Foreword

Perinatal medicine is among the most challenging and beautiful areas of study and practice. It deals with events before birth, when the fetus is a patient and during the immediate neonatal period. The World Association of Perinatal Medicine is dedicated to the study of all aspects of perinatal biology, physiology, screening, diagnosis, management and ethics, with the goal of continuous quality improvement in the care of maternal, fetal and neonatal patients.

This textbook is based on a previous work that was produced by the European Association of Perinatal Medicine in 1998. Because perinatal medicine is now a global area of study, it is appropriate that the current textbook is a product of the World Association of Perinatal Medicine. The bonds that link perinatologists together transcend geographic, political, religious and lingual differences, resulting in a globalization that optimizes clinical care.

This textbook consists of over 200 chapters divided into 20 sections, which span the depth and breadth of the field. Beginning with the history of perinatal medicine and ending with the challenges facing this specialty in developing countries, this book is a comprehensive text designed to provide insight and guidance to clinicians throughout the world with state of the art information, written by the world's leading perinatologists.

We are grateful to the authors of the 205 chapters and the editors of the 20 sections, who have worked so diligently with us to produce this textbook, which we believe bears testament to the importance and success of international collaboration in perinatal medicine.

Introduction

I Birth and youth of prenatal and perinatal obstetrics*

E. Z. Saling

Introduction

Singular observations of the infant in the prenatal period, as well as the first elementary attempts at diagnostics and therapy, stretch back over generations, centuries and up to thousands of years. However, until the beginning of the 1960s, the only possible method of clinical 'assessment' of the intrauterine patient, apart from the fetal movements observed by the mother herself, was auscultation of the fetal heart beats with a simple stethoscope. The following statement made in 1966 by two English pediatricians Dobbs and Gairdner in an editorial in *Archives of Disease in Childhood* aptly sums up the situation:

> Up to now the formidable inaccessibility of the human foetus has meant that foetal medicine (apart perhaps from foetal electrocardiography [author's note: which was in a basic experimental state and should not be mistaken for cardiotocography.]) has virtually not existed. In an age when man has been able to measure most things from an atom to a galaxy, it is thus paradoxical that to measure his own size during the most critical and precarious period of his life, he still has to depend upon the extreme fallibility of the palpating hand.

Thus, today we can draw the following conclusion: systematic exploration of the intrauterine space during pregnancy and labor did not start until the 1960s. This, therefore, can be considered the beginning of prenatal medicine and the related clinical subspecialty 'prenatal and perinatal obstetrics'.

According to Dobbs and Gairdner, four innovative techniques brought about the real breakthrough. They stated:

> With the advent of the techniques of amnioscopy and foetal blood sampling and of amniocentesis and foetal transfusion, we witness the end of the long period of foetal inaccessibility, and we hopefully believe the start of the science of foetal medicine.[1]

Amniocentesis and fetal transfusion

As far as we have been able to ascertain, the first report about amniocentesis appeared in 1881 by Lambl, as a means of decompressing a hydramnion.[2] In 1930, Meness *et al.* performed the first amniography.[3] Not until 70 years after Lambl's first amniocentesis was this technique used by Bevis in 1952 for diagnosing Rh erythroblastosis.[4] This was an important prerequisite for both spectrophotometric analysis of amniotic fluid[5] and the first trials involving the treatment of the preterm fetus with severe Rh disease,[6] developed by Liley in Australia. Liley is especially renowned for the development of his 'Liley Scheme', which has been used as a nomogram for bilirubin limits. With this method, clinicians were provided with information enabling them to decide whether the fetus should be treated by intra-abdominal blood transfusion or if the pregnancy should be terminated when the fetus was sufficiently mature, in order to perform an exchange transfusion immediately postpartum. Today, amniocentesis is one of the standard techniques used in various fields of prenatal obstetrics.

Intrauterine transfusion, developed by Liley in 1963,[6] was used in cases of severe Rh erythroblastosis. This measure is one of the very first milestones of prenatal obstetrics in so far as it was the first real breakthrough in intrauterine, i.e. fetal, therapy. The effectiveness of intrauterine transfusion can be explained by the fact that the fetus resorbs through its peritoneum the compatible donor blood that is injected into the peritoneal cavity. Gradually, the donor erythrocytes reach the fetal blood circulation via the ductus thoracicus.

*This chapter covers a period of limited time and has therefore been taken over unchanged from the first edition

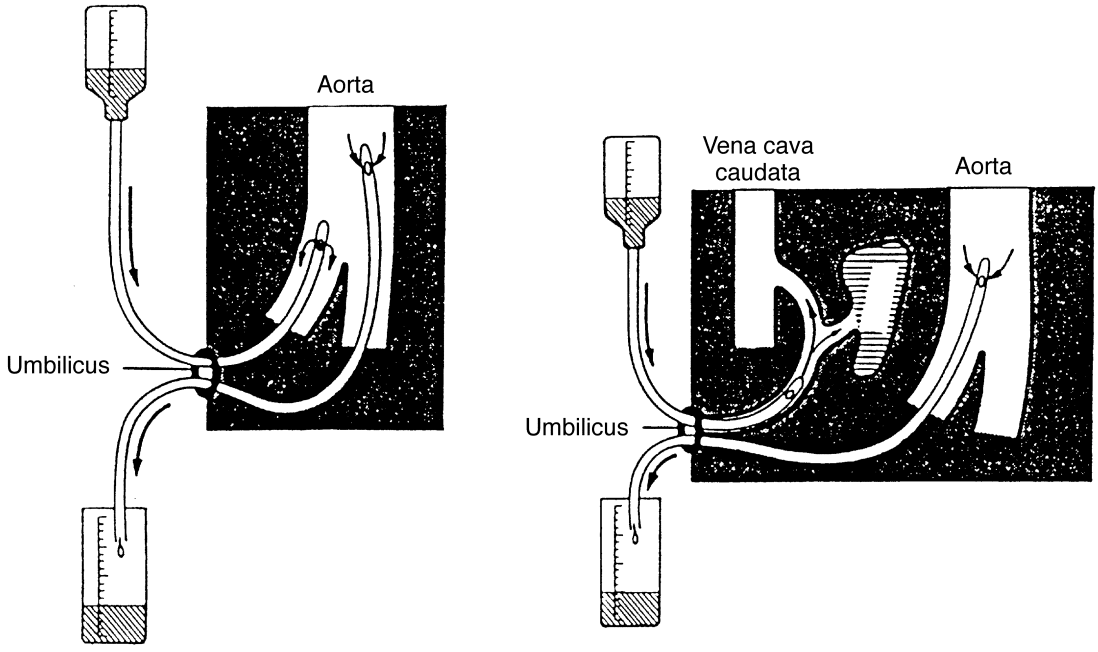

Figure I.1 Two options using the two-catheter technique for exchange transfusion in a newborn: infusion and simultaneous exfusion to and from the aorta (left) and infusion into the venous system and simultaneous exfusion from the aorta (right).

In the meantime intrauterine intraumbilical transfusions have been performed since 1986 mainly with the help of ultrasound[7] and even intracardial transfusions have been described.[8]

Fetal blood sampling

Of broader clinical importance, *fetal blood sampling during labor* – as a method of daily routine in the labor room – was the main step initiating the start of a completely new medicine, which up to that point was non-existent.

Before the introduction of fetal blood analysis (FBA), we were using other techniques, which, subsequently, brought us nearer this special new field. Several of the progressive steps described have been achieved by us as clinically engaged obstetricians. Today, these activities seem rather curious in so far as such efforts have belonged to the domain of neonatologists for some decades.

At the end of the 1950s we started examinations to determine the most effective method for resuscitation of an asphyxiated newborn immediately after delivery. At that time, the thorax compression methods, mouth-to-mouth respiration, intragastric O_2 insufflation and various other methods were still being used.[9] We came to the conclusion that most of these methods were not effective enough.[10] This motivated us to develop equipment for endotracheal O_2 respiration and we began to prove its efficiency. One component of the equipment was a laryngoscope for newborns, which, according to a recent recommendation in a textbook of anesthesiology,[11] is particularly suitable for the intubation of very small premature newborns.

An important development was that for the very first time we had been successful in catheterizing the aorta of the newborn immediately after delivery via the easily accessible umbilical arteries.[12] We used this method for a new two-catheter technique (Figure I.1) of exchange transfusion in erythroblastotic newborns[13] and, in addition, we withdrew samples for blood analysis from the central circulation of the asphyxiated newborn to prove the efficiency of the different techniques of resuscitation.[10] For these examinations, in cooperation with K. Damaschke, we developed a fast micromethod in order to determine the oxygen saturation in very small blood samples.[14]

A decisive step forward was the idea of *withdrawing fetal blood samples from the presenting part* of the fetus in cases of Rh erythroblastosis, thus enabling us to perform, before delivery, the most important serologic and hematologic examinations, such as the Coombs test, hemoglobin concentration, hematocrit and the blood group. This resulted in important progress in some cases of severe Rh erythroblastosis as it enabled us to begin exchange transfusions shortly – in six cases, 5–10 min – after delivery.[15]

The fast O_2 microanalysis, which had recently been developed, and the knowledge that blood samples could be taken so easily from the skin of the presenting part of the fetus provided us with the additional idea of performing fetal blood gas analyses. This was the birth of FBA. Almost at the same time, equipment for measuring pH in micro blood samples was developed and we were also able to examine fetal acid–base balance.

The first FBA *during labor with pH and O_2 saturation measurement* and *pCO_2 calculation* was performed on June 21, 1960. This was the first documented direct approach to the human fetus before birth.

Information on FBA was first published in the form of a report of a lecture presented at an official meeting of the Berlin Society of Obstetrics and Gynecology in 1961.[16] The first original article appeared in a journal in 1962.[17] In 1984, the latter publication became a so-called 'citation classic' of Current Contents after it had been identified by the Institute for Scientific Information in Philadelphia as one of the most cited items in its field.

Only a day later, on June 22, 1960, a blood sample for FBA was taken from the buttock of a fetus. In addition to the FBA during labor for the first time, for clinical purposes we performed an acidity measurement in blood from the umbilical artery and vein of this infant. Thus, the *complementary assessment of the newborn by also measuring the pH in umbilical vessels*, employed by many obstetricians today, was also created. The best routine assessment of the newborn immediately after delivery is achieved by the Apgar score for the basic clinical status, combined with our acidity values giving information about the biochemical status of the newly born baby. Historically, the two above-mentioned days were of special importance in the field of *combined examination of the acid–base balance in the fetus and neonate immediately after delivery.* The way in which we practiced the method can be seen in Figure I.2, in which the rubber stamp used in the labor room is described. The first publications describing the combined diagnosis of the newborns' condition, using the modified Apgar score as the clinical (physical) part and our acidity score as the biochemical part with the recommendation for routine clinical use, appeared in 1965[18] and 1966[19] in German as well as in 1968[20] and 1974[21] in English.

FBA received international attention through the activities of the Montevideo group. Joseph Bieniarz, a coworker of Roberto Caldeyro-Barcia for many years, with knowledge of the German language, undertook the task of reviewing German scientific literature. In this way, our first publication on FBA in 1962[17] and our studies published later in 1963[22] concerning normal fetal blood gas and acid–base values during labor, of which actual pH values (Figure I.3) were the most important, aroused particular interest in Montevideo. In 1964, Roberto Caldeyro-Barcia, who unfortunately passed away on November 2, 1996, organized a historic meeting. The invited guests were Stanley James, Edward Hon, Fred Kubli and myself. A photograph of the main participants and a short report on this international symposium can be found in the Editor's Preface in the first issue of the *Journal of Perinatal Medicine*.[23] After this meeting, FBA also attracted attention in North America and was introduced step by step in many places, its importance becoming accepted clinically and for research purposes.

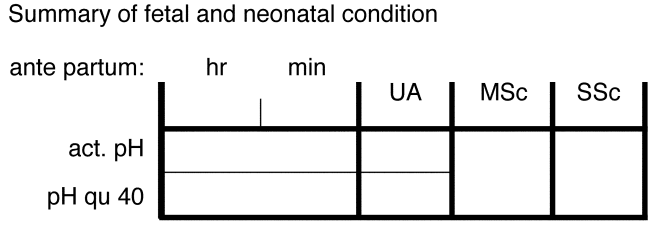

Figure I.2 Rubber stamp for summary of all results obtained concerning fetal and neonatal assessment.[19,20] In the first column the time in hours and minutes, actual pH and pH qu 40 (pH after equilibration of a blood sample with 40 mmHg pCO_2; this pH expresses the metabolic acidity and can directly be compared with actual pH values) of the lowest fetal blood pH measured during labor are recorded and in the second column (UA), the umbilical arterial actual pH and pH qu 40 immediately after delivery. The points achieved in our main score (MSc), a modified Apgar score, and in a subsidiary scoring system (SSc) are recorded in the left and right hand boxes, respectively. The subsidiary score contains the timed first breath, the first cry, the regular respiration and pink flash after delivery and is more objective and more reliable than the Apgar score.

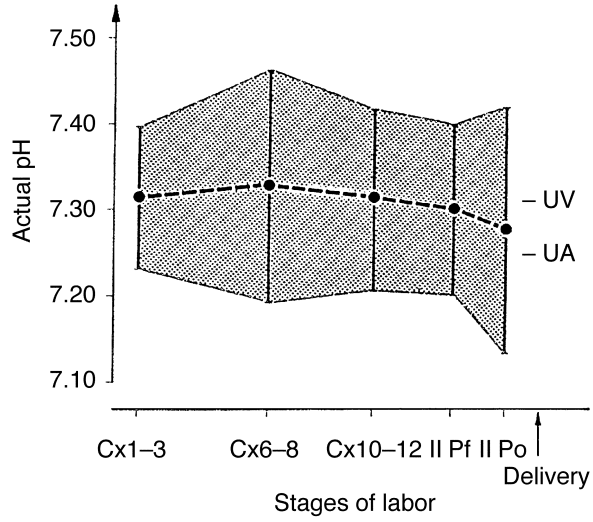

Figure I.3 Actual pH values of fetal scalp blood samples and of blood from umbilical vessels during different stages of normal labor ($x \pm 2$ s). Cx, cervix dilatation (cm); II, second stage; Pf, presenting part on pelvic floor; Po, on pelvic outlet.[18–20]

Amnioscopy

Another procedure that was developed at the beginning of the 1960s and which immediately became widespread is *amnioscopy*, a report on which was first published by us in 1962.[24] This procedure is based on the fact that hypoxic risks to the fetus in late pregnancy progress very slowly in most cases and that in more than 99% of these fetuses, passage of meconium actually occurs, which can then be detected amnioscopically (see below). A further advantage of amnioscopy is that amniotic fluid remains green for several days, and therefore it can safely be diagnosed by amnioscopic checks at intervals of 48 h. Amnioscopy continues to

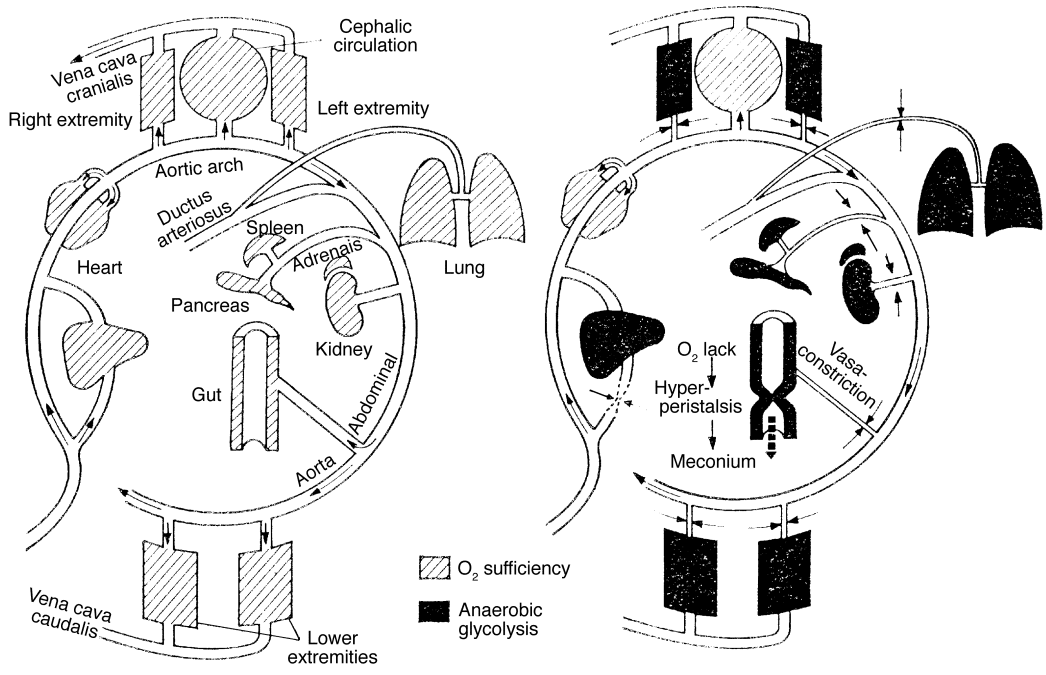

Figure I.4 Our first concept of the oxygen-conserving-adaptation of the fetal circulation.[26,27] Left: Normal arterial supply, with full oxygenation, to heart, brain and all other parts. Right: Reduction of oxygen supply leading to vasoconstriction in the extremities, abdominal viscera and lungs. Local hypoxemia leads to anaerobic glycolysis.

enjoy widespread popularity, particularly in countries with limited financial resources, because it is simple to use and does not require a great deal of equipment and takes only a short time. Furthermore, amnioscopy, as already mentioned, is very reliable in its early selection of fetuses at chronically advanced hypoxic risk. The method fails if a fetus with amnioscopically clear amniotic fluid, i.e. no passage of meconium, should die. This happened only eight times in more than 12,000 supervised high-risk pregnancies, i.e. only 0.6/1000.[25]

Some pathophysiological backgrounds that gave amnioscopy such a high diagnostic reliability are based on common circulatory reactions special to the fetus and can be explained by the concept we developed in 1966, namely, the *O_2-conserving adaptation of the fetal circulation*.[26,27]

This concept, now more than 30 years old, represents the basic principle for the Doppler diagnostics used today (Figure I.4). Our explanation in the 1960s was that the borderline oxygenated fetus reduces its O_2 consumption by restricted circulation of those organs that are not of vital importance and increases, relatively, the circulation in the vital organs such as brain and heart. Reduction of different areas of circulation has been found by Dawes in many animal experimental studies.[28,29] According to our concept, the intestinal organs are also affected, where the intestine reacts with hyperperistalsis. As a result, there will be a passage of meconium with high certainty during the last 4–6 weeks before the date of birth, which can be easily detected via amnioscopy.

The results of Doppler ultrasound investigations initially achieved by Arabin *et al.* in our Institute as early as 1987[30] provided an interesting new confirmation of our O_2-conserving adaptation concept, at this time already 20 years old. In severely growth-retarded fetuses even when a loss of enddiastolic blood flow velocities had already occurred in the umbilical artery and in the fetal aorta, there was an increase in the enddiastolic flow in the common carotid artery. Since then many further confirmations have been published in the same direction.

Many years after our publications the new term 'brain sparing effect' appeared in the Anglo-American literature. This was certainly regrettable as the colleagues who created this new term and 'rediscovered' the known principle overlooked two decisive facts:

(1) There was already a more appropriate term, which had been in existence for many years, without the necessity of formulating a new one.
(2) The new term, as far as it went, was incorrect since the pathophysiological situation concerned contains not only a 'brain sparing' but also a 'heart sparing' effect and possibly also sparing effects on other organs, for instance, the adrenals.

Some of the following comments about 'birth and youth of pre- and perinatal obstetrics' are mainly based on our previous report about 'historic landmarks of perinatal medicine in obstetrics'.[31]

Cardiotocography

In 1968, 8 years after FBA was introduced, *cardiotocography* also became available for clinical use. Cardiotocography is one of the important landmarks in prenatal obstetrics. Historic steps lead back to Pestalozzi, who in 1891 recorded the heartbeats of a twin in breech presentation with a sphygmograph[32] and also Hofbauer and Weiss, who recorded the first phonocardiogram in the year 1908.[33] Cremer was successful in designing the first electrocardiogram in 1906.[34] The first continuous cardiotachogram, conducted from an anencephalic fetus, was described by Caldeyro-Barcia and coworkers in 1958.[35] The electrode was inserted into the rump of the fetus through the abdominal wall of the mother, using the harpoon principle. The same principle was successfully used by Rech in 1931 in animal experiments.[36]

In 1966, with his 'one-poled' silver–silver chloride electrode (CLIP-electrode), that could be inserted vaginally, Hon introduced direct fetal electrocardiotocography during labor.[37] An electrode is fixed on the fetal head; a second counter-electrode lies in the vagina where it is in contact with the mother. The spiral electrodes most widely used were developed by Junge in 1967.[38] All these recordings of the fetal heart rate, combined with the recording of the intrauterine contractions, pioneered by Caldeyro-Barcia and Hon, required the use of very complicated equipment and could, therefore, only serve experimental and scientific considerations. The real breakthrough leading to practical clinical usage came in the mid-1960s, when Hammacher, in cooperation with Hewlett and Packard, was successful in developing the cardiotocograph (CTG), which is still known by the same name today. The equipment was based on the phonocardiographic principle and enabled the elimination of all disturbing noises by electronically controlled comparisons of the time interval between two successive first heartbeats and two successive second heartbeats.[39] In this way it was possible to achieve reliable, specific registrations of the fetal heart rate. The first prototype of the equipment for routine use was tested by Hammacher in Düsseldorf in 1966. Widespread clinical usage started in 1968. The first systematic comparisons between pathological cardiotocograms and the acid–base balance of the fetus were published by us in 1968.[40] Doppler ultrasound cardiotocography found widespread popularity in the 1970s due to the simplicity of applying the wide-angled transducer operating on the abdominal wall of the mother. However, due to the considerable deviations from the real beat-to-beat variability that sometimes occurred, it was heavily criticized. It was not until the beginning of the 1980s that ultrasound cardiotocography was accepted in expert circles; this happened after the industry – namely the Toitu company in Japan – employed the so-called 'auto-correlation principle' in 1977, which made a recording available that was much more in accordance with the beat-to-beat variability.

From the very beginning we have warned against using cardiotocography as a single method and we introduced the combined fetal monitoring during labor for the first time by recommending the use of both methods – CTG routinely and, if indicated (abnormal CTG), additionally FBA. This was, already in 1968, the *start of combined electronic and biochemical monitoring* of the fetus.[40] This kind of monitoring remains the safest and most efficient way of supervision of the fetus during labor, provided it is used clinically according to our experience and to the recommended strategy. In the meantime a great number of papers have been published in which FBA formed either solely or partly the subject matter. We also contributed and tried to explain further basic aspects, additional clinical findings and recommendations as well as criticisms about misuse of modern fetal monitoring during labor.[41–46]

In connection with such a critical statement we once gave a humorous, less scientific but impressive and illustrative description of the advantages and disadvantages of cardiotocography in simple terms.[44] For this purpose we took an example from nature:

The cardiotocogram situation can be compared with the screaming of monkeys in the jungle: when danger is imminent they always scream. When there is a threat of hypoxia, the CTG is almost always suspicious or pathological. But monkeys have the typical attribute of screaming much too often; especially when there is no danger at all. The CTG often does this too, in the figurative sense. It is suspicious or pathological, but there are no real reasons to suspect dangerous fetal hypoxia – as measurements of the acid–base balance can clearly prove. This is unfortunately the reverse side of cardiotocography which many obstetricians either fail to recognize or push aside with naive credulity. If the newborn are vigorous after operative delivery – as regards their acidity and clinical state – then many colleagues excuse their management by saying that a hypoxia had just been avoided by well-timed intervention. Anyone who performs FBA, can give enough examples how often such excuses are self deception or a misguidance to the patient.

Unfortunately, too many clinicians and investigators did not follow the recommendations we had expressed from the very beginning, namely not to use cardiotocography as a single method to supervise the fetus but to combine it with FBA when an abnormal heart rate pattern appears. The adverse effects of the last 30 years are well known. They range from the polemic public discussions about fetal monitoring to recent debate about the rare intrapartum origin of cerebral palsy. We think most of such negative consequences could have been avoided with the use of combined electronic–biochemical supervision. So, for instance, the argument that false estimation of 'modern monitoring' was the main reason for the wrong conclusion, that cerebral palsy was so often caused by

malpractice of obstetricians in the labor ward, is not correct from our point of view. This misleading assumption would never have been made if combined supervision of the fetus during labor (CTG plus FBA) – which has now been available for almost three decades – had always been correctly used everywhere as a standard method in routine practice, for the pathogenetic contradiction (cerebral palsy without proven hypoxia) would then have been obviously recognized at the very beginning and not now after almost 30 years.

Ultrasound scanning

Without doubt, one of the most important landmarks of prenatal obstetrics is *ultrasonic diagnostics.* It not only serves to supplement the typical attribute of the obstetrician's acknowledged palpatory skill, but in many respects competes with it as an instrument of equal or superior capability.

The 'father' of obstetrical and gynecological ultrasonic diagnostics is Ian Donald. Donald *et al.* in 1958 published the first scans of fetuses aged 14 gestational weeks.[47] Donald and Brown published pictures of a hydatid mole, a hydrocephalus and the first prenatal measurements of the biparietal diameter with the help of the A-mode procedure in 1961.[48] This was the beginning of fetal biometry and the diagnosis of gestational age later improved by measuring the crown–rump length. Sonographic placental diagnostics began when Gottesfeld demonstrated cross-sectional pictures of the placenta.[49,50] Important steps forward were made in the diagnosing of malformations through the progress achieved in ultrasonic techniques and by the detailed presentation of fetal organs, particularly with the gray-scale technique developed by Kossoff *et al.*[51]

Sonographic vitality diagnostics started with the first registration of fetal movements in the 7th week of gestation by Donald,[52] and also with the first registration of fetal heart movements with the help of the Doppler procedure performed by Callaghan *et al.* in 1964.[53] In 1967, Kratochwil and Eisenhut reported on evidence of fetal heart actions in the 6th week of gestation with the help of the A-mode procedure.[54] In 1973, Reinold reported on qualitatively different movement patterns of the fetus and their prognostic value.[55] In 1971, before real-time ultrasound had been developed, Boddy and Robinson gave proof of fetal thorax movements with the help of an A-scan.[56]

Stimulated by studies resulting from animal experiments by Dawes,[29] numerous systematic investigations of fetal breathing movements, among others by Gennser,[57] were undertaken with the help of real-time procedure. Studies on the complex behavioral pattern of the fetus in early pregnancy were published by De Vries *et al.*[58] and on behavioral states in advanced pregnancy by Nijhuis et al.[59]

Blood flow measurements using the ultrasound Doppler technique are a new landmark in prenatal supervision. With the help of this technique it was possible to make non-invasive measurements of the uterine and fetal blood flow, which allow conclusions to be drawn concerning the placental hemodynamics. The first report on the use of the Doppler technique for examining fetal blood flow in the umbilical artery was published in 1977 by Fitzgerald and Drumm.[60] Studies followed on the first measurements in the umbilical vein, by Gill,[61] and on measurements of blood flow in the fetal aorta, by Eik-Nes *et al.*[62] Campbell *et al.* presented a new important contribution in 1983 enabling us to measure the uteroplacental flow.[63]

Tocolysis

Another step forward during the 'youth era' was the application of betamimetics to inhibit contractions. The now classical term *tocolysis* was introduced by Mosler in 1964.[64] The use of tocolytics for prevention of prematurity is now obsolete as prematurity is caused mostly by ascending infection. At the present time, the real task of tocolytic substances applied antepartum is to postpone premature labor for a short period of a few days to perform lung maturity treatment of the highly endangered premature fetus.

There is no controversy as to the advantage of using betamimetics during labor for intrauterine resuscitation. The first clinical applications were undertaken in 1969 by the Galdeyro-Barcia group[65] and shortly afterward by Gamissans *et al.*[66] and Esteban-Altirriba *et al.*[67] It has been confirmed that acute hypoxic complications in the fetus can be relieved by the administration of a relatively high dose of bolus injection or an infusion to the mother. The use of tocolysis during labor has also proved to be of clinical value in cases with hypertonic or hyperactive uterine dysfunction. Tocolysis has also led to considerable improvements in the *external version* of the fetus from breech to vertex presentation. Unnecessary cesarean sections can be avoided using this method and a number of infants are spared the risk of vaginal breech delivery. We performed an external version near term under tocolysis for the first time in 1974, published in 1975.[68] The method, when properly applied, does not provide any serious risk to the fetus. Up to now, no infant has died as a result of the use of this method in over 2000 versions performed in our department.

Cervical ripening

Further progress in modern obstetrics was achieved by the introduction of *cervical ripening* by prostaglandin application into routine practice by Calder in 1975,[69] after Lippert had developed the prostaglandin gel

principle in 1973 in this country for use in artificial abortion.[70] By means of general local administration (extra-amnially, intracervically, intravaginally) of prostaglandin E, numerous operative deliveries can be avoided in cases with an unripe cervix.

Lung maturation diagnostics

The clinical picture of 'respiratory distress syndrome' was first described by Hochheim in 1903.[71] In 1947, Gruenwald suggested that there was linkage with the surface tension in the lungs.[72] Clements called the postulated component reducing the surface tension 'pulmonary surfactant' and discussed its central importance as an antiatelectasis factor in 1956.[73] In 1959, for the first time, Avery and Mead suggested a relation between low surface activity and the occurrence of respiratory distress syndrome.[74] Graven reported in 1968 on the determination of phospholipids in human and monkey amniotic fluid and assumed an association between a low concentration of phospholipids and the probability of respiratory distress syndrome developing.[75] Gluck *et al.* were able to prove a close relation between the phospholipid content of the amniotic fluid and fetal lung maturity. They started their work in 1968 and in 1971, published the most often cited study on this particular subject.[76]

Lung maturation therapy

Neonatal morbidity and mortality have been decreasing during the past decades. The reasons for this are:

(1) There has been improvement in neonatal intensive care, particularly in artificial respiration techniques and application of surfactants.
(2) The widespread use of tocolytic substances has enabled us to delay premature delivery until lung maturation can be improved with the aid of various drugs. The glucocorticoids hold the leading position in this group.

In 1968, Buckingham *et al.* developed the hypothesis that glucocorticoids promote fetal lung maturation – on account of the stimulation of alkaline phosphatase proved in experiments on animals.[77] Liggins supported this hypothesis in 1969 with his observations during artificial induction of labor: the lungs of prematurely induced lambs that had been given glucocorticoids were clearly more mature than the lungs of lambs of the same gestational age that had not been treated in this way. He postulated, after this chance observation, that glucocorticoids bring about an acceleration in the formation of surface-active substances in the lung via enzyme induction.[78]

In 1972 Liggins and Howie, in their epochal prospective study, were able to transfer the experience achieved in animal experiments to human beings.[79] The occurrence of respiratory distress syndrome after antepartum administration of betamethasone to the mother could be reduced from 24% to 4.3% compared to the control group, who received no therapy. According to Liggins and Howie, the preventive effect of betamethasone is all the more efficient the lower the gestational age (26–32 weeks).

General discussion and conclusions

The last part of this contribution is directed to further historical facts, to some general views and to structural consequences. Basically, some points should be taken into consideration when describing the history of this new 'prenatal medicine' or 'prenatal obstetrics' as a whole. We believe that such a recapitulation is of importance as our mainly foreign colleagues, particularly the younger ones, no longer seem to be aware how, where and when this new medicine started.

The *foundation of scientific associations* concerned with this speciality developed accordingly. In 1967, the first national society, the German Society of Perinatal Medicine, was founded. One year later (1968), in Berlin, we started the first international society, the European Association of Perinatal Medicine.

The term 'perinatal' instead of 'prenatal' in the German and European societies has been chosen because, from the very beginning, we wanted to achieve close cooperation with neonatologists. In fact, it mainly concerned and represented the medical progress that prevailed in the prenatal area and was, for instance, reflected in 80–90% of topics of prenatal medicine at nearly all German congresses in this field, each of which attracted more than 2000 participants.

The Society of Perinatal Obstetricians in America was founded in 1977 and represents one of the most dynamic national societies in the world at the present time.

During our lifetime not only has outer space been opened up in such a spectacular fashion, but also on a biological level an equally important development has started rolling and has still by no means come to a halt; I mean the medical exploration of our own 'intrauterine space', our 'prenatal cradle'. Very few people are aware of this fact.

A disastrous conclusion drawn by many influential colleagues in our country and also in many other places was to think from the beginning that we were dealing with a special narrow and limited field – a field of medicine of particular interest to only a few colleagues and practiced mainly by the younger ones from time to time. And so it was thought, based on the conventional all-round structure of obstetrics and gynecology as a whole and according to the *status quo ante*, that all these revolutionary events could be taken into consideration and the rotation principle could still be maintained. The consequences of this grave error of judgment continue, even today, to give

cause for concern to a wide extent in some parts of Europe.

Realization of structural consequences began at an appropriately early stage in the United States. The setting up of 'Units of Maternal–Fetal Medicine', begun in 1972, made successful the consequent use of the prenatal part of perinatal medicine within the framework of the complete field of obstetrics and gynecology.

The term 'fetal medicine', which is still used today in the form of 'maternal–fetal medicine', had probably not been considered enough when it was introduced at the very beginning for clinical purposes. Unfortunately, it does not include the embryonic period, which also belongs to our clinical competence. The consequence is that other subspecialties have been more aware of this and are using this term, for example, in the name of their society, namely, European Society of Human Reproduction and Embryology. We, therefore, prefer the general term 'prenatal medicine', which some colleagues use erroneously for only a special subordinated field, mainly for diagnostics of anomalies and some special therapeutic procedures in early pregnancy. As an alternative, the term 'pre- and perinatal obstetrics' would be appropriate, if preferred.

On the basis of the enormous progress already achieved in 1967, we recommended a structural reform of the discipline in our country and the setting up of units of modern obstetrics and prenatal medicine.[80] However, up to now many European university departments, particularly in our country, do not have such units. The consequences are depressing as regards highly qualified research activities and our international image. Due to the lack of the necessary requirements, not enough interested colleagues could remain working in this field for a longer period to become adequately specialized and to obtain appropriate career chances. Consequently, some of the European countries concerned have only a few internationally reputed 'perinatal obstetricians'.

The birth and youth of prenatal obstetrics and perinatal medicine were to a large extent a product of European clinicians and scientists, although many impulses in numerous fields of medicine since the Second World War have come from abroad, particularly from North America. It is therefore particularly commendable that the European Association of Perinatal Medicine again took up the initiative and, under the leadership of such a powerful and outstanding colleague as Asim Kurjak together with the participation of so many renowned experts, is publishing an extensive current review about our great field of perinatal medicine.

These great steps forward have by no means come to a halt, as many opposed to this direction of development have been artlessly suggesting for years. It would be most improbable if a practically newly opened extensive area – as represented by the intrauterine space up to the beginning of the 1960s – should be fully explored medically within only 38 years. The work will certainly go on and perhaps when the next generation period is over, several of the modern achievements, of which we are so proud today, may be regarded as obsolete. New pioneers will take over our role then, and the next generation will again continue this course of medical science and course of life.

II Memories of the World Association of Perinatal Medicine

S. Sakamoto

The First International Congress of Perinatal Medicine, 1991, was the first global meeting of scientists, clinicians, midwives and persons who are concerned with perinatal medicine. Although academic exchange in this field had been active on the regional level, this congress was the first worldwide meeting of its kind following agreement at the Rio de Janeiro FIGO meeting in 1989.

How was the World Association of Perinatal Medicine (WAPM) born? Its history

On the occasion of the new publication on perinatology, we had better look back at the history of the international congress of perinatal medicine to know how the WAPM started its activity.

Since the 1960s, there has been a scientific breakthrough in perinatology, due to the remarkable development of medical science. As a result, many federations of perinatology were born: the European Congress of Perinatology, first started in 1968, the high-level scientific exchange system in the USA, the Asia Oceania Federation of Perinatology (1979) and the Latin–American Federation (1980s).

The idea of having an international-level body for perinatal medicine came to the mind of the pioneers. In Europe, Prof. E. Saling took up the initiative to set up the international congress of perinatology, which was unfortunately discontinued, and Prof. E. Cosmi proposed the foundation of the international-level federation on the occasion of the European Congress of Perinatology, Rome, in 1987, and preparatory work has just started. In 1989, on the occasion of the FIGO Congress, Rio de Janeiro, Prof. R. Caldeyro-Barcia, a famous perinatologist from Uruguay and former FIGO president, had a meeting with the invited participants from about 40 countries, around 70 doctors, for a discussion on how to set up the international body. The objectives were unanimously approved, but it was hard to decide on a method of setting up the proposed federation. Then I proposed 'Let's have one international congress under a suitable person in a suitable place, and at the end of the congress, Mr. Chairman, you should have a general assembly and ask the delegates again to vote whether the foundation of an international body is necessary or not?' Prof. Caldeyro-Barcia and all the participants agreed with this idea and finally nominated me as the president of the congress, requesting that the congress be held in the autumn of 1991 in Tokyo. Preparation for the congress was expected to be completed within 2 years.

The congress was held under the name of the First International Congress of Perinatal Medicine, in November 5–8, 1991, at the Keio Plaza Hotel in Tokyo, and was attended by 1580 participants from 45 countries, and a total of 516 invited and oral and poster papers were presented. It was a great success. Prof. R. Caldeyro-Barcia chaired the general assembly held immediately after the congress was over and about 60 delegates from 45 countries attended. They rated the first congress very highly and the foundation of an international body the, World Association of Perinatal Medicine, was unanimously accepted.

Thus, the WAPM was satisfactorily formed. All members signed as founders. Annual fees, etc. were carefully discussed, but as the discussion took time, the chairman proposed the election of officers and entrusted them with the preparatory work.

I was then elected as the first president of WAPM. Other officers were also elected.

I thought the second congress should be held in Europe and I proposed Prof. Cosmi as the president and Rome as the venue. As Cosmi and I worked for FIGO as members of the executive board, I knew he had a strong wish to be the president of the congress. Then, the chairman closed the session, with congratulatory remarks.

I believe that WAPM is really Prof. Robert Caldeyro-Barcia's legacy, just as FIGO, IFFS and IAMANEH are called Hubert de Watteville's legacy. And the First International Congress was nominated naturally as the first congress of WAPM.

His Imperial Majesty Akihito's opening address

His Imperial Majesty Akihito kindly attended the opening ceremony of the First International Congress of Perinatal Medicine and welcome party with Her Majesty Michiko.

The success of this congress, I believe, was due to his speech, which was full of deep thoughts and stimulating messages.

At the request of the sixth president of WAPM, Prof. Kurjak, I quote here our emperor's address:

> It is my heartfelt pleasure to convene the First International Congress of Perinatal Medicine in Tokyo, where the East meets the West. Perinatal cares, which address the safety and happiness of mother and child, have always been pursued in earnest by both obstetricians and pediatricians. At last, in 1968, the academic outline of perinatal medicine, called perinatology was established in Europe. Hence, perinatal medicine has become new and important area in academic fields. During the following two decades, with remarkable advancements in science, important discoveries were made, in succession, about the fetus, which previously had been kept in a black box. It is truly noteworthy that neonatology also has become a brilliant specialty, and academic findings are now vigorously exchanged in feedback between researchers. As a biologist, I fully understand that perinatology in a broad sense consists of maternal medicine, fetal medicine and neonatology.
>
> I am deeply impressed that scholars from many specialties reached beyond their own territories and exchange expertise to establish a new academic branch, the core of which is new life. I am convinced that deep reverence of life as well as love of mankind has made it possible. I would like to praise the pioneers and their followers who gather here today.
>
> When we reflect on the situation of mother and child at a global level, we realize that the achievements from advanced studies benefit only people in advanced nations. I am pained to think that young mothers, newborn babies and infants in many developing countries where people face problems associated with population explosion do not benefit from the fruits of advanced studies. All lives, great or small, have an equal right to enjoy happiness and maintain dignity. I pray that you take that initiative to extend helpful hands to these less fortunate people.
>
> In this International Congress, not only advancements from studies but also other efforts are joined to spread reality-based information. In that regard, the Congress will make great achievements. It is my sincere hope that the Congress will create a milestone.

The Emperor and Empress are extremely concerned with perinatal medicine. His Majesty spoke with infinite care to make sure no word was left unheard. Everyone at the opening ceremony could not help but be captivated by his Majesty's warm personality. It was the moment when people who have taken separate ways to reach the peak of perinatal medicine came together to achieve the ideas of the future.

Progress and development of fetal medicine up to the First Congress, 1991

Fetal care was initially developed to prevent fetal disorders by improving obstetrical care related to labor and delivery. It became clear that neonatal care, in collaboration with obstetrics and pediatrics, was essential in obtaining a better prognosis in newborn infants, which led to the establishment of perinatal medicine.

Since the 1960s, 20 years have passed. Perinatal medicine has achieved tremendous progress in safe care for mother and child. Furthermore, as neonatal care has developed to neonatology, fetal therapy is now becoming a new scientific field – fetal medicine. However, looking back, the scientific level at around 1980 was like this.

Development of perinatology

Experiments in perinatal medicine, such as pathophysiology of the fetus and neonatal hypoxia and metabolic analysis of thermogenesis of neonates, were carried out during the 1960s.

Progress in fetal medicine

Progress in fetal therapy can be divided into three phases according to therapeutic objectives. The first decade, 1960–1975, is defined as a period of fetal emergency care. Many trials were concentrated on diagnosis of fetal distress (this word has since been changed) and resuscitation of newborn infants.

The following decade, 1975–1985, was a period of long-term management of abnormal fetuses during pregnancy. The introduction of ultrasonographic observation brought about new diagnostic techniques in fetal inspection.

This decade, and the following 5 years (1985–1990), brought a new era of fetal therapy in which we can apply individualized diagnostic measures and therapeutic devices to different types of fetal disorders.

Establishment of fetal emergency care

Fetal emergency care was established by the progress in fetal monitoring. Cardiotocography and chemical diagnosis of fetal blood gave a very accurate diagnosis of fetal distress. Biochemical analysis of maternal hormone secretion and blood enzymatic distribution also provided criteria for placental dysfunction. These led to diagnosis of chronically affected fetuses.

Therapeutic effects, caused by oxygen inhalation and maternal infusion therapy, could be satisfactorily evaluated and gave more accurate timing of emergency care for the fetus. However, caution against unnecessary management due to overdiagnosis was advised elsewhere.

