resistance

Pathophysiological basis

The progressive deterioration of the villous microcirculation is reflected in the Doppler study of the umbilical artery, when the functional obstruction reaches 50% of the villous arteriolar system, and significantly modifies the pulsatility index (PI)[12] (Figure 121.1).

Before this percentage is reached, the capacity of the placental reserves covers the theoretical deficit of gaseous exchange, provided the maternal supply line remains satisfactory.[13]

Doppler hemodynamic profile

The hemodynamic profile is completely normal over a certain period (generally 3–6 weeks), and there is no pathology of any kind. The flow velocity waveform (FVW) of the umbilical artery is normal (positive blood flow over the whole cardiac cycle, with normal PIs, resistance or conductancy.[14,15] Doppler studies on the remaining vessels (aorta, common carotid and middle cerebral arteries) also prove normal. We can therefore speak of a 'normal hemodynamic pattern'.

In a Doppler study we carried out on 82 cases of growth retardation confirmed at birth, we demonstrated that 36 of them (43.9%) had a normal umbilical PI; the study of the remaining fetal vessels proved normal in all these cases (Table 121.1). For this reason, we consider it unnecessary in practice to widen the hemodynamic study of the fetus when the umbilical FVW is normal.

Biophysical correlation

Both the cardiotocography and the remaining parameters of the biophysical profile are normal.

Biochemical correlation

The study of fetal blood gases by funiculocentesis is normal. According to the limits of our current experience, such an exploration is therefore not justified when the Doppler study is normal.

Obstetric outcome

The perinatal mortality rate is not increased.

Reduction in umbilical blood flow

This is the first objective sign of the start of chronic fetal distress brought on by the placental lesion.

Pathophysiological basis

It has been demonstrated that the functional obstruction of over 50% of the villous arterioles is translated into a clear deterioration of the umbilical FVW[6] (Figure 121.1).

Although some studies claim that the umbilical artery is not always the first vessel affected,[16] in our experience and in that of other authors,[17,18] an increase in umbilical resistance is usually the first observable hemodynamic signal when there is a placental lesion affecting the villous microcirculation. In 15–20% of fetuses with growth retardation with a placental cause, the abrupt decrease in pO_2 can give rise, through the aortic and carotid chemoreceptors, to an increase in the aortic and/or cerebral PI, which exceeds and/or precedes those observed in the umbilical artery. On the other hand, it is also possible to observe pathological values of the aortic or cerebral PI before an alteration in umbilical perfusion, when the cause of fetal distress does not reside in the placenta but in a disorder in the mother's internal medium (hypoxemia through maternal cardiorespiratory pathology, an acute deficit of specific nutrients, severe anemia, etc.), or in her hemodynamics

Table 121.1 Cases of intrauterine growth retardation, grouped into four groups according to the pulsatility index (PI) results in the umbilical artery and the fetal hemodynamic profile (FHP); thoracic aorta PI, common carotid artery PI and middle cerebral artery PI. The pH of the umbilical vein was measured at birth

		Cases		Perinatal mortality		pH < 7.20	
Group	Association	*n*	%	*n*	%	*n*	%
I	Normal umbilical PI + normal FHP	36	43.9	0	0.0	6	16.6
II	Normal umbilical PI + abnormal FHP	0	0.0	—	—	—	—
III	Abnormal umbilical PI + normal FHP	22	26.8	0	0.0	8	36.3
IV	Abnormal umbilical PI + abnormal FHP	24	29.2	6	25.0	15	62.5
Total		82	100.0	6	7.3	29	35.3

(e.g. hypertensive crises with a renal or endocrine origin). Even in these cases, umbilical conductance may be increased.

Alternatively, there is irrefutable experimental evidence that a placental lesion is followed by a decrease in umbilical arterial perfusion. Morrow *et al.*[10,11] working with fetal sheep subjected to an embolism of the villous microcirculation (plastic micropistons 50 μm in diameter), observed gradual changes in the FVW of the umbilical artery similar to those described in human fetuses subjected to growth retardation through villous pathology (reduction in end-diastolic blood flow, zero diastole and, finally, reverse blood flow). The cause, therefore, of the deterioration of the umbilical FVW lies in the increase in microvillous vascular resistance, which while primarily inducing a deficit in the perfusion in the umbilical artery, is also the reason for a progressive decrease in the pO_2 in the umbilical vein. Hypoxemia is thus the result and not the cause of the hemodynamic umbilical–placental alteration. This is why a reduction in pO_2 without any placental lesion does not give rise to any change in the umbilical FVW,[10,11,19,20] and neither does this change occur through an increase in hematic viscosity or a rise in maternal blood pressure.[10,11]

Doppler hemodynamic profile

A moderate increase in umbilical resistance is the only finding capable of revealing the onset of chronic fetal distress for a specific period of time, the duration of which largely depends on how quickly the placental lesion takes effect. During this period, the Doppler study of the rest of the fetal circulatory system, including the aorta, is usually normal. In our experience 56% of fetuses with growth retardation presented an altered umbilical PI, but of these only 52% were accompanied by a pathological hemodynamic pattern.

The umbilical FVW presents positive flow velocities throughout the entire cardiac cycle, but the pulsatility (or conductance) indices reveal values outside the accepted limits for the gestation.

The only compensatory hemodynamic process that can be observed at this time, with the use, in particular, of color Doppler, is the reopening of the ductus venosus, the caliber of which is physiologically reduced at the end of the second trimester. This mechanism makes it possible to extract a significant amount of blood from the fetal liver, and this goes directly to the heart. This 'shunt' can delay by some weeks the need for a centralization of the blood flow, but induces the appearance of typical asymmetric growth retardation.[18]

In the cerebral circulation, it is also possible to confirm, in some cases, the existence of a decrease in the PI of the M_2 sector of the middle cerebral artery, with the M_1/M_2 index passing from below 1 (normal) to over 1 (pathological). This occurrence, secondary to the selective vasodilatation of that arterial tract, which can be considered as the subcortical sector of the artery, represents a preservation mechanism for specific areas in the brain, and precedes the authentic brain-sparing effect.

The objective of these two compensatory mechanisms is to delay as far as possible the stimulation of the aortic and carotid chemoreceptors, which will set in motion the centralization of flow.

Biophysical correlation

All the parameters of the biophysical profile, including the cardiotocographic study, are normal, as are the results of 'vibroacoustic stimulation' (VAS) tests and even the stress tests (test of strength, oxytocin test, etc.). This is because these variables are affected only when hypoxia of the fetal brain and/or heart occurs.

Biochemical correlation

The fetus is normally in normoxia. In our experience, it is not necessary to carry out diagnostic funiculocentesis

in this phase if there is confirmation that centralization of the blood flow has not begun.

Obstetric outcome

There were no fetal deaths in our statistics for this group but there was a significant increase in the percentage of small-for-dates neonates. For this reason, the percentage of neonates with pH below 7.20 reached 38%. In fact, the percentage of intrapartum fetal distresses tripled, proof of a greater fetal vulnerability. The cesarean rate rose to 30–40%.

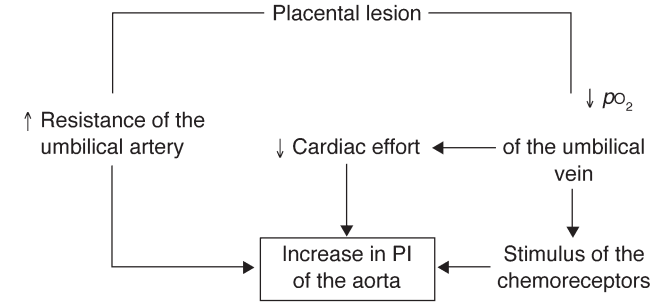

Figure 121.2 Outline of the mechanisms that influence the pulsatility index (PI) in the aorta after the placental lesion.

Centralization of blood flow

Pathophysiological basis

As the resistance in the umbilical arterial system increases, there is also a corresponding decrease in the pO_2 in the umbilical vein. This means that the fetus must carry out, in addition to a reopening of the ductus venosus, a redistribution of its blood flow once a specific pO_2 value has been reached, in order to protect its most important structures from hypoxia. As we have already explained, this redistribution consists of a circulatory centralization with selective vasodilatation of certain organs, such as the brain, the heart and the adrenals, and a vasoconstriction of other sites such as the lung, the intestine, the skin, the kidney or the skeleton. This redistribution can be seen with Doppler, which records a successive increase in the PI of the aorta and the renal artery, and a decreased PI in the common carotid artery and the intracranial vessels.

These changes in the perfusion of the various organs are primarily mediated by neuronal stimulation, whether directly by stimulation of the vagal center or through the aortic and carotid chemoreceptors. In 1969, Dawes *et al.*[21] confirmed that the aortic chemoreceptors in sheep respond to small reductions in arterial oxygen levels. However, it is very probable that these vasoconstriction phenomena are modulated by other factors, such as, for example, the direct effect of hypoxemia and acidemia on certain tissues through liberating vasoactive substances, secretion of catecholamines, or an overall increase in the activity of the autonomic nervous system.

Although the chronological pattern is not well established, it seems that the first vessel to be affected after the umbilical artery is the aorta. The increase in resistance in the descending thoracic aorta is the result of the combined action of several factors: an increase in umbilical–placental resistance, arterial vasoconstriction resulting in progressive hypoxemia and, finally, a decrease in myocardial contractility.[22] Lingman *et al.*[23] postulate an inverse relationship between myocardial contractility and the aortic and umbilical PI (Figure 121.2).

Doppler hemodynamic profile

Doppler study reveals an increase in PI, not only in the umbilical artery but also in the descending thoracic aorta and its branches, such as the renal artery.[24–28] There is a progressive loss of end-diastolic velocity in both vessels when the resistance reaches a certain level. At the same time, there is a noticeable decrease in the PI of the cerebral and common carotid arteries, evidence of a further vasodilatation process.

In our previously mentioned study, of the 82 cases of IUGR studied, 46 (56.1%) presented a pathological umbilical PI, 52% of the fetuses also had an abnormal increase in the PI of the thoracic aorta and 41.1% presented a further decrease in resistance in the common carotid and/or middle cerebral arteries.

It is often possible to recognize three phases in the centralization of blood flow.

Initial phase. The PI in the umbilical artery is high, but there are still positive values in the Doppler frequencies throughout the whole cardiac cycle, even in telediastole.

On the other hand, the FVW of the common carotid artery, which has no end-diastolic frequencies until weeks 32–34,[29] recovers its end-diastolic flow shortly after a proven moderate increase in intracranial perfusion. This suggests that the fall in the PI of the common carotid artery is due to the reduction in the resistance of the cerebral vessels.

The study of the umbilical PI/middle cerebral PI (U/C) relationship can prove particularly helpful in making a definitive assessment of centralization at this stage. Several authors[17,30,31] maintain that this is the best fluxometric index for tracing IUGR.

Advanced phase. The umbilical FVW shows zero diastole. The first to disappear were the telediastolic frequencies, but afterward the lack of blood flow affected the whole diastole. According to Trudinger,[12] this situation occurs when an 80% obstruction in the villous arteriolar system has been attained. The FVW of the aorta also loses its end-diastolic values.

In conjunction with this deterioration in the umbilical blood flow, the vasodilatation of the cerebral vessels arrives at its maximum point, which means that the PI of both the common carotid and the middle cerebral arteries attain their lowest values.

Terminal phase. In addition to an absence of end-diastolic flow, there is the onset of a reverse flow, both in the umbilical artery and in the aorta, and this obviously aggravates the prognosis. As well as the arterial hemodynamic findings already described, there are signs in this phase of cardiac insufficiency, revealed by Doppler study of the fetal venous circulation through a decrease both in the velocity peaks in the exit tracts and in the ventricular ejection force, and through a possible visualization of the coronary blood flow.[32]

As regards the venous return circulation, there are three signals:

(1) Raised reverse blood flow in the inferior vena cava, coinciding with auricular contraction. This finding, which reveals difficulties in the blood flow through the right atrium, can be due both to alterations in the fetal cardiac frequency and to deficient auricular contractility.[33–35] The reverse flow can reach up to 30% of the total blood flow (under normal conditions this does not exceed 10%).
(2) Reduction in the telediastolic velocity values in the ductus venosus (in the notch that reflects the auricular contraction). This reduction can lead to an inversion of the blood flow. This would be secondary not only to the increase in telediastolic volume determined by the increase in the peripheral resistance, but also to the reduction in the capacity for myocardial response.
(3) 'Venous' pulsation in the umbilical vein, with an apparent cyclical decrease in the venous flow, coinciding with the zero diastole of the umbilical artery.

As regards the exit blood flows, there have been reports of their progressive deterioration in this phase, with a clear reduction in their velocity peaks and decreased cardiac output.[36] The most recent observation in this respect is probably the reduction in the values of the so-called 'ventricular ejection force' (VEF).[37]

It has been demonstrated that the VEF values of both the right and the left ventricles are similar and increase throughout gestation in fetuses with normal growth. In contrast, there is a significant decrease in both ventricles, below the fifth percentile of the normality curves, in the terminal phase of the centralization of the blood flow.[37] Furthermore, there is an excellent correlation between the VEF values and the severity of the acidosis registered by funiculocentesis. It can therefore be stated that this hemodynamic finding is significantly related to a serious fetal compromise.

The visualization of the coronary blood flow, in the context of a severe uteroplacental insufficiency, must be interpreted as a very serious sign of fetal distress, probably *pre mortem*. The phenomenon is particularly visible in the diastole.

The coronary vasodilation, which makes it possible, can be the result of three different types of mechanism: (a) an attempt at compensation provoked by low myocardial oxygen pressure; (b) loss of myocardial contraction force, which causes a reduction in the pressure on the coronary arteries (especially during the diastole) and (c) decrease in the velocity of the intracardial blood flows, with the same result as in (b).