In this period, diagnostic criteria for fetal distress by different methods were proposed by distinguished researchers. Pathophysiological diagnosis for encephalopathy of the fetus and neonate, and fetal endocrinology have become subjects of extensive research.

Long-term management of fetus *in utero*

The second decade of progress in perinatology was defined between 1975 and 1985. Progress in ultrasonic diagnosis of the fetus resulted in the second advanced stage in fetal care. Abnormalities in fetal growth could be accurately diagnosed by fetometry. In addition, a cross-sectional view of the fetus gave us a new indication for therapeutic measures, such as fetal surgery, fetal biopsy, reproductive physiology, etc.

Blood flow determination by Doppler ultrasound enabled us to monitor circulatory conditions in the fetus. These contributed to long-term management of the fetus *in utero*.

Congenital hydrocephalus develops rapidly around the 28th week of gestation.

Close observation of cerebral thickness gives the exact timing of induction of labor. Radical neurosurgery to construct permanent drainage followed by delivery saves the baby from mental disorders.

Accurate diagnosis of placenta previa and precise determination of fetal growth could be easily obtained by ultrasonography.

Intrauterine blood transfusion, or even an exchange transfusion through the umbilical vein when blood incompatibility occurs, could be carried out by guided catheterization under ultrasonography.

Genetic diagnosis done by amniocentesis, chorionic villi sampling and neonatal blood sampling, developed during this period, was also one of the remarkable advances in fetal medicine. Some of the inborn errors of metabolism that affect the mental development of the newborn, such as methyl maronic acidemia or galactosemia, can be treated by maternal administration of cyanocobalamin or a low-galactose diet for the mother. Folic acid therapy has been recommended to prevent fetal spina bifida.

A typical medical intervention in the handicapped fetus with hydrocephalus is described as an example. Enlargement of BPD was clearly shown ultrasonographically. Progress of ventricular dilatation and thinning of the cerebral cortex by CT were carefully monitored along with fetal growth and maturation.

Our case was born at 36 weeks of gestation by cesarean section followed by neurosurgery of continuous drainage. Both the fetus' maturation tolerance to surgical stress and the prognostic limitation of the ventricular enlargement were carefully taken into consideration in determining the time of delivery.

By CT scanning, performed 1 week after surgery, a remarkable reduction in ventricular size was noted. The baby recovered smoothly and obtained normal mental development at the age of 1 year.

Individualization in fetal therapy

Advances in bioengineering and molecular biology in recent years contribute greatly to the scientific basis of perinatal medicine. Feto-maternal interaction of growth factors and endothelial functions of chorionic villi gave basic consideration of the pathogenesis of intrauterine growth retardation (IUGR).

Feto-maternal interaction was clearly demonstrated by IGF-1 regulation in relation to fetal growth. This is an example of research work picked up from many works.

Production of IGF-1 is switched over from the maternal liver to the placenta. Activity of IGF-1 in the placental environment is regulated by the autocrine function of the villi and paracrine function of villi and decidua. The hPL and placental GH stimulate IGF-1 and its binding protein production in the maternal liver. Binding protein is also regulated by protease from deciduas. These facts suggest that duplicate cycle for IGF-1 regulation functions during pregnancy. Fetal growth factors are independent of the maternal side; however, they show their activity substrate dependency on maternal transport of nutrients. IGFs mainly have three types of structure, IGF-1, -2 and -3, and they have different functions. Other growth factors concerning the fetal growth should be studied carefully.

Coagulation and fibrinolysis system – thrombomoduline

This system is another example of the new approach to analyze placental circulation in PIH. It became clear that trophoblast has an endothelial function maintaining smooth blood circulation in the intervillous space, where most slow and complicated blood streams exist, and easily forms infarction during abnormal conditions, in cases such as PIH. Our data clearly indicated decreased trophoblastic thrombomodulin activity in PIH, which referred to endothelial function. This is one of the explanations for the fact that remarkable IUGR takes place in severe PIH. Endothelial function in pregnancy is also an important field of study.

Fetal surgery

A direct therapeutic approach to the fetus, such as catheter replacement and experimental trial of gene manipulation, may lead to radical treatment *in utero*. Open fetal surgery may lead to complete correction of fetal anomalies. Direct catheter replacement in

half-delivered fetuses with urethral obstruction at the 30th week through the incised uterine window was first performed in 1990. The window was closed and the amnion was supplied through a catheter. The baby was successfully managed for a considerable period *in utero* after surgery. Radical urethral reconstruction was performed in the neonatal period. This shows that fetal medicine is obtaining general consensus for clinical use.

Several years ago, the international symposium 'The Fetus as a Patient' was held with the high expectations by all perinatologists. Fetal medicine, which started from emergency care of fetal distress 25 years ago, is now able to apply total medical care to the fetus. Our hope symbolized in 'The Fetus as a Patient' is now being realized.

Finally, I would like to conclude by saying, 'Whenever, wherever, we have our hopes and dreams, they will certainly be realized and bring a brighter future in perinatal medicine'.

The above examples are samples of perinatal research and treatment performed around the 1980s. More developed research work had been performed by the pioneers, but member of which were quite limited.

In this book the most developed data will be described. You may find a dramatic development in perinatal medicine in the period from 1991 until 2005.

Closing remarks

While the 20th century was the era of advance in science and technology, with the emphasis on physics, the 21st century is the era of chemistry and the genome, and can be called the period of respect for life and establishment of human dignity. People who are sick or suffer from extreme poverty long for the normalization of the quality of life and the life worth living. It is our duty to deal with such evidence and respond to the wish of those countless people. Naturally, these actions require highly advanced science and appropriate as well as reasonable means of healing.

Medicine must not only be highly advanced but must also bring peace to lonely souls. Life-long education also is our own choice and duty, imposing on our experience. Physicians must be always disciplined to be humble. Medical care should not be ruled by temporal good intention or judgment, but should aim at the future of humankind, especially of the mother and child.

For the younger generation:

- What we should do, is taught by the mind and body of patients.
- What we should not do, we learn from the history of evidence, and valuable experience.

Last, I would like to close my remarks with my own view for medicine, which was first proposed in the 1991 Congress.

May our international festival of academia be a forum and an opportunity to turn human dreams to hopes, and hopes to reality, thus bringing to all humanity true peace and happiness. (1991)

III Perinatal medicine in the United States

E. J. Quilligan

It is always difficult to set a date as to when perinatal medicine began in the United States. During the 1940s, 1950s and 1960s there seemed to be a significant increase in research, both basic and clinical, regarding the pregnant mother and her fetus. This was fueled by the increase in federal grant funds, the increased numbers of full-time faculty in Obstetrics and Gynecology and the developing technology that would allow measurement of hitherto inaccessible fetal and maternal parameters. For example, the intrauterine catheter allowed the development of a new understanding of the work required by the uterus during labor and how abnormalities of the contraction pattern may lead to abnormal labor.[1] The development of more sophisticated electronics allowed the recording of the fetal heart rate throughout labor.[2]

Another factor important in the development of perinatal medicine was the growing awareness that a pregnant patient with medical complications, such as diabetes, needed completely different care from a non-pregnant diabetic. In the past it was usually the case that the obstetrician managed the pregnancy and an internist managed the diabetes. This occasionally led to difficulties as the two physicians were not working in concert. It was found that the well-prepared obstetrician could manage both with better outcomes for mother and fetus.

A more specific date can be set for the beginning of the subspecialty of maternal fetal medicine in the United States. The American Board of Obstetrics and Gynecology, under the leadership of Gordon W. Douglas, MD, organized a meeting in 1969 to determine the feasibility of subspecialty certification or boards in Obstetrics and Gynecology.[3] I was fortunate to chair the discussion on maternal fetal medicine. It was the consensus of our committee, and ultimately the Board, that there were adequate numbers of obstetricians and gynecologists who were primarily interested in maternal fetal medicine from a clinical and research standpoint to justify a subspecialty board or certification. A similar conclusion was reached with regard to oncology and reproductive endocrinology. The next 2 years were spent in developing the subspecialty divisions and getting the necessary approval from the American Board of Medical Specialties. It was decided that rather than being subspecialty boards, the parent board would offer certificates of special competence in the areas of maternal–fetal medicine, oncology and reproductive endocrinology. This was primarily due to the fact that the American Board of Medical Specialities had recently granted several subspecialty boards and had a temporary moratorium on new ones. We felt it was of no particular advantage to be a subspecialty board.

The American Board of Obstetrics and Gynecology did establish divisions of Maternal Fetal Medicine, Oncology and Reproductive Endocrinology in 1969. I was appointed the first head of the division of Maternal Fetal Medicine. There was one representative of the parent board in our division, Dr Harry Prystowsky. There were four additional members of the original division, Donald L. Hutchinson, MD, Edgar L. Makowski, MD, Joseph Seitchik, MD and Fredrick P. Zuspan, MD.

The purposes of our division were as follows: (1) to improve the health care of mother and fetus suffering from diseases peculiar to or related to gestation, by elevating the standard of education and training related to abnormal obstetrics, enhancing the recruitment of qualified physicians in this field, by improving the organization and distribution of patient care and increasing knowledge; (2) to evaluate the qualifications of educational programs offering training in maternal and fetal medicine for the purpose of providing improved patient care and adequate preparation and experience for the physician intending to become a specialist in this field; (3) to define periodically and to publish from time to time the details of formal training, which the division considers essential to attain eligibility for the examination; (4) to establish procedures whereby the knowledge and skills of a candidate for advanced certification may be evaluated, and examinations designed to determine the individual's competence as a specialist in maternal and fetal medicine and (5) to recommend to the Board for advanced certification of physicians who have demonstrated to the satisfaction of the Division their possession of special knowledge and a high degree of professional competence in the management of disorders of the mother and fetus.[4]

One of the first major decisions that had to be made was one that affected all the divisions, namely, how to treat those individuals who considered themselves subspecialists but had no formal training or had training that had not been Board approved: the grandfathers. Three choices were available: (1) have no grandfathers, make all candidates undergo board-approved training; (2) permit anyone who thinks they are qualified take the examinations, which would be for a specified period of time, and (3) allow all grandfathers to receive a certification. There was a lively discussion of this question with many feeling there should be no grandfathers. The threat of a protracted suit in one of the other divisions led us all to accept the second option: permit those who thought themselves qualified to take the examination. This option would be open only for a period of 2 years after the initial examination. The candidates choosing this option were required to submit an application, which described their residence training and any fellowship training they had taken. In addition, we required a case list of all complicated pregnancies they had managed during the previous 2 years as well as the total number of normal pregnancies they had managed during the same time period. A bibliography of all articles, book chapters and abstracts, including reprints of original articles, was a requirement. The type of application gave the Division the material needed to make a judgment as to whether an individual qualified as a grandfather.

The number and type of examinations were rather easily determined. The parent board had both written and oral examinations. All subspecialty divisions decided to follow that example. The scope of the written examination included (1) genetics, biochemistry of genes and chromosomes, gene transformation in man, cytogenetics and karyotyping, population genetics and genetic counseling; (2) teratology, knowledge of embryology, drugs that affect the fetus, viral effects on the fetus, bacterial effects on the fetus and radiation effects on the fetus; (3) maternal physiology; (4) fetal physiology; (5) effects of maternal disease on the fetus; (6) effects of pregnancy on maternal disease; (7) immunology; (8) evaluation of fetal welfare during pregnancy and labor; (9) newborn adjustments and adaptations to health and disease; (10) infection in mother and fetus, diagnosis and therapy; (11) immunologic disorders; (12) intrapartum disorders and (13) general knowledge of investigative concepts and techniques and the knowledge necessary to critically evaluate studies in maternal and fetal medicine. An individual passing the written examination was eligible to take the oral examination after 2 years of practice. The 2 years of practice was waived for grandfathers. Requirements for the oral examinations included a case list for the 2 years of practice and a thesis of original clinical or basic research. The oral examination was conducted by two examiners and a neonatologist questioning the candidate for 3 h on the thesis, case list and knowledge of maternal–fetal medicine including investigative concepts.[4]

The Division developed the required training program, which was of 2 years' duration with the following requirements: (1) training could be obtained in one or more institutions; (2) at all times there must be evidence of a patient population adequate to assure the candidate of a satisfactory experience; (3) comprehensive care of maternal and fetal disorders requires (a) a high-risk pregnancy unit with adequate numbers of pregnant patients presenting special problems defined as high risk, adequate supervision by individuals competent in the care of high-risk pregnant patients and adequate laboratory and monitoring equipment, (b) a genetics unit with a qualified geneticist and laboratory to perform genetic analysis including karyotyping and biochemical studies, (c) a newborn care unit with a noenatologist director and adequate numbers of newborns requiring intensive care and (d) a pathology service with a qualified fetal and newborn pathologist and (4) there should be a program director certified as a Diplomate of the American Board of Obstetrics and Gynecology who is judged to be qualified to direct such a program. The last requirement was soon changed to a person certified as a subspecialist in maternal–fetal medicine. Each new training program was inspected by one or more division members.

A significant number of changes have occurred since the initial candidates were examined in 1973. After the second oral examination the neonatologists were not used since this area was felt to be primarily in the realm of a new subspecialty within pediatrics, neonatology. In 1975 the case list for oral examination was reduced to 18 months before the application was submitted.[5] In 1977 obstetric anesthesia was added to the scope of the oral examinations and an obstetric anesthesiologist was a required part of the training program.[6] The 1978 bulletin did specify that 'The program must include two university-level courses, one in qualitative techniques which should include biostatistics and other areas such as epidemiology and research design and implementation. The second course must be relevant to the specific subspecialty. Both courses must be approved by the division. All courses must have an examination which the candidate must pass'. Also in 1978 the thesis requirement was changed to a paper in press or published within the past 3 years in a peer review journal.[7] In 1979 the ultrasound unit was required in the training program and ultrasound became a part of the written and oral examinations.[8] In 1986 a *Guide of Learning* was published by the Board, which gave a much more complete outline of the scope of knowledge required by a subspecialist.[9] Perhaps the most significant change occurred in 1998 when the division decided to lengthen the training to 3 years.[10] The Division, from its inception, felt that research was a very important part of the training program. This was evident in the first bulletin, which stated: 'The candidate must possess (a) an understanding and general knowledge of

investigative concepts and techniques as they relate to maternal health and fetal development and (b) the knowledge necessary to evaluate studies relative to maternal and fetal medicine'. It was expected, though not specifically stated, that one of the 3 years be spent in research.

The type of practice for a maternal and fetal medicine subspecialist has changed significantly during the 30 years since the inception of the division. Initially, the subspecialist was primarily a consultant for pregnancy with complications. With the development of sophisticated ultrasound and the increasing understanding of genetic abnormalities, a significant portion of the subspecialist's time is spent doing ultrasound.

A reasonable question might be what is the result of the development of the subspecialty of maternal and fetal medicine? This can be answered both numerically and philosophically. Numerically, there are currently 62 approved programs in maternal and fetal medicine. There have been 1542 candidates certified. Philosophically, I believe it has resulted in significantly better care for the pregnant patient with complications. This is difficult to prove because there have been so many changes in practice during the same time period, such as the development of neonatal intensive care units, antepartum fetal monitoring and the development of ultrasound. All of these and more may have resulted in the significant decreases in perinatal mortality and stillbirth rate. The integration of care in a single individual who is focused on the pregnant patient with a complication such as diabetes or hypertension, in my opinion, must result in improved care.

IV A perspective on perinatal medicine

E. V. Cosmi

The process of fetal growth and development of the human fetus at birth has always attracted the attention of scientists. Hippocrates, 460–370 B.C., suggested that when the onset of labor is near 'the fetus becomes agitated and breaks the membranes'. Leonardo da Vinci said that 'the child grows daily more within the body of its mother that when it is outside of the body, and this teaches us …'. In the 17th century Sir William Harvey suggested a direct role of the fetus in the initiation of parturition, a concept that was endorsed by Van Deventer in the same century and by Spielberg in 1882.

Subsequently many animal experimentations and human observations have attempted to discover the many mysteries of fetal and neonatal growth and development, the features of the cardiovascular and respiratory systems, some relevant aspects of energy metabolism, temperature control and their integration by hormonal and nervous mechanisms, the role of the placenta, the initiation of labor, the transition from the intrauterine to the extrauterine life of the fetus, etc.

Considering comparative physiology it has been recognized that general principles should hold in every species with peculiar adaptation to particular needs.

Some species lend themselves well to a particular type of study, e.g. the fetal lamb, because it is relatively large and comparable by weight to the human fetus and because the uterus of the ewe does not at once contract, has been used for various studies, including fetal breathing movements (FBMs) and lung maturity. The fetal rhesus monkey has been studied mainly because its brain is more closely related to that of the human fetus and of the newborn at birth; furthermore, since the lamb's brain is only 1.3% of body weight at birth, whereas that of the fetal rhesus monkey is 12%, the latter is a better model for studying the distribution of cardiac output (CO).[1]

Finally, the hemochorial placenta of the rhesus monkey and also that of the pig are more suitable for the study of placental transfer of gases, other supplies, and drugs than the cotyledonary placenta of the ewe.

The beginning of fetal physiology is rooted in the measurements of placental and fetal growth and in comparative studies of placental histology that were made long before physiologic data could be collected and properly understood. The pioneers of this approach are many; they include Sir Joseph Barcroft (1946)[2] and, around the 1960s, D. H. Barron, H. Prystowski, C. A. Villee, P. Grunewald, R. Margaria (Turin, Italy), R. E. Cooke, E. Ramsey, I. Leitsch, F. C. Hytten, E. G. Makowski, F. C. Battaglia, G. Meschia, A. N. Rudolph, G. S. Dawes and others.

Because perinatal biology encompasses marked differences among mammals in placentation, fetal and neonatal development, and in the adaptation made by the mother during pregnancy and lactation, the young of different species are often said to be at different maturity at birth. Nevertheless, most mammals and the human infants have one thing in common, i.e. they all must have developed, by the time they are born, the circulation and the lungs, which will permit maintenance of an independent existence outside the uterus. Initially, following acute experiments in animals, Barcroft[2] believed that the fetus was living *in utero* under conditions of anaerobiosis or semianaerobiosis, thereby introducing the concept of 'the Everest *in utero*', i.e. the fetus living under low oxygen tension. This concept was further supported by the low pO_2, pH and high pCO_2 found at birth in the umbilical arteries and vein of the human fetus. Chronic experiments performed in several pregnant animals and their fetuses have refuted this misconception and have shown instead that the oxygen supply and consumption, and the acid–base status of the fetus are similar to that of the mother.[3–8] These results have been substantiated in the human fetus by James *et al.*[9], Caldeyro-Barcia,[10] and Saling.[11] They have found that during labor and delivery fetal pO_2 and pH decrease whereas pCO_2 and buffer base increase.

The introduction of the micromethod of P. Astrup of blood sampling and acid–base status analysis has permitted the confirmation of these studies in animals and subsequent studies in the human fetus and neonate. Normally, although the PaO_2 of the fetus is around 30 Torr, hemoglobin-O_2 saturation is around 90%, also because of the double (maternal and fetal) Bohr effect on the O_2 transfer across the placenta.[12]

Another concept that was put forward was that although the fetus has a relatively high tolerance to noxious agents, many noxious factors can affect its normal intrauterine development, physiologic

performance, and subsequent adaptation to the extrauterine life. These factors may originate in the mother, the placenta, or in the fetus itself. Other sources of trouble include environmental, nutritional, pharmacologic, and toxicologic factors; hematologic, hormonal, metabolic, immunologic, and genetic disorders; and infections diseases (for a review see Cosmi and Caldeyro-Barcia[12]).

Considerable efforts have been made to elucidate the morphology and the physiology of the placenta because the homeostasis of the mammalian fetus depends almost entirely on its function and on maternal homeostasis. Chorioallantoic placentas differ remarkably in shape and structure from one mammal to another and their classification on the basis of shape, morphometry, morphology, function, and the presence or absence of a maternal (decidual) component has resulted in considerable controversy.

In humans the implantation and subsequent development of the placenta depend on certain changes in the endometrium that culminate in the formation of the decidua. Basically, the human placenta has a chorioallantoic structure in which the precocious differentiated mesoderm of the allantois forms the umbilical cord.

Prof. P. M. Motta from the University 'La Sapienza' of Rome has contributed significantly with electron microscopy to clarify the process of implantation of the fertilized human ovum.[13]

In humans shortly after fertilization, the ovum is implanted and the trophoblast erodes the endometrial capillaries. At the end of the second week the endometrial veins have been eroded and communicate with the lacunar spaces. At about the 15th day, endometrial spiral arterioles are eroded and maternal inflow to the intervillous space is established. By the 16th day the entire surface of the ovum is covered with branching villi containing vascular primordia. Between days 20 and 21 after the beginning of nidation the chorionic villi show a well-defined ultrastructure with a relatively undifferentiated Langhans' layer and highly differentiated syncytiotrophoblast layer, located peripherally. By days 22 and 23 the embryonic vessels have formed an anastomotic network of channels within the villi. By 12 weeks, other villi are found, which fill the intervillous space. Each primary villus with his branching and rebranching villi constitutes a fetal cotyledon, which is the functional unit of the placenta. The villous core contains fetal capillaries, fibroblasts, the Hofbauer cells (which are morphologically similar to macrophages, originate from the mesemchyma, and possess pinocytotic and histiocytic activity), and other mesenchymal elements.[12]

One of the major advances in perinatal genetic diagnosis has been the introduction by Bruno Brambati (Milan, Italy) of chorionic villi sampling,[14] which can be performed at 9–10 weeks' gestation, thereby offering earlier diagnosis than amniocentesis and the analysis of the amniotic fluid (AF), which is performed between 14 and 18 weeks' gestation, or cordocentesis which is performed around 20 weeks' gestation for hematologic problems, infections, metabolic and enzymatic diseases. However, chorionic villi and cordocentesis are coupled with significantly higher complications than amniocentesis. The basement membrane contains immunoglobins IgG and IgA, which probably represent maternal blocking antibodies to trophoblastic antigens, thereby preventing the rejection of the placenta. Various proteins are produced by the placenta in increasing amounts during gestation. Some, such as pregnancy-specific β_1-glycoprotein (SP_1, $PS\beta_1G$), pregnancy-associated plasma protein C (PAPP-C) and α_2-glycoprotein (PAPP-α_2G), are probably trophoblast-specific antigens described by Bohn.[15] These are mainly released into the maternal circulation, where they can be measured and used as an index of placental function, whereas other proteins have enzymatic or hormonal activity. Recently, for prenatal genetic diagnosis the following tests have been introduced using maternal blood: (1) double test – determination of PAPP-A and human chorionic gonadotropin β (hCG-β) (free) performed between 9 and 13 weeks' gestation *vis à vis* fetal nuchal translucency; (2) triple test – determination of hCG-β or hCG-β (free), α-fetoprotein, and free estriol between 14 and 19 weeks; (3) quadruple test – as above plus determination of PS-β at the same gestational age; and (5) pentatest – as above plus inhibin. The reliability of these tests is much less than that of amniocentesis and fetal cell culture. However, they may be indicative of certain fetal chromosomal abnormalities.

Different types of fetal nucleated cells have been found in maternal blood by Adinolfi[16] and our group,[17] providing the possibility for non-invasive prenatal diagnosis of genetic abnormalities; however, the results of these and further studies have been inconclusive. The same holds for the study of fetal nucleated cells obtained by washing of the cervical fornix.

Lo *et al.*[18] and Farina *et al.*[19] have studied the DNA of fetal cells in maternal circulation for non-monogenic diseases such as abortion, pre-eclampsia, and IUGR. Although promising, this approach needs further studies.

The placenta, like the fetus and the mother, produces certain enzymes and hormones that influence not only its function but also those of the other two compartments – e.g. composition of the nutrients supply from the maternal circulation to the fetus, maternal and fetal metabolism, and eventually fetal growth. Conversely, placental function is influenced by fetal and maternal enzymes and hormones. The placenta possesses enzymes that are absent in the fetus, and enzymes lacking in the placenta are present in the fetus. The integrated placental and fetal functions act as a unit, and the *feto-placental unit* is indispensable for the production of most steroid hormones as suggested by Diczfalusy[20] (see below).

Several enzymes have been isolated and their activity varies during gestation, i.e. lysosomal hydrolase activity reflects the need for specialized functions (e.g. lysosomal hyaluronidase, which probably plays an important role in the regulation of placental permeability, increases with gestation).

The human placenta synthesizes and stores carbohydrates, lipids, proteins, nucleotides, and nucleic acids,[12] possesses mixed function oxidation systems and aryl hydrocarbon hydrolase involved in the transportation of xenobiotics and epoxides.[12] It is rich in 11β-ol-dehydrogenase, which *converts active steroids into inactive 11-ketosteroids*. Therefore, the question has been posed as to whether certain corticosteroids, e.g. betamethasone, administered to the mother reach the fetus in sufficient quantities to elicit their biological effect – i.e. acceleration of fetal lung maturity (FLM).[12] The placenta also contains monoamine oxidase and catechol-*O*-methyltransferase, which significantly effect the transfer of the catecholamines. Renin is also produced by the placenta. This enzyme is released into the AF. The placenta is unique in its capacity to form proteins and steroid hormones, i.e. hCG, hPL, hPRL, human chorionic thyrotropin, somatomedins C and A,[21] and adrenocorticotropic hormone (ACTH) related peptides, i.e. hCG, α-melanocyte-stimulating hormone, thyroid-stimulating hormone, and luteinizing hormone releasing factors, β-lipotropin, and β-endorphin, as demonstrated by Fraioli and Genazzani.[22]

The placenta produces large amounts of progestogens and estrogens in increasing concentrations during pregnancy. These hormones have important effects, such as the regulation of fetal growth, development, and sexual differentiation; uterine growth and contractility; the onset of labor; and uteroplacental blood flow. Estrogen production is not due solely to the placenta but to the interaction between the mother, placenta, and fetus, which *act as a unit*.[20] The production of E_3 involves the formation of precursors by fetal and maternal adrenals; 16α-hydroxylation of DHAS and E_1 or E_1 sulfate by the fetal and the maternal livers; and aromatization by the placenta. The concentration of E3 in body fluids increases steadily throughout a normal pregnancy.

Concerning the *fetal circulation* in the mature placenta, it is worth mentioning that in the definitive (tertiary) villi, arterioles and veins are given off from axially oriented trunks to supply and drain an extensive anastomosing capillary network, which lies superficially beneath the surface syncytium. Fetal blood is in close contact with maternal blood, being separated by a thin syncytiocapillary membrane.[23] Information on the fetal circulation has been derived principally from animal experiments, using a variety of methods, i.e. cineangiocardiography, blood gas analyses, blood flow measurements by electromagnetic flow meters, distribution of radioisotope-labeled microspheres, dye dilution, radioisotope methods, and Doppler ultrasound. Some of the findings from these experiments have been corroborated for the human in studies of the human fetus itself.

A variable portion of the blood returning from the fetal placenta via the umbilical vein is distributed to both right and left lobes of the liver and reaches the interior vena cava via the hepatic veins. The remainder of the blood returning from the placenta is shunted directly to the inferior vena cava via the ductus venosus in amounts varying between 20% and 90% of umbilical–portal blood flow. In the left atrium, blood from the inferior vena cava mixes with blood coming from the pulmonary veins in a ratio of about 4.5:1. Thus, the abdominal organs, the lower body, and the placenta are supplied with blood with a lower pO_2 than the coronary circulation, heart, neck, and brain.[24]

The right and the left ventricles work in parallel by virtue of the presence of the foramen ovale and the ductus arteriosus. Approximately 40% of the combined CO returns to the placenta, while only 7% flows through the lungs; the remainder perfuses body tissues. To define fetal CO, Assali *et al.* introduced the term 'effective CO' – i.e. the total volume of the blood that is distributed to the body and the placenta.[25] This represents the sum of the left ventricular output and the ductus arteriosus blood flow, and does not include coronary blood flow and the flow to the lungs. Rudolph had introduced the term 'combined ventricular output', which represents the total volume of blood ejected by both ventricles and includes pulmonary and coronary flows.[24]

It has been suggested that changes in differential CO that may occur in the fetus as a result of changes in the venous return or outflow impedance are adjusted homeometrically by the Frank–Starling relationship.[7,25,26] Rudolph[24] (from the Cardio-Vascular Institute of San Francisco, directed by Julius Comroe) has criticized this theory and indicated that the Frank–Starling mechanism is essentially inoperative in the fetal myocardium because of the large shunts between the left and the right sides of the heart, and because of the fact that the two ventricles work in parallel. Thus, in contrast to the adult, the fetus has only a limited ability to increase CO by increasing stroke volume. The increase in CO is accomplished primarily by increasing the heart rate (HR).

The cardiovascular system of the fetus is under the direct control of the autonomic nervous system through peripheral chemoreceptors and baroreceptors. In the human fetus the clearest evidence for autonomic activity is the transient bradycardia associated with uterine contraction and abolished by administration of atropine to the mother, as shown by Caldeyro-Barcia *et al.*[27] The fetal cardiovascular system is capable of responding to various humoral and pharmacological agents.

Moderate fetal hypoxemia and/or hypercapnia cause a rise in arterial pressure, vasoconstriction in

the lungs, and little change in umbilical vascular resistance. At the same time, umbilical, coronary, carotid, and superior sagittal sinus blood flows increase, ensuring a better oxygen uptake and supply to vital organs. Fetal heart rate (FHR) increases initially in response to hypoxemia, but if hypoxemia persists and/or becomes more pronounced, bradycardia develops.

Fetal hypoxemia of a marked degree and/or acidemia also induce an increase in blood flow to vital organs (i.e. heart, brain, and adrenal glands), but cause a decrease in blood flow to non-vital organs (i.e. lungs, gut, spleen, kidneys, and the carcass). The selective vasoconstriction in the latter organs is accompanied by hypertension and bradycardia and later, if it persists, by anaerobic glycolysis and metabolic acidemia. Although hypertension tends to increase perfusion pressure and umbilical blood flow, with marked hypoxia and bradycardia umbilical blood flow will fall.[12]

The cardiovascular response of the fetus to hypoxia and acidosis with redistribution of the systemic circulation is a defense mechanism for conserving the oxygen supply to vital organs and for adjusting to the effects of accumulated metabolites, such as carbon dioxide and hydrogen ions. This defense mechanism is similar to that of diving mammals – e.g. the ability of the fetus of the seal and of other mammals to survive its mother's prolonged dives,[28,29] also called, less precisely, the brain sparing effect. However, it is limited, for although CO remains virtually constant, the blood redistributed to vital organs may be diverted away from the placenta, thereby further reducing the oxygen supply to the fetus.[12,24] A fall in CO will cause a marked reduction in umbilical blood flow. The survival time of the asphyxiated fetus depends on the concentration of glycogen in the myocardium before the asphyxial episodes.

FHR and ECG: FHR and ECG monitoring are the oldest and most frequently used methods of fetal surveillance.[30,31] The ultrasound technique, based on the Doppler principle,* is the method most widely used for recording FHR. Concern still exists as to its relative value, accuracy of interpretation, and prognostic significance. Caldeyro-Barcia *et al.*[30,31] combined the recording of uterine contractility with FHR monitoring. Subsequently, Hon *et al.*[32] applied a similar method and obtained analogous results.

Direct fetal ECG was obtained by placing a bipolar electrode directly on the fetus either transcervically or by maternal transabdominal puncture. With this method one detects changes in ECG pattern and FHR that may coincide with early alterations in fetal homeostasis and neonatal morbidity. The technique has been refined by the use of special nonpolarizable clips, suction, hooks, or other types of transcervical electrodes, monitoring devices and group averaging of a series of consecutive ECG complexes.[32,33] In Italy, fetal ECG has been studied extensively by Pardi *et al.*[34] Opinions pertaining to alterations in fetal ECG and their reliability and accuracy in predicting fetal distress vary considerably. Prolongation of the P–R and Q–T intervals, widening of the QRS complex, and isoelectric or inverted T-waves have been observed in conjunction with fetal hypoxia and acidosis. Shortening of the Q–T and P–R intervals with peaked, biphasic, and inverted P-waves, and inversion of the T-wave have been also recorded in the presence of severe fetal asphyxia. Forms of 'arrhythmias' have been observed – i.e. nodal extrasystoles, atrial flutter, atrial and ventricular premature beats in the form of persistent bigeminy, paroxysmal atrial tachycardia, and heart block. However, in both the human and the animal fetuses, no definite relationship was found between ECG abnormalities and the acid–base status of the fetus. Although ECG abnormalities could represent a possible early sign of fetal distress, their significance in relation to fetal homeostasis and neonatal outcome has not been settled.[4,12]

Doppler ultrasound has been recently introduced in the study of fetal circulation and several vessels including umbilical artery (UA), descending aorta, internal carotid artery, middle cerebral artery (MCA), ductus venosus and renal artery have been investigated. Preliminary statistical correlations between perinatal complications and abnormalities in indices of flow resistance have been reported, suggesting a potential role for Doppler ultrasound in the management of high-risk pregnancies. Several indices have been introduced to analyze flow velocity waveform, including pulsability index (PI) and resistance index, by several groups including Arduini and Rizzo,[35] Campbell and Bower,[36] Kurjak *et al.*,[37] and Chervenak and McCullough.[38] It has been found that absent or reversed diastolic blood flow of UA and low PI in MCA are often associated with alteration of FHR. However, no reference values on large population studies are available for flow velocity waveforms. Transcutaneous pO_2 and pulse oximetry and computerized FHR have also been introduced to improve the accuracy of the latter with variable results.

Fetal breathing activity in utero has been a matter of controversy for a long time. Rhythmic, periodic FBMs were observed and/or recorded in humans between 1888 and 1911 by Ahlfeld,[39] Weber,[40] Ferroni of Florence,[41] and Reifferscheid,[42] and in animals from 1781 until 1941.[12,43] These reports have been almost universally ignored or discounted as artifacts, and subsequent studies have in general denied that FBMs are normally present *in utero*, provided the fetus is not disturbed by physical stimuli or asphyxia. They have been rediscovered around 1970 in the fetal lamb by Dawes and coworkers,[44,45] Condorelli, Cosmi,

* This principle was theorized in 1794 by the Italian biologist Lazzaro Spallanzani, i.e. the bat's ability to 'see'. The bat gets bearing by sound rather than light.[12]

and Scarpelli.[29,46–48] Studies in human fetuses have demonstrated that FBMs are normal phenomena of intrauterine development.[12,43,48] Observation of both animal and human fetuses have indicated that FBMs might provide an index of fetal well-being.[42,44] In the human fetus, FBMs have been studied by injecting isotopes into AF, by means of force transducers placed on the maternal abdomen, and, more precisely, by ultrasound. Various systems have been used to quantify ultrasonic signals of FBMs, including A-mode, continuous Doppler systems, T-mode, time–distance recording systems, and real-time B-scan.[12,43]

Recently, we have measured nasal flow velocity waveforms (NFVW) with continuous or power Doppler, *vis à vis* the thoracic and abdominal movements, in more than 1800 human fetuses[49] and have observed that during gestation the fetal respiratory patterns are similar to those we had observed in preterm and term newborns,[50] i.e. they start at around 20 weeks' gestation as abdominal movements followed by thoracic movements and NFVW as gestational age advances. We have correlated FBMs during gestation with FLM and have found that the full development of FBMs indicates FLM.[49]

Amniotic fluid indices: *Amniocentesis* and the analysis of AF have been introduced successfully by Bevis,[51] Liley,[52] and Freda *et al.*[53] for the spectrophotometric analysis of AF at wavelengths between 300 and 700 nm in case of Rh alloimmunization and erythroblastosis fetalis. When AF contains bile pigments that absorb monochromatic light at wavelengths between 525 and 375 nm, there is an elevation above the expected slope of the curve, with a peak around 400 nm. The magnitude of this departure from the expected curve (between 525 and 375 nm) is proportional to the concentration of bilirubin and related pigments, while its width is constant and reflects the condition of the fetus.[12,52,53] Liley's method offers a more precise quantification of AF bilirubin concentration, but the upper limits of normality are too low, leading to an overestimation of the degree of fetal compromise. Freda's method takes into consideration the trend rather than the absolute concentration of bilirubin and related pigments. During the same year Freda introduced Rh gammaglobulins for the prevention of Rh alloimmunization;[54,55] since then, the disease has practically disappeared.

Amniocentesis has been widely used for *culturing and karyotyping* of AF cells by Valenti *et al.*[56] and Steele and Breg.[57] Recently, diagnosis of many genetic diseases has been performed particularly after the completion of the study of genome mapping and the introduction of fluorescence *in situ* hybridization and polymerase chain reaction techniques. It is possible to diagnose fetal sex and a variety of genetic disorders including Down's syndrome, Duchenne/Beker muscular dystrophy, deafness, cystic fibrosis, fragile X-syndrome, hemoglobinopathies, e.g. hemophilia, inborn errors of metabolism. Amniocentesis is performed between 14 and 18 weeks' gestation.

Fetal lung maturity: In recent years various laboratory tests for AF constituents to predict FLM have been developed. They can be divided into biochemical [determination of surfactant phospholipids (PLs)] and biophysical methods (e.g. surface tension, microviscosity).[12] Gluck *et al.*[58] were the first to demonstrate that the lecithin–sphiengomyelin ratio of AF provides an index of FLM. This ratio can be used to predict whether or not neonatal respiratory distress syndrome (NRDS) will develop in the infant if born within 24–48 h of amniocentesis. The same group measured other AF PLs, i.e. phosphatidylinositol and phosphatidylglycerol, and introduced the lung profile.[59] Clements *et al.* in 1972 introduced a simple and rapid screening method: the shake test.[60] Various tests have been introduced,[12] including lamellar body count and Doppler ultrasound.[61] These tests have good predictive values, high specificity, and sensitivity.

We have demonstrated that fetal urine contributes to AF PLs,[62] although in much lower concentrations than fetal pulmonary PLs.[63]

The pulmonary surfactants play a critical role in the survival of the fetus in the extrauterine life, especially in case of premature delivery and other forms of high-risk pregnancy, because a prompt and effective ventilation is required at birth. In turn, this depends on the alveolar stability (alveolar resistance to collapse) and thus on lung maturity. When FLM is not fully reached, delivery almost invariably results in NRDS. This disease is responsible for a major portion of perinatal mortality and morbidity (including neurologic and intellectual defects).

In recent years our understanding of perinatal lung development and of the pathophysiology of neonatal lung adaptation has increased considerably as a result of intensive studies by various investigators. Much experimental work has focused on the functional significance of the surfactant system of the lung during transition from fetal to neonatal life, on its role in the pathogenesis of NRDS, and on various methods that can facilitate the adaptation of the premature infant to extrauterine life.[64]

In 1903 Hochheim[65] first described the formation of hyaline membrane in the lungs of two infants dying from respiratory insufficiency in the neonatal period. Because of this finding, the term generally used to describe this disorder until 1959 was 'hyaline membrane disease' (HMD). Subsequently, it was realized that early pathologic hallmarks of HMD are atelectasis and intra-alveolar edema [in part perhaps representing unresorbed fetal pulmonary fluid (FPF)], whereas hyaline membranes, which develop at a later stage of the disease, may be absent in infants dying within a few hours of birth. The membranes are made up of degenerated epithelial cells, blood cells, fibrin, and components of the alveolar lining layer.

NRDS begins shortly after birth. The classical picture of tachypnea, expiratory grunting, sternal and intercostal inspiratory reactions, inability to maintain adequate oxygenation in room air, cyanosis, the diffuse hypolucency, and the air bronchogram at chest x-ray, all indicate alveolar instability, i.e. decreased functional residual capacity. Expiratory grunting represents an attempt by the newborn infant to overcome alveolar collapse. In fact, by prolonging the expiration and increasing the pressure within the alveoli, the neonate obtains a better diffusion of oxygen across the air–blood barrier. It is noteworthy that the method of therapy with mechanical ventilation of the lung under positive end-expiratory pressure is based on this premise. In fact, Gregory *et al.* noted that when cyanotic babies cried they turned pink as a result of Valsalva's maneuver.[66] The clinical picture of NRDS may be mimicked by 'transient tachypnea', or the so-called NRDS type II, due to slow resorption of FPF. However, this latter symptomatology usually disappears in less than 24 h, whereas that of NRDS lasts at least 24 h.[60]

The pathophysiology of NRDS was poorly understood until the discovery of pulmonary surfactants.[67,68] In 1959, Avery and Mead[69] were the first to demonstrate the deficiency of surfactants in saline extracts of lungs from infants who had died of NRDS. Several subsequent reports have confirmed that lungs of newborn infants with NRDS have a high surface tension[70,71] and therefore tend to collapse. This finding is in agreement with the abnormal characteristics observed in pressure–volume curves from lungs of infants with NRDS: high opening pressure required to inflate the alveoli; more important, poor ability to maintain a residual volume of air once all distending pressure is removed; and small hysteresis between inflation and deflation curves.[63,70,71]

Under normal conditions, the surface tension on expiration is extremely low because surfactants are present in the alveolar air–liquid interface. King and Clements[72] have suggested that the alveolar stability is determined by low surface compressibility. Colacicco and Scarpelli,[73,74] in their *in vitro* studies on surface properties of pulmonary dipalmitoyl lecithin, have indicated that surface tension is virtually zero and have thus substantiated the original 'zero surface tension, antiedema' theory of Pattle.[67] The implication of this is that surface tension is of primary importance in maintaining alveolar stability in the newborn infant as compared to older individuals, since the former have less rigid chest walls, and therefore the opposing force to alveolar collapse is low.[64,71] Many diverse theories have been proposed to define the etiology and pathogenesis of NRDS, most of which emphasize the prominent role of surfactant deficiency, secondary to prematurity. Liggins[75] showed in the 1960s that ablation of the anterior pituitary gland of the lamb fetus resulted in prolongation of pregnancy, whereas subsequent administration of ACTH or corticosteroids initiated labor. In the latter case, the preterm newborn seldom had serious lung problems such as RDS. This indicated, both to Liggins and Howie[76] and to Avery,[77] that administration of glucocorticoids to the mother might accelerate FLM. Liggins also demonstrated a primary role for progesterone in the maintenance of pregnancy in the sheep model, an observation that led to the estrogen–progesterone ratio hypothesis developed by Csapo.[78] Controlled clinical trials have been performed with i.m. injection of one, two, three doses of betamethasone (12 mg each, 24 h apart), dexamethasone (12 mg/day), or hydrocortisone (a single dose of 100 mg) to the mother. The results have been in general promising with few side effects. To avoid these it has been suggested by NIH consensus conferences and the European Study against Immature Lung that one course of betamethasone should be used, avoiding a second course of 1 week later.[79,80] Other drugs have been used both in animals and in humans to accelerate FLM, with less promising results than glucocorticoids.[79] Cosmi *et al.*[81,82] have injected supplementary surfactant (SS) obtained from pig lungs into the amniotic liquid close to the nostrils of the human fetus after the administration of aminophylline to the mother to induce FBMs, thereby favoring the entrance of SS into the fetal trachea and upper airways, in cases of severe fetal distress and/or preterm labor, and have obtained good results. These findings have been confirmed in humans by a Chinese group[83] and in animal experiments.[84] It should be noted that after the pioneering study of Fujiwara in 1980 supplementary surfactant has been used successfully for the treatment of rescue babies, i.e. with NRDS, and recently for early (prophylactic) treatment of NRDS (for a review see Cosmi *et al.*[80]).