The first autoregulating mechanism described could be called a heart-sparing effect, and this has been studied in detail.[32]

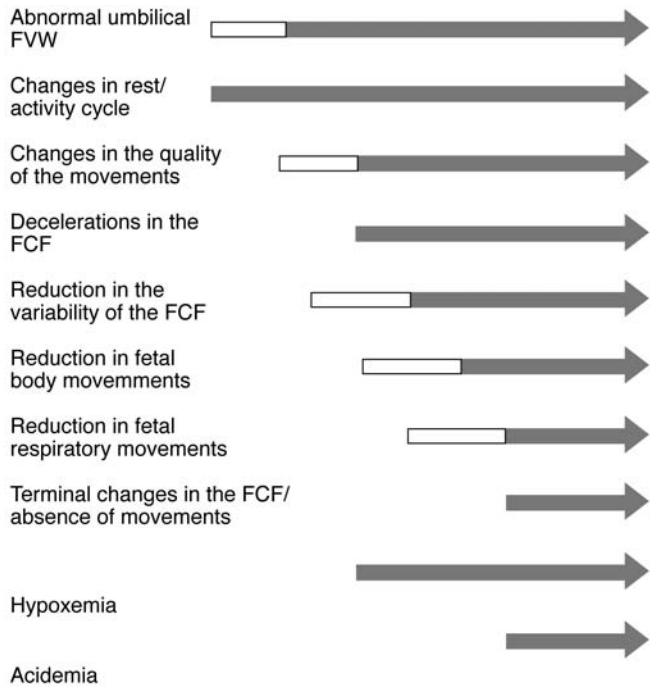

Figure 121.3 Chronological correlation (represented by the different lengths of the arrows) of the biophysical signs of fetal deterioration. The open parts of the arrows represent the silent phase whereas the hatched parts represent the detection phase. FVW, flow velocity waveforms; FCF, fetal cardiac frequency.

Biophysical correlation

In the initial phase of centralization, the cardiotocographic readings can still apparently be normal and Manning's biophysical profile proves to be unaltered or doubtful (5–7 points).

The biophysical parameters affected most early on are concerned with behavior: changes in the cyclical periods of rest/activity[38] and a decrease in multiple rolling movements (Figure 121.3).

Although there is an increase in the pathological results of the biophysical stress tests with respect to the previous stage, we have not been able to establish whether their comparative percentages are significantly different statistically.

However, in the advanced phase there is a progressive deterioration in the fetal cardiac frequency register and late decelerations appear. The time lapse from the pathological quality of the umbilical PI until the appearance of late decelerations in the register has been evaluated as between 9 and 60 days,[39,40] with a mean of 2–3 weeks.[41–43] Echographically, on the other hand, there is an ostensible decrease in fetal movements

(somatic and respiratory) and in fetal tone. There can be a marked decrease in amniotic fluid; Phelan *et al.*[44] obtained indices of between 5 and 8. If all these data are marked in accordance with Manning, the biophysical profile usually attains a score of under 7. In this phase the number of positive oxytocin tests is already clearly significant, as are the force tests and the vibroacoustic stimulation. We are then confronted with the decompensation of a chronic fetal distress, which, until then, could be considered as compensated.

Finally, in the late phase, and owing to the loss of cardiac automatism, not only do apparent late decelerations appear in the cardiotocographic reading, but there is also noticeable loss of reactivity. These ominous readings do not appear until 2–3 weeks after the minimum values of the cerebral PI have been attained. In fact, this interval depends on the ability of the fetus to compensate for the reduction in its metabolic supply.[42]

The biophysical profile shows very low values, always under 5, owing to the alteration of all its parameters (severe decrease in fetal movements and tone, etc.) and an increasingly significant oligohydramnios (Phelan's index under 5).

Biochemical correlation

When the velocimetric values are altered not only in the umbilical artery, but also in the remaining fetal vessels (aorta, common carotid and middle cerebral arteries), there is a risk of low pO_2 and pH values in the fetal blood obtained by cordocentesis.[17,30,38,45,46] In fact, centralization gets under way only when the fetus is already suffering from a degree of hypoxemia and acidosis.

In the initial phase, with end-diastolic frequencies still present in both the umbilical artery and the aorta, the percentage of cases with hypoxemia does not generally exceed 25–30%.

The situation changes dramatically in the advanced phase, when the end-diastolic values of the Doppler frequency in those two vessels disappear: in this case 70–80% of the fetuses present hypoxemia, and 40–60% present acidosis.[17,30,46,47] The majority of authors[48–50] consider that the absence of end-diastolic flow signifies pathological results in the acid–base study of the fetal blood.

Finally, in the terminal phase, practically all the fetuses have a pO_2 of between 2 and 4 SD below the mean.[51]

Obstetric and neonatal outcome

A high number of deaths in fetuses (250 per 1000) and neonates are concentrated in this group, and there is a significant increase in neonates with pH under 7.20 (83.3%). A cesarean section was performed in all our cases. Furthermore, the surviving fetuses present a high number of complications (e.g. necrotizing enterocolitis and hemorrhages), which are attributable to the persistent vasoconstriction of specific organs.[52]

Various authors[14,15,53] have observed that the absence of end-diastolic values in the aorta accurately predicts neonatal morbidity.

Arduini *et al.*[54] have designed a test that determines whether fetuses will have a specially bad prognosis if they are not immediately extracted. They administer oxygen humidified at 60% to the mother, and carry out a fetal hemodynamic study using Doppler before, just after and 20 min after therapy. If the PI values are not substantially modified, the fetuses will suffer a rapid deterioration.

Decentralization of blood flow

Montenegro *et al.*[17,30] give this name (decentralization of blood flow) to the irreversible hemodynamic changes that follow on from the centralization of blood flow and that precede fetal death.

Pathophysiological basis

If the hypoxia persists, a phenomenon of generalized fetal vascular paralysis will ultimately occur.

We can probably hypothesize that the situation is similar to those described in the fetuses of monkeys[55] or sheep[56] subjected to severe and sustained hypoxemia. The appearance of cerebral edema and the resulting increase in intracranial pressure hinder the mechanism for cerebral blood perfusion. The cerebral edema is probably brought about by the local accumulation of lactic acid resulting from the sustained anaerobic metabolism, which alters the permeability of the cellular membrane, increases the osmotic intracellular pressure and ultimately leads to the edema and eventual tissue necrosis.

The result of all this is that, in addition to the hypoxemia of the cerebral centers, there is a progressively irreversible interference in the control mechanisms of the arterial tone. This situation usually occurs when the hypoxemia is extreme: more than 4 SD below the mean.[51,57,58]

Doppler hemodynamic profile

The diagnosis of decentralization of blood flow essentially rests on two findings:

(1) Confirmation of resistance in the umbilical and peripheral circulation (aorta, renal, etc.) with the presence of reverse end-diastolic flow and
(2) Increase, after a brief period of stabilization, in the PI in the intracranial arteries, the values of which can appear normal; there are even FVW without diastoles or with reverse flow.[59]

It is not known how much time can pass from the onset of this picture until *in utero* fetal death, but it is probably no more than 2–3 days, and in many cases only a few hours; this explains the remote possibility of observing it through Doppler.

Biophysical correlation

If a cardiotocographic examination is carried out at this point, it is certain that a terminal pattern will be observed, indicating the so-called 'intrauterine brain death syndrome'.[60–65] The readings invariably show a fixed fetal cardiac frequency, with no variability from one heartbeat to another and a complete absence of accelerations or decelerations, even when contractions are induced by an oxytocin test or an EVA is performed. The biophysical profile, on the other hand, will show an immobile atonic fetus, drawn in on itself and with hardly any amniotic fluid, although some authors[64,66] have described some cases with hydramnios. The score will not exceed 2 points.