Other important discoveries have been made in perinatal medicine, i.e. that prostaglandins have a definite role in parturition, followed by the observations that there is a surge of certain prostaglandins in maternal plasma and urine during parturition, that the administration of drugs such as aspirin and indomethacin suppresses uterine activity, and that administration of prostaglandin precursors (either exogenous, e.g. arachidonic acid, or endogenus, e.g. PLs from fetal urine into the AF[62]) is capable of inducing labor. It is now universally recognized that certain prostaglandins are clinically effective for induction of labor.

A link between infection and preterm delivery was proposed by Romero and Mazor[85] in 1988. The paradigm of infection-driven preterm labor has led to a better understanding of the cytokines produced by the placenta and the fetal membranes and by deciduas. It triggered the discovery of new uterotonins such as interleukin (IL) 1β, IL-6, tumor necrosis factor, endothelin-1, and transforming growth factor β-1, and of certain uterine relaxants, such as relaxin, prostaglandin inhibitors, thromboxane, and, more recently, nitric oxide. Cytokines and eicosanoids appear to interact on each other's production in a cascade.

At this point the complexities of the labor–delivery issue are abundantly clear as fetal–placental–maternal

parameters search for a unifying mantle (placental insufficiency, fetal distress, and endorphins?) or new biologically active substances (peptides such as corticotrophin releasing hormone, placental activin, and oxytocin?).

The unique stresses, both positive and negative, that *Homo sapiens* brings to the 'evolutionary' picture are also quite considerable. For example, preterm labor is now linked to social, economic, and environmental factors, including low economic status, poor working conditions, environmental pollution, maternal malnutrition, and substance abuse with cocaine and other drugs, smoking and alcohol being particularly offensive.

Stress generically and related biologically active substances such as oxytocin, antidiuretic hormone, catecholamines, and certain placental hormones also involved in the perception of pain have been recognized as labor inducers. Indeed, humans and animals under stressful conditions tend to initiate labor. The best example is given by the siege of Leningrad during World War II, when half of the pregnant women either aborted or delivered preterm overnight.

Notable advances are being made by researchers and public health officials to ameliorate the social economic challenges and to find new therapeutic approaches, e.g. in the areas of pain relief, inhibition of preterm labor, and fetal therapy, including surgical approaches. The pioneering transabdominal intrauterine recording method induced five decades ago by Alvarez and Caldeyro-Barcia[10,12,30] has led to useful observations on the pharmacology of the human uterus and on the effects of uterine contractions on the fetus. Many utero-inhibitory drugs have been introduced and tested with different results.[86] A major advance of pain relief during labor and delivery has been the introduction of regional (epidural and spinal) blocks with the i.v. prophylactic hydration of the mother combined with 1000 NS or 500 dextrane solution 1 h before the block to avoid hypotension from sympathetic blockade.[86,87]

Many formidable challenges remain. For example, the mode of delivery, vaginal vs. cesarean section, is a matter of continuous debate; the biophysical approach to fetal monitoring during labor is moving into the era of computers and maybe of nanotechnology; the invasive technique of fetal scalp blood sampling and acid–base status determination have been replaced by pulse oximetry and other techniques. Ultrasound and Doppler technology, including three-dimensional imaging, have entered the labor world. New methods of pain relief are sought and used with increased frequency. New technologies are being introduced at such a pace that soon they will be extended to the home environment, where the use of telemedicine[88] can be applied, not only for monitoring uterine activity, blood pressure, and maternal glycemia, but also in the neonatal cardiorespiratory system for the diagnosis and treatment of apnea of prematurity and sudden infant death syndrome.[50] Assisted reproduction techniques also pose a particularly intriguing challenge to the perinatology team, i.e. the obstetrician, biologist, neonatologist, anesthesiologist, midwife, and nurse, because of the increased incidence of complications during pregnancy, labor, and delivery. Among the opportunities brought by the new technologies that address the fetus and its mother directly, are the questions of propriety and ethics,[38] which are among those covered in many symposia, workshops, congresses, and books on perinatal medicine.

It is noteworthy that in 1984 I founded in Erice (Sicily, Italy) a permanent School of Perinatal Medicine, which is very active. Furthermore, around the same year, I founded the Italian Society of Perinatal Medicine, which is composed of the above specialists. In 1988 I Founded the World Federation of Perinatal Medicine which in 1991 became the World Association of Perinatal Medicine.

It seems that we are now in a period of development of that art, which may be characterized as the period of assimilation into academic medicine and medical practice. To some degree or other, each one of us has known the aura of anxiety in which perinatal medicine is cast. To whom does it belong? Obviously, it belongs to the perinatologist. But then, who is the perinatologist? Of course he is each one of us. He is the obstetrician, the fetologist, the neonatologist, the pediatrician, the anesthesiologist, the basic scientist, … . He is in fact the amalgamation of all and in this amalgamation he loses the primordial title as he practices and becomes the perinatologist. At some centers he is so designated, and his discipline – perinatal medicine – is so recognized. But at too many other centers he continues to strive to dispel the anxiety and to complete the assimilation. There is no question that the fall of departmental barriers will result in even greater achievements in this new era of perinatal care. Eleanor Roosevelt once said that we are indeed one world and should strive to live our lives that way. Similarly, perinatal medicine is a unified body of knowledge, a science in its own right.

1 Transition at birth

O. D. Saugstad

Introduction

The transition from fetal to postnatal life is characterized by a number of dramatic changes in physiological, biochemical, immunological, and hormonal functions. The fetus is fully dependent on the maternal supply not only of oxygen and nutrients but also of a number of hormones and other important substances. The thermal control of the fetus is also taken care of by the mother. Intestinal and breathing movements as well as non-shivering thermogenesis are partially inhibited. Large organs such as the lungs and liver are not very active. The fetus is also asleep most of the time. These are some important reasons why the oxygen requirements and metabolism are low in fetal life. Cardiac output is low with a low systemic blood pressure. A relatively low blood glucose level and oxygen supply is therefore sufficient to ensure substrate for energy metabolism at this stage.

During the last trimester the fetus prepares itself to meet the extrauterine milieu; energy stores are established, minerals and trace elements are deposited, both white and brown fat accumulate, the lungs mature both structurally and biochemically. The last means that the surfactant system matures and the antioxidative defense develops in order for the fetus to breathe and to be able to withstand the sudden increased oxidative stress induced by the high oxygen concentration in ambient air. Many epithelial transport functions of different organs mature in late fetal and early neonatal life.

After birth, the newly born infant is responsible for its own oxygenation and ventilation. The partially inhibited status of the fetus is immediately reversed at birth. It is awake, aroused, breathing, and crying. Metabolism increases with a subsequent increased oxygen demand, and the newborn can initiate lipolysis and mobilize glucose. The higher oxygen consumption of the brain is one reason the newborn brain is more vulnerable to hypoxia than in fetal life. The sharp increase in oxygen exposure makes it necessary for the newborn infant to protect itself from oxygen toxicity. Transition to birth is therefore not only a matter of redistribution of the circulation, maturation of the lungs and the surfactant system with alveolar gas exchange, it is much more complex and probably only a small part of this is understood. In the following some of these aspects will be discussed.

Growth

General principles

The greatest growth rate in human life occurs in the fetal period. The increase from a fertilized egg to a term newborn infant is in weight 6×10^{12}, in length 5000-fold, and in surface area 61×10^{6}. After birth, growth slows down, still the greatest postnatal growth rate occurs immediately after birth.

Prenatal growth is dependent on maternal, placental, and fetal factors. In the first trimester growth occurs by increase in cell number, in the second trimester there is an increase both in number and in cellular size. In the third trimester growth is mainly by cellular growth since the rate of mitosis slows down. During the first two trimesters the fetus has reached approximately one-third of its term weight. In this period only 50 g of fat is accumulated in contrast to approximately 500 g deposited in the last trimester. Of the approximately 95 kcal/kg/day needed by the fetus 40 kcal are spent for growth. Prenatal growth is dependent on autocrine and paracrine growth factors such as insulin-like factors 1 and 2; however, insulin also plays a major role in prenatal growth. Macrosomia is a well-known effect of fetal hyperinsulinism, and these children have increased body fat at 1 year of age. Abnormal patterns in insulin-like growth factor (IGF) 2 gene expression may lead to the Bechwith Wiedemann syndrome. These infants are large with elevated insulin levels.

Postnatal growth is mainly regulated through pituitary growth hormones (GHs), thyroid hormone, and other hormones. GH is high in the fetus; however, the number of GH receptors is low. That GH plays some role in fetal growth is reflected in the poor growth of children with GH deficiency or GH receptor deficiency (Laron syndrome), and its action is mediated by IGFs. During the first weeks of extrauterine life GH falls, and already in the first day of life a pulsatile release of GH is detected with a pulse periodicity of

73 min, with higher peaks and more frequent pulses found in small for gestational age (SGA) than in appropriate for gestational age (AGA) infants. This pulsatility is controlled by the stimulatory GH-releasing hormone and the inhibitory somatostatin, both produced in the hypothalamus. Thyroid hormone is a major factor in postnatal growth and an acute elevation with a peak in thyroid stimulating hormone (TSH) is found immediately after birth, with a decline the first 5–6 days after birth. Leptin is produced in adipose tissue and also regulates growth. Its role in fetal life is unknown, but high concentrations are found in the umbilical cord with a gradual decrease over the next 3 months. Androgens decrease leptin values, so that girls have higher concentrations than boys from birth; the significance of this seem not to be understood.

The changes in body composition the fetus undergoes with the advancement of gestation is a progressive decrease in total water, extracellular water, sodium, and chloride and an increase in intracellular water, potassium, calcium, and magnesium. The postnatal body composition changes are characterized by an increase in adipose tissue with a peak around 4–6 months, a progressive decrease in body water with a relative increase of intracellular water.[1–6]

Fluid shift

In early fetal life approximately 95% of the fetus is water, which gradually decreases throughout gestation, being 80% at 8 months and 75% at term. Mode of delivery does not seem to influence this. Simultaneously with this decline in body water there is a drastic decrease in extracellular and a gradual increase in intracellular water. This tendency continues until 9 months of age, when body water constitutes 62%. However, the total body water related to surface area does not change very much in this period. Maximal intracellular water of 43% of body weight is reached at 2 months of age at the same time when extracellular water is 30%. The term newborn loses 5–10% of its body weight and the preterm more. This is mainly due to loss of water; however, it is not clear whether this loss is predominantly from the extra- or intracellular space or perhaps both.

In the newborn's first days of life the blood volume is to a large extent dependent on placental transfusion at the time of delivery, which can be up to 25–50 ml/kg within 3 min. Whether or not this increase in blood volume of 50% is harmful is not clear. A delayed cord clamping may lead to a gradual increase in hematocrit within a couple of hours. This is caused by plasma loss of 30 ml/kg the following 4 h due to a shift of fluid from the plasma into the interstitial space in addition to an increased urinary output.[7,8]

Recently, it has become clear that specific water channels, aquaporines, play an important role in water transport and water balance. Aquaporines 1 and 4 have been found in the brain, 9 in the skin, 2 in the kidney, etc. The newborn kidneys' reduced ability to concentrate the urine is probably due to the lack of aquaporines. Aquaporines are active also in the perinatal period and probably are important for removing fluid from the lung and in so-called transitoric tachypne of the newborn.

Carbohydrates

Glucose is the major source of energy in fetal life and the fetus is entirely dependent on glucose delivery from the mother. It seems that the human fetus does not produce glucose until the end of gestation, and the brain requires a continuous glucose supply that is received from the mother – at term at a rate of 4–7 mg/kg/min. This equals 6–10 g glucose/kg/day and represents approximately 60% of the calories needed by the fetus. Glucose is transported by facilitated carrier-mediated placental diffusion. Several facilitated glucose transporters have been identified and recently cloned. They comprise a family of structurally related families and are designated GLUT. The primary function of these is to mediate the exchange of glucose between blood and the cytoplasm of the cell. Several of these GLUT are present in early fetal life.

Blood glucose is lower in the fetus compared with the mother but there is a significant correlation between maternal and fetal levels at least if the maternal levels are not too low (< 4.4 mmol/l), below which fetal concentrations are independent of maternal levels. At birth, the transplacental supply of nutrients is abruptly interrupted. The newborn infant therefore has to produce glucose from its own endogenous stores until feeding is started. At birth blood glucose is 60–75% of maternal levels and then falls over the next 1–2 h stabilizing at 2.5–3.3 mmol/l (45–60 mg/dl) in healthy term infants within 24 h. Maternal glucose supplementation during labor and delivery seems to blunt this decrease. With the initiation of feeding it increases, and after 24 h is between 2.5–5.0 mmol/l (45–90 mg/dl).

Glucose can be metabolized to either lactate, which occurs in anaerobic conditions, or to acetyl coenzyme A (Ac-CoA) under aerobic conditions. Pyruvate can be metabolized to either lactate or Ac-CoA; this is partly regulated by the relative amounts of the isoenzymes of lactate dehydrogenase (LDH). In adult brain the LDH isoenzyme composition favors aerobic oxidation of glucose but in the fetal and newborn brain the LDH composition allows anaerobic glycolysis. The placenta is impermeable to both insulin and glucagon, which are produced by the fetus at least from the 10th week of gestation. Glucose stimulates insulin in the third trimester only.

In late gestation, approximately 50% of the glucose is converted to glycogen in the liver and muscle, and to fat in the liver and adipose tissue. Glucose storage is regulated primarily by insulin but also by glucocorticoids. Glycogen is low until approximately 36 weeks of gestation; however, it triples in the liver until term,

when it reaches a maximum both in the liver and in the skeletal muscles. In other organs such as myocardium and lungs the peak is reached somewhat earlier, declining toward term. Postnatally, glycogen is the initial substrate for glucose, but only for a few hours. Within 24 h after birth the glycogen stores are more or less exhausted. Gluconeogenesis from fat and protein is therefore necessary to meet the metabolic demands, and this is in principle a postnatal event. Fat is therefore an important substrate for glucose production in the early newborn period. Although key enzymes for gluconeogenesis are present in the liver from early fetal life, gluconeogenetic activity is not expressed *in utero*, at least not until near term. In late gestation, fetal gluconeogenesis therefore occurs and may contribute to fetal glucose levels especially if the glucose supply from the mother is reduced, for instance, during maternal fasting or by intrauterine growth retardation. Initiation of lipolysis and gluconeogenesis is promoted by hormonal and enzymatic changes occurring in the first day of life. The insulin/glucagon ratio rapidly decreases after birth and the high postnatal concentrations of catecholamines, cortisone, and TSH contribute to this. In the newborn infant glycerol can be converted to glucose, contributing up to 20% of the hepatic glucose production. It has been shown that preterm infants of less than 28 weeks' gestation have the capability of gluconeogenesis from glycerol.[9–13]

Proteins

In the second and third trimester protein synthesis is especially high, however, with a reduced rate toward term. The term newborn infant has about 0.5 kg of protein after a many-fold linear increase in the last half of the gestation. Protein synthesis slows down toward term but is still high, approximately fivefold higher than adult levels. In fact, not only synthesis is high in fetal life, but breakdown of proteins is also increased, giving a high protein turnover in the fetus. There is a substantial difference between organs, with the highest rate of protein synthesis in the placenta, heart, and liver (half-life 1 day) compared with a half-life of 1 week in muscle. A number of growth factors may be responsible for this, such as IGF-1. For this reason the amino acid concentration in fetal plasma is higher than later in life, and the fetal/maternal amino acid ratio in plasma is high with a peak in the second trimester, when it is approximately 3:1, falling to 1.5:1 toward term. Intrauterine growth retardation is characterized by a falling fetal/maternal plasma amino acid ratio mainly due to an augmentation in the maternal levels.

Amino acids are transported across the placenta by both a direct active transfer of essential amino acids and placental cytosolic synthesis of non-essential amino acids. A number of amino acid transporters – at least 12 – have recently been identified. The rate of amino acid utilization is about 4 g/kg/day, similar to the estimated intake of very premature infants. A protein intake in the postnatal period of 2.8 g/kg/day is close to the minimal intake needed to ensure weight gain and nitrogen retention equal to intrauterine rates, and a protein intake of 3–4.3 g/kg/day is recommended. Some amino acids that are non-essential in postnatal life are essential in fetal life due to inadequate maturation of enzyme systems. One example of this is the absence of cysthionase, making the fetus completely dependent on the mother's cystine supply. During the first hours postnatally there is a rapid fall in plasma amino acid levels.[14,15]

Lipids

The fetus requires both essential and non-essential fatty acids from the mother, and fat represents one-sixth of the body weight at term.

Free fatty acid supply to the fetus may occur through a process of facilitated membrane translocation involving a plasma membrane protein, placental synthesis and release into the umbilical circulation, or lipolysis of triglycerides, lipoproteins, or phospholipids from either the maternal or the fetal side. The free fatty acid concentration and composition in the fetus reflect maternal values. It is well known that maternal manipulation with diet may change the growth and development of the fetus. For instance, mothers fed a diet high in docosahexenoic acid deliver babies with higher birth weight. These children seem to mature earlier and have a higher IQ at the age of 4 years. Triglycerides are hydrolyzed to fatty acids by lipoprotein lipases, which are secreted by capillary endothelium. Lipoprotein lipase is stimulated by insulin and is present in fetal life with low activities in muscle and heart but higher in the lungs. This may be of importance for surfactant synthesis and maturation. After birth, the activity of this enzyme increases both in preterm and term infants. However, in preterm infants the clearance of circulating triglycerides is reduced due to a lower enzyme activity than in the term infants, and this activity seems to be directly related to the degree of prematurity. In the human fetus, the enzymes for cholesterol and lipoprotein metabolism develop early in gestation. As low-density lipoprotein (LDL) receptor expression also increases in gestation serum cholesterol and LDL decrease to levels lower than that observed in early postnatal life. In breast-fed infants these metabolites increase rapidly and are doubled from day 1 to day 7 of life but are still only half of the adult levels.

In the last 8 weeks of gestation subcutaneous fat increases rapidly from approximately 20 to 350 g, and deep body fat from 10 to 80 g. The total fat content increases from 6 g at 22 weeks to 500 g at term.

Fatty acid catabolism is an important energy source in postnatal life. High concentrations of free fatty acids and glycerol soon after birth indicate the onset of lipolysis and lipid oxidation. Free fatty acids and

glycerol increase sharply and peak around 120 min after birth. Beta-oxidation of fatty acids occurs in the mitochondria. Ac-CoA is transesterified to carnitine by carnitine acyltransferase located on the inner mitochondrial membrane. Fatty acid oxidation is limited in the fetal myocardium because of a low concentration of carnitine and a limited number of mitochondria. Liver, brain, placenta, and lung also have limited capacity to oxidize fatty acids. After birth, however, fatty acid oxidation increases substantially and remains high until the time of weaning.

Lipogenesis is found in fetal tissue from 12 weeks of gestation and is stimulated by insulin and inhibited by glucagon or cAMP. Fatty acid synthesis declines after birth when the diet is milk, which is rich in fat. Placental transfer of ketone bodies in contrast to glycerol has been described. The fetus uses ketone bodies as substrates for oxidation and lipogenesis.[10,16–19]

Mineral metabolism

The placenta actively transports calcium to the fetus to allow rapid fetal skeletal mineralization. From 20 to 26 weeks of gestation fetal levels are maintained about 0.25 mmol/l (1mg/dl) above the maternal level. In the last trimester calcium stores quadruples. In humans two-thirds of the mean 30 g calcium in a healthy term fetus are transported in the last trimester. At birth the constant calcium supply is interrupted and there is a normal fall in serum calcium in the first hours after birth, reaching a stable level after 24–48 h of age of about 2–2.25 mmol/l. During the next few days there is a subsequent gradual increase, resulting in serum calcium of about 2.5 mmol/l at 1 week of age. In one study serum ionized calcium concentrations decreased from a mean 1.45 mmol/l at birth to 1.33 mmol/l at 2 h and 1.23 mmol/l at 24 h of age.

At birth parathyroid hormone is low, increasing two- to fourfold during the first 2 days of life, giving an efficient response after 3–4 days. In contrast, calcitonin levels are high in the newborn, thereby inhibiting calcium mobilization from bone. Magnesium, zinc, and phosphorus are also transported actively across the placenta from the mother to the fetus. During the first week of life magnesium levels show small variations, correlating directly with serum calcium and inversely with phosphorus. Adequate zinc levels are needed for normal fetal growth and postnatally the requirements are approximately 2 mg/day. Zinc deficiency in infancy may lead to failure to thrive and reduced immunological function. Globally, zinc deficiency represents a major health problem in infancy.[20–23]

Hormones

The endocrine system is involved in growth, reproduction, cellular nutrition, as well as energy, thermal, cardiovascular and fluid homeostasis. Many hormones do not cross the placenta but are found in the fetus around 10–12 weeks of gestation. This is true for GH, insulin, prolactin, and thyroxin.

Prolactin may play an important role in regulating fluid balance in fetal life. At term its levels are 20-fold higher than adult levels and decline rapidly in the first weeks after birth. This reduction may be linked to the decline in total body water after birth. Prolactin may also have a maturational effect on the pulmonary surfactant system in combination with glucocorticoids and thyroidea hormones. Thyrotropin-releasing factor regulates TSH and prolactin secretion. As early as 12 weeks of gestation it is clear that the fetus produces thyroxin and around 13 weeks of gestation TSH-producing cells have been identified. TSH both stimulates growth and contributes to differentiation of the thyroid gland. TSH does not cross the placenta and tri-iodothyronine (T3) and thyroxine (T4) do not cross in sufficient quantity for the fetus. The fetus is therefore dependent on its own pituitary and thyroid hormones in addition to supply from the mother. In contrast, thyrotropin-releasing factor crosses the placenta and stimulates fetal TSH. Fetal total and free T4 as well as thyroxin-binding globulin values increase during the gestation and reach the level of the mean adult values around 36 weeks. In umbilical cord blood TSH is low and increases rapidly within the first 10–15 min after birth, and T4 reaches a peak after 48 h as a response to the high TSH concentration. TSH remains high the first days of life before it reaches its low normal adult levels. The half-time of T4 is much shorter in the neonatal period compared with adult life, making the thyroxin requirements many times higher than in the adult period.

From the eighth week of gestation the fetal adrenal converts prenenolone to dehydroepiandrosterone sulfate, which in the fetal liver and other tissues is hydroxylated to 16-hydroxy-dehydroepiandrosterone, which passes to the placenta and forms estriol. Since estrogen is important in maintaining pregnancy the fetus therefore contributes to this itself.

The fetal adrenal cortex promotes fetal organ enzyme maturation and in the last part of gestation adrenocortico-tropic hormone and cortisol levels increase in the fetus influencing maturation of enzyme systems in the lung, gastrointestinal tract, and possibly other organs. After birth, cortisol levels decrease, reaching adult levels by the age of 2–3 months.[2,22,24–27]

Stress at birth

There is a dramatic activation of the adrenal, the sympathetic, and the parasympathetic systems toward term. The sympathoadrenal system develops in fetal life and the newborn infant has large adrenals and extra chromaffin tissue in the paraganglia. The adrenal cortex matures toward term and releases substantial amounts of epinephrine and norepinephrine near

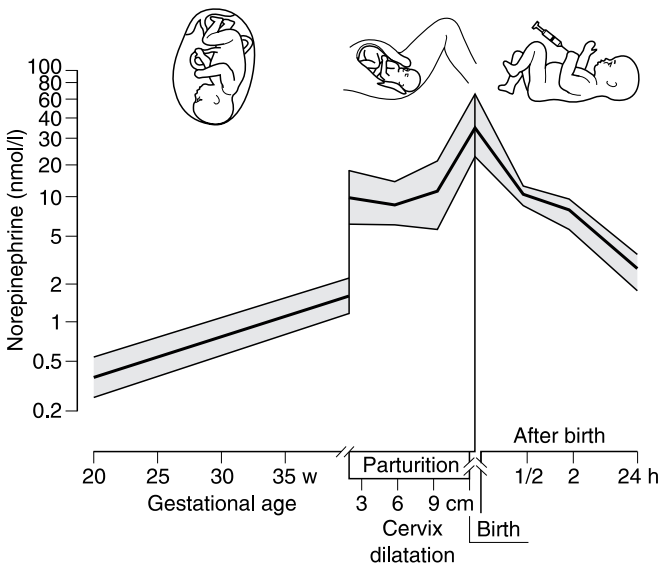

Figure 1.1 Norepinephrine concentration before, during, and after birth. From Lagercrantz.[28]

term. Corticosteroids around birth mature the surfactant system by inducing its synthesis, as well as antioxyenzymes in the lung, and further play a role in the labor process. Corticosteroids also induce the expression of phenylethanolamine-*N*-methyl-transferase, which converts norepinephrine to epinephrine. The transition at birth is characterized by high levels of catecholamines, angiotensin and vasopressin. The catecholamine levels are higher than in any other period of life under physiological circumstances. Norepinephrine constitutes approximately 85% of the total catecholamines and in plasma is normally increased 20-fold or more during the first stage of labor. Also, in the newborn infant the catecholamine levels are very high, continuing to rise immediately after birth then decreasing to the prelabor levels during the first 24 h or so (Figure 1.1). This is vital for successful postnatal adaptation.

The newly born infant is normally awake and alert. In these few hours, before it falls asleep, it is supersensitive to sensory stimulation. This arousal might be caused by the catecholamine surge at birth. An activation of catecholamines in the brain, especially in the locus ceruleus in the brainstem, takes place, and the turnover of norepinephrine increases several fold before birth. The high concentration of catecholamines also increases myocardial contractility, increases peripheral vascular resistance, promotes surfactant secretion, reduces production and increases absorption of lung water, mobilizes glucose and free fatty acids as energy substrates, and initiates non-shivering thermogenesis. The increase in circulating catecholamines at birth therefore probably is vital for cardiovascular adaptation at birth. Rhythmic lung inflation also increases plasma catecholamine levels as does cooling and umbilical cord clamping.

Sympathetic nervous activity, especially of the baroreceptors and chemoreceptors, increases during gestation and the influence of the parasympathetic system on the resting heart rate increases with maturation. In fetal life sympathetic tone is high and is important in maintaining fetal arterial blood pressure. The basal sympathetic tone fluctuates in the normal state and this is more important in fetal than in newborn life to generate blood pressure variability and is related to change in the behavioral state of the fetus. At birth the activity increases further, for instance, in renal sympathetic nerves, three- to fourfold; this is, however, observed only in full-term and not in preterm animals. This effect is also blunted by antenatal dexamethasone.[28,29]

Development of breathing

In the fetus spontaneous and rhythmic activity of the diaphragm and respiratory muscles occurs already from weeks 10–11 of gestation. The fetal breathing is, in contrast to postnatal breathing, not continuous, and with advancing gestational age fetal breathing movements become more sporadic and occur only during electrophysiological activity comparable to rapid eye movement (REM) states. From about 30 weeks of gestation the breathing seems to be more strongly influenced by the behavioral state and a powerful central inhibitory mechanism is functioning during non-REM activity. Near term the human fetus performs breathing movements approximately 25–30% of the time. In contrast to the adult in whom hypoxemia stimulates breathing, in the fetus it causes a rapid depression independently of the physiological state. This is also regulated centrally, possibly via some metabolites such as adenosine.

The first breath occurs normally at 10–30 s of life but is delayed in birth asphyxia and also in those given pure oxygen compared with room air. Immediately after birth breathing is irregular and deep but within minutes a regular breathing rhythm is established, and such a continuous breathing rhythm is activated by a number of stimulants. Separation of the placenta in itself stimulates respiration, perhaps by decrease of inhibitory substances such as adenosine and PGE_2, which are produced there. Since the concentration of, for instance, prostaglandin I_2 (PGI_2), decreases relatively slowly after birth, other factors must be responsible for the rapid initiation of respiration. Oxygenation of the lungs itself seems to stimulate respiration and may contribute to this establishment.

It is clear that respiratory control in the postnatal period is multifactorial. Airway mechanoreflexes, thermoregulation, chemoreflexes, and behavioral states are important. The influence of the behavioral states on breathing patterns in the newborn is important, especially since the newborn spends so much time asleep. During wakefulness and REM sleep, breathing is irregular; in quiet sleep, breathing is slower and more regular.

Immediately after birth thermal inputs play a major role in regulating the respiration. A cool environment stimulates breathing and it has been suggested that the increased metabolic drive this initiates in order to keep the infant in the thermo-neutral zone stimulates breathing. After a few weeks the thermo-neutral zone widens and this mechanism seems to be less influential. Instead vagal stimuli become more important and stretch receptors in the airways and lung parenchyma and chest wall determine both breathing depth and frequency. Lung inflation inhibits respiration, this phenomenon is known as the Hering–Breuer reflex and is more active in the newborn than in the adult and more active in the term than in the preterm infant. Further, it is more active during quiet sleep than in active sleep (REM sleep). The importance of mechanosensory receptors in the airways in regulating the respiration plays only a minor role immediately after birth and increases in the first weeks after birth.

The chemoreceptors in the carotid body respond both to pCO_2 and pO_2. In fetal life the set point for pO_2 is much lower than in postnatal life, which means they are silenced immediately after birth. The sensitivity of the chemoreceptors both in the carotid body and in the aorta then slowly shifts toward adult levels during the next few days. In fetal life the chemoreceptors increase their activity when paO_2 decreases below 2.7–3.3 kPa (20–25 mmHg). After birth, resetting of the chemoreceptors increases their activity if paO_2 decreases below 12–13.3 kPa (90–100 mmHg). The mechanism for this resetting is not fully understood and it has been suggested that the level of catecholamines, such as dopamine in the carotid body, may play a role. Four to seven weeks postnatally chemoregulation is established as the most important regulator of the respiration.

Hypercapnia affects the fetal breathing movements in REM-like sleep only, but much more weakly than after birth when resistance to hypercapnic respiratory stimulation disappears during the quiet sleep state. Sensitivity to CO_2 increases with increasing gestational age and is therefore less developed in the preterm than in the term infant. Hypoxia in the term newborn infant results in hyperventilation for some minutes followed by normalization or reduced ventilation due to a fall in respiratory frequency. This second phase of ventilatory depression is more marked in the preterm infant, who often will not go through the initial hyperventilation when exposed to hypoxia and thus has a response to hypoxia similar to the fetus.[30–33]

Perinatal transition of the lungs

The lung development goes through several stages: the embryonic (3–7 weeks postconception), pseudoglandular (5–17 weeks), canalicular (16–26 weeks), saccular (24–38 weeks), alveolar (36 weeks to 2 years postnatally). A detailed description of these is found in several textbooks. Suffice here to mention that in the canalicular stage the appearance of vascular canals multiplies to form the alveolar-capillary respiratory membrane, which is the air–blood barrier and the future gas exchange surface. The epithelium is thinner and gas exchange may take place at the end of this stage. The saccular stage is characterized by dilatation of terminal respiratory units into alveolar saccules and ducts, with a reduction in the interstitial tissue. The alveolar stage is characterized by the formation of secondary alveolar septa that partition the terminal ducts and saccules into mature alveoli. The alveolar septa become thinner during this stage, which also increases the surface area of the lungs significantly. Most alveoli (80%) are formed after birth.[31,34]

Inflation

In fetal life the lungs are fluid filled and a normal fluid volume is a major determinant of normal lung growth. Lung liquid is actively secreted by epithelial cells, but the formation and volume decrease toward term. At birth an abrupt stop is needed. It seems that labor itself more than mechanical squeezing of lung fluid clears the lung of its liquid. The secretory process in fetal life is abruptly switched to allow absorption from the lung lumen into the fetal circulation. Two hours after birth the lung liquid normally is cleared. Epinephrine, but not norepinephrine, seems to be important to induce Na^+ transport out of the lumen. Epithelial sodium (Natrium) channels (ENaC) are important regulators of lung liquid clearance and parallel the rise of cortisol in late gestation of guinea pigs. Recently, the role of water channels, so-called aquaporines, for clearing lung water after birth has been focused on (see the section 'Fluid Shift'). Transitory tachypnea of the newborn is considered by many as a condition in which an inadequate lung liquid clearance is found due to a low stress at birth (exemplified by C-section). At birth the infant must inflate its lungs to provide a large enough area for gas exchange in the course of a few minutes. The first respiratory effort must be large enough to overcome the great resistance caused by the surface tension of the lung liquid. Pulmonary surfactant lowers the surface tension and therefore facilitates the expansion of the lung. In the absence of surfactant a positive end expiratory pressure of about 28 cm H_2O to avoid lung collapse and maintain an adequate functional residual capacity is necessary.

Inflation of the lung of a normal infant at birth is probably nearly accomplished with the first cry if it is vigorous. Karlberg and coworkers recorded the first breath in a series of 11 normal term infants to occur at the age of 6–93 s. Opening of alveoli occurs serially, each unit going to full inflation before the next one opens. Lung inflation is extremely rapid and after only one-third of a second the lungs look inflated as assessed by chest x-ray. Pleural pressures vary from 10 to 70 cm H_2O subatmospheric during the first

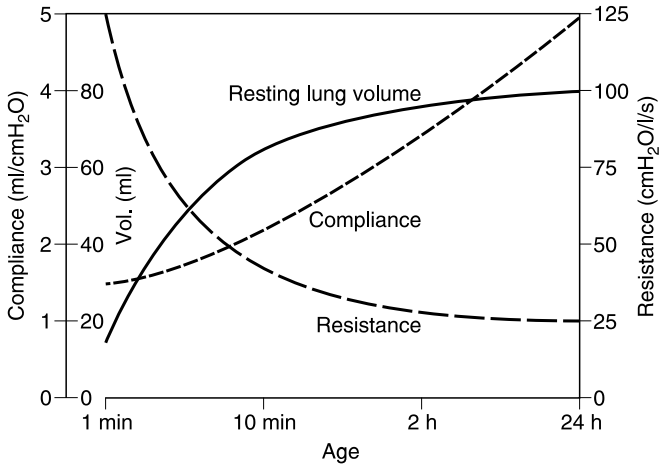

Figure 1.2 Change in lung mechanics in the first 24 h of life. From Godfrey.[36]

breath. Others have registered opening pressures around 30 cm H_2O. This large pressure is applied for only 0.5–1 s and during the first expiration there is a high positive pleural pressure of 20–30 cm H_2O. The pressure difference from inspiration to expiration in one single breath may therefore be formidable, up to 100 cm H_2O. Still, most children need an intrathoracic pressure of less than 10 cm H_2O to open their lungs vs. 4 cm H_2O in normal breathing. The tidal volumes of the first breaths in term infants were found by Karlberg and coworkers to vary between 12 and 67 ml.

Functional residual capacity increases quickly from about 17 ml/kg at 10 min of age to 25–35 ml/kg at 30 min, the same as 4 days of age. Lung compliance increases gradually during the first week of life and by 1–2 days of life the compliance is four- to fivefold greater than it was during the first few breaths. Simultaneously, resistance to airflow is decreased by one-half to one-fourth of the first registered values (Figure 1.2).

Following the initial inflation of the lung, the intra-alveolar lung fluid moves into the interstitium and is partially absorbed by the capillaries. Cold, light, noise, increased force of gravity, and falling pO_2 and pH all contribute to the initial gasping and subsequent breathing. The intrathoracic pressure an infant can generate is also dependent on the stability of the chest wall and the strength of the respiratory muscles. Following aeration of the lungs the pulmonary vascular resistance decreases and pulmonary blood flow increases, left atrial pressure increases, and the foramen ovale closes (see the section 'Transition of the Circulation').[35–38]

Gas exchange

In the umbilical vein blood pH has a mean of 7.33 in normal-term infants and in arterial umbilical blood reaches a minimum of about 7.20–7.25 a few minutes after birth and then is normally between 7.33 and 7.36 at 20 min of age. In some investigations pH already at 1 h reaches 7.40–7.42. pCO_2 in umbilical vein cord blood has a mean of 5.7 kPa (43 mmHg) and $paCO_2$ peaks around 8–9.3 kPa (60–70 mmHg) immediately after birth and then quickly normalizes to around 5.3 kPa (40 mmHg) or even a little lower than this by 20–60 min after birth. paO_2 in umbilical vein cord blood has a mean of 3.7 kPa (28 mmHg) and quickly rises to 6.7–8 kPa (50–60 mmHg) within the first 20–60 min after birth and then gradually increases toward adult levels over the next days, depending on how quickly the foramen ovale and the ductus arteriosus close.[39]

Surfactant

Pulmonary surfactant is synthesized, stored, secreted, and cleared in the type II cells in the alveoli. There are almost twice as many type II cells than the flat type I cells but they cover only 5–10% of the alveolar surface. In addition to surfactant, they synthesize and secrete many other bioactive components such as coagulation factors, cytokines, growth factors, and lysozyme and lysosomal enzymes. Active synthesis of surfactant begins in the second trimester and around 35–36 weeks adult pool size is obtained. At term only a fraction of the normal amount of surfactant is present in the alveoli. With lung inflation at birth a dramatic secretion of surfactant occurs and a normal pool of surfactant is established in the alveoli after a few hours.

Maturation of surfactant is delayed by 1–2 weeks in males compared with females and is not only dependent on the amount of surfactant produced but also on the surfactant composition. It has been shown in several mammalian species that considerable changes take place in the composition of surfactant as maturation of the fetus occurs. One of these is the increase of phosphatidyl choline and dipalmitoyl phosphatidyl choline with a concomitant decrease in phosphatidyl ethanolamine. This is reflected by an increasing lecithin/sphingomyelin ratio in amniotic fluid during the maturation process. The percentage of disaturated lecithin increases and reaches about 50 around 34 weeks of gestation. The acidic phospholipids of surfactant follow a different pattern. At around 34–35 weeks phosphatidyl glycerol becomes present and increases; simultaneously, phosphatidyl inositol peaks before it decreases toward term.[40]

Surfactant proteins

Experiments with several animal species have shown that the production of surfactant proteins in the fetal lung increases toward term. In humans mRNA for surfactant proteins A, B, and C were detected as early as 13 weeks of gestation and by 24 weeks their levels were 50% and 15% of the adult levels of mRNA for surfactant proteins B and C, respectively. In contrast,

mRNA for surfactant protein A is very low before 24 weeks of gestation. In rat lung surfactant protein A increases substantially during the last 3–4 days of gestation, reaching a peak at the first day of life. In adult lungs its level doubles compared with the neonatal level. In humans surfactant protein A normally appears in amniotic fluid around 30–32 weeks of gestation and increases with surfactant lipids toward term. Surfactant protein B increases more gradually during gestation and continues to do so the first days after birth with a slight decrease in the adult. Glucocorticoids seem to increase the production of surfactant proteins A, B, C, and D. The hydrophilic surfactant proteins A and D are important for host defense and the hydrophobic proteins B and C for stabilization and rapid adsorption and spreading of the surfactant film. Surfactant protein B deficiency is a rare autosomal recessive disorder leading to lethal respiratory distress even in term infants. Recently, mutations in the transport of surfactant protein B from the lamellar bodies in type 2 cells to the surface have been detected giving a similar clinical picture as surfactant protein B deficiency. Surfactant protein C deficiency is an autosomal recessive disease and clinically not as dramatic as surfactant protein B deficiency, but it may lead to interstitial inflammation and pulmonary fibrosis.[41–43]

Transition of the circulation

Vascular changes

In fetal life the pulmonary and systemic vascular systems are coupled in parallel in contrast to the postnatal period when the blood circulation is coupled in series through the right side of the heart to the lungs and then through the left side of the heart to the systemic circulation to return to the right side of the heart through the systemic and the pulmonary vasculature (Figure 1.3). The fetal circulation is characterized by a low systemic and a high pulmonary vascular resistance, the opposite of the situation in postnatal life. The fetal circulation is designed to provide a large blood flow to the placenta and supply less to the lungs since the fetal lung has no gas exchange until birth. Due to the large surface of the placenta the fetal circulation has a low resistance, and the blood pressure therefore need not be high. The fetal circulation is further characterized by the presence of three shunts, which facilitate venous return from the placenta. These are the ductus venosus and the two right to left shunts reducing blood flow through the lungs (foramen ovale and ductus arteriosus). Through the foramen ovale (the opening between the right and left atrium) and the ductus arteriosus (the connection between the pulmonary trunk and the aorta), blood is bypassed away from lung tissue into the systemic circulation. The three shunts mentioned above therefore contribute to a separation between blood rich in oxygen and nutrients supplied from the placenta via the umbilical vein; this blood supplies the brain and myocardium.

During fetal life, blood is oxygenated in the placenta and returns to the fetal body via the umbilical vein, which joins the portal vein in the hepatic sinus. About 40% of the combined ventricular output goes through the placenta. This volume of blood, approximately 200 ml/kg fetal weight per minute, can be distributed through the ductus venosus directly into the inferior cava vein bypassing the hepatic micro-circulation, or it can pass via the portal veins through the hepatic circulation and then enter the inferior caval vein through the hepatic veins. In the fetal sheep about 70% of the venous return is derived from the lower portion of the body, and 20% from the superior vena cava. Of the remaining 10% approximately 7% comes from the pulmonary circulation – a fraction increasing toward term – and 3% from the myocardium. About 55% of the umbilical venous return passes through the ductus venosus and the rest mainly through to the right lobe of the liver.

The fetal liver is a highly compliant organ able to regulate the distribution of umbilical blood flow during fetal stress. Umbilical blood flow does not change significantly from normal values when fetal hypoxemia is induced by maternal hypoxia; however, the intrahepatic circulation is redistributed so that flow through the ductus venosus is increased. This increased flow is

distributed to favor the brain, myocardium, and placenta in order to secure more oxygenated blood to these vital organs during hypoxemia. After traversal through the ductus venosus and entry into the inferior caval vein, oxygenated blood from the placenta does not mix with deoxygenated blood from the lower body. This blood when entering the inferior caval vein streams in parallel with blood from the lower body. When entering the right atrium the blood from the placenta and the blood from the lower body are split by *crista dividens* and blood originating from the ductus venosus preferentially crosses the foramen ovale into the left side of the heart and therefore the myocardium and the head are supplied with oxygen-enriched blood. Blood from the lower body and right liver lobe preferentially passes through the tricuspid valve into the right ventricle together with blood from the superior vena cava. Thus, blood with lower oxygen content is pumped out of the right ventricle and reaches the lower parts of the body.

Doppler studies in humans have demonstrated that the ductus venosus is a narrow vessel projecting a high-velocity jet posteriorly to reach the foramen ovale. The high peak velocity in the ductus venosus may give the blood sufficient momentum to reach the foramen ovale without extensive mixing with deoxygenated and nutrient poor blood. Blood streaming, therefore, not only occurs in parallel, but also side by side at different velocities when entering the right atrium.

Umbilical venous blood has a pO_2 of 4–4.7 kPa (30–35 mmHg). After mixing with portal venous and inferior caval blood the pO_2 is about 3.5–3.7 kPa (26–28 mmHg). Venous blood returning from the superior cava vein has a pO_2 of 1.6–1.9 kPa (12–14 mmHg) and this combines with the inferior caval vein stream passing through the tricuspid valve, giving a pO_2 in the right ventricle of 2.4–2.5 kPa (18–19 mmHg). The pO_2 of the blood entering the left ventricle and the ascending aorta is about 3.1–3.3 kPa (23–25 mmHg), slightly less than in the proximal part of the inferior caval vein due to mixing with blood from the pulmonary veins in the left atrium. The descending aortic blood, which is a mixture of blood passing through the ductus arteriosus and the aortic isthmus, has a pO_2 of 2.7–2.9 kPa (20–22 mmHg). Postnatally there is essentially no mixing of blood oxygenated in the lungs and systemic venous blood.

Fetal pulmonary vascular resistance falls with advancing gestational age primarily due to the great increase in the number of pulmonary vessels, expanding the total cross-sectional area of the vascular bed. Pulmonary blood flow and pulmonary artery pressure increase substantially in the fetal sheep from midgestation toward term.[44–49]

Establishment of the postnatal lung

The most dramatic changes in the circulation occur at birth when gas exchange through the lungs is established. Immediately after birth the umbilical placental blood flow is stopped and the pulmonary circulation is established adequately. Neither in the placenta nor in the umbilical cord vessels are adrenergic or cholinergic nerve fibers detected. So the regulation of cord flow is probably mainly due to vasoactive factors. Within a minute after birth umbilical blood flow is less than one-fifth of the fetal level. Simultaneously, a significant decrease in umbilical artery and vein diameters is observed within another minute. The mechanisms behind this are not fully understood but cooling, increased oxygen tension, and stretching of the cord may play a role. Locally produced mediators such as serotonin are powerful constrictors of umbilical vessels. The umbilical vessels also constrict by mechanical stimulation, particularly stretching, and the constriction is upheld by the immediate increase in systemic oxygen tension. Simultaneously, venous return through the inferior caval vein is reduced by removal of the placental circulation. Cessation of venous return reduces flow through the ductus venosus and this vessel therefore closes passively within 3–7 days after birth.

After birth, ventilation of the lungs with air results in a four- to tenfold increase in pulmonary blood flow, which is associated with a relatively rapid fall in pulmonary vascular resistance (Figure 1.4). These effects are mediated by mechanical lung changes, lowering of pCO_2, and increase in pO_2, each factor accounting for the pulmonary vasodilator effects seen after birth.

In addition to the structural adaptation of the pulmonary circulation after birth there are a number of vasoactive substances participating in the regulation of the pulmonary vascular tone in the perinatal period. The pulmonary vascular endothelium is central in the regulation of vascular tone. By stimulation the endothelial cells may release vasoactive substances into the circulation, or release lung tissue enzymes involved in the activation or inactivation of vasoactive mediators.

In recent years endothelium-derived relaxing factors such as nitric oxide (NO) have been identified and together with PGI_2 may be responsible for the rapid decrease in pulmonary vascular resistance that occurs at the onset of normal ventilation after birth. In fetal circulation there is an increased production of nitric oxide compared with adult levels. This nitric oxide contributes to the low vascular resistance and increased flow, for instance, in the gastrointestinal tract. Increased fetal oxygen tension increases the release of NO. The increase in pulmonary blood flow in response to the high oxygen concentration at birth as well as distention of the lung seems to be mediated, at least partly, by NO. This system seems to be especially potent near term, the reaction of the preterm is diminished. Endogenous NO production is augmented due to induction of especially endothelial nitric oxide synthase (eNOS). In the baboon both inducible NOS and eNOS activities increase during gestation, falling toward term. However, the total NOS activity seems to

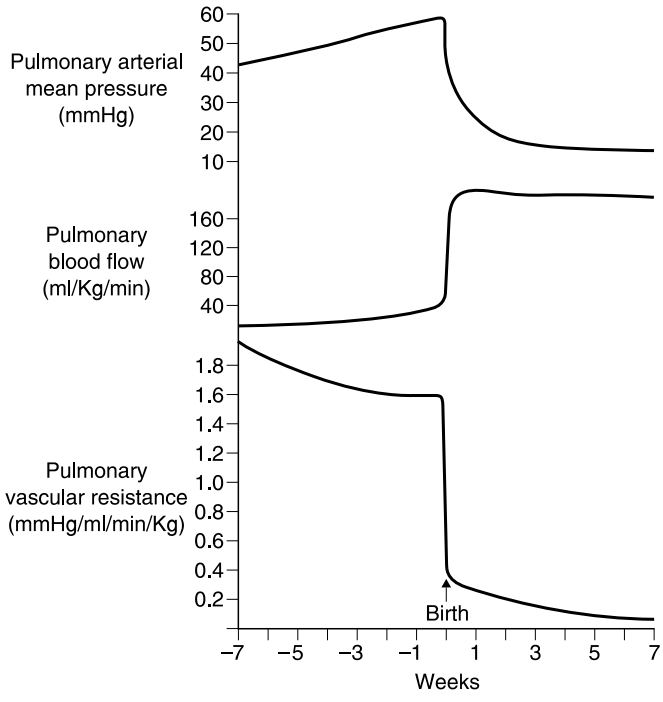

Figure 1.4 Changes in fetal pulmonary arterial pressure, pulmonary blood flow, and vascular resistance in the perinatal period. From Rudolph.[46]

be preserved. Both hypoxemia and diaphragmatic hernia decrease NOS expression. A lack of neuronal nitric oxide synthetase has been found in neonatal hypertrophic pyloric stenosis. Arachidonic acid metabolites are involved in the physiological regulation of the perinatal circulation. PGI_2 is a strong pulmonary vasodilatator. Mechanical stimulation of the lungs leads to PGI_2 production and ventilation of the fetal lung itself increases concentration of PGI_2 in pulmonary venous blood. The release of this metabolite is also stimulated by histamine, bradykinin, reactive oxygen species (ROS), and adenosine triphosphate (ATP), as well as angiotensin II, which is high immediately after birth.

Bradykinin is a potent vasoconstrictor in the umbilicoplacental circulation but otherwise is usually a vasodilatator. Bradykinin is released in fetal lungs during ventilation with air or during hyperbaric oxygenation. It is therefore possible that bradykinin could play a role in postnatal pulmonary circulatory changes. Endothelium-dependent vasoconstriction can also be stimulated by substances and factors such as acetylcholine, thrombin, serotonin, physical forces, and hypoxia. There are also endothelium-derived vascular constricting factors such as metabolites of arachidonic acid [thromboxane A_2 (TXA_2) and PGH_2], as well as endothelin and free radicals. In animal studies it has been shown that ROS are able to potently constrict the pulmonary vasculature and to dilate the ductus arteriosus. It has been shown both in the lungs and in the isolated ductus arteriosus that ROS stimulate the production of prostaglandins. In the lungs there seems to be a balance between dilating and constricting prostaglandins. The constrictor TXA_2 is elevated first, followed by the dilator PGI_2, when the pulmonary circulation is exposed to free oxygen radical generating systems. These substances therefore can have both constrictory and dilatory effects on the pulmonary circulation depending on the balance between TXA_2 and PGI_2. Superoxide radicals, for instance, can act by inactivating NO and also by activation of endothelial cyclooxygenase products. In addition, endothelin and angiotensin II have a prolonged effect on the tone and structure of blood vessels.

Remodeling of the pulmonary vasculature occurs immediately after birth, contributing to the decrease in pulmonary vascular resistance. In the precapillary arteries the endothelial cells shortly after birth become slimmer, the surface/volume ratio increases so the vessel wall becomes thinner, and the lumen diameter increases. Further, small, unopened muscular arteries are recruited to the pulmonary circulation during the first days after birth. Thus, a structural adaptation to extrauterine life consists of changes in cell shape and position. The structural remodeling during the first 2 weeks of life in the pig lungs contributes to the reduction in mean pulmonary artery pressure from 55 to 14 mmHg.

The baroreflex setting of heart rate mediated by baroreceptor fibers in the carotic body and aortic arch is active in both fetal and newborn life, but with different sensitivity and shifts toward higher pressures during development.[46,50,51]

Ductus arteriosus

The open ductus arteriosus in fetal life diverts blood away from the lungs toward the descending aorta. The patent ductus is regulated both by dilating and by contracting factors. Prostaglandins play an important role in maintaining the patency, and the ductus is especially sensitive to the dilating action of PGE_2. Oxygen is a potent constrictor of the ductus and becomes more effective the more mature the fetus is. This is due to the fact that in early fetal life the ductus has decreased muscular development, causing less contractile ability. In fetal lambs the ductus arteriosus is also more sensitive to the dilating effect of PGE_2 in the preterm than near term. This is due to a developmental alteration in the sensitivity of the vessels to prostaglandins. It is circulating PGE_2, probably produced in the placenta, which probably controls the ductus arteriosus *in utero*. After birth, when the oxygen tension increases, the ductal wall is itself capable of producing PGE_2. Reactive oxygen metabolites (ROS) may stimulate PGE_2 synthesis in the isolated ductal wall from fetal lambs. In the ductus arteriosus ROS can therefore contribute to dilatation by turning on prostaglandin synthesis in the ductal wall. The functional closure of the ductus, therefore, is promoted by an increase in oxygen tension, and a

p450 hemoprotein located in the smooth muscle plasma membrane is a receptor of the oxygen-induced events. Further, a decrease in blood pressure within the ductus itself, a decrease in circulating PGE_2 (due to loss of placental prostaglandin synthesis and increase in prostaglandin removal by the lungs), and finally a decrease in PGE_2 receptors in the ductus wall also contribute to constriction of the ductus. In full-term infants closure of the ductus arteriosus occurs in two phases with a functional closure within the first hours after birth due to smooth muscle constriction, and the anatomic closure caused by closure of the lumen due to thickening of the intima and loss of smooth muscle cells. This is caused by progressive thickening of the intima, so it eventually occludes the constricted lumen. Smooth muscles migrate from media into the intima layer. Vascular endothelial growth factor plays an important role in this intimal 'cushion'.[52–54]

Myocardium

At the end of gestation, right and left ventricular systolic pressures are equal, 65–70 mmHg. The cardiac output of the right ventricle is, however, in fetal life 50% higher than the left ventricle mainly due to the fact that the left ventricle has a high afterload caused by the high vascular resistance of the head, neck, and forelimbs, while the right ventricle's afterload is lower because of the low umbilical–placental resistance. The removal of the low-resistance placental circulation results in an increase in systemic vascular resistance. The combined ventricular output in the fetal lamb is about 500 ml/kg/min; however, after birth there is an increase in total cardiac output and during the first few days each ventricle ejects approximately 350 ml/kg/min. During the next weeks in the newborn lamb there is a rapid decrease in cardiac output to a level of about 150 ml/kg/min and then it falls slowly to the adult level of 70–80 ml/kg/min. Cardiac output changes parallel changes in oxygen consumption.

O_2 consumption is almost identical in the adult and fetal hearts; however, the fuel used by them is different since the adult heart uses fatty acids and the fetal heart is an obligatory user of carbohydrates as a substrate for oxidative phosphorylation. In the fetal lamb 60% of these carbohydrates are lactate, 35% glucose and 5% pyruvate. This can explain why a fall in circulating glucose concentrations results in myocardial depression in fetal and neonatal life but not later in life. In fact, it has been shown that fatty acids are detrimental to fetal cardiac function. In order to use fatty acids as fuel they must be transformed to Ac-CoA, which is transesterified with carnitine and in this form is transported across the mitochondrial membrane by the transport enzyme carnitine-palmitoyl transferase (CPT). CPT is inhibited by malonyl-CoA, which is high in fetal life. Malonyl-CoA is regulated by glucagon and during the delivery glucagon concentration increases sharply, thereby reducing the concentration of malonyl-CoA and releasing CPT inhibition allowing fatty acid oxidation to proceed.

The contractile properties of the myocyte also differ in fetal and adult life. Only about 30% of fetal cardiac muscle consists of contractile elements compared with approximately 60% in the adult. The velocity of shortening of the myocyte is also lower in fetal life. Especially, preterm infants and to some degree also term infants have therefore a much reduced ability to tolerate an increase in afterload. The change from fetal to adult performance seems, however, to occur quickly after birth.

At birth, cardiac output increases considerably and the left ventricular level is doubled compared with fetal levels. This higher left ventricular inotropy and performance is due to sympathetico-adrenal stimulation after birth, and T3 seems to be important in maturation of the fetal myocardial response. After birth, myocardial contractility is greatly increased but because of the high demands on the circulation to provide the increased oxygen requirements for metabolism, there is also little reserve available, and thus volume loading results in only a small rise in cardiac output. In a fetus an increase in heart rate gives a fall in end diastolic volume and stroke volume unless ventricular diastolic filling is maintained. The rearrangement of the circulation after birth leads to an increased end diastolic left ventricular volume, which leads to an increased stroke volume. The days after birth a gradual decrease in cardiac output per kilogram is observed returning to the fetal levels.

Fetuses at midgestation have individualized heart rates that are stable. The control of heart rate variability seems to develop later and fetal heart rate variability is predictive of neonatal heart rate variability not until 30 weeks. With increasing gestation there is a reduced fetal heart rate variability and this demonstrates the development of the autonomic nerve system during gestation. Heart rate at birth is around 160–180 beats/min and decreases to 120 beats/min in sleeping newborn infants and to 140–160 beats/min in awake newborn infants. The postnatal situation compared with the fetal is characterized by a decrease in heart rate, postextrasystolic potentiation increases, and inotropic responses to catecholamine elevation, suggesting that the postnatal heart has greater potential reserves than in fetal life.[45,46,49]

Shift in oxygen transport

The newborn infant has a higher oxygen demand than the fetus and the oxygen consumption typically is increased between two- and threefold in the first days of life. O_2 consumption per kilogram of body weight is higher in the newborn than in the adult and the fetus. In adult life O_2 consumption is about half that in the

immediate newborn period; however, when compared with body surface area this age difference seems to disappear. The delivery of oxygen to the tissues depends on (1) the oxygen content of the blood, (2) the cardiac output, (3) the distribution of the circulation, and (4) the affinity of oxygen to hemoglobin. In fetal blood there is a high affinity to oxygen. The postnatal decrease in hemoglobin O_2 affinity is caused by an increase in adult hemoglobin at the expense of fetal hemoglobin, and an increase from birth in the concentration of 2,3-diphosphoglycerate (DPG). During gestation until 34 weeks, fetal hemoglobin comprises about 90% of the total hemoglobin, falling to 80% at term, and from birth to 8 months of age there is a gradual decline in fetal hemoglobin to less than 2%. Fetal red cells have a higher oxygen affinity than adult cells, which is achieved by a reduced interaction between fetal hemoglobin and 2,3-DPG than in adult hemoglobin. The concentration of 2,3-DPG in fetal and adult cells is almost the same. 2,3-DPG present in the erythrocytes decreases the affinity to O_2 through an allosteric action with the hemoglobin molecule. DPG does not bind as strongly to fetal hemoglobin as the adult hemoglobin. In addition, it is low immediately after birth, making a high O_2 affinity immediately after birth with a p50 of approximately 2.7 kPa (20 mmHg) vs. 4 kPa (30 mmHg) at 8 months of age. Therefore, in the newborn period and early infancy when the fetal hemoglobin concentration is high, intraerythrocyte change in 2,3-DPG has little effect on p50; however, later in life the modulating effect of 2,3-DPG on oxygen affinity plays a more important role. In the fetal period the high oxygen-carrying capacity and greater oxygen affinity of fetal blood in fact compensate for the one-fifth to one-fourth oxygen tension of adult blood, ending with rather similar oxygen saturation at term and in adult life. Fetal blood also is slightly hypercarbic and acidotic, whereas the maternal blood is hypocarbic and alkalotic. The Bohr effect, that is, the shift in the oxygen equilibrium curve to the right by increased pCO_2 or decreased pH, giving a higher oxygen tension, is more pronounced with a lower pH and more efficient in the fetus. In addition, a higher temperature of the fetus contributes to a shift in the fetal dissociation curve to the right.[55–57]

Tissue injury

Energy metabolism

Most of the oxygen taken into the body is used in cell energy metabolism. The metabolic process is a redox process where energy is released in a stepwise fashion and stored as ATP. Energy metabolism can schematically be divided into three parts. In step 1 glucose, amino acids and fatty acids are broken down to Ac-CoA. In the second step Ac-CoA enters the tricarboxylic acid (Krebs) cycle, the final common pathway of all fuel substrates in aerobic cells. Here, acetyl groups are metabolized to form carbon dioxide and hydrogen ions. In step 3, the hydrogen ions enter the respiratory chain of the cell, a series of electron carriers linked to oxidative phosphorylation, with ATP formed in a stepwise manner. Oxygen is the final electron acceptor and is necessary for continuous oxidation of reduced coenzymes in the respiratory chain. Oxygen, therefore, can be considered as the 'garbage cleaner' of energy metabolism taking care of its waste products, the electrons, after having traversed through the respiratory chain.

The energy metabolism tends to keep the energy charge, EC [$EC = 0.5([ATP] + [ADP]/[ATP] + [ADP] + [AMP])$], of the cell at an optimal level, which is around 0.85. This can be achieved in two ways, either by increasing the ATP concentration or by increasing the catabolism of AMP. In hypoxia with lack of energy the cell might be forced to choose the latter alternative. An accelerated breakdown of AMP occurs. This is a hazardous compensation since the cell might lose its purine pool irreversibly. One of the intermediate breakdown products is, however, adenosine. This metabolite has important control feedback functions in brain hypoxia, partly because it is an active vasodilatator and thus contributes to a higher oxygen supply to hypoxic tissues and partly because adenosine in itself cuts down brain metabolism. When adenosine accumulates because of energy deficiency, this metabolite fights back by contributing to an increased oxygen supply and a decreased energy need. This is important also because a breakdown product from adenosine is hypoxanthine. This metabolite accumulates in tissues and body fluids during hypoxia and its extracellular concentration reflects the intracellular energy charge. However, hypoxanthine is also a potential oxygen radical generator during reoxygenation and it is therefore probably advantageous for the organism to try to keep the hypoxanthine concentration as low as possible.

Before the cell's energy charge falls markedly, several biochemical compensatory mechanisms are activated. First, glycolysis is accelerated many fold. Pyruvate is reduced to lactate, while nicotinamide adenine nucleotide (NADH) is oxidized to NAD^+. This is the basis for the use of lactate as a clinical marker of hypoxia. Lactate augmentation merely reflects the compensation mechanism. Although hypoxanthine and lactate parallel each other in many clinical settings, hypoxanthine nevertheless more correctly reflects the intracellular energy status of the cells.

As soon as oxygen delivery to the cells declines the mitochondria also change their metabolism to utilize available oxygen more efficiently. The compensation takes place 30–60 min after a reduction in oxygen supply. In the fetus or in the immediate newborn period mitochondrial adaptation already is maximal. A fetus has a respiratory capacity of about 300% of the adult, but by 10–14 days after birth the newborn and adult levels equate in this respect. What does this

mean for the fetus and newborn? First, they are able to utilize the limited oxygen supply very efficiently. On the other hand, the fetus is unable to make cellular respiratory adaptations if hypoxia occurs. From this point of view, the fetus and newborn are more vulnerable to hypoxia than older patients.

Hypoxic injury to the perinatal brain

It has been known since Boyle's classical experiment in 1670 that newborn animals can resist hypoxia longer than adult ones. In the 1960s and 1970s it was shown that the preterm monkey can withstand hypoxia longer than the term one. In fact, in the fetal monkey there was an exponential relation between duration of hypoxia and gestational age when the outcome measure was neurologic brain injury (cerebral palsy). The younger the animal the longer it could resist hypoxia before brain injury occurred. Thus, mature fetal rats survive in pure nitrogen more than 25 times longer and 1-day-old rats about 10 times longer than adult rats. One part of the explanation for this seems to be that newborn animals can preserve cerebral circulation and thus ensure supply of substrates for energy metabolism better than in the adult. Further, it is known that oxygen demand of the brain is lower in fetal life and increases with gestation. The immature brain has smaller neurons, which are less branched with fewer synapses. The energy requirement is therefore lower and the cerebral metabolic rate of oxygen is lower in the immature brain compared with the adult. The fetal brain is also able to use alternative sources such as ketone bodies as fuel for energy metabolism. Further, the glycolytic capacity allows the immature brain to regenerate ATP at a higher rate than in the adult brain.

The perinatal period is also accompanied by dramatic neurochemical changes. The concentration of excitatory amino acids such as glutamate peaks around term and may contribute to a higher sensitivity to hypoxia in the term compared with the preterm infant.[58,59]

Apoptosis and necrosis

Apoptosis is an important part of development and homeostasis. For instance, in the developing brain perhaps up to half of the cells undergo apoptosis, in spite of the fact that the distinction between apoptotic and necrotic death is considered less clear than previously. These two modes of cell death are considered by many as a continuum running from apoptosis to necrosis more than two different entities. Infants who have undergone secondary energy failure after, for instance, birth asphyxia, have a tendency to lose their neurons by necrosis, while those dying *in utero* have experienced more apoptotic death. The same injury may induce apoptosis in the fetus or newborn and necrosis in the adult organism. To make it more complex the same cell may undergo apoptosis if the injury is mild and necrosis if it is severe. Oxidative stress plays an important role in initiating apoptosis, for instance, through opening up the mitochondrial permeability transition pore. This reduces the mitochondrial membrane potential and release of substances that are involved in apoptosis, for instance, cytochrome *c* and Apaf-1, both of which activate caspase-3, which is specifically involved in the apoptotic execution. As mentioned already, the fetus is more susceptible to oxidative stress than the term newborn and therefore also perhaps more susceptible to this mechanism.[60]

Development of antioxidants

In fetal life paO_2 is around 3.3 kPa (25 mmHg) and after birth rises quickly to 8 kPa (60 mmHg) over the next 30 min. In order to survive in an oxygen-rich atmosphere antioxidant systems must be well developed at birth. A number of defense systems have been described. In the lung and kidney, maturation of antioxyenzymes such as superoxide dismutases, glutathione peroxidase, and catalase seems to occur near term in animal fetuses. In fact, the maturation of these systems occurs in parallel with the maturation of the surfactant system. Furthermore, preterm infants with gestational age of 24–29 weeks have only 50% activity of Cu/Zn superoxide dismutase in cord erythrocytes compared with term infants. Glutathione is a major intracellular antioxidant and is found in high concentrations (mM) in eukaryotic cells. Glutathione is the substrate for glutathione peroxidase, which catalyzes oxidation of reduced to oxidized glutathione at the expense of hydrogen peroxide. The rate of glutathione synthesis from methionine is strongly reduced in preterm infants compared with term ones. These data therefore suggest that at least the intracellular defense against free radicals is low in many organs in fetal life and probably also in the human fetus. A preterm infant is therefore more vulnerable to increased oxidative stress and attacks of free radicals than a term one. In contrast to the intracellular defense, extracellular antioxidants seem to be adequately developed at term, and the concentration of several extracellular antioxidants such as ascorbate is very high in the umbilical cord (see Chapter 6).[61–64]

Thermal regulation

In fetal life the body temperature is efficiently regulated to be 0.5°C higher than the maternal. The tight linkage between fetal and maternal body temperature is called a 'heat clamp', which prevents the fetus from independent regulation of its temperature. At birth a dramatic change in the thermal environment occurs. During the first hours of life core body temperature can fall to less than 36°C if the newborn is not taken care of optimally. After 8 h, body temperature has usually returned to the normal adult range. Since the

newborn infant has a relatively large body surface area and limited thermal insulation it is necessary to wrap the newborn infant adequately. The newborn infant in fact has the capability to regulate the temperature by sweating and can also respond to a cool environment by increasing the metabolic rate. This takes place without shivering, is activated by catecholamines, and the heat is generated mainly from brown fat, which is present in large amounts in the full-term infant. Although the fetus may mobilize brown fat the thermogenic responses still are very low. These require increased oxygen and substrate consumption. The combination of hypoxia and hypothermia therefore is dangerous.[25,65]

Skin

The transition from intra- to extrauterine life is dramatic for the skin, perhaps the largest organ of the body. It immediately must be a barrier to water loss; it takes part in thermoregulation, protects against infections, has an antioxidant function, and protects against UV light. The skin is a barrier to chemicals and is needed for tactile discrimination as well as being an important emotional and psychological link between the child and its caregivers. The skin of the term in contrast to the preterm infant also has a highly developed immunological system. *In utero* the skin is in a sterile environment but already in the birth canal it is colonized and specific cells in the epidermal layer take part in host defense.

Prenatally, lipid synthesis is necessary for production of vernix caseosa, forming a barrier that is needed for successful adaptation to postnatal life. The vernix also may function as an endogenous skin cleanser removing, for instance, carbon particles. Of interest is that both the stratum corneum of epidermis and the brain contain very high concentrations of ceramides. The close embryological relation between these two organs both derived ectodermally makes this an interesting observation. At birth the epidermis is pH neutral but rapidly over the first postnatal weeks, it develops an 'acid mantle' that is characteristic of human skin. This acidic surface can be destroyed by using alkaline soaps for infant bathing and is delayed in very low birth weight infants. The acid mantle is believed to be important in antimicrobial defense as well as in keeping the integrity of the epidermal barrier. Postnatally transepidermal water loss that increases after birth is an important regulator of DNA and lipid synthesis in the epidermis.[66]

Circadian rhythms

The clock for the circadian rhythms is set by the suprachiasmatic nucleus. It is fascinating that the neurons in this area of the brain *in vitro* oscillate within a period close to 24 h. This is regulated by light, which in a complex way affects gene expression of transcription factors. Efferent pathways from the suprachiasmatic nerve control the pineal function and regulate the rhythms of endocrine, cardiovascular, temperature, and even behavioral circadian variations.

From midgestation the suprachiasmatic nucleus is present in the fetus and diurnal rhythms are found in the human fetus after 20 weeks. Whether or not they are intrinsically regulated or are due to maternal control, for instance, via maternal melatonin rhythms, is unclear. However, in fetal life the maternal rhythms are mainly followed by the rhythm of the mother exemplified by cortisol fluctuations. In contrast, fetal autonomic activity that controls the heart rate follows a 12-h cycle and not the mother's 24-h rhythm. This 12-h rhythm disappears immediately after birth and around 2–4 weeks the 24-h rhythm is established. It takes 8–12 weeks before postnatal circadian rhythms in sleep and wakefulness as well as plasma cortisol and melatonin are established.[25,67]

Gene activation at birth

In the near future the transition at birth will be described by a shift in different gene activities and not only by physiological and biochemical changes. Labor affects the mRNA encoding for a number of enzymes such as tyrosine hydroxylase, dopamine-beta-hydroxylase. mRNA encoding for substance P increases many fold in the nucleus tractus solitarius the first days of life. Substance P probably plays a role in the central respiratory control by promoting the hypoxic drive from peripheral chemoreceptors. Depression of genes is also described at birth and in some circumstances there is a shift from one isoform to the other. One example is the expression of genes that encode the muscle-specific and non-muscle-specific isoforms of cytochrom oxidase subunit VIa during pre- and postnatal life of striated muscle in the mouse. The non-muscle form is the predominant isoform in fetal life and is gradually at the end of gestation and early neonatal life replaced by the muscle-specific isoform both in cardiac and in skeletal muscle.[68]

Conclusion

In order to understand both normal development as well as disease processes in the newborn infant it is necessary to have insight into the complex changes that occur in relation to birth. Previously, physiological processes have been emphasized giving us valuable knowledge on the perinatal transition of the cardiovascular and pulmonary systems. Recently, biochemical changes in relation to birth have been understood more fully as, for instance, the maturation of the surfactant system and antioxidative systems.

Presently, more and more data will accumulate, teaching us how the transition at birth is regulated at the gene level. In this way it could hopefully be possible to modulate the disease processes in relation to the birth processes in a much more efficient and powerful way than we understand today.

2 Neonatal jaundice

F. Rubaltelli and C. Dani

Introduction

Neonatal jaundice is one of the most common conditions of the newborn. Neonatologists are concerned about this problem, not only for the risk of bilirubin encephalopathy in very low-birth-weight infants and in full-term infants with hemolysis due to different causes (rhesus and ABO hemolytic disease, glucose-6-phosphate dehydrogenase deficiency, etc.), but also because of the anxiety that jaundice in the full-term neonate gives to parents.

In neonates, jaundice becomes apparent at higher serum bilirubin concentrations in comparison to adults (5–7 mg/dl or 85–120 mmol/l in comparison to 2–3 mg/dl or 35–50 mmol/l). If we take into account clinically evident jaundice, we can say that almost 60–70% of term infants and almost all prematures present with jaundice. But, if we consider a cutoff of >12.9 mg/dl (220 mmol/l), which in full-term infants is the most accepted limit to consider jaundice as deserving attention, only 5% or less present with a serum bilirubin concentration higher than that.[1,2]

Neonatal jaundice is principally the result of transient deficiency of bilirubin conjugation, some deficiency of hepatic uptake and intracellular transport, and an increased enterohepatic circulation of the pigment. It is notable that bilirubin production in the newborn is two or more times greater than that in the adult per kilogram of body weight.[2] The serum bilirubin level at any point in time is dependent on the rate of bilirubin production minus the rate of bilirubin excretion.

The largest portion of bilirubin is derived from heme breakdown of hemoglobin, myoglobin, mitochondrial and microsomal cytochromes, catalase, and peroxidase. Heme degradation probably occurs by auto-oxidation after reduction of ferric (Fe^{3+}) heme to the ferrous state (Fe^{2+}) by the action of heme oxygenase and reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) cytochrome *c* (P450) reductase.[3,4] The methene-bridge carbon of the heme is eliminated as carbon monoxide (CO). At the end of this process biliverdin is formed, and is subsequently reduced to bilirubin through the activity of biliverdin reductase. For each molecule of bilirubin formed, a molecule of CO is produced, which constitutes the basis for measuring bilirubin production by determination of the CO concentration in the expired air, or the carboxyhemoglobin content of the blood.[2]

Three isoforms of HO have been isolated: inducible heme oxygenase (HO-1), constitutive heme oxygenase (HO-2), and the more recently discovered and less active heme oxygenase isoform (HO-3).[5] HO-1 is a known stress response protein, whose transcription can be induced by a whole array of stresses, including endotoxin, transition metals, heme, hemoglobin, and other heme proteins.[6] Indeed, it has been suggested that HO-1 induction might represent a generalized response to oxidative stress[5,7,8] and that it could confer cellular protection against oxidant stress. However, recent studies suggest that HO-1 induction might not always be beneficial and that the release of redox-active iron from heme might induce an increase of oxidative stress.[9,10] Moreover, *in vitro* studies[11,12] suggested that the possible protective antioxidant action of HO-1 could occur within a narrow range, as when HO-1 is overexpressed, and free-iron release may obviate any cytoprotective effect against oxidative stress.[13]

Bilirubin solubility

Bilirubin is derived from heme by separation from methene-bridge. The configuration on the C-5 and C-14 bridges is very important, and bilirubin preferentially takes the *Z* form. Moreover, (*Z*,*Z*)-bilirubin IXa has a configuration that makes the formation of intramolecular hydrogen bridge linkages possible. For this reason it is almost insoluble in aqueous media (1–10 nmol/l at pH 7.4), but dissolves readily in a number of non-polar solvents. The degree to which bilirubin (B) ionizes with the propionic acid residue depends on the pH, and this is decisive both for the distribution of the molecule and for its toxicity:

$$B^{2-} + H \leftrightarrow BH^{-}; \; BH^{-} + H + \rightarrow BH_2$$

The dissociation constants cannot be determined with absolute precision owing to the problem of solubility, but they are found to be approximately $pK_1 = 4.4$ and $pK_2 = 6.5$.[14]

All modifications of the molecule that prevent the formation of hydrogen bridges cause an increase in water solubility. In the human, this takes the form of an esterification of the residue of propionic acid with glucuronic acid, which makes excretion in the bile possible. Obviously, monoconjugated bilirubin is less soluble than diconjugated bilirubin, and can thus precipitate in the biliary tract forming stones. Alkalinization (salt formation) or the addition of non-polar solvents, such as chloroform, methanol, ethanol, etc., also results in better solubility, and this is the key mechanism used in the laboratory to differentiate between direct-reacting (mostly the conjugated form) and indirect-reacting (unconjugated) bilirubin.

Distribution of bilirubin in the body

The distribution of bilirubin in the body is essentially determined by its firm binding to albumin. However, the presence of a visible jaundice seems to be due, at least in part, to the presence of bilirubin in the skin. Therefore, there is a dynamic competition between tissue-binding sites and albumin-binding sites. In fact, albumin binds bilirubin according to the law of mass action:

$$\text{Bilirubin} + \text{albumin} \leftrightarrow \text{albumin}-\text{bilirubin}$$

$$\frac{(\text{albumin}-\text{bilirubin})}{\text{albumin} \times \text{bilirubin}} = \text{KA}$$

Two classes of binding sites have been observed: a primary binding site with an extremely high affinity for bilirubin ($KA_1 = 7 \times 10^7$ l/mol at 37°C) and one or two other binding sites with a lesser affinity ($KA_2 = 5 \times 10^5$ l/mol). The concentration of free bilirubin is mostly determined by the molar relationship between bilirubin and albumin. However, bilirubin can be displaced from its binding site by certain drugs, such as sulfisoxazole, benzoate, salicylate, etc. Nowadays, every drug intended for use in newborns must be accompanied by the evidence that it has no effect on bilirubin–albumin binding.[15]

At the hepatic level, bilirubin is taken up at the sinusoidal membrane level, but about 40% is then regurgitated into the plasma again. The albumin–bilirubin complex seems to bind to specific receptors located on the basolateral surface of the sinusoidal plasmatic membrane of the hepatocyte much better than bilirubin alone.[16] In the hepatocyte, bilirubin reacts with binding proteins, the most important being glutathione *S*-transferase, thus preventing its regurgitation into the plasma. Bilirubin has a low solubility in water due to the fact that its hydrophilic groups are masked by hydrogen bonds; however, it is made hydrosoluble by esterification in the endoplasmic reticulum, with one or both propionic acid side chains reacting with a sugar residue to form mono- or diesters; in this way the formation of hydrogen bonds is prevented.[17]

The formation of bilirubin glycosides is catalyzed by uridine diphosphate (UDP) glycosyltransferase, an enzyme system that utilizes bilirubin as an acceptor substrate, and UDP sugars (especially glucuronic acid) that act as donor substrates. Transfer from binding proteins to the enzyme system does not necessarily require a higher affinity for the enzyme-binding site, because bilirubin is far more soluble in membranes than in the aqueous cytoplasm, and the reaction could therefore take place simply by means of a favorable partitioning. Furthermore, the bilirubin monoglucuronide could be converted to diglucuronide by the same enzyme system, following a 180° rotation of the monoglucuronide molecule, or it could even be excreted without modification in the bile.

Oxidative stress and neonatal hyperbilirubinemia

Several reports have emphasized the antioxidant role of bilirubin, which in human neonatal plasma seems to have a greater antioxidant potency than urates, α-tochoferol, or ascorbates.[18] In particular, unconjugated bilirubin is able to scavenge singlet oxygen with high efficiency to react with superoxide anions and peroxyl radicals, and to serve as a reducing substrate for peroxidases in the presence of hydrogen peroxide or organic hydroperoxides. Nevertheless, although the antioxidant effect of bilirubin as a scavenger of reactive oxygen species is well documented *in vitro*[19–22] as well as in animal studies,[23] its role *in vivo* has not been definitively cleared in preterm infants.[22–27]

Recently, two studies investigated the possible relationship between plasma bilirubin levels and oxidative stress in newborn infants[28,29] excluding the fact that bilirubin acts as an antioxidant agent *in vivo*. It was demonstrated that the decrease of plasma bilirubin level (probably induced by phototherapy) was associated with the concurrent increase of HO-1 activity in blood and the decrease of oxidative stress, suggesting an antioxidant effect of HO-1 exerted *in vivo* by mechanisms other than bilirubin formation. These protective mechanisms could involve the removal of the pro-oxidant heme, the removal of hydrogen superoxide during the degradation of heme, the induction of ferritin synthesis, which sequesters redox-active iron, and the regulation of superoxide anion production. Other possible mechanisms could involve the multiple ways by which CO modulates inflammatory processes, such as the reduction of neutrophil adhesion and extravasation,[30] the reduction of histamine release from mast cells and human basophils,[31,32] the inhibition of the expression of proinflammatory cytokines, such as TNFα and IL-1β, and an increase of anti-inflammatory cytokine IL-10.[33]

These studies confirmed the findings of Yigit *et al.*,[34] who found no correlation between oxidative stress and total bilirubin in preterm infants with non-hemolytic

hyperbilirubinemia, and Gopinathan *et al.*,[35] who observed no correlation between plasma bilirubin level and total plasma antioxidant capacity in preterm infants. On the other hand, Belanger *et al.*[36] found an association between reduction of the antioxidant capacity of plasma after exchange transfusion, and the ensuing decrease of bilirubinemia. This result, however, as indicated by the authors, could be explained by factors other than bilirubin decrease, such as oxidative stress induced by a large amount of transfused blood and the consequent overload of iron through transfusion. Hammerman *et al.*[37] found a correlation between total bilirubin serum level and plasmatic antioxidant capacity, but the bilirubinemia of their patients was lower than that reported in other studies. To explain these conflicting results it may be considered that the correlation between plasma bilirubin level and the antioxidant capacity of the plasma could change at low and high values, and could be affected by phototherapy through its lowering effect on bilirubin, which, moreover, could also explain the lack of correlation between bilirubin and HO-activity.

Causes of neonatal jaundice

Physiological jaundice

The so-called physiological or developmental jaundice (which could be especially harmful for the small preterm infant) is due to an imbalance between increased pigment load and reduced hepatic handling. The latter seems mainly determined by the low activity of bilirubin UDP glucuronosyltransferase, the hepatic microsomal enzyme that conjugates bilirubin with one or two sugar moieties. It is now accepted that, even in the absence of impaired biliary secretion, a fraction of the esterified bilirubins formed in the liver normally refluxes from hepatocyte to the plasma. Measuring the esterified bilirubins in the plasma of newborn infants has made it possible to demonstrate definitively that neonatal jaundice is mainly due to an increased bilirubin production with subnormal conjugation.[38] On the other hand, infants with the lowest plasma concentration of total bilirubin exhibited the highest fraction of conjugates. The percentage of diconjugates relative to total conjugates is 15% on the first day of life. This value tends to increase slightly with age.[38] In premature infants, serum monoconjugates paralleled the course of total and unconjugated bilirubin, but the values were significantly lower than those found in full-term infants.[17,38]

From the practical point of view, we can rule out the diagnosis of physiological jaundice if plasma or serum bilirubin concentration exceeds at any time 12.9 mg/dl (220 mmol/l) in full-term infants or 5–8 mg/dl (85–138 mmol/l) in preterm infants,[39] if jaundice becomes evident in the first 24 h of life, if bilirubin concentration increases more than 5 mg/dl/day (85 mmol/ l/day), and if direct reacting plasma bilirubin exceeds 1.5–2 mg/dl (25–35 mmol/l) (it is important to determine conjugated bilirubin by a chromatographic method[17,38]).

Jaundice in breast-fed neonates

An increased incidence of early-onset jaundice has been reported in breast-fed infants, both full-term and preterm.[40,41] However, an increased bilirubin synthesis, demonstrated by an increased CO production, possibly secondary to caloric deprivation, has not been proven.[42] The process of bilirubin conjugation, investigated in breast-fed and formula-fed infants, by means of the determination of serum concentrations of unconjugated and esterified bilirubin, and the proportion of diesterified (as a percentage of esterified bilirubin) pigment, appeared not to be different between the two groups of infants, showing that bilirubin production and conjugation were not different.[43] In addition, a recent study comparing the incidence of neonatal jaundice in 605 infants exclusively breast-fed on demand, in 623 who received both breast- and formula feeding, and in 226 exclusively formula-fed demonstrates that the incidence of neonatal hyperbilirubinemia (>12.9 mg/dl or 220 mmol/l) in full-term infants is both insignificant (< 5%) and not correlated with demand breast-feeding.[1] These results were recently confirmed in a population of 2174 infants with gestational age ≥37 weeks where hyperbilirubinemia was not found to be correlated with breast-feeding, but rather with an increased weight loss, dehydration, and caloric deprivation, which could enhance the enterohepatic circulation of bilirubin.[44]

Hemolytic jaundice

Fetomaternal blood group incompatibility, particularly ABO and rhesus hemolytic disease, are the most common causes of severe jaundice. Nowadays, rhesus hemolytic disease is infrequently due to maternal prophylaxis with antirhesus immunoglobulins. However, ABO hemolytic disease still remains an important cause of indirect hyperbilirubinemia and anemia in full-term as well as preterm infants. Suspicion of ABO or rhesus hemolytic disease must be confirmed by a direct Coombs test carried out on the newborn blood.

Glucose-6-phosphate dehydrogenase (G-6-PD) deficiency

G-6-PD deficiency is frequently associated with neonatal jaundice and sometimes kernicterus. The pathogenesis of this jaundice remains in part unclear, because increased erythrocyte breakdown is not always the major factor in its development.[45] In some patients, overt hemolysis, due to different substances, is detected, and in others no signs of hemolysis are detectable (normal level of carboxyhemoglobin). In this group of patients it has been shown that a deficiency in bilirubin conjugation does exist.[45] It is possible that G-6-PD is

also involved in some steps (possibly UDP glucuronic acid synthesis) of bilirubin conjugation.