Only on very rare occasions will it be possible by echography to confirm the existence of cystic periventricular cerebral lesions (porencephaly) or evident ventriculomegaly,[65,67,68] the consequence of the hypoxic necrosis.[60,67–69]

Figure 121.4 presents the probable sequence of the pathophysiological mechanisms and biophysical signals, which can be observed through exploration, in a case of IUGR through uteroplacental vascular insufficiency.

Biochemical correlation

As has already been mentioned above, a funiculocentis will confirm extreme hypoxemia (values of pO_2 −4 SD below the mean and a significant acidosis).

Obstetrical outcome

This is a situation that results in either fetal or neonatal death, especially if an emergency extraction is carried out. A cesarean section is therefore generally considered unnecessary.[65]

The role of Doppler in the decision to terminate the gestation

The decision to terminate the gestation, and the birth route, must be taken in the light of:

(1) Objective data on the fetal condition (e.g. type of IUGR, presence or absence of congenital defects, onset of centralization of blood flow);
(2) Degree of fetal pulmonary maturity and
(3) Specific clinical characteristics of the case (e.g. parity, cervical conditions).

If it is an intrinsic, harmonic IUGR, with evidence, or a high probability, that there are fetal anomalies (trisomies, malformative syndromes), it is advisable to wait for the results of the tests on pulmonary maturity, fetal hemodynamics, etc. and attempt birth by the vaginal route. If there is no confirmation of any congenital defects, the procedure should be the same as in extrinsic IUGR.

In the case of extrinsic, or disharmonic IUGR, the tests currently available for controlling a fetus should be a guide as to the appropriate time to interrupt the gestation.

Our current state of knowledge and diagnostic possibilities give us two options as regards when to extract the fetus:

(1) Interrupt the gestation when the cardiotocographic reading is abnormal and/or there are clear signs of chronic fetal distress (reduction in tone and fetal movements, oligohydramnios, observation of meconial fluid by amnioscopy), which implies high levels of asphyxia and perinatal morbidity and mortality[70,71] or
(2) Interrupt the gestation at the onset of the centralization of blood flow, thus increasing the prematurity rate.

In order to reduce the latter risk to a minimum, especially if the gestation has not reached 30 weeks, it is advisable to study the fetal blood gases by means of funiculocentesis. This step should especially be taken when the PI values in the umbilical artery and aorta are obviously altered but there is still end-diastolic flow. If the diastole is zero, and especially in cases of reverse flow, the fetal prognosis is very poor and funiculocentesis proves to be useless.

With a fetus which is mature, or in the transitional maturing phase, the decision to carry out the interruption must always be made before the disappearance of the diastolic velocities. The decision will always be somewhat late by the time that zero diastole has appeared, given the high number with acidosis (70%) and perinatal deaths in this group.

Fetal defensive mechanisms against hypoxia: biochemical study of fetal deterioration

We are well aware of the resistance and capacity for adaptation of the fetal organism, as compared with adults of the same species, when confronted by hypoxia. It is common knowledge, for example, that newborn rats survive without oxygen 30 times as long as adult rats. However, the immature fetus probably has a much less well-developed capacity for adaptation.

Fetal defense against hypoxia uses various mechanisms of widely differing teleological significance,[72] from the appearance of a polycythemia, designed to increase the transportation of oxygen through the fetal blood;[73] to the dilatation of the placental vessels, as a consequence of an excess carbon dioxide.[74] If we concentrate on the most important of these mechanisms, we could say that the preservation of life, and particularly of the brain, is the fruit of a collaboration between a mechanism for neuroendocrine regulation (paraortic and carotid ganglions, sympathetic–parasympathetic play, adrenal glands, release of catecholamines) and the