Congenital non-obstructive, non-hemolytic jaundice

Crigler–Najjar disease is a rare disorder of bilirubin metabolism caused by a deficiency of hepatic UDP-glucuronyltransferase, and characterized by high serum levels of unconjugated bilirubin that appear in the first days after birth and continue through life. Based on the responsiveness of the serum bilirubin concentration to phenobarbital, this disease can be distinguished as either type 1, which does not respond to phenobarbital, or type 2, which responds to barbiturates and other drugs that induce enzyme synthesis. Type 2 is probably caused by a partial enzymatic deficiency. In type 1 and type 2 Crigler–Najjar disease, it is possible to detect traces of monoconjugated but not diconjugated bilirubin both in serum and in bile.[46]

Bilirubin entry into the brain

Some clinical observations suggest that several mechanisms may be involved with the entry of bilirubin pigment into the brain. In fact, bilirubin seems to enter into the brain both as free bilirubin acid and as bilirubin–albumin complex, by passage through a disrupted blood–brain barrier that is often caused by hyperosmolality and hypercarbia. It seems that even during physiological jaundice, there is a steady passage of unbound bilirubin across this barrier. Furthermore, these low levels of bilirubin do not seem to be harmful; in fact, it is also possible that cerebral stores of bilirubin oxidase are able to metabolize bilirubin *in loco*. Obviously, the entry of bilirubin into the brain can be significantly increased in the presence of high plasma bilirubin concentrations, particularly if the albumin-binding capacity is exceeded.[47] Ahlfors *et al.* reported that in term newborns unbound bilirubin levels between 0.9 and 2 μg/dl produce subtle and reversible changes in auditory brainstem response latency, and described the case of an infant who developed a kernicterus at a total bilirubin concentration of 31.7 mg/dl and unbound bilirubin concentration of 7.7 μg/dl.[48] However, in preterm infants bilirubin-induced changes in auditory brainstem response can begin at an unbound bilirubin level of 0.5 μg/dl and kernicterus becomes likely at 1–1.5 μg/dl.[49]

Effects of bilirubin on neurologic functions

It is well known that bilirubin acts to uncouple oxidative phosphorylation and, consequently, inhibits the respiratory chain by causing certain toxic effects.[50] However, a number of studies carried out on experimental animals show no difference either in bilirubin binding between different brain regions or in the rate of bilirubin disappearance from the cerebral tissues.[51] Moreover, it is still unclear as to why bilirubin has a preferential localization at the level of the basal ganglia. One proposed explanation relies on the possibility that bilirubin may be metabolized locally at different rates.[51] In fact, the typical findings of kernicterus are a yellow staining of the subthalamic, dentate, and inferior olivary nuclei and the globus pallidus. Cell culture models suggest that bilirubin initially interacts with cellular membranes, affects ion channels and neurotransmitters, and ultimately leads to deranged metabolism and cell death.[52] The clinical picture of kernicterus is also fairly uniform in these children, with convulsions and opisthotonus followed by hypotonia, high-pitched crying, and fever. The sequelae in the survivors consist of neurogenic hearing disorders, choreoathetosis with asymmetrical spasticity and paralysis of upward gaze, together with other neurologic manifestations. Ambulation, despite severe athetosis, is generally reached by the age of 5 years.[53]

Brain stem auditory-evoked potentials are altered by bilirubin in various ways.[54,55] In some studies, it has been observed to change the conduction latencies; in others, it lowered the conduction wave amplitude, both of which fit in with the follow-up observation of deafness in kernicteric babies. Some studies note reversibility of these altered potentials through lowering of high bilirubin levels.[4,56,57]

Bilirubin-induced membrane potential lowering may impair nerve conduction along the auditory pathway, which may be reversible if each cell endures only temporary malfunction or if a sufficient number of neurons in the nerve survive the toxicity to maintain function.

It is commonly accepted that (1) bilirubin may be toxic for cells, (2) kernicterus can occur when unconjugated bilirubin levels are high, and (3) the mechanism of bilirubin toxicity is mostly unknown.

Measurement of bilirubinemia

The majority of the published studies on bilirubin in infants were made measuring its level on capillary blood with spectrophotometric methods. Some studies compared capillary and venous measurement of bilirubinemia, but their results were conflicting.[58,59] Therefore, to confirm a high plasma bilirubin level in a venous sample is not recommended. Recently, new devices have permitted an easier and more reliable transcutaneous measurement of bilirubin. The Chromatics Colormate III™ (Chromatics Color Science International Inc., New York, NY, USA) is still based on the color of the skin, estimating serum bilirubin from skin reflectance (skin color), whereas the BiliCheck™ (Respironics, Murrysville, PA, USA) measures transcutaneous bilirubin by utilizing the entire spectrum of visible light (380–760 nm) reflected by the skin. Data obtained using BiliCheck™ suggest

that this device provides measurements within 2–3 mg/dl (34–51 μmol/l) of the serum bilirubin concentration.[60] These devices could be used as screening tools but, in some circumstances, also as substitutes for serum bilirubin measurements, in particular, when its value is lower than 15 mg/dl (257 μmol/l).

Treatment of neonatal hyperbilirubinemia

Bilirubin is bound to albumin in the blood, and when its concentration exceeds the binding capacity of the carrier, unbound or free bilirubin concentration increases and results in its redistribution between the tissues (brain) and the vascular space (free bilirubin theory). Thus, not only is the serum bilirubin concentration important in judging whether an infant is at risk of bilirubin toxicity, but the albumin concentration and the bilirubin/albumin ratio are also of critical importance. In fact, Ahlfors suggests that when the bilirubin/albumin ratio is < 8 mg/g (136 mmol/g) and the neonate appears well, exchange transfusion is probably not necessary.[61]

Exchange transfusion, first performed in 1925 by Alfred Purvis Hart and then implemented by L. K. Diamond in 1947 using the umbilical vein to withdraw and to perfuse blood, was the only treatment available until 1958, when Cremer and colleagues[62] showed that both sunlight and blue light were able to reduce jaundice in newborns. In fact, phototherapy is now the most widely used method worldwide for the treatment of jaundiced babies.

The mechanisms by which light renders the insoluble bilirubin molecule (bilirubin IX-alpha *Z*,*Z*), at physiologic pH, soluble and rapidly excretable in the biliary tract are the transformation of the *Z*,*Z* configuration at the C4–C5 and C15–C16 double bonds to the *E* configuration in one or both double bonds, thus forming the configurational isomers *E*,*Z* or *Z*,*E* or *E*,*E*.[63–65] Of these isomers, the predominant one is the *Z*,*E* form. However, the *Z*,*E* change is reversible, and after phototherapy it reconverts in the bile or in the intestines to the *Z*,*Z* isomer. In addition, intramolecular cyclization of bilirubin can occur as a result of phototherapy, to form a structural isomer called lumirubin, which cannot be reconverted to native bilirubin. Moreover, lumirubin, which is formed at a lower rate in comparison to the configurational isomers, seems to be excreted more rapidly in the bile than the other isomers.

There is a striking regional selectivity that causes isomerization to take place at the double bond of the CH-bridges. Because of the specific preference evidenced by one-half of the bilirubin molecule in binding to human albumin, the *E* configuration in position 15 is the main isomer formed. This selectivity is lacking to a large extent in a number of the animals used in experimental studies. Finally, the available data suggest that bilirubin is bound to albumin at the site of the light effect, namely in the skin.

The extent to which isomerization, cyclization, or oxidation exerts the therapeutic effect of light is determined mainly by the quantum yield of the photochemical reactions and the speed of the transport processes up to the excretory phase.

The quantum yield of configurational isomerization is probably very high; isomers are formed very quickly, and they can be detected within a few minutes after light treatment. On the other hand, photocyclization proceeds more slowly, and depends on the wavelength employed. Moreover, the quantum yield of bilirubin oxidation is very low, and it is most probable that the excretion of catabolites formed in the process takes place rapidly. Since the excretion rate of lumirubin is very high, it is conceivable that, in phototherapy for neonatal jaundice, bilirubin photocyclization is the most effective mechanism of bilirubin photometabolism, followed by configurational isomerization, and, finally, photo-oxidation.

The bronze baby syndrome (BBS)

The BBS is a rare pathological condition that appears during phototherapy. The typical characteristic is a grayish-brown discoloration of the skin, serum, and urine. This condition was first described by Kopelman *et al.*,[66] who observed the typical discoloration in the skin of a newborn following phototherapy. They found that the onset of the syndrome was linked to an increase in conjugated bilirubin, implying a cholestatic disorder; moreover, they also related it to hemolytic anemia. Since then, various authors have attempted to explain the biochemical mechanism responsible for the onset of this syndrome.[67,68] In this connection, Kopelman *et al.* noted a reduced bilirubin-binding capacity in newborns suffering from BBS. They suspected that bilirubin photoproducts might be responsible both for the bronze discoloration and for the change in binding capacity ascertained by the salicylate method. Autopsy evidence later showed that this peculiar discoloration was also present in the kidneys, liver, and peritoneum. Clark *et al.*[67] and Rubaltelli *et al.*,[68] in particular, found anatomical signs of kernicterus in two newborns who died with this syndrome. They considered this observation to be the confirmation that the pigments responsible for BBS increase the risk of bilirubin neurotoxicity, as suggested by the reported decline in the albumin-binding capacity.[66,69]

In 1982, a notably higher concentration of porphyrins was found in the serum of patients with BBS.[70] Two cases of this syndrome, with very high serum porphyrins, probably due to some degree of cholestasis, were described.[71,72] The porphyrins were identified as Cu^{2+}-uro-, Cu^{2+}-copro-, and Cu^{2+}-protoporphyrin. In fact, the absorption spectrum of serum specimens

from infants with BBS showed spectral features typical of bilirubin (peak absorption around 460 nm), as well as an intense band with a peak at about 400 nm and broad absorbance in the near-UV and the 600–700-nm region. The latter two features were not confirmed by the absorption spectra of control sera. The sera of bronze babies also exhibited a wide range of fluorescence emission spectra with peaks at 585, 619, and 670 nm. This finding indicates that absorption in the 400-nm band does not reflect the presence of residual hemoglobin in the serum because hemoproteins are known to be devoid of any appreciable fluorescence in the red region. Instead, the emission spectra observed are characteristic of porphyrin compounds.

Chromatographic separation led to the conclusion that the main component is Cu^{e+}-protoporphyrin IX, although small amounts of Cu^{e+}-coproporphyrin II and Cu^{e+}-uroporphyrin III are also present. These porphyrins do not seem to have an appreciable photosensitizing effect. Furthermore, there was no evidence of significant alterations in the UV spectrum of irradiated serum from infants with BBS or in cord blood serum with added synthetic Cu^{e+}-porphyrins. This is due to the well-known shortening of the half-life of excited porphyrin as a consequence of the binding of the Cu^{e+} ion on the tetrapyrrolic ring.[73]

These investigations show that the grayish-brown skin color is a result of the photolability of the Cu^{2+}-porphyrins. Indeed, Cu^{e+}-porphyrins in the serum of infants with BBS or in aqueous solutions are converted under irradiation with visible light into brown photoproducts with a higher absorption in near-UV and red spectral regions. Moreover, the presence of bilirubin increases the photodegradation rate of Cu^{e+}-porphyrins, suggesting that bilirubin acts as a photosensitizer in this process.

Guidelines for the treatment of unconjugated hyperbilirubinemia

Full-term newborn infants

Neonatal jaundice (total serum bilirubin concentration > 12.9 mg/dl (220 mmol/l) occurs in around 5% of normal neonates.[1] In the majority of cases it is a physiologic or developmental jaundice,[1,74] which does not need any treatment. However, it is important to exclude the presence of a rhesus or ABO hemolytic disease, and the possibility that the jaundice could be an early sign of an inborn error of metabolism, or sepsis, etc.

It is suggested that a direct Coombs test plus blood group and rhesus determination should be carried out on the cord blood of every neonate, and when jaundice is present, the neonatologist should evaluate the appropriateness of a serum bilirubin determination in relation to the day of appearance and intensity of the jaundice, etc. A serum bilirubin level of 20 mg/dl (340 mmol/l) in a normal full-term newborn infant is no longer considered an indication for exchange transfusion.[74] In the absence of a hemolytic disorder, and with a bilirubin level in the range 20–25 mg/dl (340–425 mmol/l), exchange transfusion might be considered, but this decision must be based on a careful evaluation of the risk/benefit ratio.

Following Wennberg's suggestions,[47] one should take into consideration not only the serum bilirubin level but also the albumin serum concentration: that is, by multiplying the albumin value in grams by 7, a value is obtained which corresponds to the level when an exchange transfusion is indicated.

It is recommended that phototherapy be started during the first 24 h of life if the serum bilirubin level exceeds 4–7 mg/dl (70–120 mmol/l), or during the second 24 h of life if it exceeds 11–15 mg/dl 190–260 mmol/l), and in all cases whenever it exceeds 15 mg/dl (260 mmol/l). Phototherapy should be carried out for at least 24 h, and should be interrupted when serum bilirubin concentration is decreased by ≥ 2 mg/dl (≥ 35 mmol/l).

However, the American Academy of Pediatrics has recently published guidelines for the management of hyperbilirubinemia in the newborn infant of 35 or more weeks' gestation, which report in depth on current recommendations for prevention, diagnosis, and treatment of neonatal jaundice.[75] The approach to jaundice in preterm infants appears more difficult because there are no specific evidence-based guidelines for the use of phototherapy and exchange transfusion in these infants. Different authors have reported a range of plasma bilirubin levels for intervention in various circumstances, but none of these indications has greater validity than another.[39] However, considering that in preterm infants kernicterus has almost disappeared probably because of aggressive phototherapy, it is probable that the current management of jaundice in these infants is correct.

Other possible therapeutic interventions are immunoglobulin therapy in immune hemolytic jaundice and administration of the heme oxygenase inhibitor Sn-mesoporphyrin. Alcock *et al.*, in a meta-analytical study on term and preterm infants with rhesus and ABO incompatibility, found that the rate of exchange transfusion decreased significantly in the immunoglobulin-treated group.[76] As for Sn-mesoporphyrin, its use is very promising both for the prevention and for the treatment of neonatal jaundice. However, this drug is as yet under research and is not commercially available (see Kappas[77]).

Premature newborn infants

In the past few years, a number of studies have shown that currently neither kernicterus nor clinical signs of bilirubin encephalopathy are found in premature babies (see the important review of Conolly and Volpe[78]). These findings were reported despite the fact that higher serum bilirubin concentrations were

allowed compared with the studies reported in the 1960s and 1970s, when kernicterus was not a rare occurrence.[79,80] It is possible that the improved quality of health care has reduced the appearance of preterm kernicterus, the pathogenesis of which is still not completely understood.[80–85]

The definition of prematurity (< 37 weeks of gestational age) includes neonates of very different gestational ages. Moreover, a generous use of phototherapy has allowed a reduction of high serum bilirubin concentrations, and as a result exchange transfusion is no longer used very often. However, it seems rational to initiate light treatment independently of the age of the premature infant, whenever the serum bilirubin concentration is ≥ 8 mg/dl (135 mmol/l), provided that no hemolysis is present. In fact, exchange transfusion must be considered when bilirubin reaches the level of 18 mg/dl (305 mmol/l). Furthermore, for the premature newborn one can use Wennberg's formula[47] to identify infants needing exchange transfusion: multiplying by six the value of serum albumin concentration (in g) one obtains the threshold value for exchange transfusion.

3 Management of hypotension in the neonatal period

S. J. English

Introduction

Hypotension is a commonly encountered problem on the neonatal intensive care unit. It occurs in up to 40% of very low-birth-weight (< 1500 g) infants, and is almost universally seen in the extreme preterm baby, most commonly in the first 48 h after birth. Its importance lies in its possible causal link with brain injury in these infants.[1–4]

There are numerous controversies surrounding the management of hypotension in the preterm infant. As more extremely preterm babies are surviving, our accepted definitions of hypotension are being challenged. The level of blood pressure required to maintain tissue perfusion in these babies is unknown, and the effects of standard therapy are relatively under-researched. As a result, the level of hypotension at which treatment is instigated, and the treatment chosen, largely remain subject to personal preference.

Definition

Normal blood pressure has proven difficult to define in preterm babies, partly because it varies with gestational and postnatal age,[5,6] but also because the range of blood pressure, which will ensure adequate organ perfusion, is not known. There have been a number of studies attempting to define the normal range of blood pressure in the neonate. These have resulted in two widely accepted definitions of hypotension:

(1) Mean arterial blood pressure less than the 10th centile for gestation/birth weight and postnatal age.[1]

(2) Mean arterial blood pressure less than gestational age in weeks. This is derived from the first definition, following the observation that the 10th centile for mean blood pressure is roughly equal to the gestational age.[5] It is worth remembering, however, that this is only valid in the first 48 h of life, and that blood pressure rises steeply over the first five postnatal days.

Most neonatal units use the gestational age as a guide when instituting treatment for hypotension. It is important, however, to assess other markers of tissue perfusion, such as capillary refill time, the presence of metabolic acidosis, and urine output when deciding whether to treat.

Pathogenesis

Hypovolemia

Hypovolemia causes hypotension by decreasing the preload, leading to reduced cardiac output. In neonates, hypovolemia may result from acute hemorrhage (antenatal or postnatal), or from fluid loss due to capillary leak, as seen in septicemia or acute abdominal pathology. It is generally accepted that hypovolemia is an uncommon primary cause of hypotension in the sick preterm infant.[7] It may, however, be implicated in a small number of babies, and should always be considered.

Myocardial dysfunction

There is good evidence that myocardial dysfunction plays an important role in the development of hypotension in preterm infants in the first few hours of life.[8] There are several factors that contribute to myocardial dysfunction, the foremost of which is immaturity of the myocardium. Hypoxic damage to the heart muscle, acidosis, sepsis, and the presence of a ductal shunt will all adversely affect myocardial function, leading to decreased cardiac output and hypotension. Congenital structural heart defects may also present with hypotension secondary to reduced cardiac output.

Downregulation of adrenergic receptors

There is growing evidence that a proportion of sick preterm infants have relative adrenal insufficiency, demonstrating a low cortisol response to human corticotrophin releasing hormone.[9–12] Because glucocorticoids have a role in regulating the expression of

cardiovascular adrenergic receptors, these infants may be incapable of responding to endogenous or exogenous sympathomimetic agents.[13]

Measurement

Intra-arterial blood pressure monitoring through an umbilical or peripheral arterial catheter is widely accepted as the gold standard. Studies comparing oscillometric with invasive measurement demonstrate that, providing cuff size is standardized, oscillometric measurement seems to be accurate within the normal range.[14,15] However, concern has been expressed that at the lower levels it consistently overestimates the blood pressure, providing false reassurance to the clinician.[16] In situations where intra-arterial monitoring is not possible, it is important to also assess other markers of tissue perfusion.

Clinical relevance

Tissue perfusion

In neonatology, blood pressure is regularly used as a marker of systemic organ perfusion, and our efforts to maintain normal blood pressure are based on the belief that we are preserving tissue perfusion. Unfortunately, there are few data to support this. In preterm infants there is only a weak correlation between blood pressure and cardiac output.[17] Furthermore, since blood pressure is the function of blood flow and systemic vascular resistance, blood pressure may not reflect the blood flow in end organs, as the vascular resistance will vary. Several methods that may be useful for assessing systemic blood flow and tissue perfusion in neonates are being evaluated.

Left ventricular output is often used in adults to assess systemic blood flow. Measurements of ventricular outputs in neonates may be confounded by shunts through a patent ductus or foramen ovale. Systemic blood flow in the superior vena cava of newborn infants has been successfully measured, using Doppler echocardiography. Flow in the superior vena cava is thought to reflect blood flow in the upper body, particularly the brain, and appears to correlate well with left ventricular output in babies with a closed duct.[18]

Near-infrared spectroscopy (NIRS) has been used to measure hemoglobin flow and venous saturation in the forearm of hypotensive preterm babies.[19] Using this technique, it has been demonstrated that peripheral oxygen delivery and consumption are lower in hypotensive babies, but that oxygen extraction is similar to normotensive controls, with no rise in lactate concentration. This suggests that in hypotensive babies, peripheral oxygen delivery is still adequate for tissue demands, challenging the need to routinely correct hypotension. NIRS has also been used to monitor cerebral circulation in sick premature infants. Unfortunately, it has not been clearly demonstrated whether there is a direct relationship between mean arterial blood pressure and cerebral intravascular oxygenation.[20,21]

As NIRS and cardiac output measurements are not continuous, their role in the decision to treat a blood pressure level remains unclear. They do, however, question our present practice of using a single value below which treatment should be started. Further research in this area is obviously needed before techniques such as this have direct relevance to the management of hypotension.

Cerebral injury

Sick VLBW infants have reduced cerebral vascular autoregulation compared with term infants with the postulated effect that significant hypotension may lead to cerebral hypoperfusion.[22,23] Episodes of systemic hypotension have been linked to cerebral hemorrhage, ischemia, and an increased risk of long-term neurological sequelae.[1,3,4] Hypotension is thought to lead to intraventricular hemorrhage by causing ischemic damage to the germinal matrix, which bleeds on reperfusion. It is unlikely that overenthusiastic correction of hypotension is involved, as episodes of hypertension are not associated with the occurrence of intraventricular hemorrhage. There is no clear evidence that systemic hypotension, in itself, leads to periventricular leukomalacia,[3] although it may be a factor in babies who are also septic. Interestingly, there is little evidence to support the view that treating hypotension prevents any of these sequelae.

Management

The aim of treating hypotension is to preserve adequate organ perfusion and thus to prevent complications, such as cerebral injury. However, a cause for hypotension should always be sought before treatment is instituted. Important conditions to exclude include:

- Blood loss
- Pneumothorax
- Sepsis
- Patent ductus arteriosus
- High positive intrathoracic pressure (secondary to mechanical ventilation)
- Heart failure

If one of the above causes is identified, the primary treatment of the hypotension is to institute the specific treatment for the underlying condition. In most instances, a cause for hypotension in the neonatal period will not be determined, although myocardial

dysfunction has been identified as a common factor, and treatment will be initiated on the basis of unit protocols. These normally follow a stepwise approach, beginning with volume support followed by inotropes and in some the use of steroids.

Volume support

As previously discussed, hypovolemia is an infrequent cause of hypotension in the sick preterm infant.[7] It is also difficult to diagnose in the immediate postnatal period, as indicators, such as urine output and capillary refill time, are unreliable. However, because it does occasionally occur, and it is relatively easy to treat, most units adopt a policy of moderate volume replacement prior to the institution of inotropes.

Fluids available for volume replacement may be either crystalloid or colloid. The main difference between the two is the oncotic pressure effect, according to Starling's law, and the theoretical difference in the length of time they remain in the intravascular space. However, the volume administered appears to be more important than the protein content in producing a sustained increase in blood pressure in preterm infants,[24] and isotonic saline has been shown to be as effective as 5% albumin for treating hypotension in this population.[25] Crystalloids are also significantly cheaper than colloids, and do not carry the same infection risk.

As colloid and crystalloid are equally effective in treating hypotension in the neonatal period, and considering the other advantages of using isotonic saline, it would seem that the safest approach to volume replacement would be to use 10–20 ml/kg 0.9% saline given over 30 min in the first instance. For babies who are likely to be hypovolemic secondary to protein losing conditions, such as babies who have undergone gastrointestinal surgery, 4.5% albumin should be reserved.

Dopamine and dobutamine

Since myocardial dysfunction plays an important role in the development of hypotension in preterm infants in the first few hours of life,[8] it is clear that inotropic agents should be of some benefit in the management of hypotension in these babies. The use of inotropes is, however, historically based rather than evidence based, and there are few data relating to associated mortality and morbidity.

Unsurprisingly, dopamine is more effective than volume expansion in restoring normal blood pressure in preterm infants.[26] Dopamine is an exogenous sympathomimetic amine that exerts its cardiovascular effects by the dose-dependent stimulation of dopaminergic and α- and β-adrenergic receptors. In the preterm population dopamine causes a dose-dependent increase in mean arterial blood pressure in doses of 5–20 μg/kg/min.[27–29]

The main hemodynamic effects of dopamine are to increase myocardial contractility and peripheral vascular tone. The increase in myocardial contractility is caused both by a direct stimulation of α- and β-adrenoceptors and indirectly through its action on β_2-adrenoceptors, stimulating the release of endogenous noradrenaline.[30] In adults, the vasotonic effects of dopamine are dose dependent. At doses < 5 μg/kg/min dopamine stimulates peripheral dopaminergic receptors, resulting in the selective dilatation of renal, mesenteric, and coronary arteries. At higher doses >10 μg/kg/min it causes vasoconstriction by stimulation of α-adrenergic receptors. The dose-dependent effects of dopamine on vascular tone in the preterm neonate are less clear,[29,30] although there are emerging concerns that it may have a potent vasoconstrictive effect on the pulmonary vasculature.[31]

Studies in adults suggest that, in sick hypotensive patients, there is a downregulation of adrenergic receptors, requiring much higher doses of dopamine to maintain blood pressure.[13] However, there have been no such studies in neonates. The fact that some preterm infants may also have relative adrenal insufficiency[9] may explain the occurrence of pressor resistance. Further research is clearly required in order to define a maximum dose for dopamine, as the use of high doses (> 25 μg/kg/min) has not been studied.

Dobutamine is a relatively cardioselective sympathomimetic amine, which exerts its positive inotropic action by direct stimulation of cardiac α- and β-adrenoceptors. It has several theoretical advantages over dopamine: (1) it has limited chronotropic effect, (2) its use is not associated with an increase in systemic vascular resistance,[27] and (3) it does not rely on release of endogenous catecholamines for any part of its action.

There is relatively little research into the use of dobutamine in preterm neonates, and it is generally used as a second-line drug in patients unresponsive to dopamine. It is infused at rates of 5–20 μg/kg/min,[27,32–35] and has been shown to increase left ventricular performance in these doses.[36] The use of high doses (> 25 μg/kg/min) has not been studied. Dobutamine can cause hypercontractile heart failure in the presence of left ventricular hypertrophy, resulting in paradoxical hypotension.[37] It should therefore be used with caution in babies with existing cardiac disease.

In the preterm infant, dopamine is significantly more effective than dobutamine in the treatment of systemic hypotension, with no differences in short-term complications, such as intraventricular hemorrhage and necrotizing enterocolitis.[38] No data are available on long-term outcome for either drug.

Other agents

Most neonatal units advocate the use of adrenaline or noradrenaline in cases where dopamine and dobutamine have failed to maintain 'normal' blood pressure.

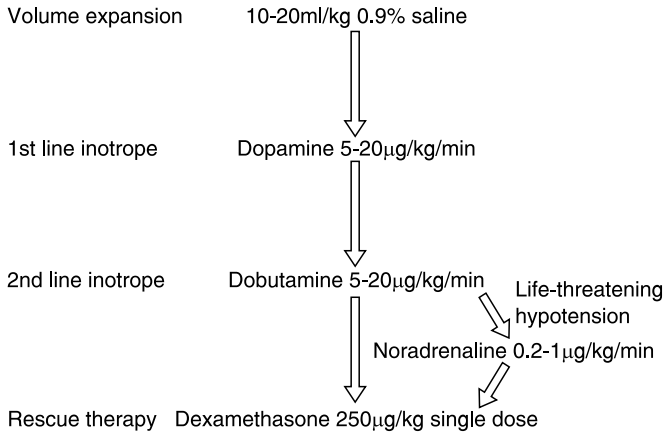

Figure 3.1 Flow chart for management of hypotension in neonates. From Dasgupta and Gill[49] with permission.

However, very few studies have looked at the use of these agents in preterm infants, most of the data originating from animal studies. Both adrenaline and noradrenaline, when used in addition to dopamine, do restore normal blood pressure in sick, hypotensive neonates without causing significant cerebral, myocardial, or renal vasoconstriction.[39,40] The use of these agents is, however, associated with a high mortality rate of over 50%.

Dopexamine, a relatively new synthetic catecholamine, with predominant β_2-adrenergic and dopaminergic activity, has been shown to be effective in raising blood pressure, and improving arterial pH and urine output.[41] In neonates who are hypotensive secondary to septic shock, methylene blue, an inhibitor of soluble guanylate cyclase, has been shown to be effective in increasing blood pressure.[42]

Further research is clearly needed in this area before the routine use of any of these agents can be recommended.

Steroids

Antenatal steroids are now commonly given to mothers in preterm labor. They have been shown to have an independent effect (from the effect on respiratory distress syndrome) on reducing the incidence of hypotension in the preterm infant.[43]

In neonates with hypotension, who are unresponsive to volume or pressor administration, there is growing evidence that steroids may be of some value. The theory is that infants with refractory hypotension may have relative adrenal insufficiency.[9–12] The resulting low levels of circulating cortisol in these babies may be insufficient to counteract any down-regulation of cardiovascular adrenergic receptors, which occurs in critical illness,[13] rendering them resistant to treatment with sympathomimetic agents.

In infants with severe hypotension refractory to both volume expansion and inotropes, treatment with either single-dose dexamethasone or a 5-day course of hydrocortisone has been shown to be successful with discontinuation of inotropes within 54 h. This effect is sustained for many days following the administration of steroids.[12,44–46] Although the effect may not be evident for up to 6 h, in my experience it is usually seen within 2 h of treatment.

There are some groups who have advocated the use of hydrocortisone in smaller doses as prophylaxis against hypotension in at-risk VLBW infants.[47] Side effects from postnatal steroids, including the long-term risk of adverse neurological outcome, are well documented and probably prohibit prophylactic use.[48]

Based on the available evidence, the use of steroids in the treatment of severe, intractable hypotension, resistant to inotropes, is probably justified. This may be in the form of a single dose of 250 μg/kg dexamethasone or a 5-day tapering course of hydrocortisone starting at 2.5 mg/kg qds. Obviously, there is a balance of risks against benefits, but the short-term benefit of preventing death must outweigh the long-term risks, which are anyway unproven. Further research is obviously needed to determine the optimum dose and course.

Conclusion

The management of hypotension in preterm infants remains a controversial area in current neonatal practice. Research in this area is relatively limited, which in part is probably due to the difficulty in obtaining continuous measures of tissue perfusion. There is no consensus on either the definition of hypotension or the level at which treatment should be initiated. The effects of aggressive correction are relatively under-researched, and there are few data on morbidity and mortality in relation to the use of volume support and inotropes. The aim of management must be to attain adequate tissue perfusion and oxygenation, but there may be little or no relation between blood pressure and organ perfusion. Further research is required in methods of assessing tissue perfusion, which can be used alongside monitoring of blood pressure to guide the neonatologist in deciding when to intervene.

Continuous invasive arterial blood monitoring remains the preferred method of recording blood pressure. Decisions to treat hypotension should be based on the general condition of the infant, not on the mean arterial blood pressure alone. On the basis of the available evidence Figure 3.1 outlines a suggested guideline for the management of hypotension in the neonatal period.

4 Cytokines and neonatal disease

L. Cornette and H. Logghe

Fetal and neonatal inflammatory responses

This review is designed to guide the reader through the framework given in Figure 4.1, summarizing the concept of perinatal inflammation/infection and current factors that may influence the overall outcome under study. Several diseases in the newborn, such as sepsis, chronic lung disease and broncho-pulmonary dysplasia (CLD/BPD) and necrotizing enterocolitis (NEC) are characterized by the presence of inflammation. Given the mounting evidence suggesting a continuum between ante- and postnatal inflammation, and adverse neonatal outcome,[1,2] we will first study the fetal inflammatory response, prior to expanding on inflammatory responses emerging in the neonatal period.

By definition, an inflammatory response is a protective response to an infection or an injury, mediated by proinflammatory cytokines, i.e. low molecular weight glycoproteins, predominantly produced by the monocyte–macrophage cell line at the inflammatory site. Proinflammatory cytokines (e.g. IL-1β, IL-18, IFN-γ, TNF-α) are primarily responsible for initiating an effective defense (i.e. acute phase response) against exogenous pathogens, whereas anti-inflammatory cytokines (e.g. IL-4, IL-10) are involved in the downregulation of exacerbated inflammatory processes and the maintenance of homeostasis for proper functioning of the vital organs.[3]

Fetal inflammatory response syndrome

The majority of women delivering before 28 weeks, with or without preterm premature rupture of membranes (PrePROM), show evidence of intrauterine infection. A mechanism postulated is microbial invasion of the uterine cavity resulting in a fetal systemic cytokine or inflammatory response through aspiration, otitis, conjunctivitis or omphalitis.[4] However, only a small proportion of these women will have a positive amniotic fluid culture.[5] Intra-amniotic *inflammation* would therefore appear to be a better predictor for imminent preterm delivery rather than intra-amniotic *infection*.[6]

Such active participation of the fetus in a systemic antenatal inflammatory response is therefore commonly

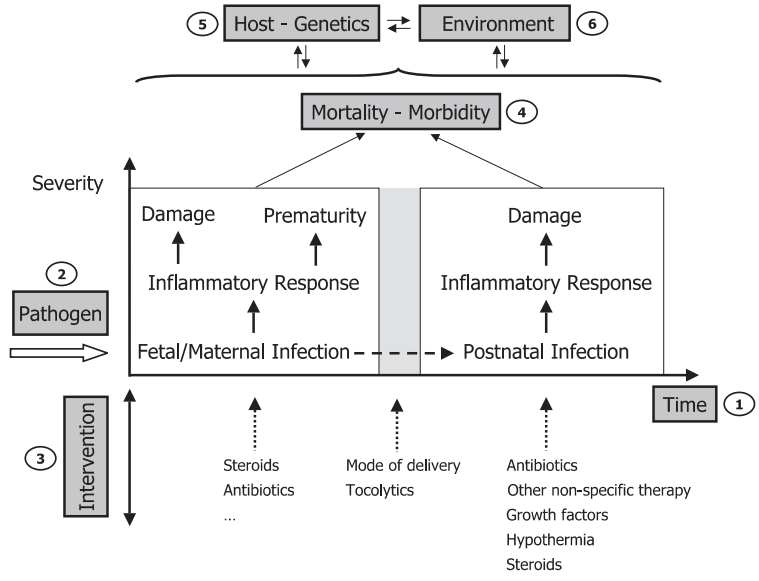

Figure 4.1 The fetal/neonatal inflammatory response. Illustration of antenatal and postnatal inflammatory responses and six factors that may influence the overall outcome.

studied using cordocentesis techniques. Indeed, the fetal inflammatory response syndrome (FIRS) was originally defined by relating increased fetal cord plasma IL-6 to the onset of spontaneous preterm labor (through increased fetal adrenal cortisol production and subsequent prostaglandine release).[7] More recent studies have revealed that the FIRS involves the synergistic action of different cytokines and several complex host defense mechanisms.[8] In addition, through the study of differential placental vs. fetal immune cytokine responses within animal models, we now know that an FIRS, rather than the maternal infection, causes fetal multiorgan injury.[9]

Fetal brain/fetal neurotoxicity

The fetal brain has been extensively studied within the context of intrauterine inflammation.[10,11] Funisitis, i.e. infection of the umbilical cord, and chronic chorioamnionitis have been associated with an increased risk of intraventricular hemorrhage.[12,13] Fetal vasculitis has been linked with an 11-fold increased risk of development of periventricular echolucencies.[14] Histopathological examination of infant brain specimens shows overexpression of TNF-α in the microglia cells of periventricular leukomalacia (PVL) lesions, with cytokine production being highest in infected infants.[15]

However, a clear link between intrauterine infection/inflammation and neurological outcome in preterm babies is not confirmed in all studies, as much of the confusion arises from different timings of blood sampling across different studies. Cytokine levels in neonatal blood (day 2 or 3) are likely to be influenced by respiratory or infectious complications, as well as different levels of intensive care, and thus may be different from umbilical cord blood levels.[16] In order to establish a causal link between antenatal infection and neonatal brain disease in individual cases, one needs to provide evidence of placental infection, elevated inflammatory mediators in both umbilical cord and postnatal infant blood, presence of moderate to severe encephalopathy and/or neuroradiological confirmation of brain injury.

Proposed mechanisms for neurotoxicity associated with proinflammatory cytokines comprise (1) a direct cytolytic effect on neurones and oligodendrocyte precursors (either through *in situ* cytokine production or through systemic cytokines crossing the blood–brain barrier), (2) induction of excitatory amino acid release, (3) increased caspase activity resulting in amplified apoptosis, (4) abnormalities in the coagulation cascade or (5) fetal hypotension.[10,14,15,17] Further clarification of these and other mechanisms will increase the likelihood of successful therapeutic interventions.

Many studies focus on the interaction between cytokine and excitatory amino acid release (e.g. glutamate). It is now recognized that an antenatal inflammation-related insult to the central nervous system comprises both infection (proinflammatory cytokine release) and hypoxia-ischemia (excessive excitatory neurotransmitter release). The interaction between both entities is, however, complex. First, injury to the brain during antenatal infection may be secondary either to cytokinemia, i.e. cytokines crossing the blood–brain barrier, or to the interruption of placental blood flow resulting in asphyxia.[17] Second, animal work indicates that administration of a low dose of bacterial endotoxin (LPS) dramatically sensitizes the immature brain to injury and induces cerebral infarction in response to short episodes of hypoxia-ischemia that by themselves cause little or no injury.[18] Third, increased levels of IL-1 and TNF-α and neutrophil invasion into infarcted areas have been reported following hypoxia-ischemia in the absence of infection.[18–20] Fourth, complex interaction effects between both inflammation and excitotoxicity exist, as, for example, IL-1β perpetuates excitotoxic brain damage *in vivo*, whereas it ameliorates neuronal death *in vitro*.[20] Others have reported similar dual neurotrophic and detrimental effects exerted by cytokines following ischemia.[21] Finally, a complex interaction between hypoxia-ischemia and inflammation is also reflected in the neuropathology of white matter (WM) abnormalities observed in infants born to mothers with chorio-amnionitis.[22] Careful review of animal work suggests that cytokines can be neurotoxic through a process of 'sensitizing' the immature brain, i.e. lowering the threshold at which a hypoxic-ischemic insult triggers apoptosis.[23] Further clinical studies investigating the relationship between fetal infection/inflammation, feto-placental thrombosis and subsequent adverse neurological outcome will therefore be challenging.[24]

Other fetal morbidity

Fetal exposure to infection/inflammation, similar to antenatal administration of glucocorticoids can, on the one hand, result in maturation of the *lungs*. However, antenatal chorio-amnionitis can also prime the fetal lung to respond differently to postnatal events, increasing the risk of CLD/BPD (see below).[25]

Histological chorio-amnionitis has been associated with a noticeable reduction of volume and corticomedullary differentiation of the *thymus*, a reduced number of thymocytes and infiltration of macrophages into the parenchyma.[26]

Finally, a FIRS can result in preterm delivery (and, hence, possible neonatal morbidity), as increased fetal and not maternal serum IL-6 is one of several cytokines that precedes imminent preterm delivery.[8]

Neonatal inflammatory responses

Sepsis

The progression to septic shock in infants born to mothers with acute chorio-amnionitis is rarely seen in the immediate neonatal period. However, a significant association between funisitis and congenital sepsis has been described.[2]

Neonatal sepsis in the absence of chorio-amnionitis is predominantly mediated by IL-1, IL-6 and TNF-α. Sepsis-related mortality is well correlated with multiple-organ failure (MOF), caused by uncontrolled inflammation, immunodeficiency (prolonged neutropenia, lymphopenia, hypogammaglobulinemia) and endothelial injury with thrombotic microangiopathy. Septic newborns have low von Willebrand factor (vWF) cleaving metalloprotease activity (ADAMTS13), resulting in high amounts of circulating ultralarge vWF multimers that lead to microvascular platelet thrombosis and MOF.[27]

Little is known about the profile of pro- and anti-inflammatory cytokines in septic preterm infants, in whom the immune system may be considered as immature. An exaggerated proinflammatory response together with an inadequate anti-inflammatory compensation may result in an adverse clinical outcome, as a persistent high IL-6/IL-10 ratio implies a poor prognosis in very low-birth-weight patients.[1] Alternatively, a persistently high IL-10 concentration can be an early indicator of a poor prognosis in preterm neonates with sepsis.[28]

Necrotizing enterocolitis

NEC is a devastating intestinal disease that primarily occurs in low-birth-weight premature infants. Its etiology is not well known, and may consist of intestinal immaturity, intestinal ischemia, changes in microbiological environment related to enteral feeding practices, with an increased inflammatory response as the final common pathway. The evidence suggesting a causal association between chorio-amnionitis and subsequent NEC is very sparse, although some retrospective case–control studies suggest a significantly higher frequency of PrePROM and chorio-amnionitis in infants with NEC.[29]

Inflammatory mediators involved in NEC are tissue and circulating proinflammatory cytokines (IL-1, IL-6, IL-8, TNF-α), platelet-activating factor, leukotriene C4, iNOS, endothelin-1 and thromboxane. These mediators are believed to stimulate signal transduction and gene transcription, leading to apoptosis or programmed cell death, secondary inflammation, increased intestinal wall permeability and, ultimately, necrosis. Conversely, IL-10, IL-11, IL-12, erythropoietin and epidermal growth factor have been shown to play an important role in the prevention of intestinal injury. Using a neonatal rat model, the protective effect of maternal milk has been associated with increased ileal production of anti-inflammatory IL-10.[30] Also, enteric organisms such as non-virulent *Salmonella* strains are capable of attenuating intestinal inflammatory responses.[31]

Chronic lung disease/bronchopulmonary dysplasia

Many aspects of the inflammatory response in the context of CLD/BPD remain to be elucidated.

On the one hand, artificially induced lung inflammation through intra-amniotic injection of proinflammatory cytokines in rabbits results in increased lung volumes, increased surfactant production and improved gas exchange.[32] Likewise, fetal exposure to chorio-amnionitis can lead to enhanced lung maturation, similar to the effect yielded by antenatal glucocorticoids.[25] This is in line with the findings from the UK Epicure study, indicating that infants born below 26 weeks' gestation are more likely to die in the absence of chorio-amnionitis and antenatal administration of glucocorticoids.[33]

Alternatively, as previously mentioned, antenatal inflammation can disrupt the process of alveolarization, resulting in alveolar simplification and priming of the fetal lung, rendering it vulnerable for further injury postnatally.[25,34] Indeed, prolonged postnatal mechanical ventilation (> 7 days) of lungs that are primed in this way, together with postnatal infection (sepsis or pneumonia), may result in a secondary inflammatory response and the development of CLD/BPD.[35,36] Support for this hypothesis stems from the observation that predominantly memory cells from the immune system, i.e. lymphocytes and monocytes, are observed in broncheo-alveolar lavage fluids obtained from ventilated and antenatally inflamed animal lungs.[37]

Ongoing lung damage in the premature infant may also be caused by failure to downregulate inflammatory responses.[38] Data suggest that preterm newborns with lung inflammation may be unable to activate the anti-inflammatory cytokine IL-10. Comparing preterm infants with term infants in respiratory failure, the ability of lung macrophages to produce TNF-α is nearly identical, whereas a trend toward diminished levels of IL-10 expression exists in the preterm group.[39] Such data suggest an imbalance between pro- and anti-inflammatory responses, leading to CLD/BPD.

The role of transforming growth factor-β, i.e. a cytokine participating in adult chronic inflammatory diseases, is still to be elucidated in neonatal inflammatory processes.[40]

Retinopathy of prematurity (ROP)

ROP is an ischemia-induced proliferative retinopathy, affecting premature infants with low birth weight. The process of retinal neovascularization in ROP is complex, involving several angiogenic factors, such as vascular endothelial growth factor. Potential medical therapies for ROP include not only modulators of such angiogenic factors but also endogenous inhibitors and anti-inflammatory drugs. The latter drugs have proved to be efficacious against neovascularization in several animal models of oxygen-induced retinopathy, and are currently already trialled for adult diabetic retinopathy and age-related macular degeneration.[41]

Perinatal inflammatory responses, neonatal disease and neuro-morbidity

Both animal and clinical data suggest that intrauterine infection can be linked to adverse neurological

outcome either via infection/inflammation-induced WM damage or via infection/inflammation-induced preterm birth.[42,43] A recent meta-analysis (23 studies) revealed a significant association between clinical chorio-amnionitis, cystic PVL (RR, 3.0; 95% CI, 2.2–4.0) and cerebral palsy (CP) (RR, 1.9; 95% CI, 1.4–2.5), whereas histologic chorio-amnionitis was associated with cystic PVL (RR, 1.6; 95% CI, 1.5–2.9) but less with CP (RR, 1.6; 95% CI, 0.9–2.7).[12] The same group recently described an increased risk for neurological sequelae in term infants with funisitis.[44]

It is also likely that postnatal infection/inflammation contributes to a long-term adverse neuro-development, as a recent UK trial indicated a four times higher risk of CP among infants with neonatal sepsis compared to those without.[45] A significant association between increased levels of inflammatory cytokines in the newborn and the development of spastic di-, quadri- and hemiplegia has been demonstrated,[24] with increased concentrations of cytokines (TNF-α, IL-1β, IL-6 and the anti-inflammatory IL-10) correlating with cerebral lesions detected by MRI.[46]

However, several variables account for the observation that not all studies suggest such an association between infection/inflammation and adverse outcome in newborn infants (see Figure 4.1), i.e. (1) timing issues, (2) nature of the infectious/inflammatory process, (3) established and new anti-insult strategies, (4) morbidity in organs other than the brain, (5) genetic influences and (6) environmental factors.

Timing issues

Clinical chorio-amnionitis is based on the acute presence of two or more of the following clinical signs: maternal temperature, maternal tachycardia, fetal tachycardia, maternal leucocytosis, uterine tenderness and foul-smelling amniotic fluid. However, intrauterine infection may also remain undetected for months as a *chronic* indolent inflammatory process. Also, bacterial vaginosis can result in intrauterine colonization present at conception; if the organisms are not cleared within 4–8 weeks after the expanding membranes seal the endometrial cavity, the infection may result in preterm delivery. Hence, in the absence of clear criteria to identify the severity and duration of *in utero* infection, it is not surprising that the clinical outcome is unpredictable, ranging from normal fetal development with histologic chorio-amnionitis as an incidental finding to severe chorio-amnionitis leading to *in* or *ex utero* death with long-term neurological sequelae.[25]

Type and presence of pathogen

Not only timing but also the nature of the infection may determine the outcome.[43] For example, administration of a low dose of *Escherichia coli* (O55:B5) endotoxin to rats, prior to short periods of hypoxia-ischemia, increases the overall brain injury.[18] However, the opposite effect is observed using a different bacterial toxin (lipoteichoic acid) in a similar rat model.[47] Amniotic fluid contaminated with *E. coli* but not with *Ureaplasma urealyticum* and *Mycoplasma* increases the risk of CLD/BPD,[48] although one could point out that the latter two species are more difficult to grow *in vitro*.

Evidence suggests that preterm delivery and neonatal morbidity may be better predicted by the degree and nature of the FIR to infection (i.e. the host response) than by the presence of (a combination of) pathogens (i.e. positive amniotic cultures).[8,49] It is within this context that functional polymorphisms of the different cytokines may play a role as they may determine each individual's genetic susceptibility and response to infection (see below).

Anti-insult strategies

As perinatal infection/inflammation seems to be an important risk factor for adverse neonatal outcome, the development of appropriately designed (brain) protective strategies will, to a great extent, become indispensable in neonatal care over the next decade.[50] However, the difficulties experienced hereto are at least threefold: (1) we are currently unable to prospectively identify those infants at greatest risk for developing (neuro)morbidity; (2) the presence of both beneficial and detrimental physiologic effects by cytokines complicates any targeted intervention; (3) the origin of perinatally acquired brain damage is currently thought to be multifactorial, possibly including hypoxia/perfusion failure, thyroid hormone deficiency, genetic factors, thrombotic processes, growth factor deficiency, excess free reactive oxygen production and antenatal infection.[51]

Antenatal strategies

Steroids. Endogenous glucocorticoids, released by the fetal adrenal cortex, downregulate the expression and action of cytokines both in the periphery and in the brain.[52] Likewise, antenatal administration of exogenous steroids can result in a reduced FIR.[53] Antenatal steroids administered to women at risk of preterm delivery decrease the risk of death, respiratory distress[54] and protect very low-birth-weight infants against the risk of neuro-morbidity.[55] However, antenatal steroids do not reduce the incidence of CLD/BPD, as the drug induces alveolar simplification and hence primes the lungs for postnatal ventilation-mediated injury.[25] In addition, whereas betametasone yields an initial suppressive effect on inflammation, it may ultimately result in 'late inflammation'.[56]

It thus seems that the exposure to infection/inflammation together with antenatal administration of glucocorticoids can both 'mature and injure' the fetus. The 'net effect' in terms of adverse neonatal outcome may depend on exposure to postnatal noxious interventions such as ventilation, high concentration of oxygen, etc. These time-dependent interactions between steroids and inflammation warrant further investigation.

Antibiotics. The administration of antibiotics following PrePROM results in a significant reduction in chorio-amnionitis, a delay in delivery and reduced neonatal morbidity (e.g. neonatal infection, use of surfactant, oxygen requirement, abnormal findings on cranial ultrasound).[57] Due to an increased risk of NEC, coamoxiclav should be avoided, while erythromycin seems a better choice, possibly because of a smaller endotoxin release by damaged bacteria.[58] The current treatment for clinical chorio-amnionitis is delivery of the fetus and subsequent treatment with antibiotics. Maternal treatment in such cases is ineffective because the amniotic cavity is largely a sequestered site, inaccessible to antibiotics.

Mode of delivery. Normal labor is always associated with some form of hypoxic stress, which may be detrimental if the fetal brain is more vulnerable to hypoxia in the presence of antenatal infection/inflammation. However, there is no clear evidence that suggests an elective cesarean section is more neuroprotective than normal labor in the case of (chronic or acute) chorio-amnionitis.

Postnatal strategies

Non-specific therapy for severe sepsis comprises antibiotics, aggressive fluid resuscitation, inotropes and ventilatory support. More specific strategies are aimed at tapering of sepsis-related immunodeficiency syndromes by using recombinant growth factors, such as granulocyte colony stimulating factor (CSF), granulocyte macrophage CSF and interferon. Recombinant activated protein C is an anti-inflammatory, antithrombotic and fibrinolytic agent that has been successfully used in severe sepsis in adults. However, its use is not approved in infants or children.[59]

Treatment of NEC currently consists of antibiotics and hemodynamic stabilization, with, in some cases, the need to proceed to surgery. However, a better understanding of the mechanisms underlying its pathogenesis is needed. For example, understanding the protective effects of maternal milk could be beneficial either in the prevention of NEC or in the development of future therapeutic strategies to cure NEC.[30]

Postnatal steroids are commonly administered in severe CLD/BPD, as data suggest that preterm newborns with lung inflammation may be unable to activate anti-inflammatory cytokine pathways.[39] Dose-related inhibition of cytokine synthesis is indeed observed when treating monocytes with dexamethasone *in vitro*.[60] Although early postnatal anti-inflammatory therapy could help in preventing CLD/BPD, prophylactic dexamethasone cannot be recommended, as there are a number of potential interactions between surfactant and cytokine effects on the preterm lung that have not been fully evaluated.[38] In addition, postnatal administration of steroids has been associated with neurodevelopmental impairment, warranting further randomized controlled evaluation of its risks vs. benefits.[61]

It is to be hoped that we will see multicenter clinical trials over the next decade, evaluating inflammatory protection and inflammatory response modification in the newborn infant. This requires further detailed animal work of immune modulatory drugs and their kinetics within the newborn age group.[62] Inflammatory protection can be achieved by exogenous administration of IL-10, although complex differential effects between its central and peripheral effects need further exploration.[63] The exogenous administration of response modifiers/receptor antagonists currently evaluated in animal models (e.g. IL-1β receptor antagonist or soluble TNF receptor) may not be without risk, as many of the proinflammatory cytokines exhibit fragile equilibria of biological activity.[64] As an example, the presence of TNF-α can have beneficial effects, whereas blocking TNF-α in adults with septic shock results in increased mortality.[65] Future strategies therefore must aim to 'redress the optimal cytokine balance' rather than 'prevent the inflammatory response'.

Morbidity in organs other than the brain

Is there evidence that a neonatal inflammatory response (e.g. sepsis, NEC) involves an increased risk of neuro-morbidity?

Sepsis/NEC

The role of proinflammatory cytokines during sepsis/NEC in the etiology of CP remains controversial. However, preliminary reports suggest a significant association between TNF-α, IL-8 and an abnormal cognitive and psychomotor outcome at the age of 24–28 months.[66]

Lung inflammation

A complex interaction exists between lung and brain inflammatory processes. Lung disease has been mimicked in transgenic mice that overexpress human IL-1β in the respiratory epithelium.[67] The expression of a number of genes participating in inflammation was also increased in their brains, although no major histological differences were detected compared to control animals. Ventilation of inflamed preterm lungs may also result in more lung inflammation, creating an excess of cytokines in the systemic circulation, which in turn may promote the development of CLD/BPD, and, in addition, may result in remote (brain) damage.[37]

Host-genetics

Single-nucleotide polymorphisms (SNPs) consist of single base substitutions in a DNA sequence. Almost all genes contain SNPs, but only a minority of SNPs result in amino acid variation in protein products. In addition, many of the functional SNPs occur in the promotor region rather than the gene itself and affect protein levels through altered transcription. Polymorphism-association studies compare the prevalence of a genetic marker in persons with a given condition to the prevalence in controls.[68] Gene polymorphisms that may influence perinatal outcome through alteration of the response to infection have

been reported for the IL-1 receptor antagonist,[69] IL-6,[70] interferon-γ[71] and TNF-α.[72] Likewise, cytokine gene polymorphisms may modify the risk of brain injury and hence act as an endogenous inflammatory response modification mechanism.[22] As an example, the IL6-174(G|C) genotype has been associated with impaired neurological outcome in preterm children.[73]

Cytokines are able to mediate intravascular cell adhesion, coagulation and/or thrombosis, and vasoconstriction. In the presence of an existing thrombophilia or a cytokine polymorphism resulting in increased susceptibility to infection, the actions of these cytokines in the fetal brain may be enough to result in adverse neurological outcome.[74]

Such outcome-related research is complicated by the fact that one needs to examine the frequencies of several cytokine genotypes, in infants as well as in mothers, while taking into account demographics, newborn illness severity and several other risk factors. The ultimate goal is to use identified SNPs as a biologic guide to target new anti-inflammatory strategies toward the most genetically vulnerable premature infants (i.e. pharmaco-genomics).

Environment

Impaired neurodevelopment after a fetal/neonatal inflammatory response most likely occurs via a complex interaction between genetic and environmental processes, such as home environment, maternal education, socioeconomic and ethnic backgrounds.

Conclusion

We investigated the available evidence, suggesting a link between inflammatory responses and adverse neonatal outcome. Currently, there is no silver bullet to prevent an impaired neurodevelopmental outcome in the event of a fetal and/or neonatal inflammatory response. Future research needs to focus on (1) the relation between fetal, maternal and neonatal inflammatory processes, i.e. CLD/BPD and NEC; (2) the interaction between inflammatory responses and genetic or environmental factors; (3) the use of advanced techniques for laboratory research and neuro-imaging and (4) large and well-designed observational studies that use well-defined outcome variables for transparent logistic regression analyses in large samples of patients, with sufficiently long periods of follow-up.[64] Although such research will be complex, only then can we become successful in the identification of pre- and postnatal risk profiles that permit the introduction of new anti-inflammatory interventions in the newborn.

5 Advances in neonatal ventilation

S. M. Donn and S. K. Sinha

Introduction

Ever since Hippocrates first described the use of intubation and positive pressure ventilation to support respiration approximately 2400 years ago, the goals of mechanical ventilation have remained essentially unchanged. We continue to attempt to achieve and maintain adequate pulmonary gas exchange, minimize the risk of lung injury, reduce the patient work of breathing, and optimize patient comfort. The introduction of surfactant replacement therapy, antenatal corticosteroid treatment, and the deployment of state-of-the-art mechanical ventilators have all changed the demographics of the 'old BPD' and presented new challenges in neonatal intensive care. Although we have made a start, the evidence as to how best to approach the problem is as yet insufficient on which to draw specific therapeutic conclusions or make clinical recommendations. Until we have created a sufficient evidence base, it seems prudent, therefore, to rely on the basic tenet of medicine, 'Primum Non Nocere: First, Do No Harm'. Therapy, in this case mechanical respiratory support, should be directed at avoiding the potentially damaging effects of oxygen therapy, the trauma from excessive pressure and/or volume, the adverse consequences of atelectasis; and the role of inflammation and infection in the pulmonary injury sequence, which is now well established. In addition, the new technology has given us the opportunity to observe the potentially deleterious effects of inappropriate airway flow, referred to as 'rheotrauma'.[1] The challenge is to identify the most appropriate device, technique, and strategies, especially as philosophies of respiratory management differ so widely among the individual clinicians and institutions.[2]

The past

The last three decades brought tremendous advances in the management of newborns with respiratory failure. The use of continuous distending pressure, first introduced by Gregory *et al.*,[3] was a remarkable step in maintaining the alveolar stability and improving survival in premature infants with respiratory distress syndrome (RDS). Mechanical ventilation of newborns resulted in the first report of a new disorder, bronchopulmonary dysplasia (BPD), also referred to as chronic lung disease (CLD), described by Northway *et al.* in 1967,[4] in which infants developed chronic parenchymal lung and airway injury characterized by inflammation and squamous metaplasia of the respiratory epithelium.

The 1970s brought the widespread practice of mechanical ventilation to neonatal intensive care, utilizing primarily continuous flow, time-cycled, pressure-limited ventilators. It dramatically extended the limits of viability, although the incidence of BPD continued to rise. In 1975, Philip attributed the pathogenesis of BPD to the combined effects of exposure to oxygen and positive pressure ventilation over time.[5]

The technological revolution accelerated in the 1980s with the advent of high-frequency ventilation (HFV). This new form of mechanical ventilation utilized delivered gas volumes that were smaller than the anatomical dead space at very high rates in an attempt to lower airway pressure and achieve more uniform gas distribution within the lung. Continuous 'non-invasive' monitoring was introduced, with transcutaneous gas monitoring and pulse oximetry becoming readily available. Toward the end of the decade, surfactant replacement therapy became a reality, overcoming the biochemical effects of the premature lung. Yet, CLD persisted.

The 1990s were characterized by the continued proliferation of technology. Real-time breath-to-breath pulmonary monitoring became feasible, and with it a host of new ventilator modes and modalities were introduced into clinical practice, such as synchronized intermittent mandatory ventilation (SIMV), assist-control (patient triggered), pressure-control, pressure-support, and volume-targeted ventilation. This decade also saw a dramatic change in the demographics and the nature of CLD. Infants surviving RDS were even smaller and more premature. Chronic lung changes (the 'new BPD')[6,7] were now characterized by a decrease in alveolarization of the lung, with less inflammation and scarring, but with diminished surface area and functional lung units. The incidence

of CLD approached 30–40%, depending on how one chose to define it.

The present

Management strategies in the new millennium represent a broad spectrum with little consensus, ranging from non-invasive techniques to the highly invasive extracorporeal membrane oxygenation (ECMO). Almost all of the clinical trials conducted to date, which have utilized CLD as the primary outcome measure, have failed to demonstrate a benefit in lowering its incidence.

Continuous distending pressure

Continuous positive airway pressure (CPAP) is a form of distending pressure applied to the airways of a spontaneously breathing infant. It works by abolishing the upper airway occlusion and preventing atelectasis of the lungs, thus maintaining adequate functional residual capacity (FRC). CPAP as a primary strategy was popularized by the work of Wung and colleagues beginning in the early 1970s.[8] This approach was based on a dependence on spontaneous breathing, the avoidance of sedative and paralytic drugs, and the acceptance of 'abnormal' blood gases. The approach did result in a dramatic reduction in CLD, but it was never subjected to a randomized clinical trial. Moreover, only pulmonary and not long-term neurodevelopmental outcomes have been reported. In recent years, there has been a resurgence in the use of CPAP because it is a non-invasive technique and easy to apply. Several different devices and ways to administer CPAP are now available including the Infant Flow Driver® and Bubble CPAP®.[9,10]

The infant CPAP system™ (Electro Medical Equipment Ltd, Sussex, England) uses a dedicated flow driver and gas generator with fluid-flip, variable flow, CPAP. The Bernoulli effect directs gas flow toward each nostril, and the Coanda effect causes the inspiratory flow to flip and leave the generator chamber via the expiratory limb. This is supposed to assist spontaneous breathing and reduce the work of breathing by decreasing expiratory resistance and maintaining stable airway pressure throughout the respiratory cycle.

In the Bubble CPAP® system (Fisher and Paykel, Auckland, New Zealand), the blended gas is heated and humidified and then delivered to the infant through a secured nasal prong cannula. The distal end of the expiratory tubing is immersed under water, and at 4 l/min of gas flow the CPAP pressure generated is equal to the level of the CPAP probe. Varying the depth of the underwater link, the expiratory tube can vary the CPAP pressure. It has also been proposed that chest vibrations produced with Bubble CPAP® may contribute to gas exchange. Bubble CPAP® appears to be an effective and inexpensive option for providing respiratory support to premature infants.

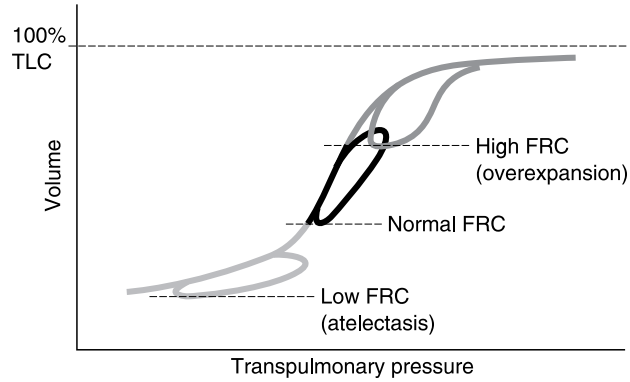

Figure 5.1 Static pressure–volume relationship. Optimal ventilation occurs at normal FRC, where compliance is best and incremental volume changes occur at the least pressure change. Ventilating above FRC results in overexpansion of the lung and increases the risks of baro- and volutrauma; ventilating below FRC may result in atelectasis and its attendant consequences.

There are as yet no controlled trials to compare the efficacy or superiority of one system over another. Many questions are as yet unanswered. Is there a 'best' way to provide CPAP? Does primary CPAP therapy delay or alter the benefit of surfactant replacement therapy in babies who ultimately require it? Is caloric expenditure higher than with mechanical ventilation? Does Bubble CPAP® confer any physiologic advantages?

Conventional mechanical ventilation (CMV)

CMV attempts to deliver physiologic tidal volumes to the patient with the lung at or near FRC. In doing so, we are utilizing the steepest portion of the pressure–volume relationship, where pulmonary compliance is the best and where the change in delivered volume occurs at the lowest increment in driving pressure. The concept is demonstrated nicely in Figure 5.1, a schematic pressure–volume graph. Ventilation at normal FRC, the middle loop, results in the best hysteresis and compliance axis, compared to either ventilating at high FRC, the upper loop, which leads to overexpansion and the risk of baro- and volutrauma, or ventilating at low FRC, the lower loop, which leads to atelectasis and the risk of atelectotrauma.[11–14]

The principles of mechanical ventilation are based on pulmonary physiology.[15] Oxygenation is a function of mean airway pressure. Mean airway pressure is usually adjusted by increasing the peak inspiratory pressure (PIP), the positive end-expiratory pressure (PEEP), and/or the inspiratory time. Ventilation refers to carbon dioxide removal and is the product of tidal volume and frequency (rate). The tidal volume is proportional to the difference between the PIP and the PEEP, a value referred to as the amplitude. It is crucial that clinicians understand that there are significant

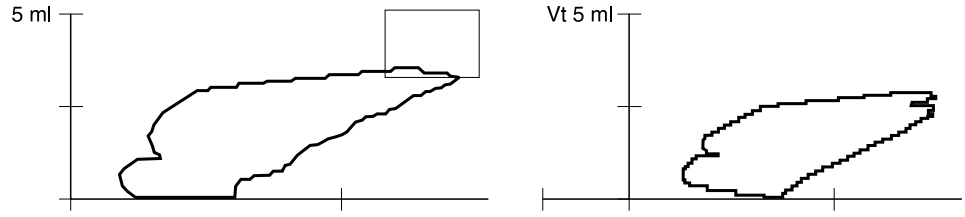

Figure 5.2 Left: Real-time pressure–volume loop demonstrating overinflation. Note the flattened portion at high pressure, where no additional volume is recruited. Right: A normal pressure–volume loop, showing satisfactory hysteresis.

differences among the various neonatal respiratory disorders and that differing pathophysiologic conditions call for different strategies. For instance, a preterm baby with RDS (low lung volume, homogenous disease) is very different from a term baby with meconium aspiration syndrome (high lung volume, heterogenous disease).

Mechanical ventilation is as much an art as a science. Great care must be taken to balance the life-saving benefit and the potentially injurious effects of positive pressure ventilation. Excessive inspiratory pressure can be detected by real-time pulmonary graphic monitoring.[16] This is shown in Figure 5.2. On the left, the pressure–volume relationship demonstrates hyperinflation, with exaggerated hysteresis and an upper inflection point on the inspiratory limb. A more normal pressure–volume relationship is shown on the graph on the right.

Until recently, the effects of airway flow on pulmonary mechanics have only been conceptual. Airway flow, which is the time rate of volume delivery, must be appropriately controlled. Rheotrauma refers to injury caused by inappropriate flow. If flow is excessive, it may result in turbulence, gas trapping, and inadvertent PEEP, leading to overdistension and the potential for thoracic air leaks. If flow is inadequate, it may create 'air hunger' or 'flow starvation' and increase the patient's work of breathing.

Turbulence, or non-laminar flow, can be created by excessive circuit flow. This can decrease the efficiency of gas exchange. If inspiratory airway flow exceeds expiratory airway flow, gas trapping and inadvertent PEEP may develop, increasing the risk of air leaks and contributing to elevated pulmonary vascular resistance. Paying close attention to respiratory time constants, the product of resistance and compliance, may help to avoid this.

Gas trapping can also be detected by real-time monitoring. Figure 5.3 demonstrates an abnormality in the expiratory flow waveform, which does not return to the zero flow baseline prior to the initiation of the next breath. This pattern calls for immediate adjustments in ventilator parameters, such as a reduction in flow, a decrease in the inspiratory time, or a slowing down of the ventilator rate if mandatory ventilation is being used.

For more than 30 years, neonatal ventilation has been accomplished using time-cycled, pressure-limited devices. This form of ventilation is easy to use and leaves all parameters to the discretion of the clinician. The baby may breathe spontaneously between the mechanical breaths from continuous flow in the ventilator circuit. These spontaneous breaths receive ventilatory support by PEEP only. Recent technological advances have introduced a variety of newer modes of ventilation, which were not available to neonatal populations before. They are also based on sound physiological principles, but often cause confusion. It is important that clinicians make themselves aware of the commonly used nomenclature. This can be best understood by using a hierarchical organization of ventilator modes:[17]

(1) Parent mode – determined by the control variable. This can be pressure, volume, or flow, and at any one time the mechanical breath can be controlled by only one of these.
(2) Daughter mode – determined by the breath type, which has four phases (phase variables):
    - Initiation of inspiration (trigger)
    - Inspiration (limit)
    - The change from inspiration to expiration (cycle)
    - Termination or expiration (baseline variable).

Pressure, volume, flow, and time are used as phase variables and determine the parameters of each ventilatory cycle. For example, in time-cycled, pressure-limited ventilation (TCPLV), the ventilator controls the airway pressure and the inspiratory phase lasts according to the time set by the clinician. On the other hand, in volume-controlled ventilation, the ventilator controls and measures the tidal volume generated by the machine irrespective of lung compliance. A ventilator is flow controlled if the gas delivery is limited by flow. This type of ventilator also controls the tidal volume even though it does not measure it directly.

Pressure-targeted ventilation

Modalities of ventilation that target pressure as the dependent or 'limit' variable include TCPLV; flow-cycled, pressure-limited ventilation (FCPLV); pressure-control ventilation (PCV); and pressure-support ventilation (PSV). What all of these have in common is a fixed pressure limit that the ventilator will not

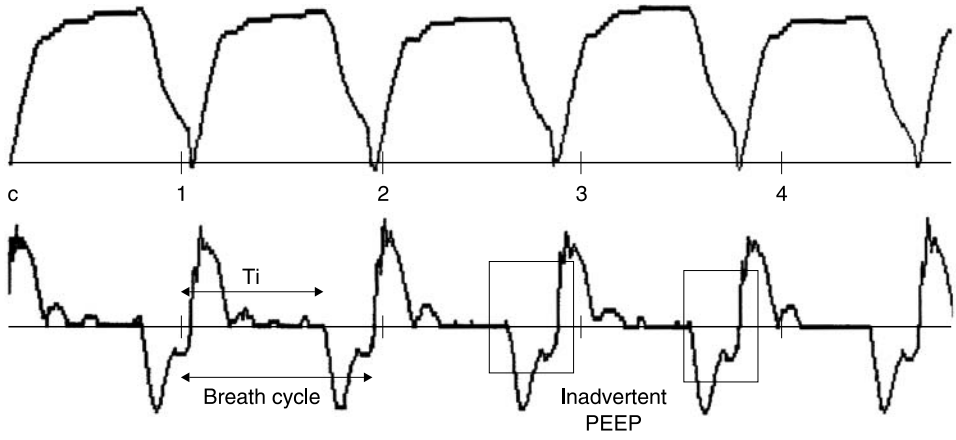

Figure 5.3 Real-time pressure (top) and flow (bottom) waveforms. The flow waveform demonstrates gas trapping. The expiratory portion (below baseline) does not return to a zero flow state (baseline) before the initiation of the subsequent breath, which prevents complete emptying of the lung.

exceed. Thus, delivery of tidal volume depends primarily on the patient's lung mechanics, of which compliance is the most contributory. TCPLV has a fixed inspiratory time and flow rate, FCPLV has a variable inspiratory time (set by the patient) and a fixed flow rate, and PCV has a fixed inspiratory time and variable inspiratory flow rate, which is proportional to patient effort. PSV is a spontaneous mode, used to support spontaneous breathing, generally during weaning. It can be used alone (if there is reliable respiratory drive) or in combination with synchronized intermittent mandatory ventilation (SIMV). Pressure-support breaths are flow cycled, so there is variable inspiratory time, and offer variable inspiratory flow proportional to the patient effort. Pressure-support breaths are pressure limited and may also be time limited.

Pressure-targeted modalities may be used in several modes. IMV involves the delivery of mechanical breaths at a fixed rate, selected by the clinician, with the patient able to breathe spontaneously between mechanical breaths. SIMV also involves a fixed mechanical rate, but the ventilator looks for spontaneous effort during a timing window in order to synchronize the start of a mechanical breath with the start of a spontaneous breath (see 'Triggered Ventilation', below). Assist-control ventilation provides a mechanical breath each time the patient breathes spontaneously, provided the trigger threshold is met, and also has a set control rate in case of patient apnea or inability to exceed the trigger threshold.

Volume-targeted ventilation

More recent technological advances have also enabled measurement of delivered tidal volumes and made possible the reintroduction of volume-targeted ventilation to newborn infants.[18] This form of CMV allows the clinician to select a specific tidal volume to be delivered to the patient. Pressure is permitted to fluctuate, creating a 'self-weaning' style of ventilation. Volume cannot truly be used as a cycling mechanism in the newborn, because of gas leaks around the uncuffed endotracheal tubes used in clinical practice, so it is better to refer to this form of CMV as volume-targeted, volume-limited, or volume-controlled ventilation. One of the advantages it offers over pressure-limited ventilation is that it responds to changes in pulmonary compliance. If compliance improves (e.g. following the administration of surfactant), pressure is decreased. Conversely, if compliance decreases (e.g. with pulmonary edema), pressure is increased to provide the desired tidal volume. Earlier, technological limitations of volume-targeted ventilation included high trigger sensitivity and asynchrony, slow response times (long trigger delays), highly compliant circuits (leading to increased compressible volume loss), and inability to both provide and measure the small tidal volumes required by premature infants. These have all been overcome (although not all of the devices providing volume-targeted ventilation can accurately measure tidal volume at the proximal airway).

Few studies to date have examined the effects of volume-targeted ventilation on neonatal outcomes. The investigation of Sinha *et al.*[19] randomized larger preterm infants to receive volume-targeted or pressure-targeted ventilation with tidal volume delivery tightly controlled. Infants assigned to the volume group had a shorter duration of ventilation, a strong trend to less CLD, and fewer severe neuroimaging abnormalities than the pressure group. Since this study, advances in the technology have enabled the delivery of even smaller tidal volumes and extended the capability to provide volume-targeted ventilation to the smallest premature infants. A large clinical trial is presently under way.

Hybrid forms of ventilation

Attempts have been made to combine the best features of both pressure-targeted and volume-targeted ventilation, resulting in a number of hybrid modalities.[18,20–22] Volume-guarantee® and pressure-regulated volume control® ventilation utilize a breath averaging

technique to constantly adjust delivered tidal volume in response to changing patient lung mechanics. Volume-assured pressure support® adjusts the delivery of gas during a single breath to provide a minimum tidal volume by extending the inspiratory time and slightly ramping inspiratory pressure until the desired volume has been provided.[23] All three of these modalities appear promising but are in need of further investigation.

Proportional assist ventilation (PAV)[24] is an adaptive form of mechanical ventilation in which the inspiratory pressure is determined by the elastic and resistive properties of the patient. In the only published clinical trial, PAV was noted to be associated with lower mean airway and transpulmonary pressure at an equivalent fraction of inspired oxygen and similar carbon dioxide removal rate. Again, preliminary results are encouraging and ongoing evaluations may help to define the role of this modality.

Mandatory minute ventilation is a modality that combines SIMV and PSV. The desired minute ventilation (the product of tidal volume and frequency per minute) is set by the clinician, and as long as the patient is able to meet this target spontaneously, all of the breaths are pressure supported. If the minute ventilation falls below the desired level, the ventilator will provide additional 'catch-up' SIMV breaths using a breath-averaging technique. This form of ventilation is also being actively investigated.

Permissive hypercapnia

A recent lung-protective strategy that has been evaluated is permissive hypercapnia. This approach was based on an observation by Kraybill *et al.* in 1989,[25] in which infants displaying the highest carbon dioxide levels had the lowest incidence of BPD. The rationale behind permissive hypercapnia is that it decreases volutrauma, reduces the duration of ventilation, decreases the complications associated with hypocapnia, and increases oxygen unloading at the tissues by the Bohr effect. Two prospective controlled trials[26,27] did demonstrate a reduction in the duration of ventilation, but failed to show a decrease in the incidence of CLD. Although the strategy is attractive, further work is necessary to determine its place in the management of neonatal respiratory failure.

Triggered ventilation

Although IMV was the major ventilatory mode utilized for newborns for more than 25 years (Figure 5.4, left panel), it was not without hazard. One of its major drawbacks is the development of asynchrony, where the ventilator cycles at a programmed rate and the patient breathes independently, sometimes with and sometimes against the mechanical breath. Asynchrony has been shown to have adverse physiological consequences. 'Fighting the ventilator' may lead to inconsistent tidal volume delivery, increased work of breathing (and the need for higher mechanical support), inefficient gas exchange, and airleaks. Other organ systems may also be affected. Nearly 20 years ago, Perlman and Volpe[28] demonstrated the adverse effects of asynchrony on cerebral blood flow velocity and its high association with intraventricular hemorrhage.

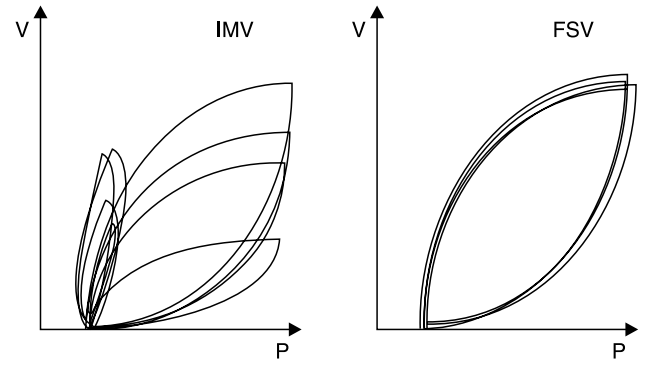

Figure 5.4 Graphic comparison of IMV (left) and flow synchronized ventilation (FSV; assist-control) (right). Note the wide variability of delivered tidal volumes in IMV, depending on whether the baby and ventilator are in or out of phase. In FSV, every breath is the same, since baby and ventilator are always 100% synchronous.

Figure 5.4 is a graphic comparison of IMV (left) and flow synchronized assist-control ventilation (right) and the difference is striking. In addition to the relatively feeble spontaneous breaths, supported only by PEEP, pressure-targeted IMV can result in widely variable tidal volumes, depending on whether the baby and the ventilator are in or out of phase with one another. Synchronization results in a consistently reproducible pattern of gas delivery with nearly identical pulmonary mechanics with each breath.

Synchronized or patient-triggered ventilation utilizes a patient-derived signal to initiate a mechanical breath. The signal is a surrogate of spontaneous breathing and may be a change in airway flow or pressure, abdominal movement, or thoracic impedance. One of the keys to successful triggered ventilation is a short response time or trigger delay. This is the interval between reaching the trigger threshold and the delivery of gas to the proximal airway. Long trigger delays mean that the baby may be considerably into the inspiratory cycle before receiving mechanical support, thus increasing the work of breathing and decreasing synchrony.[29]

Flow signals may also be used to terminate a breath, thus fully synchronizing the baby and the ventilator in both inspiration and expiration. This is referred to as flow-cycling. Flow-cycling is advantageous during assist-control ventilation as a safeguard against gas trapping and inversion of the inspiratory–expiratory ratio. If a baby becomes tachypneic during time-cycled assist-control, the fixed inspiratory time means that the expiratory time will become shorter and shorter as the baby breathes faster and faster. With flow-cycling, the inspiratory time will become shorter, since the breath terminates at a percentage of peak inspiratory

flow rather than at a fixed time. Flow-cycling is also incorporated in PSV, where an inspiratory pressure 'boost' is applied to spontaneous breaths to help overcome the work of breathing imposed by the narrow lumen endotracheal tube, ventilator circuit, and demand valve. Pressure-support ventilation is primarily a weaning mode, but is also a form of synchronized ventilation[30] (Figures 5.5 and 5.6). Unfortunately, the evidence base for synchronized ventilation is also variable, and its role in the prevention of BPD still needs to be determined.[31–33]

High-frequency ventilation

HFV is generally divided into two subcategories. High-frequency jet ventilation (HFJV) uses a jet injector and pulsed or interrupted flow, usually in the range of 240–600 breaths/min. It involves passive exhalation and is thus dependent on the elastic recoil of the lungs for emptying. It is used in tandem with a conventional ventilator, which provides PEEP and conventional or sigh breaths. High-frequency oscillatory ventilation (HFOV) is different from HFJV and involves the use of distending pressure to inflate the lung to a static volume, and usually piston-driven displacement during inspiration and active exhalation. Typical rates for HFOV are 8–15 Hz. The gas volumes delivered are even smaller than those during HFJV. Management is relatively straightforward with oxygenation controlled by adjusting mean airway (distending) pressure and ventilation controlled by adjusting the amplitude of the oscillations.

HFJV was shown to be more effective than rapid rate CMV in the management of preterm infants with pulmonary interstitial emphysema, but few studies have examined its effect on CLD as a primary outcome measure. One study by Keszler *et al.*[34] did show a reduced incidence of CLD and a decreased need for home oxygen, but the comparison group was ventilated with IMV and the results of this study may not be applicable today.

HFOV has been more intensively studied, but the investigations have yielded conflicting results. In 1996, Gerstmann *et al.*[35] demonstrated increased survival without CLD, but Rettwitz-Volk *et al.*[36,37] found no differences in a 1998 report. Thome *et al.* showed a shorter time to extubation in an earlier trial, but a later study in 1999[38] found no differences in the incidence of death, CLD, or intraventricular hemorrhage. The two most recent studies, both published in 2002, also had discrepant results. The Neonatal Ventilation Study of Courtney *et al.*[38] found a small reduction in the incidence of CLD, whereas the UKOS study of Johnson *et al.* found no reduction.[39] The Courtney study utilized SIMV with inspiratory times of 0.25–0.4 s in the comparison group; the Johnson study utilized IMV with inspiratory times set at 0.4 s. Perhaps, the work of breathing was higher in the former study and may explain some of the differences in the results.

At present, the use of HFOV as a primary treatment strategy does not appear to be supported by the available evidence. The latest recommendation of the Cochrane Library[40] is consistent with this.

Extracorporeal membrane oxygenation

ECMO is a form of extracorporeal life support in which the circulation is diverted from the body to an artificial lung for gas exchange. ECMO was originally done through catheters placed in the right common carotid artery and right internal jugular vein (veno-arterial), but this necessitated permanent ligation of these vessels. Veno-arterial ECMO has now been largely replaced by veno-venous ECMO, using a double-lumen catheter in the right interval jugular vein. It has been shown to be efficacious in infants > 34 weeks of age or > 2000 g, who have reversible respiratory failure, unresponsive to 'conventional' treatment, and with a $> 80\%$ probability of death. Although ECMO is technically feasible in infants as small as 800 g, it requires systemic anticoagulation, and thus the risk of severe cerebral hemorrhage precludes its use in smaller newborns.

Neonatal ECMO utilization for respiratory failure has declined substantially as newer treatments, such as inhaled nitric oxide (iNO) and HFV, have evolved. However, it remains as the penultimate rescue technique in infants with suitable indications.[41]

iNO therapy

Nitric oxide in conjunction with appropriate ventilatory support is currently indicated in the management of newborns of term and near-term gestation with hypoxemic respiratory failure associated with evidence of pulmonary hypertension. Its use in the management of hypoxemic respiratory failure in the preterm infant, however, has not yet been established and any such use remains investigational.

The physiologic rationale for the clinical use of iNO in hypoxemic respiratory failure is based on its ability to achieve sustained and potent pulmonary vasodilation without causing systemic hypotension. Persistent pulmonary hypertension of the newborn (PPHN) is a disorder associated with diverse underlying pathologies, which is characterized by high pulmonary vascular resistance causing extrapulmonary right-to-left shunting of blood across the patent ductus arteriosus, foramen ovale, or both, leading to severe hypoxemia. iNO abolishes or decreases this shunt by lowering the pulmonary arterial pressure, often producing the immediate improvement in oxygenation seen in infants with PPHN.

The Neonatal Inhaled Nitric Oxide Study Group (NINOS)[42] and the Clinical Inhaled Nitric Oxide Research Group (CINRGI) are the pivotal multicenter-randomized trials that have demonstrated that iNO therapy improved oxygenation and reduced the need

for ECMO treatment in term and near-term (≥34 weeks' gestation) infants with hypoxemic respiratory failure and PPHN by 15–24%.

Finer recently reviewed the role of nitric oxide for respiratory failure in infants born at or near term.[43] Twelve eligible randomized-controlled trials were included in the analysis. iNO therapy was shown to reduce the incidence of combined outcome of death or the need for ECMO. The reduction was purely in the need for ECMO; mortality was not reduced. This finding primarily results from the efficacy of rescue ECMO for these infants.

The role of iNO in preterm infants with hypoxemic respiratory failure is controversial. Unblinded clinical studies and case reports have shown that iNO acutely improves oxygenation in preterm infants.[44] In a recent controlled trial, Schreiber *et al.*[45] showed a reduction in the combined outcome of survival without CLD in preterm infants given iNO early compared to those given placebo. The effect was only seen in infants who had less severe respiratory failure (oxygenation index <7) at entry and not in more sick babies. Another study, the INNOVO trial from the UK, failed to demonstrate any benefit,[46] but it recruited babies who had more severe respiratory failure. Additional trials are under way and until we know more, the role of iNO in preterm infants remains uncertain.

Monitoring

Continuous monitoring of the mechanically ventilated newborn has been a major technological advance. In the earlier era of mechanical ventilation, monitoring was intermittent and inferential. Assessments were made on the basis of a daily chest radiograph to crudely estimate lung volumes, and occasional blood gas measurements to evaluate gas exchange. Transcutaneous oxygen monitoring demonstrated the foibles of this approach. The development of pulse oximetry and continuous invasive therapy has enabled tighter control of oxygenation and ventilation, and the introduction of real-time pulmonary graphic monitoring[16] has finally given the clinician breath-to-breath feedback on the interaction between the ventilator and the patient. It allows for the customization or 'fine tuning' of ventilation for the individual baby and the evaluation of treatments that have a narrow therapeutic index. Monitoring is not a substitute for close clinical observation, but it can serve to augment the bedside care of ventilated newborns.