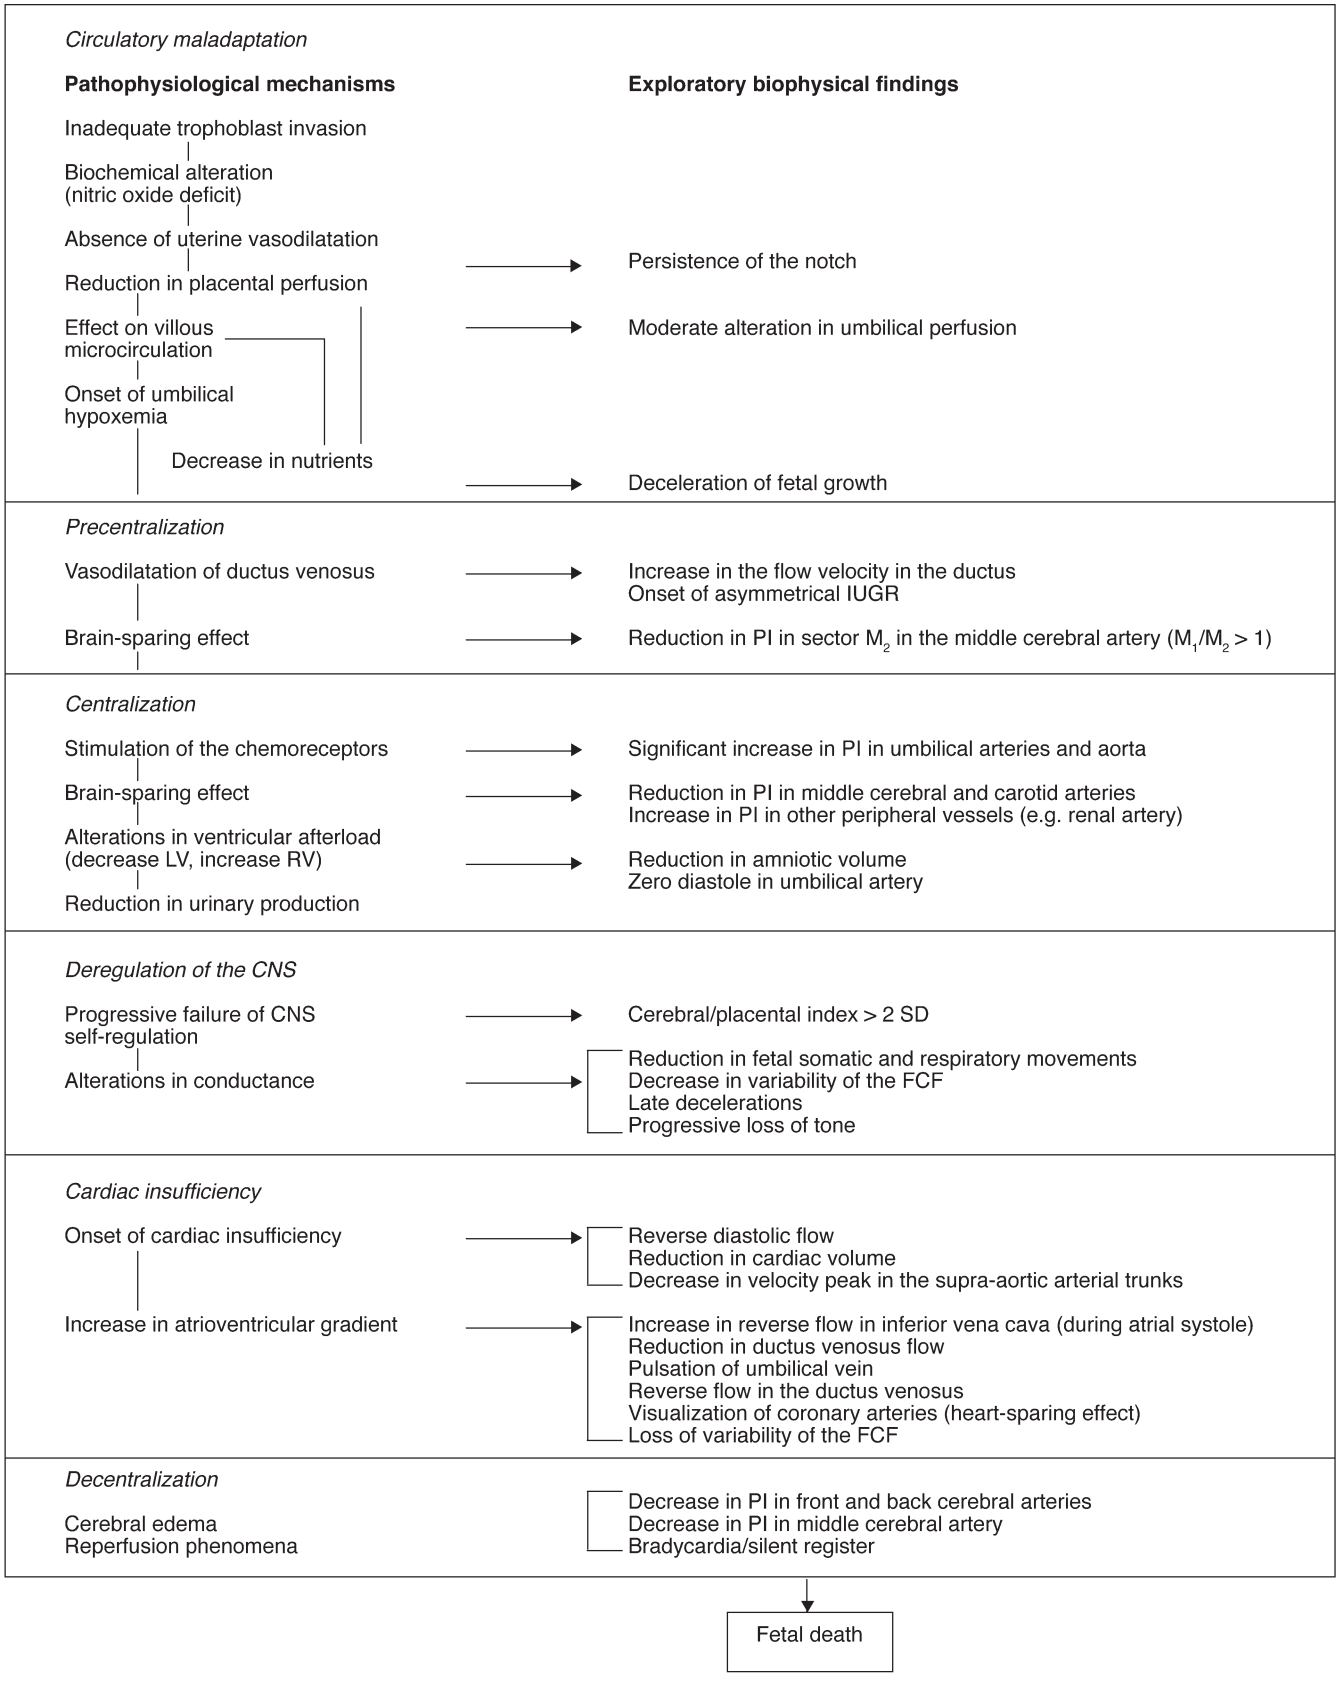

Figure 121.4 Sequence of the pathophysiological mechanisms and biophysical signals. IUGR, intrauterine growth retardation; PI, pulsatility index; LV, left ventricle; RV, right ventricle; CNS, central nervous system; FCF, fetal cardiac frequency.

mechanisms for maintaining cellular and systemic homeostasis.[75] The integrity of the various systems, especially that of the central nervous system, depends on the precise adjustments made between these biophysical and biochemical mechanisms when they show regulation among themselves, from their own genetic program of specialization.

A considerable number of mechanisms are interrelated in order to regulate the hemodynamic changes that we have described. Hypoxemia and hypercapnia induce dilatation of the cerebral blood vessels. This is attained by means of the stimulus to the chemoreceptors already alluded to, but there is also an increase in sympathetic activity (epinephrine and norepinephrine – adrenalin and noradrenalin) which, along with the release of arginine–vasopressin, increases the peripheral vascular resistance.

The fetus, unlike the adult, responds to hypoxia with bradycardia. The decrease in pO_2 in the umbilical vein stimulates the aortic and carotid chemoreceptors.[76,77] Later on, this bradycardia is maintained by peripheral vasoconstriction, which raises fetal blood pressure and stimulates the arterial baroreceptors.

From the energetic point of view, the fetus falls back on the release of energy via the biochemical energy release mechanisms under conditions of anaerobiosis. Although this recourse allows it to survive for a time, in the long run it leads to energetic failure, to the exposure of its glucogen reserves and the acidification of its internal medium.

There is relative agreement that a fetus responds to hypoxia in an ordered and systematic manner, which wavers only when the ictus is severe and has exceeded certain limits. This seems particularly to be the case when, as in uteroplacental insufficiency, the limitations both on energy and on oxygen occur progressively. Fetal deterioration is also, with some exceptions, progressive.

Owing to our current knowledge of fetal pathophysiology, it is possible to identify five stages in the process of fetal deterioration: full fetal adaptation, energy failure, hypoxia without ischemia, hypoxia with ischemia and reperfusion and death.

Full fetal adaptation stage

In this stage, which is relatively silent from the hemodynamic point of view, the most noteworthy feature is the precentralization of blood flow.

There are hardly any discernible changes on the biochemical front in this first stage of fetal adaptation to hypoxia. It is only when the situation becomes chronic that, in addition to a progressive decrease in the plasma concentration of glucose and amino acids, there is an increase in the production of erythropoietin. The generation of the latter is stimulated, both in fetuses[78,79] and in adults,[80] by chronic hypoxia, which correlates satisfactorily with growth retardation[81] and fetal metabolic problems (e.g. diabetes, preeclampsia). The raised erythropoietin values are followed, on the other hand, by an increase in the number of circulating erythroblasts, as a probable consequence of a mechanism for the premature release of red cells by the bone marrow, or of a persistence in hepatic erythropoiesis, all of which are mediated by erythropoietin.[82,83]

Energy failure stage

From the hemodynamic point of view, this stage sees the centralization of blood flow, with a selective vasodilatation of organs such as the brain, the heart or the adrenals, and a vasoconstriction of other territories, such as the lung, the intestine, the skin, the kidney or the skeleton.

On the biochemical–energetic front, anaerobic glucolysis enables the fetus momentarily to attain a substitute energy source in order to survive. However, if the conditions for fetal oxygenation do not improve, this defense mechanism will become not only inoperative but also dangerous. In effect, owing to the accumulation of lactic acid, it will lead to a fall in the pH and metabolic acidosis; there will also be a progressive depletion of energy reserves (hypoglucemia, the loss of stored glucogen, etc.) with a significant decrease in adenosine triphosphate (ATP). The ultimate consequence is energy failure.