Weaning from mechanical ventilation

Weaning refers to the process in which the work of breathing is shifted from the mechanical ventilator to the patient. For the baby to be successfully weaned and extubated, there are a number of physiologic essentials. The baby must have reliable respiratory drive and be capable of sustaining alveolar ventilation once support is lessened, then removed. This requires neuromuscular competence. Adequate calories must be provided to fuel the work of breathing (but too many non-nitrogen calories can also increase carbon dioxide production). Factors known to impede the weaning process should be avoided or at least considered. They include electrolyte imbalance and metabolic alkalosis, anemia, infection, patent ductus arteriosus and/or congestive heart failure, neurologic dysfunction, and the effects of pharmacologic agents, such as analgesics and sedatives.

In general, the most harmful parameters should be decreased first. If the fraction of inspired oxygen is high, it should be weaned to less than 0.4 as oxygenation permits. If PIP or PEEP is high, it should likewise be decreased. The advent of triggered ventilation has altered weaning strategy, since reduction in the ventilator rate during assist-control does little if the patient is breathing above the control rate. Most studies to date have demonstrated that any form of triggered ventilation is superior to IMV in decreasing the time of ventilation.[47] Care should be taken to avoid fatiguing the baby by decreasing the ventilator rate during (S)IMV, since there is no support for spontaneous breathing other than PEEP. Perhaps, augmenting this with PSV will be the solution.

Controversies are still abound regarding adjunctive treatments during the weaning process. Although studies do support the use of methylxanthines, concerns exist regarding long-term safety. Similarly, diuretics and bronchodilators have been used with varying success, but some measure of efficacy should be assessed if treatment is to be continued. Corticosteroids have received a great deal of attention, primarily related to their use in the prevention and treatment of BPD. Neurodevelopmental concerns appear justified,[48,49] and the use of corticosteroids in the weaning/extubation process should be limited to short-term treatment of infants who have failed extubation because of upper airway edema.

Prior prospective indices to determine readiness for extubation have not been helpful. However, the ability to measure pulmonary mechanics, tidal volume, and minute ventilation has been shown to have a high positive predictive value in determining when to extubate a preterm infant recovering from RDS.[50] Alternatively, in the larger infant, one might consider extubation when the degree of support appears to equal the imposed work of breathing. This is another area ripe for investigation.

Optimizing mechanical ventilation

How can we optimize conventional ventilation? First, we need to ask good clinical questions. Second, we need to design the right tools to answer them. Third, we need to accurately and succinctly define our terminology and our outcome measures. A significant example of this is how we choose to define BPD.

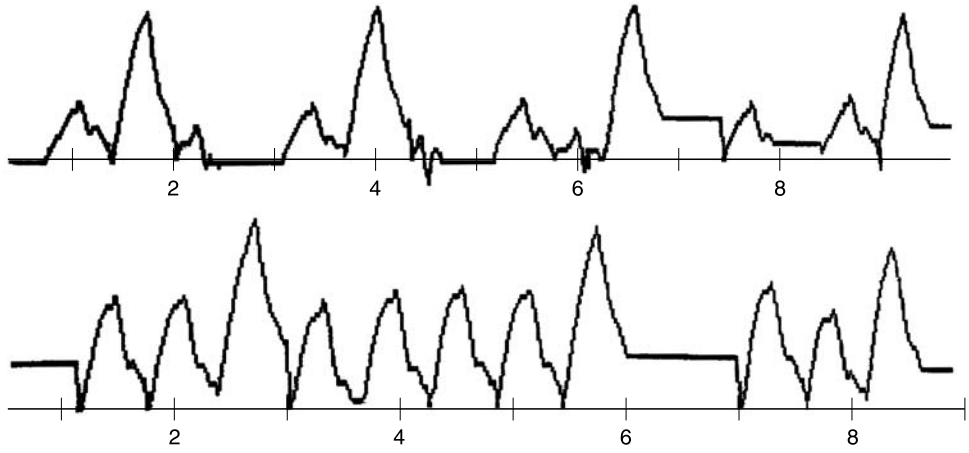

Figure 5.5 Top: Larger breaths are mechanical SIMV breaths, smaller breaths are spontaneous, supported only by PEEP. Bottom: Pressure support has been added to spontaneous breaths. These partially supported breaths are not quite as robust as the SIMV breaths (by choice), but are far better than the unsupported spontaneous breaths in the upper panel.

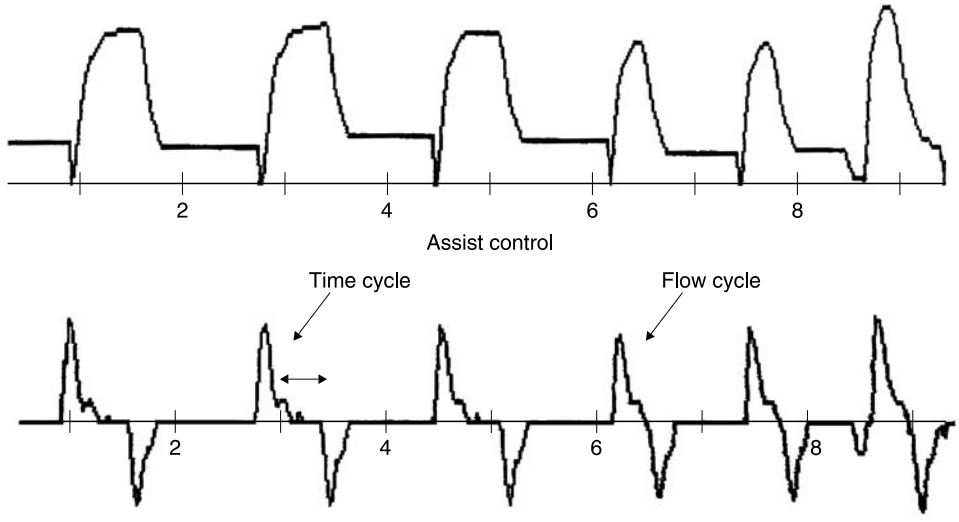

Figure 5.6 Pressure (top) and flow (bottom) waveforms demonstrating the differences between time-cycling and flow-cycling. In time-cycling, the inspiratory phase continues for a fixed period; expiration does not begin until the exhalation valve opens. This results in a plateau pressure. In flow-cycling, inspiration ends as a percentage of peak inspiratory flow. Thus, inspiration cycles directly into expiration and results in a more spiked pressure waveform.

There can be an enormous variation in the incidence of BPD within the same population, depending on how one chooses to define BPD. We need to find a better way to do this, and the work of Walsh *et al.* on determining a functional or physiological definition of CLD is an encouraging beginning.[51]

We clearly need to develop a better evidence base with respect to the multiple ways we can now ventilate babies. From this, we should be able to ask even better questions. It is possible that we have relied too heavily on meta-analysis, and we need to understand its limitations. Again, as an example, although the focus of most analyses has been on ventilation practices, which may very well be the most important variable affecting pulmonary outcomes, are the cited studies adequately controlled for other clinical parameters that can and do impact the pathogenesis of BPD, including nutritional practices, management of blood pressure and fluids, the approach to the PDA, the use of analgesics and sedatives, and respiratory drugs, antibiotic practices, ancillary care, and, very importantly, the variability in the host response?

The future

As we ask the important questions, other outcomes, besides just CLD, need to be considered. CLD is an intermediate outcome variable, but it may not be as important as looking at longer-range assessments, of which neurodevelopmental outcome is probably the most important. Similarly, short-term measures may also be

significant. For instance, if there are no differences in either CLD or neurodevelopmental outcomes between two styles of ventilation, we should pay close attention to the short-term measures, such as patient comfort, cost-effectiveness, and acute complications, such as pneumothorax and days of ventilation.

What is the ideal mode of ventilation? It is one that delivers a breath that synchronizes with patient's own spontaneous respiratory effort. It maintains adequate and consistent tidal volume delivery and minute ventilation at low airway pressures. It is able to respond to sudden or unpredictable changes in pulmonary mechanics or patient demand. It provides the lowest possible work of breathing for the baby.

What is the ideal ventilator? It is one that achieves all of the important goals of mechanical ventilation. It provides a variety of modes and modalities that can ventilate even the most challenging pulmonary diseases. It has monitoring capabilities to adequately assess ventilator and patient performance. It has safety features and alarms that offer lung protective strategies. Most importantly, perhaps, it is used by a clinician willing to investigate its optimal uses and clinical applications.

Where do we go from here? The technology is only going to become more complex, the choices more numerous, and the decisions more perplexing. It will be imperative for us to harness the technology appropriately and, most importantly, safely.

Acknowledgment

We acknowledge the useful contribution from Dr Samir Gupta, Senior Clinical Fellow, and Mrs Victoria Hall, PA, in preparing this manuscript.

6 Clinical care of the very preterm infant

L. Hellström-Westas, L. J. Björklund, M. Lindroth, S. Polberger and V. Fellman

Regionalization of care

The concept of regionalization of perinatal care was introduced in the late 1960s in Canada,[1] and during the 1970s, perinatal centers were established in developed countries. The goal was to identify the high-risk pregnancies and to transfer mothers to tertiary hospitals, which were organized, staffed, and equipped for the multidisciplinary task of providing optimal maternal and neonatal care. In Europe, the regionalization of preterm infants in the late 1990s was evaluated in a survey (EUROPET) showing that there were great variations in the regionalization programs between different countries.[2,3] In some countries, governmental policies exist; in others, national scientific societies issue guidelines, usually stressing intrauterine transfers and delivery in level III centers for very preterm infants. The size of the delivery units varies considerably, the average number of births per maternity unit being 500–3000. Large maternity units usually have adjacent level III neonatal intensive care units (NICU), although their organization varies.[4]

In USA, a trend toward deregionalization has occurred since the late 1980s, referring to a process of moving away from transfers to referral centers providing the highest quality of care to promoting competing hospitals with less expertise. The difference in functioning level is not clear to the public, and thus decisions on which caring centers to choose may be taken on non-medical grounds, such as convenient location.[5] Deregionalization may also be a result of too small tertiary neonatal units without the possibility of admitting all newborn patients requiring intensive care. As a result of the remarkable increase in survival of the very preterm infants during the past decades, the patient load in tertiary NICUs often exceeds their capacities. Thus, the criteria used for defining high-risk pregnancies tend to be stricter, i.e. only the most immature infants are transferred to level III units and less immature preterm infants with considerable morbidity risks are increasingly treated in level II units. This development is unfortunate, since the way that perinatal care is organized may have a substantial impact on clinical outcomes, such as mortality and disability rates. Birth at a hospital with a regional NICU is associated with a lower risk-adjusted mortality than birth at a hospital with no NICU, intermediate NICU of any size or small community hospitals.[6]

The size of the NICU has an impact on the outcome, as, for example, was reported in a Finnish national study where the lowest mortality and disability rates were reported in the largest academic NICU.[7] In a California study on preterm infants with birth weight less than 2000 g, risk-adjusted neonatal mortality was significantly lower for births that occurred in hospitals with level III NICUs with an average census of more than 15 patients/day.[8] No evidence-based recommendations are available on the optimal size of a NICU. However, a reasonable-sized NICU is mandatory for running a neonatal service with all the necessary functions: neonatologists available around the clock, experienced staff, full range of medical intensive care with cardiology and surgical services, including bedside operations, and capacities to expand the facilities during high-demand periods, e.g. due to preterm multiple births. Regional units should have an academic function, providing high-quality specialist training and performing research on their preterm cohorts as well as repeated quality assessments of treatment strategies. Further, tertiary academic units should participate in national and international networks, e.g. for collaborative use of quality improvement techniques, and translation of research into practice, which may result in accelerated and effective practice changes and implementation of evidence-based interventions.[9]

The rapid development of technology in newborn medicine, e.g. ventilators and incubators for preterm infants, leads to a continuous need for new investments

in intensive care equipments. Centralization of neonatal care decreases the need for overlapping functions in level III and level II centers, especially investments in expensive technology. Regional resources for expensive front-line equipment should be allocated to the regional center, which should have responsibility for evaluating them scientifically and keeping them in continuous use, thus providing a high level of technical know-how to the staff. The performance of intensive care could be facilitated by a computerized clinical information system, which ensures precision in physician orders, improves medication management, facilitates reporting, and provides detailed documentation of care and continuous monitoring of parameters from technical equipment. Implementation of a computerized physician order entry has been shown to reduce medication turnaround times and medication errors.[10]

The limited health resources can be efficiently used with a well-organized tiered network with regionalization of highly specialized intensive care and several level II units for the intermediate care.[11] This organization model aims at a balance between efficiency and accessibility to services and requires transfer of the preterm infant after the intensive care period to the next level unit.

Transport

Regionalization of perinatal care requires a well-organized transfer service as well as presents an opportunity to establish a safe and efficient transfer network.[12] The goal should be that all high-risk pregnancies are identified antenatally and the transfer to the perinatal center with level III NICU should take place *in utero*. However, there will be a small group of preterm infants acutely delivered outside the tertiary perinatal center, as well as newborn infants with unexpected complications and postnatal disorders, who need to be transferred postnatally to the regional center.

Neonatal transport service requires an appropriate referral system, trained personnel, and management structures.[13] Depending on the population base and the geography different solutions can be applied. For emergency postnatal transports of very preterm infants to the level III units, it is crucial that the transport team is trained in neonatal intensive care of this patient group. Prior to the transfer, the infant should be stabilized and the intensive care should be continued and monitored during the transport. According to the EUROPET survey in 1996 on large NICUs in Europe, the average national inborn rate of preterm infants of less than 30–32 weeks' gestation exceeded 75% in the majority of countries.[14] Thus, the need for postnatal transports of very preterm infants is fortunately an uncommon situation, which, however, is a highly demanding task in order to avoid transport-related complications.

The neonatal intensive care unit

The goal should be to deliver all very preterm infants in a tertiary perinatal center with a neonatal unit well experienced in all aspects of intensive care. Active management has contributed to the improved prognosis for very preterm infants during the last decade[15,16] in addition to other factors, such as level of antenatal care and socioeconomic factors, and administration of antenatal steroids. Ideally, the NICU should be located close to the delivery unit and to the operating theatre, so that intrahospital transports can be avoided after delivery. It is necessary for neonatal units, which treat very preterm infants, to develop clinical routines for the care of these infants. Such routines should include guidelines for minimal handling and strategies for keeping the number of invasive procedures to a minimum. The noise level in the NICU is often high, and, consequently, measures should be taken to reduce noise and light and include environmental guidelines.

Immediate care at birth

The initial clinical care of the very preterm infants differs from the care of more mature infants in several aspects. In this context we will emphasize the initial care of extremely preterm infants born before 28 weeks' gestation. The very preterm infants have higher mortality and are more likely to develop intraventricular hemorrhages (IVH), symptomatic persistent ductus arteriosus, sepsis, necrotizing enterocolitis, and bronchopulmonary dysplasia (BPD) as compared to more mature infants.[7,17] They are also at higher risk of developing cerebral palsy and disturbances in attention and cognition. Close perinatal collaboration between obstetricians and neonatologists is essential for healthy survival of these infants.

Prior to delivery, the parents should be informed by the neonatal staff about expectations for survival and morbidity, based on recent statistics. The parents should always be allowed to express their own expectations, and if time allows also have the possibility of a visit to the NICU before the delivery. This goal can sometimes be difficult to achieve, not least with an expecting mother in active labor or with pre-eclampsia, nevertheless it should always be attempted. In vaginal deliveries, immediate postnatal stabilization of the very preterm infant can preferably take place in the delivery room, close to the parents.

The initial care of the very preterm infants should be very carefully planned.[18] Evaporative heat loss during the first minutes of life can cause severe cooling of these infants, and a low temperature on admission to the NICU is an independent risk factor of death.[17] Radiant heater open beds designed for resuscitation should be used. In addition, hypothermia can be prevented by wrapping the wet body of the infant in a

plastic bag as soon as possible after birth.[19,20] After rapid stabilization, the infant can be placed directly in a preheated incubator. This transfer can be avoided by initial use of combination incubators with both radiant heater open-bed and double-wall incubator alternatives. The incubator is then moved to the NICU and used for the continuing care of the infant. In order to minimize the disturbance of the very preterm infant, all later procedures, e.g. insertion of umbilical lines, should be done without moving the infant from the incubator.

It is of vital importance that adequate equipment for resuscitation is available in the delivery room or operating theatre. For this purpose, mobile resuscitation beds are very useful. Modern pulse oximeters can give correct values for oxygen saturation and heart rate within a few minutes after birth,[21] and it is no longer acceptable to rely on intermittent heart rate auscultation and visual assessment of skin color. The pulse oximeter probe should preferably be placed on the right hand to assess preductal saturation.[22] The more common placement on one foot may result in lower readings early in life, with a risk of unnecessary oxygen treatment. Although current guidelines still recommend that 100% oxygen should be used for resuscitation,[23] there is increasing evidence suggesting that lower oxygen exposure is beneficial for newborn infants.[24,25] Healthy, full-term infants are not expected to reach preductal oxygen saturation above 90% until 10 min after birth,[25] and there is no reason to strive for higher levels in premature infants. The resuscitation bed must be equipped with an inspired gas blender for precise oxygen administration.[22] If oxygen saturation rises above 93%, oxygen supply should be rapidly reduced or discontinued.[26]

The initial ventilatory management of the very preterm infant is currently much debated.[27] In general, previous studies recommended that premature infants should be intubated and given prophylactic surfactant early after birth, but it has been questioned whether this is applicable to current babies.[28] These babies are often more immature, but may paradoxically both have an accelerated lung maturation at birth and have a highly vulnerable lung with a disposition to develop BPD.[29] Animal studies indicate that the immature lung may be particularly sensitive to ventilation-induced injury very early after birth,[30] and epidemiological studies imply that an aggressive initial respiratory management, including early intubation and surfactant, may be associated with an increased risk of BPD.[31] In many centers, there is now a trend against routine delivery room intubation in favor of early application of continuous positive airway pressure (CPAP).[32] A recent trial showed that delivery room intubation could be avoided in 53% of infants born at 24–25 weeks' gestation.[33] Another approach, aiming to avoid mechanical ventilation early in life, is to perform endotracheal intubation immediately after birth and give prophylactic surfactant, followed by rapid extubation to nasal CPAP. However, preliminary results from one study showed that in infants born at 27–29 weeks' gestation there was no added benefit from prophylactic surfactant when early CPAP was used.[34] It is not known if the same is true also for more immature infants. Ongoing multicenter trials on delivery room management of preterm infants may provide new evidence on treatment strategies.[27]

Although the preterm infant may appear severely depressed at birth, immediate intubation is usually not indicated. Even if a prophylactic surfactant strategy is chosen, there is no proven benefit from giving surfactant before the first breath.[35] Bag-and-mask ventilation of preterm infants may be difficult, and gas exchange will probably be very inefficient unless the baby contributes by making gasps.[36] Even so, the vast majority of small infants will respond to bag-and-mask ventilation with a rapid increase in heart rate. Once the baby starts breathing spontaneously, its efforts can be supported if adequate equipment is available. Unfortunately, the commonly used self-inflating resuscitation bags have severe limitations.[37] The oxygen supply is difficult to regulate, and the bags have a poorly working pressure limitation. Consequently, high pressures (> 40 cm H_2O) are easily generated, especially at high ventilatory rates. Tidal volumes are unknown and can potentially become very large. Moreover, there is usually no way of obtaining CPAP or positive end-expiratory pressure (PEEP), and therefore no way to effectively support the baby's spontaneous breathing.

The Neopuff® Infant Resuscitator (Fisher & Paykel, Auckland, New Zealand) is a commonly used T-piece system with adjustable PEEP and peak pressure that can be attached to a face mask or an endotracheal tube. It can easily be used to apply nasal or face mask CPAP immediately after birth (see Figure 6.1). It has been suggested that a relatively high distending pressure (up to 8 cm H_2O) should be used in this situation.[37] If the baby responds well, CPAP with the same device can be continued during transportation to the NICU. In an experimental setting, the Neopuff® device produced reliable and reproducible peak inspiratory pressures and PEEP.[38,39] However, there are at present no published clinical trials evaluating this method against other systems.

At all very preterm deliveries, surfactant should be immediately available. According to Scandinavian tradition, infants are not intubated for the sole purpose of giving surfactant. However, if the very preterm infant needs intubation for resuscitation, surfactant should be given as soon as the endotracheal tube is presumed to be in a correct position. Many infants respond rapidly and may soon be breathing room air on endotracheal tube CPAP, in which case early extubation can be considered.

Even if the infant is intubated and surfactant is administered in the delivery room, there is usually sufficient time to allow the parents to see their baby

Figure 6.1 Immediate care after delivery. This vigorous and spontaneously breathing infant is just about to be assisted with face mask CPAP by the Neopuff®. An oxygen saturation probe is applied to the right foot. Photograph courtesy of Mats Blennow.

before transportation to the NICU. The father can usually take part in this transport, and photographs can be taken as a first memory. After arrival to the NICU and within the first hour of life, venous and arterial catheters are inserted for blood sampling, infusion of glucose and arterial blood pressure monitoring.

Nutrition

The beneficial effects of early enteral feeding on the development of the gut of the preterm infant are well recognized.[40,41] Recent data indicate improved short-term and long-term outcome in preterm infants fed human milk as compared to formula-fed infants.[42–44] Enteral feedings with small amounts of human milk (1–2 ml every 3 h) can usually be started within the first hours of life in very preterm infants.[45] The primary feed should be the infant's own mother's milk, but until it is available, heat-treated donor milk is used.

In order to reduce the number of invasive procedures, indwelling central venous catheters (CVCs) for fluid and drug administration can be used. Although the risks, e.g. thrombosis, with umbilical venous catheters are well known, this is for the very preterm infants an easy and rapid way of gaining venous access. Before use, the position should always be checked with x-ray and the catheter should always allow withdrawal of blood. An umbilical venous catheter, in correct position with the tip of the catheter in the inferior vena cava, is suitable for supplementary parenteral nutrition during the first days of life. Double-lumen catheters are useful, since they allow a steady infusion in one lumen, while intermittent injections can be given in the other lumen without the need for additional peripheral intravenous lines during the first days. After 3–4 days the umbilical venous catheter can be replaced by a peripherally inserted central venous catheter (PICC). When the tip of a PICC is optimally located in the upper vena cava (as checked by x-ray) it can often be used also for blood sampling.[46]

Initially, an infusion of glucose is given and replaced as soon as possible by a glucose–amino acid solution, providing glucose at a rate of 4–6 mg/kg/min.[47] Before the third day of life, there is usually no need to add electrolytes except calcium. To reduce the risk of hyperchloremic metabolic acidosis, sodium acetate should be used instead of sodium chloride in the intravenous solutions. Providing adequate nutrition and sufficient caloric intake is a problem during the first week of life in very preterm infants.[47] For this reason, intravenous lipids should be started in the first or second day of life, with close supervision of serum triglycerides. A multivitamin preparation is included in the lipid solution to reduce the risk of peroxidation. The initial daily dose of lipids is usually 0.5 g/kg, which, if tolerated without hyperlipidemia, is increased stepwise to 2 g/kg during the first week of life, and only rarely increased to 3 g/kg.[48]

The enteral milk feedings are gradually increased on a day-to-day basis. When the very preterm infant can tolerate 75–80% of the total volume intake by the enteral route, i.e. 130–160 ml/kg of a total daily volume intake of 170–200 ml/kg, the supplementary parenteral nutrition can be omitted. The infant's own mother's milk is the preferred source of the enteral nutrition. All mothers should be encouraged to express their milk during the preterm period and to breast-feed their infants after discharge from the neonatal unit. If the mother cannot supply her infant with milk, pasteurized banked donor milk is used, or a preterm formula. Administered human milk can be analyzed for macronutrient content (protein and energy)[49,50] and thus the fortification can be individually planned, aiming at a daily protein and energy intake of 3.5 (to 4.0) g/kg and 120 kcal/kg, respectively. Higher energy intakes are often required in infants with BPD. Weekly biochemical monitoring of protein status should be performed in the very preterm infants by, for example, measuring serum levels of urea and transthyretin (prealbumin).[51] Calcium and particularly phosphorus supplementation is needed for adequate bone mineralization in human milk-fed infants.[43]

Clinical monitoring

Respiratory and hemodynamic instability is common in very preterm infants. Close surveillance is essential, both during the early acute phase, characterized by postnatal adaptation and respiratory distress, and during the later stages when nosocomial infections and recurrent apneas are common. Initial clinical signs of infection may be subtle, but often precede deterioration in vital parameters. The clinical monitoring includes regular observations of vitality, color,

heart rate, respiration, body temperature, bowel movements, and diuresis.

Fluid and electrolyte balance are closely related to evaporation and heat loss from the immature skin.[52] The insensible water loss from the immature skin is highest during the first 2 days of life, and then decreases during the first week.[53] The skin of the most immature infants sometimes becomes dry and cracked during the first week of life. Various methods for preventing this, e.g. by applying prophylactic ointment, have been evaluated, but have shown that this strategy may be associated with an increased risk of nosocomial sepsis.[54] Double-walled incubators with a high humidity, starting at 80%, should be used in these infants to diminish the inevitable water losses (see Figure 6.2). The daily fluid requirements average 85–100 ml/kg. However, the most immature infants may require more during the first days of life. Serum levels of electrolytes (sodium, potassium, and ionized calcium) should be measured and monitored daily during the initial course. Hypocalcemia can usually be corrected by i.v. administration of calcium, either as bolus or added to the intravenous infusion. Hypernatremia (serum sodium above 150 mmol/l) is usually caused by too low fluid intakes, or by too large insensible water loss, or by adding sodium too early to intravenous infusions. Non-oliguric hyperkalemia sometimes occurs during the first days of life in the most immature infants and does not seem to be related to kidney function.[55] Kidney function is difficult to evaluate in the very preterm infants during the first days of life. The serum creatinine levels are often affected by the maternal creatinine level, although very high serum creatinine and urea levels, and oliguria may be seen in infants with poor kidney function. Urinary output mainly reflects the fluid balance and is also a sign that the arterial blood pressure is sufficient. A diuresis of 1–2 ml/kg/h after 24 h of age is usually adequate. Blood transfusions are often needed in the initial care of very preterm infants. In many hospitals, diuretics are given routinely after blood transfusions. This strategy has no support by controlled studies, and the frequent use of diuretics may increase the risk of nephrocalcinosis.[56] Blood and urinary glucose levels should be checked regularly, particularly during the first weeks of life, in order to avoid both hypoglycemia and hyperglycemia. Almost all very preterm infants need phototherapy for hyperbilirubinemia, and initially serum bilirubin should be checked daily.[57] In computerized clinical information systems, algorithms for insensible water loss can be included providing continuous water balance monitoring. Thus, dehydration and hypernatremia can be avoided. Continuous glucose infusion, without interruption, is important for stable blood glucose values. The most immature infants may need insulin infusion for adequate glucose intake.

Continuous monitoring of vital parameters is necessary in the care of very preterm infants. These

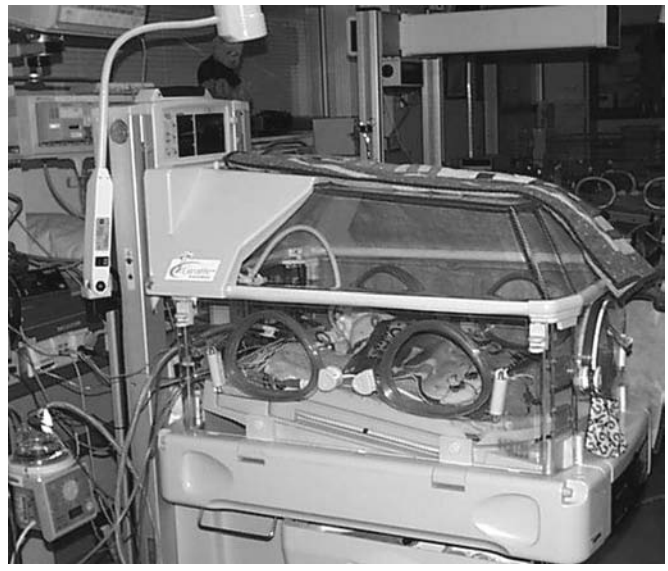

Figure 6.2 Double-walled incubators are used for optimal thermal management of very preterm infants. When the infants are stable an incubator cover can be used in order to reduce noise and light.

infants often need monitoring of electrocardiogram or heart rate, respiration, and oxygen saturation at least until they have reached 32–33 weeks' gestation. In the initial phase, blood pressure is preferably monitored through an indwelling umbilical or peripheral artery catheter, since non-invasive blood pressure monitoring is less reliable. Continuous transcutaneous measurement of blood gases, i.e. partial pressures of oxygen and carbon dioxide, is often very useful, although the fragile skin during the first days of life sometimes limits the time in which electrodes can be applied. Transcutaneous monitoring of PCO_2 levels can reduce the need for blood gas samples and give early indications of hypocarbia, which indicates that ventilator settings should be promptly reduced. Monitoring PCO_2 is important, since low $PaCO_2$ values are associated with decreased cerebral blood flow and development of periventricular leucomalacia, and also with the development of BPD.[58] Continuous monitoring of oxygen saturation is a standard procedure in all NICU's, and most units have guidelines for oxygen saturation limits in very preterm infants, often with a wide range between 85% and 95%. However, more research is needed in order to obtain evidence on whether the lower or the higher values of this range would be preferable.[59] High or unstable oxygen saturation is a risk factor for retinopathy of prematurity (ROP), and very preterm infants should be regularly examined by ophthalmologists from around 32 weeks' gestation until full term for early detection and treatment of ROP. Continuous monitoring of electrocortical activity with amplitude-integrated electroencephalography (aEEG), a simplified method utilizing one or two channels of filtered and time-compressed EEG, is increasingly being used in neonatal units. The

method shows changes over time in cerebroelectrical background activity and can be used also in preterm infants. Degree of electrocortical background depression in aEEG activity shows good correlation with grade of IVH and outcome.[60–62] The method also reveals subclinical seizure activity. Normal data for very preterm infants have been published recently.[63]

Infections

Perinatal infections (bacterial vaginosis, premature rupture of membranes, and chorioamnionitis) are important causes of very preterm birth. In contrast, early-onset bacterial infections (positive culture before 72 h age) in the offspring are uncommon, and blood cultures drawn at the time of arterial line insertion are usually negative. Increasing use of antibiotics before and during labor has led to a substantial decrease in early group B streptococcal infections, but simultaneously there has been an increase in prevalence of *Escherichia coli* sepsis.[64] These infections may have a rapidly progressive course with severe hypoxic respiratory failure and early demise.

Late-onset nosocomial bloodstream infections are much more common, occurring in between 10% and 30% of very low-birth-weight infants (VLBWI).[65] They are usually less severe than early infections, but are still associated with a significant morbidity. Coagulase-negative staphylococci (CoNS) are by far the most common pathogens, being implicated in around 50% of the cases.[66] CoNS infections often occur at around 10–14 days of age. The source of bacteremia is usually a CVC that has been colonized with CoNS, either by skin contamination during insertion or through the catheter hub during later manipulations.[67] Symptoms are unspecific and include apneas, increased oxygen requirement, respiratory insufficiency, and, sometimes, also arterial hypotension. Serum level of C-reactive protein is increased, but this may not be seen until after 12–24 h. Treatment with vancomycin is often started when an infection is first suspected, leading to a substantial overuse of this drug. It is not known how long one can safely wait before starting vancomycin treatment,[67] but in relatively stable infants it is usually possible to wait until there is an increase in serum levels of C-reactive protein. If an adequate amount of blood (1 ml) is taken for culture, vancomycin can be discontinued after 48 h if blood culture and ancillary tests are still negative.[67] Antibiotic treatment of CoNS bacteremia is often started without removal of the CVC, but if the baby has a delayed clinical response and if bacteremia persists, the line must be withdrawn.[68,69] CoNS bloodstream infections are not associated with an increased mortality,[70] but these infections often herald the start of a period of clinical deterioration with a need for mechanical ventilation, opening of the ductus arteriosus, development of BPD,[71,72] and an increased length-of-stay. There is also a concern that sepsis increases the likelihood of having an adverse neurodevelopmental outcome.

Candida infections occur particularly in extremely preterm infants. Colonization of mucoepithelial surfaces with *Candida* appears to be a prerequisite for systemic infection,[73] and invasive disease usually results from a colonizing *Candida* strain, rather than from some different isolate.[74] Colonization is most often vertical from the mother at birth, usually with *Candida albicans*, but horizontal colonization from care providers in the NICU also occurs, and is thought to be the primary mode of transmission for *Candida parapsilosis*.[74] Congenital cutaneous candidiasis is relatively uncommon, presenting with diffuse skin rash, in some cases burn-like desquamations, and sometimes pulmonary involvement in the first days of life.[69,75] There is usually no fungemia, but systemic treatment is definitely indicated in the very preterm infants. There is an association between the presence of intrauterine contraceptive devices or cerclage during pregnancy and congenital candidiasis.

Some very immature infants (mean gestational age 24 weeks) have invasive fungal dermatitis. Erosive skin lesions with crusting develop during the first 2 weeks of life. Blood culture is often positive, and the port of entry into the bloodstream is probably through dermal vessels.[75] One outbreak of systemic candidiasis was associated with the use of a petrolatum ointment emphasizing the risk that skin care products may damage the delicate dermal barrier in immature infants.[76] However, the intestinal epithelium is considered the primary portal of entry for most systemic *Candida* infections.[74] Such infections often occur in the second week of life or later, often in the aftermath of a CoNS infection treated with vancomycin, but sometimes as the first nosocomial infection in an extremely preterm infant. Other risk factors are mechanical ventilation, CVC, and treatment with broad-spectrum antibiotics, corticosteroids, or H_2 blockers. Symptoms are often unspecific. Abdominal distension and discoloration, and especially spontaneous intestinal perforation, should raise suspicion of invasive candidiasis.[75] Though *Candida* is known to cause end-organ invasion (meningitis, renal candidiasis, endocarditis, and endophthalmitis), this is rarely evident at the time of first symptoms. Serum level of C-reactive protein is usually moderately elevated. Thrombocytopenia is probably more pronounced in invasive candidiasis than in the other nosocomial infections.[66] The diagnosis of invasive candidiasis is difficult because blood cultures are often negative, but other diagnostic tests are currently under evaluation. Measurement of urinary D-arabinitol/L-arabinitol ratio may be used in neonates.[77,78]

CVCs are extremely important in the pathogenesis of neonatal candidiasis. These catheters are usually not the primary port of entry, but once in the bloodstream, *Candida* organisms can adhere to and even penetrate into the catheter wall,[78] which becomes the

source of end-organ damage, at the same time making the organisms inaccessible to antimicrobial drugs. It has been stated that removal or replacement of the CVC should be completed within 24 h of notification of a positive blood culture for *Candida*.[78] A recent review stated that if a *Candida* infection is suspected and the patient is clinically stable and has not had previous antifungal therapy, fluconazole is a suitable empiric therapy.[79] Amphotericin B should be considered in severe or life-threatening infections pending results of cultures.

Infections with Gram-negative bacteria are relatively uncommon, but often present with a more rapid clinical deterioration and may be associated with shock, coagulation problems, and increased mortality.[66,70] In many neonatal units, there has recently been a substantial increase in infection with *Enterobacter*, usually resistant to cephalosporins[80]. An empiric antibiotic policy including ampicillin and cefotaxime was shown to be associated with an increased prevalence of resistant Gram-negative bacteria, especially *Enterobacter*, as compared with a policy including penicillin and an aminoglycoside.[81] Spread of *Enterobacter* among patients is well documented, and outbreaks have been contained by simple hygienic measures and restrictions in the use of cephalosporins.[82,83]

In view of the relative immune deficiency of premature infants and the necessary invasive care with multiple broken barriers, a high prevalence of nosocomial infections may seem inevitable. However, there is a great variation among centers in the incidence of such infections, which is not explained by different case mix.[65] It follows that these infections should to a large extent be seen as preventable complications of the treatment. A recent survey showed that the staff of units with a particularly low rate of nosocomial sepsis tended to see such infections as a breakdown in care that could have been prevented.[65]

Hand hygiene is of great importance in preventing the spread of bacteria and fungi between patients. The availability of waterless alcohol hand rubs in close proximity to the incubators makes compliance more likely. In adult wards, the education of patients about the importance of hand washing and asking that they remind their caregivers to wash has been very successful,[84] and perhaps we should teach the parents of premature babies to do the same. Good nutrition with an emphasis on enteral feeding with human milk probably diminishes the risk of infection. Indwelling venous catheters and intravenous lipids are important risk factors for CoNS bloodstream infection. Strategies for maximal barrier precautions and aseptic techniques during catheter placement are important, as well as strict guidelines for blood sampling through catheters and for hub manipulations. The use of 'antibiotic locks' to prevent catheter-related bloodstream infections seems to be a promising technique, but it remains to be evaluated in clinical trials.[85] The use of fluconazole prophylaxis to prevent neonatal candidiasis is probably safe and can be considered in high-risk patients, but larger studies are needed.[86]

Developmentally supportive care

Behavioral problems, including attention deficit and hyperactivity disorders, are common among surviving children who were born very preterm.[87,88] The reasons for this are not known, but it is believed that environmental influence from the extrauterine environment negatively affects the development of the immature central nervous system.[89,90]

One of the most important aspects of the care of preterm infants is promotion of emotional attachment between the infant and its parents. Family-focused neonatal care has been increasingly practiced during the last two decades. Systematic strategies for this include free visiting hours and early involvement of parents in care procedures, e.g. diaper changes and feeding, creation of good family memories with hand- and footprints, photographs and diaries, etc. Kangaroo care promotes attachment between the infant and its parents, and development of preterm infants.[91,92] Kangaroo care can often start during the first week of life (see Figure 6.3).[93]

It was previously shown that reduced light, and day-and-night light promoted sleep in preterm infants, and this effect persisted several months after discharge.[94] Incubator covers are increasingly being used to reduce light and noise. However, as a single procedure in neonatal care their effect has only been investigated in a few studies. In a small observational study there were only minor effects on quiet sleep from the incubator covers in stable preterm infants.[95] Neonatal Individualized Developmental Care and Assessment Program (NIDCAP) is based on formal observations of the preterm infants during a care procedure. The observations are made by medical personnel, often neonatal nurses, who have received special training in this

method. Individual recommendations for the nursing care are made from the results of these observations (see Figure 6.4). Treatment with NIDCAP is associated with a shorter need for respiratory support and a shorter duration of stay in the NICU.[96,97] Recently, it was shown that NIDCAP is associated with structural changes of the brain, as shown by magnetic resonance imaging and diffusion tensor imaging techniques, and with increased neurophysiological maturation, as shown by EEG.[98]

Pain and treatment of pain

Pain is defined by the International Association for the Study of Pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage'.[99] According to this definition, pain is always a subjective phenomenon with subjective reporting. Thus, individuals, such as preterm infants, not capable of reporting pain would not experience it. However, based on empirical evidence it has been proposed that physiological and behavioral responses are valid indicators of pain.[100]

Whether the fetus feels pain, and if so from which gestational age, has been a controversial issue. The thalamo-cortical fibers, which are considered crucial for nociception, are present between the 20th and 34th week of gestation. The afferent fibers grow into the cortical plate after the 26th week of gestation, but already between 20 and 26 weeks synaptic circuits occur between the subplate and the cortical plate indicating neuro-anatomical basis for the fetus to feel pain.[101] Evoked potentials suggest that thalamic inputs reach the cortex at 29 weeks.[102] Pain threshold is lower in preterm infants than in term infants and later in life.[103] Even in full-term infants the threshold remains low after injury.[104] This suggests that the exposure to multiple procedures in the neonatal period increases pain awareness. Newborn infants undergoing intensive care are subjected to repeated daily procedures. Very preterm infants are likely to experience a large number of invasive procedures during the neonatal care period.[105,106] The most immature infants may be exposed to several hundreds of potentially painful procedures, including, e.g. blood sampling and endotracheal intubation.[105] Neonatal pain experiences may alter later pain responses in children.[89] The gentle care of very preterm infants also includes some aspects of standard care procedures, e.g. painful stimuli from venous or arterial punctures for blood sampling. Painful stimuli can cause fluctuation in arterial blood pressure, which may affect cerebral blood flow. This could contribute to cerebral hemorrhages or ischemia.[107] However, it has also been shown that blood sampling from umbilical artery catheters can affect cerebral blood volume in preterm infants. This can be avoided by very slow withdrawal of blood from the catheter.[108] Other care procedures associated with changes in cerebral blood volume in very preterm infants include endotracheal suctioning and surfactant administration (Figure 6.4).[109,110] Because of the many procedures and long-lasting mechanical ventilation, routine opioid infusion or bolus injections were introduced during the early 1990s in many NICUs for pain relief during the first day(s) of life to preterm infants undergoing assisted ventilation and repeated procedures. Several behavioral pain scales have been developed for preterm infants, but are, however, not widely used in clinical routine.[111–113] In order to administer optimal analgesia, repeated assessments using pain scales are recommended.

Controversies still exist regarding the severity of pain and the need for pain relief for preterm infants undergoing intensive care. With the development of synchronized ventilation, preference of nasal CPAP, and indwelling lines to minimize procedures, the liberal use of opioids has recently been questioned. In the NEOPAIN study[113] infants were randomized to receive either morphine or placebo infusion. The results showed that opioid-treated infants did not have a more beneficial outcome than infants in the placebo group and in some cases they even had a worse outcome. Referring to this study, the goal would be *a priori* to reduce the amount of distress and pain by the use of non-pharmacological means, including individualized care. Only when obvious pain is present, such as procedural or postoperative pain, a routine administration would be advisable. Otherwise, the use of potentially hazardous analgesics should only be given if a pain scale assessment or behavioral observations indicate the presence of distress and pain despite non-pharmacological intervention to minimize it. This approach would produce a more focused pain treatment, probably with fewer side effects.

Ethical aspects

During the last 20 years there has been a growing concern about the ethical issues surrounding the most preterm infants who are at the limits of viability and intact survival. The majority of deaths, around 80%, in very premature infants occur in the first 3 days of life in spite of full intensive care.[114] Neonatologists caring for these infants need to address the question whether to continue care or to withdraw ongoing intensive care. Such discussion may arise when the patient suffers from severe brain or pulmonary injury and the chance of survival is low and the possibility of healthy survival is extremely low.[115] The first principle of treatment is always to act in the best interest of the patient and the family according to the Hippocratic rules, i.e. never to hurt or harm, if possible to relieve, sometimes to cure, and always to console.