The explanation for this lies in the fact that, while 38 mol of ATP (equivalent to more than 100,000 stored calories) is formed under normal conditions, or aerobiosis, only 2 mol of ATP (approximately 20,000 calories) is formed for every mole of glucose metabolized by the anaerobic route. Thus, the energy obtained by anaerobiosis is equivalent to 1/17 of that achieved by oxidative degradation.

The insufficiency of ATP[84,85] leads to the functional alteration of the membrane, which alters the cellular ionic homeostasis. There is an increase in intracellular sodium ions and a withdrawal of potassium ions, all of which leads to a depolarization of the membrane, with an opening up of the calcium channels.

At a certain point, the intracellular accumulation of calcium ions goes beyond the compensatory possibilities of the cell, which does not manage to maintain its ionic equilibrium. As a consequence of this, calcium turns into a cellular toxin.

Apart from the opening up of the above-mentioned channels, there are other mechanisms for increasing intracellular calcium. The reduction in ATP gives rise to the release of calcium from the endoplasmic reticulum, and the increase in intracellular sodium, resulting from the functional lesion of the cellular membrane, also stimulates the release of the calcium ion from the mitochondria.

There are also some modifications produced in this stage, which can be verified in fetal blood if cordocentesis is carried out:

(1) A decrease in the plasma concentration of glucose as a result of anaerobic glucolysis, necessary in conditions of hypoxia, in order to obtain sufficient

energy for fetal survival. The consequences of this process are a drop in the pH, metabolic acidosis, fetal hypoglucemia[86] and, finally, a depletion of the glycogen reserves, despite the low metabolic indices.

(2) A decrease in the plasma concentration of amino acids, independent of the degree of hypoxia.

(3) An increase in the viscosity of the blood, as a result of the rise in the hematocrit. Heightened viscosity interferes with the perfusion of the vital tissues. The relative blood viscosity increases logarithmically (not linearly) with the increase in platelet aggregation.

Hypoxia without ischemia stage

The hemodynamic pattern established at this stage is known as 'severe hypoxia without ischemia' with full cerebral vasodilatation. The reactive possibilities of the centralization of the blood flow have reached their maximum level, but are in their terminal phase. The Doppler study of the renal descending aorta funicular artery shows very high indices of pulsatility, with no telediastolic velocimetric values or the presence of reverse flow. In contrast, the intracranial arteries exhibit particularly low PI values.

On the biochemical front, the intracellular ionic calcium concentration goes up substantially, and this increase represents the first link in a chain of events that will lead to neuronal death.

The most outstanding event is probably the activation of phospholipases A and C, which gives rise to a phospholipidic hydrolysis of the membrane, which then ruptures, irreversibly altering its permeability. The immediate consequence is a deterioration in the cellular homeostatic balance. On the other hand, phospholipase C catalyzes the production of inositol triphosphate, which releases calcium from the endoplasmic reticulum.

Hypoxemia with ischemia stage

In recent years, it has been demonstrated that hypoxia needs ischemia to set in motion the chain of biochemical events that originates in the irreversible lesion to the cellular membrane and end up in the massive production of oxygen-derived free radicals which produce a natural death.

When the oxygen content in the fetal blood (pO_2) falls below −3 SD of the mean, the capacity of the defense mechanisms to continue protecting the fetus is eroded. Therefore, if the asphyxia is very severe there is a failure in the centralization of the blood flow and ischemia occurs, more or less irreversibly, in all the organs that had been preserved until then. When cerebral hypoxia– ischemia is produced, the blood pressure and cardiac output fall. This phenomenon is often very abrupt, and is predetermined by the fall in peripheral vasoconstriction. Cerebral self-regulation disappears and the cerebral blood flow becomes passive.

On the hemodynamic front, there is an increase in the PI values, both in the middle cerebral and carotid arteries, which can even be accompanied by reverse blood flow, proof of the appearance of ischemia, which is secondary, among other things, to progressive cerebral edema. However, this increase is not stable, for there are brief episodes of vasodilatation (a fall in PI), which may be considered attempts at reperfusion. At the same time, we can observe a complete absence of end-diastolic values and, in most cases, reverse blood flow, in the peripheral fetal vessels.

From the biochemical point of view, the increase in the intracellular concentration of calcium sets in motion other relevant mechanisms that will make an inexorable contribution to the lesion and to neuronal death:

(1) Release from the lesioned membrane of free fatty acids, especially arachidonic acid. The latter's oxidative degradation, through both cyclo-oxygenase and lipoxygenase, generates large amounts of oxygen free radicals, which inhibit the prostacyclin synthetase. The immediate consequence is a decrease in the concentration of prostacyclin and the loss of prostaglandin (PG) I_2 and thromboxane A_2 balance.

(2) Structural change of xanthine dehydrogenase into xanthine oxygenase, which, as we shall see, precipitates the formation of free radicals from hypoxanthine.

(3) Activation of the release of excitatory amino acids, which subject the neuronal receptors to a prolonged overstimulation.

Ultimately, the consequence of all this is cellular edema and neuronal death, which can be primary if it occurs at the same time as the hypoxic ictus, or secondary if it occurs in a later phase of reperfusion.

Reperfusion and death stage

It has been well established over the last 10 years that cerebral lesions related to a lack of oxygen originate not only at the time of asphyxic ictus, but also, and very particularly, in the reperfusion phases, which take place in the centralization of the blood flow's terminal phase, as well as in its decentralization phase, thus giving rise to the so-called 'secondary neuronal death'.[86] There is, in this respect, experimental proof in fetal sheep that reperfusion, after a relatively long period of ischemia, increases the production of free radicals.[87] Free radicals play a deleterious role in every case.[88–90]

From the hemodynamic point of view, the end result is a phenomenon of generalized fetal vascular paralysis with a decentralization of blood flow.

Biochemical markers of cerebral hypoxia

In theory, it is possible to study fetal homeostasis and evaluate possible hypoxia by studying the acid–base

status of the fetal blood obtained by means of cordocentesis.[91–93]

The quantification of pO_2, pCO_2, pH and an excess of bases in the fetal blood will provide us with a mere snapshot of that status, without any retrospective information on the changes that the fetus has been able to overcome, and this will also be lacking in any prospective value as regards a possible cerebral lesion,[94,95] hence the interest in finding and developing authentic biochemical markers of fetal hypoxia.

The progressive understanding of the cellular mechanisms of hypoxia has led to the belief that the products generated throughout the cascade of chemical reactions, which ultimately lead to neuronal death, could be used as markers. This is the case with erythropoietin, excitatory amino acids, hypoxanthine, free fatty acids, lipidic peroxides and oxygen free radicals.

However, our current knowledge of these products largely comes from animal experimentation or studies on neonates that have been subjected to intrauterine asphyxia. Only some of these parameters, such as erythropoietin, have been studied in fetal blood or amniotic fluid. Studies attempting to determine markers for hypoxia in maternal blood are scarce, but these would be of real use in clinical practice. All this means that we are taking the first steps in this field and that it will be necessary to wait for some years before introducing any of these markers in day-to-day clinical practice.

We can speculate that these markers might be divided into three categories:

(1) Markers of chronic fetal hypoxia
(2) Markers of fetal decompensation
(3) Markers of reoxygenation and/or neuronal death.

Markers of chronic fetal hypoxia

Although the pH in the umbilical artery continues to be the most widely used indicator to evaluate fetal hypoxia, there is a great deal of evidence on its limited correlation with the neurological evolution of the newborn baby.[94,95] This is because, although it is an excellent indicator of recent acute hypoxia, it is incapable of indicating prolonged chronic hypoxia,[81] hence the interest in erythropoietin, which seems to be a good marker for chronic hypoxia during the second half of gestation.[96]

Erythropoietin is a glycoprotein, the production of which, both in the fetus and in the adult, is stimulated by hypoxia.[78,79,97,98] As it does not cross the placenta it is considered that, when found in large quantities in the fetal or neonatal blood, whether obtained by cordocentesis or postpartum in the blood of the umbilical cord, it may constitute a marker of chronic fetal hypoxia[99,100] from at least week 20 of gestation.[101] Accordingly, several researchers have found high levels of erythropoietin in umbilical cord blood in gestations with hypertension,[102,103] intrauterine growth retardation[83,103,104] (with a good correlation between the values of this parameter and the degree of fetal acidemia) and other pathologies that are accompanied by placental insufficiency,[104] even with totally normal umbilical pH values (Table 121.2). Likewise, there is no noticeable correlation in these cases between the values of erythropoietin and those of pO_2 in the umbilical artery.[81,102,105] However, when there was no acidosis there was only a limited relationship between high erythropoietin figures and the presence of meconium or an alteration in the fetal cardiac frequency (Table 121.3).

Salvesen *et al.*,[106] in a parallel study of maternal blood and fetal blood (obtained by cordocentesis), noted that, in gestations complicated by diabetes mellitus, maternal hyperglycemia is accompanied by fetal hyperglycemia and fetal acidemia, with a marked increase in erythropoietin. There is speculation that this increase can be due both to hypoxia and to hyperinsulinemia, or both, and that the rise in fetal hemoglobin can also be mediated by erythropoietin or hyperinsulinemia.

In contrast, the erythropoietin level is not modified in those pathologies that, although they affect the fetus, do not do so by means of an insufficiency in the placenta. This is the case, for example, in pyelonephritis.[107]

On the other hand, several authors[83,104] have confirmed a significant correlation between the

Table 121.2 Relationship between placental pathology and fetal erythropoietin and umbilical pH values (from Maier *et al.*[81])

		Erythropoietin (mU/ml)		Umbilical pH	
Placental findings	***n***	**Median**	**Range**	**Median**	**Range**
Fetal vasculopathy	14	85.6	23.7–119.7	7.28	7.22–7.31

Umbilical acidosis	24	202.4	72.6	6.1–1070.2

FCF, fetal cardiac frequency

concentration of erythropoietin and the number of circulating nucleated erythrocytes.

It seems that labor at birth with no signs of fetal distress does not raise erythropoietin levels;[108] on the contrary, some researchers[109] speculate on the possibility that the administration of β-mimetic tocolytics may stimulate the production of erythropoietin through a decrease in fetal oxygenation. They thus consider that β-sympathomimetics should be used sparingly once the fetal condition has been affected.

The determination of erythropoietin during pregnancy can be made in both fetal blood (cordocentesis) and amniotic fluid. The latter expresses the situation in the fetal serum with reasonable exactitude, although with a slight delay and somewhat lower figures.

In this way, the rise in erythropoietin levels has been confirmed in amniotic fluid (normal figures 9–12 mU/ml) in various pathologies associated with chronic placental insufficiency, but its values prove to be normal in other syndromes, such as Down's syndrome, for example.[110]

Some authors[99,100] use the determination of erythropoietin in amniotic fluid to clarify whether fetal deaths are the consequence of an acute event (normal erythropoietin), or a chronic condition (high glycoprotein values).

In practice, however, erythropoietin has principally been used as a marker of hypoxia postpartum, through the determination of its concentration in the venous cord blood.[81,108] Our experiences with this marker are collated in Table 121.4. It can be seen that its values in preeclampsia were double the normal ones in our unit, and it is confirmed that this parameter does not correlate with the values of the umbilical pH, but it does do so with the presence of meconium and anomalies of the fetal cardiac frequency, above all those that express an ectasis of the intervillous space.

Markers of fetal decompensation

The onset of severe fetal hypoxia with reactive vasodilatation of the cerebral blood vessels is accompanied by, among other chemical changes, a local increase in three markers: excitatory amino acids, hypoxanthine and free fatty acids.

Excitatory amino acids

The amino acids glutamate and aspartate, which usually play an important role as neurotransmitters, intensify their concentration in the cerebral extracellular space by up to 5–10 times the norm during episodes of hypoxia and, above all, of hypoxemia with ischemia. They are then converted into neurotoxins.

The increase in these amino acids is a consequence both of the increase in the intracellular calcium concentration in the neurons, which produce glutamate and aspartate, and the failure to absorb them on the part of the presynaptic membranes when ATP decreases.[86]

Neuronal death can occur as a consequence of two types of lesional mechanism: a 'rapid' mechanism, which takes place a few minutes after the hypoxic ictus, and a 'late' mechanism, which can begin up to 24 h after the episode. In the first case, the cellular lesion is the result of the massive entry of sodium, chlorine and water into the cell, which gives rise to an osmotic load and lysis of the cellular membrane. In the second case, in contrast, calcium ions enter through specific channels when they are stimulated by *N*-methyl-D-aspartate. This increase in the intracellular concentration of calcium perpetuates the process by gradually setting into motion the other, previously mentioned, cellular lesion mechanisms. While the rapid mechanism explains primary neuronal death, the late mechanism is more common in secondary neuronal death with successive episodes of anoxia and reoxygenation.

Table 121.4 Erythropoietin values in umbilical vessels in cases of diabetes and pre-eclampsia

			Erythropoietin (mU/ml)		
Pathology	***n***	**%**	**Mean**	**SD**	***P* value**
Diabetes	13	5.1	34.43	31.13	0.94 (NS)
Control group	240	94.9	31.72	28.58	
Pre-eclampsia	8	3.1	62.59	58.26	0.024 (S)
Control group	245	96.9	30.86	26.81	

NS, not significant; S, significant

It has been demonstrated that the levels of glutamate and aspartate in cerebrospinal fluid were, respectively, three and four times greater in animal fetuses subjected to asphyxia than in the control group,[111] and this significantly correlated with the degree of hypoxic–ischemic encephalopathy.

We can now draw on considerable information on these possible biochemical markers of hypoxia in experimentation animals (particularly sheep) and through carrying out cerebral assessments using microdialysis probes,[112,113] but there are still no studies in humans.

Hypoxanthine

During hypoxia, ATP is degraded with considerable difficulty; hence the increase in the concentration of adenosine monophosphate (AMP), which is later transformed into adenosine, inosine and, finally, hypoxanthine. The increase in these biochemical products, especially the latter, therefore represents a marker of fetal hypoxia. Thiringer[114] has demonstrated that the concentration of hypoxanthine in venous blood, during the advanced and terminal phases of the centralization of blood flow, was much greater than in arterial blood. It is possible that this is also the case in moderate hypoxia.

In the hypoxia stage with vasodilatation, hypoxanthine is successively converted into xanthine and uric acid, owing to the enzyme xanthine dehydrogenase. Its concentration in the fetal blood, like that of adenosine and inosine, is therefore only moderately intensified in this phase. Furthermore, adenosine and inosine increase cerebral blood flow, reduce carbon dioxide and modulate the neurotransmitters so that, overall, an endogenous mechanism for cerebral protection is set in motion.[115–119]

However, when ischemia ensues as a consequence of the increase in intracellular calcium, a structural change takes place, from xanthine dehydrogenase to xanthine oxygenase. The result is that the first route is blocked and uric acid is produced by means of a second route, which occasions the production of oxygen-derived free radicals. This route is the customary one in cases of reperfusion and reoxygenation after one or many episodes of neuronal hypoxia. In effect, the chronic lack of oxygen in hypoxia with stable vasodilatation avoids both the excessive stimulation of the first route and the activation of the second. However, when successive episodes of ischemia and reperfusion occur, the usual route is blocked and the 'savage route' is induced, and the concentrations of hypoxanthine and oxygen free radicals are increased.

When uterine perfusion in fetal sheep is reduced experimentally,[120] it has been noted that the highest values of hypoxanthine and xanthine in cerebrospinal fluid are found precisely in the normothermic recovery phase. These high levels of substrata facilitate the formation of oxygen free radicals, which induce encephalic lesions. After 3 days of hypoxic ictus, the necropsy on the animals showed varying degrees of edema, neuronal alterations through coagulation and necrosis, and cellular death. Such changes were especially evident in the Purkinje brain cells. These findings agree with those of several earlier studies.[121–123]

Several authors suggest, as a marker for hypoxia during pregnancy, both in animal experimentation[120,124,125] and in human clinical practice, the determination of hypoxanthine in the fetal circulation. This, they argue, could provide us with information on the gravity of the hypoxic ictus and, above all, could offer a prognosis on the subsequent fetal or neonatal encephalic cavitation (porencephaly or leukomalacia) resulting from intrauterine hypoxia/ischemia.

This marker seems to be particularly predictive in cases of periventricular leukomalacia in neonates.[126,127] Saugstad[128] and others[129,130] consider that hypoxanthine in cord blood is more specific in the evaluation and quantification of hypoxia than lactate, acid–base excess or pH, as these parameters are incapable of reflecting the intracellular energy status. The oxidation of hypoxanthine during episodes of reperfusion generates oxygen free radicals, which contribute to the destruction of the cerebral tissues and, therefore, to the genesis of leukomalacia.[127]

Some authors[131] therefore consider this parameter as a gold standard of hypoxia. There is a host of studies that relate hypoxia to high levels of this marker.[132]

Likewise, in the neonate[133] the quantity and prolongation of the urinary excretion of oxypurines (hypoxanthine and xanthine) is clearly related to the gravity of the intrauterine hypoxic episode, with its neonatal neurological consequences and an extension of the possible cerebral lesion.

Arachidonic acid

Arachidonic acid is one of the free fatty acids released after the lesion to the membrane is produced by phospholipid hydrolysis. Its release, as a result of the activity of phospholipases A and C, provokes a cascade of biochemical reactions that lead to the production of prostaglandins, thromboxane and leukotrienes. This is why, in moderate hypoxia, there is an increase in both prostacycline and thromboxane in the cerebrospinal fluid, and probably also in the fetal blood.

However, when ischemia is combined with hypoxia, the cascade of arachidonic acid alters, forming first oxygen free radicals and, later on, lipid peroxides as a by-product. These free radicals inhibit prostacycline synthetase and impede the formation of prostacycline by increasing the relative concentration of thromboxane. This imbalance precipitates vasoconstriction and excessive platelet aggregation, and produces successive episodes of ischemia and reperfusion, which considerably impair the neuronal prognosis. On the other hand, the lipid peroxides can produce vasoconstriction by directly affecting the vessels; as a result, more calcium enters smooth muscular cells of the vascular wall and endothelium-derived relaxing factor (EDRF)/nitric oxide is rendered inactive.[134]

Even when the demonstration of this imbalance of prostanoids is theoretically possible by studying the fetal blood obtained through cordocentesis, there is no published experiment that indicates that it could be useful as a marker of hypoxia.

Various researchers have shown that human neonates subjected to asphyxia during birth presented a significant rise in the majority of prostanoids investigated in the cerebrospinal fluid, especially thromboxane.[135]

Markers for reoxygenation and/or neuronal death

In this instance, we should principally mention the oxygen free radicals and their by-products.

Oxygen-derived free radicals

A free radical is any molecule that has one or more unpaired electrons (i.e. an odd number) in its outer layer. This makes them very reactive, and endows them with a strong tendency to initiate chain reactions to get rid of this extra electron, or accept another one to stabilize the unpaired electron, or join up with a non-radical molecule.

Oxygen is essential to the life of aerobic organisms. In all the cells in the organism, it is in the mitochondria (organelles which produce cellular energy or ATP) that the largest amount of oxygen is used up through being the terminal acceptor of electrons in the cellular respiration process. However, owing to its biradical nature, oxygen and its metabolites are potentially cytotoxic. The reduction of oxygen produces an oxygen superoxide radical (O_{2^-}), hydrogen peroxide (H_2O_2) and the hydroxyl radical. The reaction between oxygen superoxide and hydrogen peroxide results in more hydroxyl radicals.

When oxygen free radicals come into contact with the restored fatty acids, the so-called lipid peroxides are formed, and these stimulate the peroxidation reactions, which are extraordinarily toxic for all the cellular elements, especially for membranes.

Of the oxygen consumed by the cell, 90% is reduced by cytochrome oxidase without any formation of oxygen free radicals. Only 10%, in both the cytoplasm and the mitochondria, is reduced by other routes, which produce free radicals. Cells are endowed with a wide range of enzymatic and non-enzymatic defenses, the radical 'scavengers', to prevent the damaging effects of these radicals.

The deleterious effect takes place when an imbalance occurs between the excessive production of free radicals and lipid peroxides and the antioxidant activity of the cellular defense systems.[88,136] Oxygen, like the god Janus, has two faces: one beneficial and life-giving and the other malevolent, a producer of deficiencies and death.

As we have already seen, the free radicals are precipitated by severe hypoxia, and they are a by-product of biochemical reactions or processes such as the synthesis of prostaglandins, the conversion of xanthine into uric acid by the 'savage route' and the auto-oxidation of catecholamines.

A cellular lesion and, ultimately, cellular death, are produced as a consequence of lipid peroxidation, the rupture of the cellular membrane and the decomposition of DNA molecules. Sooner or later this is followed by the destruction of cellular aerobic respiration, the synthesis of structural and enzymatic proteins and even the cell's genetic apparatus.

These molecules are formed above all in the reperfusion and reoxygenation stage, which arises from the failure of the centralization of blood flow and finishes with its decentralization and neuronal death.

One of the gestational pathologies in which oxygen free radicals play a leading role is preeclampsia, not only because it is a generator of placental ischemia, and therefore of fetal hypoxia, but also because it is possible that the imbalance between oxidants and antioxidants is related to the pathogenesis of

pre-eclampsia.[137,138] Free radicals and lipid peroxides could be elements that link the poor immunological adaptation with the endothelial cellular ictus.[138] In fact, a significant increase in lipid peroxides has been confirmed in pre-eclampsia, with an accompanying decrease in the antioxidant capacity of the maternal blood. It is very probable that the principal source of these lipid peroxides is the placenta.