When evaluating the question on withdrawal of intensive care, the situation should be analyzed using the traditional ethical principles of (1) benefit, (2) harm, (3) autonomy, and (4) justice. This analysis should be performed in a two-dimensional model taking into account the different interest groups, i.e. the infant, parents, caretakers, and even society.[116]

For the evaluation, a summary of all medical facts is needed, from which an estimated probable prognosis is derived. Sometimes, the decision is not difficult or controversial, such as in babies with Potter syndrome (absence of kidneys) or hydranencephaly. However, when outcome is not inevitably fatal or the interest of the parents and the infants diverge, the decision making needs a thorough discussion. In these instances, non-medical factors, such as social or economical factors, may influence the decision. A decision to withdraw treatment should always be taken by a senior consultant, and usually by a team of them, after careful discussions with all involved staff. The medical course and prognosis should be carefully and repeatedly explained to the parents, and their opinion should be taken into consideration. If parents cannot accept the recommendation to withdraw treatment, the discussions should be repeated. A special situation is prolonged delivery-room resuscitation of extremely premature infants at the limits of viability, where urgent decisions usually are needed in the interest of the infant. On such occasions, thorough discussion with the parents before delivery is of the greatest importance for the decision making.[117]

There is usually time to arrange for death to be filled with dignity also for the most immature infants. Good psychological care of the parents is essential, since they will continue to live with strong and sad memories of this time. A professional, warm, and empathic care by experienced staff will assist them in this difficult situation. The parents' wishes regarding social or cultural ceremonies, e.g. baptism, or for information to or presence of relatives or friends should be fulfilled. Rituals connected to death are important for coping with the loss and sorrow after the death. The terminal care of the dying baby should be carefully planned and performed, including sufficient sedation and analgesia, in order to prevent further suffering. A dying infant should be cared for in a single room together with the parents. One or two experienced staff members should participate and assist the parents in this situation.

The outcome of very preterm infants

The outcome of very preterm infants has significantly improved during the last two decades, and especially of those with a gestational age below 28 weeks.[118,119] Most follow-up studies of preterm cohorts are defined by birth weight, either including extremely low-birthweight infants < 1000 g or VLBWI < 1500 g. The mortality rate is correlated to immaturity: the more preterm the infant, the higher the mortality.[7] The limit of viability seems to be about 23 weeks of gestation, since survival after 22 weeks of gestation is very rare, but after 23 weeks, about 10% according to regionalized long-term follow-up studies from the postsurfactant era, i.e. from the 1990s.[120–122] In a national cohort, the stillborn rate was 60% in infants delivered after 22 gestational weeks, 35% after 23 weeks, and 25% after 24 weeks,[7] suggesting that there may be a less active care during birth in the very immature infants resulting in intrapartal death or classification as dead if there is bradycardia at birth. In this cohort, the long-term survival of live-born infants born after 24 weeks of gestation was 40%, but less than one-half of them were classified as completely normally developed at 1.5 years of age.[120]

Despite increasing survival, the rate of neurodevelopmental impairment has remained similar, which results in an increased absolute number of infants with abnormalities.[122,123] Severe handicaps, such as cerebral palsy, deafness, blindness, and mental retardation, have in recent studies been reported to occur in 15–25%.[118,123] Even more common are cognitive dysfunction and learning disabilities. In a large VLBWI birth cohort study in The Netherlands, assessment at the age of 9 years showed that 56% of children in mainstream education needed special assistance at school or were below the age-appropriate level.[123] Similar results have been reported from other countries.[124] Most of the learning difficulties seem to be related to low overall IQ.[88]

Several perinatal risk factors have been associated with poor school performance, such as low-birth weight, need for assisted ventilation, and IVH.[125] Intrauterine growth restriction in preterm infants is associated with increased morbidity, and low postnatal growth, resulting in smaller size at school age and poorer school performance as compared to appropriately grown siblings.[126] The high incidence of sequelae in very preterm infants warrants long-term follow-up of regional cohorts for quality control of the demanding perinatal care and long-lasting neonatal intensive care.

7 Can we establish a universal lower limit of viability? What are the medical and ethical implications?

M. R. G. Carrapato

Introduction

Over the last few decades, perinatal mortality has been greatly reduced and in most Western countries now stands in single figures, albeit with many geographical asymmetries. The overall good results achieved are primarily the consequence of National Health Policies toward rationalization of human and financial resources with modern technology playing a subsidiary role in the high-risk pregnancy and neonate. The development of neonatal intensive care has been shown to be effective in the survival of preterm infants without a significant increase in later morbidity, at least for the larger, more mature neonates.

The World Health Organization places 22 weeks of gestational age or 500 g birth weight as the lower limit, at least for the purpose of perinatal statistics, and the International Classification of Diseases describes the perinatal period as starting at 22 completed weeks. The European Association of Perinatal Medicine (EAPM) defines the perinatal period as that which starts 'from 22 completed weeks (154 days) gestation and ends 7 complete days after birth',[1] which implies that the lower limit of viability stands at 22 weeks of gestation. The question, with all its medical, legal, social and financial implications, is how close are we, as a whole, in this pursuit?

Lower limit of viability – fact or not quite?

Biological survival will depend on not just the presence of a given organ but on its functional maturation, a sequential evolution often referred to as the 'developmental windows'. Alveolarization, essential for survival, is a process that includes anatomical, physiological and biochemical differentiation starting from about 24 weeks' gestation, progressing until term and continuing throughout the postnatal period and childhood. 'Viability', therefore, would be around 24 weeks. To lower this limit, strategies ranging from antenatal steroids, postnatal surfactant and different ventilatory modes have been attempted with some success, but as an example, after 30 years of clinical practice, antenatal steroids show quite disappointing results at below 24 weeks' gestation[2,3] and they might also delay and alter postnatal alveolarization.[4–6] Nevertheless, in recent years increased survival of very immature infants has been reported ranging, from 2% to 35% at 23 weeks and in some perinatal centers in the USA these figures approach 50% among live-born infants, between 17% and 58% at 24 weeks and vary from 35% to 85% at 25 weeks.[7–21]

Survival and outcome data on extremely preterm infants, between 22 and 26 weeks, has been widely reported and reviewed.[7,10–12,15–18,22,23] Allen *et al.*, in a retrospective study of infants born between 22 and 25 weeks, showed that mortality at 6 months' corrected age was 75% for neonates born at less than 24 weeks' gestation, with no survivors at 22 weeks while at 25 completed weeks, survival was in the region of 80%.[23] Hack and Fanaroff and Kilpatrick *et al.* showed similar survival rates of around 40% and 80%, respectively for 24 and 26 weeks' gestational age, especially after the introduction of steroids and surfactant.[12,15] Cooke has reported an increasing survival rate of extremely preterm infants from the early 1980s to the 1990s: in the early period, from 1982 to 1985, there were no survivors at 23 weeks' gestational age while in the later part of the study, between 1990 and 1993, 35% of these infants survived to discharge.[7]

Tin *et al.*, in a prospective, population-based regional survey, also showed that the survival of very immature infants has improved progressively since the early 1980s, particularly after the introduction of surfactant in clinical practice, although the impact of surfactant was only evident in those babies of 25 or more gestational weeks.[9] A national population-based study carried out in the UK and Ireland in the mid-1990s, of all infants born between 22 and 25 weeks of gestation, revealed two survivors to discharge at 22 weeks, with increasing survival rates from 11% at 23 weeks to 44% at 25 weeks.[17] However, in the last decade, survival among live births even at 22 weeks has been reported as being from 14% to 19%.[24–26] In a survey of 21 European countries registered with the EAPM, representing a wide spectrum of different regions from Scandanavia to southern, central and eastern European countries, the mortality rate for infants weighing between 500 and 749 g at birth stood at 54.4% but showed very wide variations within countries, approaching a 90% mortality rate in the less affluent countries as opposed to 26% in the more developed regions.[27] It is quite obvious from the findings of this survey that obstetric and neonatal practices, as well as available resources and facilities, play a major role in the survival of these very immature infants, but, both human and financial resources apart, why should there be such a discrepancy in reported survival rates at the threshold of viability?

There can be several reasons and explanations. First of all, many of the earlier studies referred to birth weight rather than to gestational age and therefore included more mature babies who were growth retarded [although babies of the same gestational age with intrauterine growth retardation (IUGR) usually have a poor prognosis].[22,28–31] Then, again, with some of the earlier reports referring to gestational age, how accurate was dating based on menstrual estimates in the absence of scanning in early pregnancy? Even in recent data, gestational age is often inferred from the first day of the last menstrual period with scanning only prevailing if it differs more than 2 weeks from the menstrual dates.[32–36] At this 'threshold for viability', a few days or a couple of hundred grams will make all the difference when reporting survival rates. On the other hand, many studies are regional/population based,[7,9,14,17,35,36] while others refer either to individual perinatal tertiary centers with very few numbers as a whole or to multicenter collaborative studies[13,15,23,33,34,37–41] with quite different outcomes. Some studies refer to the outcome of pregnancy from the beginning of labor, including still and live births; others include only live births, while others only survival rates for infants admitted to the neonatal intensive care units. This selection bias may overestimate survival rates by as much as 100% at 23 weeks and even up to 50% at 24 weeks.[42]

From our own experience involving 20 perinatal units, 70% of all pregnancies of less then 25 weeks gestational age at the onset of labour ended in fetal death, with no live births at 22 weeks. Amongst live births, at 23 weeks we report only the anedoctal case, but at 24/25 weeks there was, on average, an overall survival of 46% at discharge, albeit with some interunit variation (MOSAIC Study, Portuguese Northern Region, 2003: prospective study of pregnancies betwen 22 and less then 32 weeks gestation). Over an eight year period from 1996–2003, similar results are reported in Portugal for live births from unselected populational studies, with 8% survival at 23 weeks, 34.6% at 24 weeks and 49.3% at 25 weeks (Portuguese National VLBW Register). At 26 weeks both Portuguese Mosaic and the VLBW Register show figures in the order of 64–67% survival to discharge.

Also, in some perinatal centers, both obstetricians and neonatologists may invest aggressively at these lower gestational ages while in others, no active management will be contemplated because both the fetuses and the babies are considered non-viable or because of the very poor overall outcome in the event of survival.[43–48] Whether the mode of delivery at this very low gestational age will make any appreciable difference to survival is very debatable and cesarean section has not been proved to be better.[24,27,49–53] Indeed, the increasing morbidity for the mother and the future consequences of a vertical incision at this stage of pregnancy should perhaps preclude a cesarean in favor of a vaginal delivery, at least for fetal reasons. Further to all the aforementioned explanations for such discrepancies in survival reporting, other confounding data related to pregnancy will also influence survival, and therefore the outcome, namely, IUGR, pre-eclampsia, PPRM/oligohydramnios, antepartum hemorrhage, infection chorioamnionitis, etc.[15,24,49,54,55] Gender and ethnicity, especially, meet with conflicting results at these very low gestational ages.[56–60]

What is the outcome for the survivors?

Survival is not (and should not be) the only goal in perinatal medicine when attempting to establish a 'lower limit of viability'. Outcome and quality of life should, at the beginning of a new century, be a major priority. Although several follow-up studies on these very immature babies have shown that increasing survival has not been mirrored by an increase in cerebral palsy (CP), the fact is that a proportionally higher number of infants are now survivors of very low gestational age and birth weight. Furthermore, the major neuromotor, psychomotor, neurosensory and cognitive disfunctions are found especially in the most immature infants, below 25 gestational weeks.[10–14,17] Over a period of 12 years, between 1983 and 1984, in the north of England, although the survival rate at gestational age greater than 24 weeks had improved (while at gestational age below 24 weeks the overall survivor rate remained unchanged at 4%), the proportion of

survivors with severe disability remained unaltered at around 25%, with 10% being so profoundly disabled as to have to live a completely dependent life.[9] From the results of the European survey, based either on regional or on national data, it was also shown that chronic lung disease ranged from 16.7% to 60% at 36 weeks' corrected age, retinopathy of prematurity (ROP) from 5.5% to 40%, intraventricular hemorrhage Grade III from 15% to 35%, necrotizing enterocolitis from 3% to 23% and nosocomial infection from 23% to 50%. All these complications were common to all countries and were directly related to either the degree of prematurity or the survival rate, being especially prevalent at 26 weeks' gestation or less. As expected, the picture was somewhat reversed, the countries with the better survival rates showing a higher incidence of sequelae, especially in visual impairment and chronic lung disease. At the time of the survey in 1998, almost everyone in Europe was using antenatal steroids, particularly between 26 and 32 weeks' gestation, and postnatal surfactant, either prophylactically or as a rescue. In those days there were no criteria for the use of postnatal steroids. Seven countries out of 21 would never use them while, of the remaining 14, 6 would apply them early – mostly systemically, with the remainder only contemplating their use late in the course of respiratory distress syndrome (RDS), if ventilatory dependent.[27] [These figures might be somewhat distorted and not reflect usual medical practice in Europe since some neonatal units were, at the time, enrolled in a controlled trial of postnatal steroid studies – an open study of early corticosteroid treatment (OSECT).]

On this basis, it could be argued that as recently as the last decade, these very immature infants were receiving quite different treatment across the globe – even from center to center within the same area. However, Vohr *et al.*, reporting on the long-term outcome of a collaborative study of babies on the threshold of viability in the 1990s in the USA, and Wood *et al.*, from a population-based cohort in the UK and Ireland, reporting on behalf of the EPICure study group, both showed that of the surviving children with birth weights less than 750 g or gestational ages below 25 weeks, between 30% and 50% had moderate or severe neuromotor or neurosensorial disabilities and very often had multiple handicaps.[17,61] In a review of the world literature, Hack and Fanaroff estimated that of the survivors of 23 weeks' gestation, over a third had a severe disability from CP to blindness and/or deafness with subnormal cognitive function. At 24 weeks' gestation, the range of severe disability was from 22% to 45% and at 25 weeks, from 12% to 35% and, in general, these rates overlapped those of children born before the 1990s.[62]

It is quite plausible that some of the adverse outcomes in survivors at these low gestational ages may not be just the direct effect of prematurity and/or low-birth weight *per se* but also the result of the hostile intrauterine milieu leading to preterm delivery from inflammatory mediators, to IUGR, hypoxic-ischemic insults, metabolic imbalances, etc. These would perhaps explain the somewhat better, and paradoxical, reported outcome of multiple pregnancies at these very low gestational ages in contrast to the general outcome of multiples at the later stages of pregnancy, presumably because the reasons for preterm delivery would rest with multiplicity alone, in the absence of the adverse factors for singletons' preterm deliveries.[60]

Postnatal events, from nosocomial infection to anemia and hemodynamic instability, metabolic derangements of hyper/hypoglycemia and electrolytic disturbances, etc. may also play an adjuvant role in the overall picture of survival with multiple handicaps. But one area in particular should call for special caution: the possible role of iacterogenically induced disability. Many of these tiny babies are, from the very beginning, often subjected to a whole panoply of maneuvers and medications known to alter hemodynamics, blood flow and perfusion, from xantines to NSAIDs, namely, indometacin, diuretics, volume expanders, antimicrobials with known toxic side effects, paralyzing agents and sedatives, etc. In recent years, two 'old' tools in perinatal care have been submitted to re-evaluation and reappraisal, with growing concern as to their use and misuse.

Antenatal corticosteroids (ANC) have been shown to be associated with a significant reduction of RDS, neonatal death and intra/periventricular hemorrhage[63–65] with a possible synergistic effect with postnatal surfactant therapy.[66] A single course of ANC results in benefits without significant adverse effects, with long-term follow-up studies up to adulthood showing no adverse neurological or cognitive outcome.[67] Betamethasone has shown a reduced risk of cystic periventricular leukomalacia, and therefore has become the recommended steroid for enhanced lung maturation.[68] The available evidence of ANC in multiple pregnancies is somewhat conflicting regarding both use and outcome,[69] while its use in diabetic pregnancies is also controversial for the reduction of RDS, as the adverse steroid-induced hyperglycemia on fetal lung maturation may offset any beneficial effects.[70]

From animal data and observational human studies, there is increasing concern that repeated courses of ANC may lead to immediate and long-term harmful effects on growth, delay in lung and brain development,[71–76] and at present, only a single course is advocated with subsequent courses reserved for randomized control trials.[77] How much the widespread use of repeated courses of steroids in the 1990s may be playing a subsidiary role in the adverse outcome of some of these tiny survivors, in addition to prematurity and low-birth weight, remains an open question.

Postnatal steroids have been shown to promote early extubation in ventilatory-dependent extremely low-birth-weight infants but randomized control studies failed to demonstrate any significant reduction in

death rates or in the development of chronic lung disease.[78,79] Furthermore, in addition to the immediate effects of hyperglycemia, hypertension, gastrointestinal tract bleeding and perfuration, there is growing concern that postnatal steroids may also be responsible for adverse outcome on growth, CP and neurosensory impairment.[79–86] For these reasons, at the present time, postnatal steroids should only be considered for the extubation of ventilatory-dependent babies and only upon informed consent of the parents.

More than 60 years after the initial report of retinal blindness in preterm babies subjected to excess O_2 supplementation, a high proportion of these tiny babies still survive these days with more or less severe ROP. The 'optimal' level (and 'correct' monitoring) for O_2 supplementation remains as yet unknown. A few years ago an observational study of the case notes of surviving infants delivered before 28 weeks' gestation showed a significant decrease of ROP (6% vs. 27.2%) if they were maintained at SaO_2 levels between 70% and 90%. Furthermore, it was also shown that there was much less time on ventilation, less oxygen dependency at 36 weeks' corrected age, a better weight gain and, especially, no increase in mortality or CP.[87] Not surprisingly, this publication caused considerable polemic[88–93] and ongoing debate.[94–98] Understandably, SaO_2 monitoring has become common practice in most neonatal intensive care units with considerable benefit, i.e. comfort, over repeated arterial punctures and complications from invasive procedures. However, there is very little correlation between PaO_2 and SaO_2 levels, both below 84% and above 94% for SaO_2 to keep an ideal PaO_2 level between 50 and 70 mmHg.[99] Also, SaO_2 monitoring is dependent on the methodology used[100,101] and other variables will have to be considered, namely, hemoglobin levels and associated medications that may interfere with cerebral and retinal blood flow and perfusion and not just SaO_2/PaO_2 levels. Nevertheless, ROP is a significant handicap, especially at the lower limit of viability, and caution should be used in reappraising the 'physiological' saturations inferred from the more mature infants and extrapolated to these extremely preterm babies, especially in the first few days of life.

Over and above the immediate and short-term sequelae, how do these tiny survivors perform at a later stage? The available long-term evidence – school age and above – generally shows that besides neuromotor and neurosensorial impairments, a high proportion of these children reveal significant learning difficulties and behavioral and educational problems, only adding further to the burden and placing an enormous responsibility on society as a whole, particularly for the allocation of financial and human resources to provide the necessary collateral help.[102–108] Furthermore, these children will grow to adulthood into a competitive world of 'perfection'. How sensitive are we to handle their multitude of needs and how prepared are we to integrate them into society with fairness and equity?

What are the ethical implications?

Ethics, the study of ideal conduct, classed as a branch of philosophy,[109] should be above cultural barriers, be universal and center upon respect for mankind: easily said, often not practiced. Deontology, the science of duty, the branch of knowledge that deals with moral obligations,[110] the science of professional duties and etiquette,[111] is often referred to as being synonymous with ethics. Laws vary from country to country and sometimes between states within the same country.

It would thus appear to be quite unrealistic to argue the attainability of a common denominator derived from such widespread philosophical, religious and moral views, to frame it within the various legal requirements, to dictate the codes of rules and to expect it to be internationally accepted, yet that is the essence of ethics.

In perinatal medicine, the overall ethical principles of autonomy, beneficence and non-maleficence are even more difficult to apply than in most branches of medicine due to the often conflicting interests of the mother (and partner) and the fetus. The fetus, regardless of its semantic definitions, its rights, its independent moral status and so forth[112,113] is an entity representing human life. The question is, of course, when does human life begin from the biological, moral, religious, legal and social perspectives? Perhaps the concept of 'a fetus as a patient, if not a person', might be the pragmatic answer, at least, for the immediate implications of medical and ethical decisions.[114,115] For similar reasons we approach the subject of neonatal ethics from a practicing angle, focusing on medical management and decisions at the threshold of viability. Far from guidelines, these thoughts, hopefully unbiased, express our concern and independent views on the complexities of universal medical ethics.

Reports in the past 10 years of survival at 22 weeks' gestation[24–26] and less than 400 g birth weight[116] have led to a change in legislation[117] and to a redefinition of the perinatal period,[1] and the aim for the survival of the most immature of babies became only natural and pressing. Accepting the (theoretical) concept of 22 weeks' gestation as the lower limit of viability, what then is the evidence to support this claim and what is the outcome? The answer to the first question is the proverbial case that confirms the exception, and as for the quality of survival, none of the reported survivors was free from neurological sequelae.[24–26,117,118]

And what about at 23 weeks (or 23 weeks and a couple of days)? From here on it is an open game and the stakes are high, with survival rates from 2% to 35% at 23 weeks to 35% to 85% at 25 weeks.[7,10–14] It is quite clear that there are enormous geographical asymmetries even within countries with similar demographies, and it is thus not surprising that some countries will place their lower limit of viability at 24–25 weeks' gestation.[27]

The ethical questions for practicing neonatologists are whether they should accept their own reality of survival and try to improve on quality rather than quantity, or whether they should try to compete with the more advanced countries and aim for the threshold of viability? Who should decide on that? Should it be an individual (local) decision or a matter of national (regional) policy? What are the ethics and moral implications of these decisions? Could it possibly be that in practice new technologies would change matters? What would be the financial resources needed, could they be afforded and, again, what would be the ethical implications of discrimination on financial grounds?

Of the general ethical principles of autonomy, beneficence and non-maleficence, the first does not apply to the neonate for obvious reasons. However, as a person with independent moral status, the newborn is entitled to the full demands and obligations of beneficence and of *primum non nocere*. In everyday practice the concept of 'in the best interest of the patient' has also gained access to neonatal medicine in order to surmount the subtleties of definition from 'sustained life' to 'quality of life'.[119–121] However, this begs the question, in the best interests of whom – the baby, the parents, or society, and who should decide? Handicap is a notion often defined by healthy, normal people, which may or may not be shared by the affected individuals themselves. Perhaps it is a question of degree: what is more acceptable, the survival of a severely physically handicapped but intellectually sound child or, on the contrary, an individual who is completely mentally dependent but who has no physical impairment? And who will be the judge? With the present low birth rate in most Western societies, 'perfection' is understandably always the goal. However, is it not also a sign of moral perfection when a society is prepared to accept the difference, showing compassion and solidarity with its less fortunate members? On one issue at least, everyone would agree that whatever the dilemmas and however difficult, decisions must never be taken upon account of sex, eugenics, religious or economic prejudice, and never based on a doctor's own cultural or religious beliefs.[122,123]

'Futile treatment' is currently used in medicine to mean that any treatment beyond a certain point would be unjustifiable. Neonatologists, often young, are frequently faced in the middle of the night with the crucial decision (based very often upon inaccurate information on gestational age) of whether or not to initiate active, aggressive management of the extremely immature infant at the threshold of viability.

When in doubt, active resuscitative measures should be started in the labor ward.[122] The decision to further continue intensive care can always be reversed after revaluation and counseling to the parents, but this does not imply that decisions to continue or withdraw treatment should rest upon them. Decisions to withdraw or withhold treatment should always be the responsibility of the most senior physician, after discussion with all the staff, including the nurses, and upon informing the parents. The 'phantom of the law' is often used as an argument for the continuation of futile intensive care. In fact, in most places what is unlawful is the preservation of life at all costs, against the dignity of the human being. As for the ethics of treatment withdrawal, once again, what is morally wrong is to prolong useless and hopeless treatments, contradicting the Hippocratic rules of 'not to harm, if possible to cure, but always to relieve and console'. Yet, the same European survey revealed that a considerable number of countries had no policies or consensus for DNR/withdrawal of life support therapies (67% and 48%, respectively).[27] Advancing technologies can often cause procrastination over medical decisions, which, when based on a particularly sophisticated tool, may be mistaken for good medical practice. Neuroimaging is often quoted in this context: but how reliable and infallible is neuroimaging in the prediction of function? It might assist but does not replace clinical judgment of when to withdraw or withhold life-supporting therapies – that would be quite unethical and unacceptable.

Most importantly, once the medical decision has been reached to withdraw advanced life-support treatment, the baby should be allowed to die in privacy, with dignity, surrounded by the warmth, care and love of his parents with the full support of the medical and nursing staff. Fortunately, in most cases, parents accept medical judgments based on sound clinical evidence, knowledge and good faith and are almost always relieved that the decision has been taken out of their hands. Occasionally, medical decisions to withdraw or withhold treatment do not meet with the parents' agreement or approval because of their particular philosophical, cultural or religious beliefs. Frustrating as this may be, professionals must understand and accept these feelings and must continue medical treatment until such time as further counseling may reverse the parents' decision. In the last resort, if consensual agreement cannot be reached in the best interest of human dignity for the baby, the question of treatment withdrawal may be addressed to the courts.[122]

Can a universal lower limit of viability be established?

It is quite obvious from the world literature and from individual realities that a threshold exists for each and everyone, whatever it might be. However commendable the pursuit and quest to emulate the best results, for the meantime, individual thresholds must be recognized. It is within this reality that decisions can be made when faced with the extremely preterm

infant, and that an educated prognosis can be discussed with parents. Improvements can then be pursued based on continuous self-auditing, in strict adherence to the moral conduct of good medical practice toward the most vulnerable of all patients, the sick and extremely preterm infant.

Acknowledgments

Grateful thanks are due to the collaborators from the participating European countries for their invaluable assistance: Belgium, P. van Reempts; Croatia, J. Polak-Babic; Cyprus, Hadjidemetriou; Czech Republic, P. Zoban; England, N. Marlow; Estonia, H. Varrendi; Finland, A. L. Jarvenpaa; The Netherlands, W. E. Fetter, L. Kollee; Hungary, P. Temesvari; Iceland, A. Dagbjartsson; Italy, G. Bevilacqua; N. Ireland, H. Halliday; Norway, A. Meberg; Poland, J. Gadzinowski; Portugal, J. C. Peixoto; Serbia, K. Mulutina; Slovenia, M. Pajntar; Spain, E. Domenech; Sweden, G. Sedin; Switzerland, A. Moessinger; Turkey, G. Can, and also to my departmental colleagues Catarina Prior and Susana Tavares for their help with perusal of the literature.

Introduction

The 1989 St Vincent's Declaration stated, as a 5-year goal, '... that the outcome of the diabetic pregnancy should approach that of non-diabetic pregnancies'[1] and indeed, over the last 25 years significant reductions in spontaneous abortions, stillbirths, congenital malformations and perinatal mortality have been achieved at least in centers with a special interest in diabetic pregnancy and in selected populations.[2–9] However, reports have shown even in Western countries, that spontaneous abortions may be as high as 17%, the stillbirth rate to be five times greater, congenital malformations to range from 4 to 10 times the usual rate, perinatal mortality to be fivefold, neonatal mortality to be 15 times greater and that infant mortality might be trebled as the result of diabetic pregnancies.[10–13] Although population-based studies from Norway have reported considerably better outcomes,[14] data from other countries have continued to show bad results. In a cross-sectional study conducted in 12 perinatal centers in France between 2000 and 2001 involving 435 diabetic pregnancies, both types 1 and 2, perinatal mortality was six times greater than the national rate, severe congenital malformations were double and preterm delivery eight times the national level. Cesarean rates at 59%, shoulder dystocia at 7.6% and macrosomia at 17.3% added to the burden. Preconceptional care was provided in only 48.5% and 24% of women with types 1 and 2 diabetes, respectively, even though women with type 1 diabetes were being followed at least biannually in diabetic centers.[15] Unplanned pregnancies, therefore, remained at levels similar to those observed in the 1990s[16] and close to the reported rates in a recent survey in the USA.[17] In a nationwide prospective study from The Netherlands between 1999 and 2000, although planned pregnancies were observed in 84% of women with type 1 diabetes and glycemic control was considered good ($HbA_1C < 7.0\%$), in about 75% of subjects the outcome was considerably worse than the general population, with pre-eclampsia 12 times greater, cesarean sections 43%, perinatal mortality 2.8%, congenital malformations 8.8%, macrosomia 45.1% with 27.4% of shoulder dystocia and neonatal hypoglycemia in approximately two-thirds of neonates.[18] These poor results have also been reported for type 2 diabetes: congenital malformations 11 times greater, a twofold risk of stillbirth, perinatal mortality 2.5 times higher, risk of neonatal deaths 3.5 times greater and a sixfold risk of death in the first year of life.[19,20]

It would therefore appear that over 15 years on from the St. Vincent's Declaration the goal of a similar outcome for diabetic and non-diabetic pregnancies has yet to be attained.

When addressing diabetic embryofetopathy several issues are necessarily raised: What are the problems? Why does it happen? What is the outcome? Can it be avoided?

Peri(neo)natal problems of the infant of the diabetic mother (IDM)

Pregestational diabetes mellitus (pre-GDM)

The potential complications affecting the conceptus of the diabetic women have been identified for centuries[21] and range from an increased incidence of fetal demise to congenital malformations and a multitude of immediate neonatal problems including macrosomia/intrauterine growth restriction, respiratory distress syndrome (RDS), hypoglycemia, polycythemia, hypocalcemia, hyperbilirubinemia, heart failure and cardiomyopathy, renal vein thrombosis and small left colon. Although these clinical manifestations are seen, especially in uncontrolled diabetic mothers, some of the morbidities, namely macrosomia, hypoglycemia, jaundice and RDS, are still more common in the IDM despite good metabolic control and, in general, these

neonates still require a higher rate of neonatal intensive care unit admission than the control population.

Congenital malformations

Although a whole range of congenital malformations involving multiple organ systems, without specific syndromes, have been observed in pre-GDM, both types 1 and 2, some dysmorphies and malformations are more common, including the association of dysplastic external ears and oculo–auriculo–vertebral spectrum.[22] Caudal regression anomalies, in particular saccral agenesis (with a 200- to 600-fold risk ratio), neural tube and CNS defects (relative risk ranging from 3 for anencephaly to a 40- to 400-fold risk for holoprosencephaly), cardiac malformations, from ASD, VSD to TGV and truncus arteriosus (four to six times greater) to renal defects, from agenesis to ureter duplication with a risk ratio from 6 to 23 times, respectively, have all been repeatedly observed in diabetic pregnancies.[18,23–26] Most of these congenital malformations occur particularly in the offspring of uncontrolled diabetic women with very poor, or no, preconceptional care. They appear to be directly related to HbA_1C levels, ranging from levels similar to those of the general population, with 'excellent metabolic control' ($HbA_1C < 6.9\%$), to 5.1% (with 'good metabolic control', HbA_1C 7.0–8.5%) to 22.4% incidence with greater than 8.6% HbA_1C.[27] Reid and Ylinen have also shown similar results and correlation with HbA_1C, suggesting that a good metabolic control could greatly reduce the impact of congenital malformations in the outcome of diabetic pregnancies.[28,29] By enrolling diabetic women to intensive metabolic control before conception, Furhmann showed that major congenital malformations could be reduced to 1.1%, rising to high uncorrected rates for those presenting later in pregnancy.[30,31] Since then, many other authors have shown similar good results from preconceptional care aimed at good metabolic glycemic control.[4,5,7–9,32,33] From the available evidence, it would seem that tight metabolic control for at least 6–12 months prior to conception would greatly reduce the burden of congenital malformations to almost normal rates. Nevertheless, even in the best series, corrected rates for diabetes-related malformations are considerably higher than those for the rest of the population, despite good metabolic control, i.e. preconceptional care and HbA_1C levels.[4,5,7,18] This raises several points, from the evaluation of good metabolic control and the best parameters, to the question of compliance and whether hyperglycemia is the only teratogenic fuel *per se* or is additional to other predisposing or adjuvant factors, as outlined in the etiopathogeny of diabetic embryofetopathy.

Macrosomia

Ranging from 17% to 50% in the offspring of pre-GDM[15,18,34–36] macrosomia poses a major problem for both obstetricians and neonatologists. In an attempt to diagnose fetal macrosomia many different ultrasound parameters have been proposed with differing results, from estimated fetal weight to abdominal circumference, to the more sophisticated evaluation of fetal subcutaneous fat tissue thickness of various body segments (midarm and midthigh fat and lean mass, abdominal and subscapular fat mass and cheek fat), to fetal fat layer, intraventricular septal thickness, etc.[37–39] How reliably can it be diagnosed by the practising obstetrician, outside the major research institutes if, in effect, he is referring to a large for gestational age (LGA) fetus based on the estimated weight and abdominal circumference?[40,41] This is an important question. While both share common characteristics, the true macrosomic fetus will have other peculiarities due to its abnormal fat distribution, especially affecting the shoulder girdle, leading to dystocia and its complications. Should, therefore, all (true) macrosomic fetuses be delivered by cesarean section? Perhaps not, but in practice they are. As for the pediatrician, the term macrosomia is also often used to describe a large baby and, again, although sharing common problems of hypoglycemia, polycythemia, hypocalcemia and hyperbilirubinemia, the true macrosomic baby will also be a candidate for birth (intrapartum) asphyxia, brachial palsy and cardiomyopathy.

Moreover, rather than mentioning any given weight or babies' weight/gestational age, as is traditionally done for macrosomia, it would be more appropriate to refer to ponderal indices [PI = (fetal weight in grams/fetal length in cm^3) $\times 100$] against the estimated centile for gestational age.[42–44] This approach, besides differentiating the normal LGA from the true macrosomic neonate, may also have other implications, particularly with regard to long-term outcome.

Hypoglycemia

Another issue relates to neonatal hypoglycemia and its never-ending controversies. What in fact is neonatal hypoglycemia and does it matter? Methodological problems of glucose measurements – capillary to venous blood, whole blood to plasma values, sample containers and transport, etc. – all account for the different definitions of hypoglycemia. Glucose concentration in whole blood is about 10–15% lower than in plasma and due to the usually high hematocrit of the IDM, plasma, rather than whole blood, should be used for the definition of hypoglycemia. Moreover, what low blood sugar level might be harmful? Will a (given) low blood sugar level in the absence of symptoms be less damaging than when coupled to clinical manifestations? And if, at the follow-up, these children are found to be performing below par, is it because of neonatal hypoglycemia or is it due to poor antenatal metabolic control? Conversely, could it possibly be that in order to overcome hypoglycemia, the neonate is able to utilize other substrates as an alternative to glucose for brain metabolism? The answer is a partial 'yes' for lactate in the immediate neonatal period, but quite unlikely for other, more important fuels, namely ketone bodies, given the sustained hyperinsulinism-inhibiting

lypolysis. For these reasons, it would therefore be recommended to keep blood levels in the range of ≥ 2.6 mmol/l regardless of gestational and postnatal age, by promoting early enteral feeds. If oral feeds are not being tolerated or are contraindicated, i.v. glucose should be started at 5–6 mg/kg/min and may be subsequently increased according to the lack of response to 8–10 mg/kg/min. If the neonate has symptomatic hypoglycemia, especially related to neuroglycopenia, a bolus i.v. glucose administration of 0.25–0.5 g/kg should be given followed by glucose infusion at the required rate to maintain normal glycemia. As soon as possible, enteral feeds with either breast milk or formula should be promoted and gradually increased to avoid reactive hypoglycemia if glucose infusion is decreased too rapidly. Glucagon administration of 200–300 μg/kg may occasionally be required to enhance glucose release from glycogen storages and to increase hepatic acids oxidation.

Respiratory distress syndrome

Premature delivery remains a hazard due to either maternal or fetal well-being, mostly in poorly controlled women or with associated pregnancy complications or due to underlying disorders secondary to diabetes itself. Hyaline membrane disease (HMD) is more common in infants of diabetic mothers at any gestational age due to either inhibition or decreased surfactant synthesis, a consequence of fetal hyperinsulinism.[45–50] In general, both *in vivo* and *in vitro*, insulin opposes the glucocorticoid stimulating effect on lung maturation[51–53] by a complex cascade of impaired mechanisms, from blockade of fibroblast – pneumocyte – factor (FPF) release and directly inhibiting phospholipid synthesis by type 2 cells[54] to reducing surface protein synthesis[55] or both.

Antenatal corticosteroids have been shown to promote fetal lung maturation in normal pregnancies. Their use in diabetic pregnancy remains controversial as the adverse steroid-induced hyperglycemia on fetal lung maturation may offset any beneficial effects.[54] In addition, the acute rise of severe hyperglycemia in the mother needs to be taken into account and caution demands close monitoring during antenatal corticosteroid administration and several schemes have been proposed for supplementary insulin to counteract the unbalanced hyperglycemic status.[56,57]

Whether the routine assessment of fetal lung maturation by lamella body counts or lecithin/sphingomyelin ratios should be performed in reliably dated pregnancies, at term, is doubtful and lately is becoming less advocated.[58–62]

If HMD remains a common neonatal problem, RDS in the offspring of diabetic mothers is further aggravated not only by the concomitant polycythemia and hyperviscosity, hypoxia and pulmonary hypertension, occasionally heart failure, but also, especially by the high rate of cesarean sections, often without previous labor.

Hypocalcemia

Calcium homeostasis depends on the equilibrium between intestinal absorption and renal excretion under hormonal regulation. Parathormone mobilizes calcium from bone, promotes its renal tubular reabsorption and stimulates 1,25 hydroxy vitamin D production. Vitamin D increases calcium and phosphate intestinal absorption and regulates bone metabolism mediated by parathormone. Hypocalcemia, on the other hand, stimulates parathormone release. In pregnancy, calcium is actively transferred across the placenta from maternal circulation under the influence of the parathyroid hormone-related peptide (PTHrP) with maternal parathormone and vitamin D having very little influence due to their inability to cross the placenta. Fetal plasma calcium is higher than maternal levels, especially with advancing pregnancy (total and ionized calcium 10–11 mg/dl and 6 mg/dl, respectively), and consequently, the parathyroid glands show reduced activity.[63–65] At birth, following the suppression of maternal–fetal transferal of calcium, the plasma levels fall within the first 24 h of life, leading to parathormone release and the normalization of calcium levels by 2 weeks of life.[63,64] Total calcium concentrations in the neonate are dependent on gestational age, albumin levels and pH.

Hypocalcemia occurs in up to 50% of IDM, usually on the first 3 days of age, often associated to hyperphosphatemia and hypomagnesemia probably due to delayed parathyroid response and correlated to the duration and severity of maternal diabetes although the mechanisms remain elusive.[63–65] Pulmonary disease and/or asphyxia worsen the hypocalcemia.[63,65]

In the absence of clinical manifestations, it is debatable whether calcium determination should be performed routinely. On the contrary, with preterm delivery, respiratory compromise, asphyxia, sepsis, etc., calcium levels should be performed and corrected. Prolonged QTc (QT corrected for heart rate over 0.4 s) on the ECG requires special attention, but with the possibility of heart block, refractory bradycardia and hypotension, calcium administration should be carefully monitored.

Persistent hypocalcemia may be the result of the concomitant hypomagnesemia and is unlikely to be corrected if magnesium levels are not adjusted. With significant hyperphosphatemia ($Ca_2 \times PO_4 > 80$) calcium administration may lead to calcification of the soft tissues if the high phosphate levels are not lowered primarily.[63–66]

Polycythemia

The definition of polycythemia may include infants with or without symptoms having hematocrits greater than 65%. The reported incidence of polycythemia ranges from 0.4% to 12% in the newborns, but it affects up to 30% of infants of poorly controlled diabetic mothers.

Fetal red cells have a larger mean cell volume and are less deformable than more mature cells, leading to

increased viscosity. Low fetal oxygenation and tissue hypoxia increase erythropoietin levels stimulating erythropoiesis and leading to high fetal hemoglobin. Some authors speculate that fetal plasma erythropoietin concentration is significantly correlated to maternal high-affinity HbA_1C[67–69] while others suggest that the increased erythropoiesis in fetus of diabetic pregnancies may be subsequent to fetal hypoxemia, the result of hyperglycemia, hyperinsulinemia and hyperketonemia, in line with Freinkel's concept of 'pregnancy as a tissue culture experience'.[70,71] The chronic hypoxemic state *in utero* may thus explain some cases of fetal death. In the neonate, symptomatic polycythemia may present with RDS, congestive heart failure and, occasionally, pulmonary hypertension. Neurological signs include jitteriness, irritability, seizures and apnea. Potential sequelae of polycythemia may be thrombosis, gangrene and stroke. The treatment of polycythemia, especially if symptomatic, is the standard partial exchange transfusion.

Jaundice

Physiological jaundice is a common neonatal problem due to transient glucoronyl transferase deficiency, immature hepatic intracellular uptake and transport, increased enterohepatic circulation and occurs in 60–70% of the newborns. However, clinically significant jaundice (total bilirubin greater than 12.9 mg/dl at term) affects only 5% of these babies.[72]

In the IDM, the risk of clinically important jaundice is up to 30% and is due to multifactorial causes from prematurity, to polycythemia and increased hemolysis, and macrosomia, with PI rather than weight/gestational age showing a better correlation with bilirubin levels.[69,73–75]

Gestational diabetes mellitus

GDM usually develops in the second half of pregnancy. With advancing pregnancy considerable demands are placed on insulin to meet increasing maternal metabolism. If the threshold is surpassed, maternal hyperglycemia may supervene. Although some studies also point to a higher incidence of congenital malformations in association with GDM, most cases are probably pre-GDM diagnosed in pregnancy, especially type 2, with prepregnancy body mass index (BMI) and advanced maternal age playing a very conspicuous role.[76–80] Congenital malformations aside, the whole spectrum of peri(neo)natal problems overlap those of pre-GDM and contribute to the high maternal–fetal and neonatal morbidities.

The incidence of GDM varies from 3% to 5% depending on whether screening is universal or only for women at risk.

In our Institution over the 2-year period from January 1, 2002 to December 31, 2003, from an unselected population of 5930 women, after a universal 1 h of 50-g glucose screening, followed by 3 h of 100-g OGTT, 211 women were confirmed as having GDM. Seven women diagnosed in the first weeks as having had possible pre-GDM detected only in pregnancy (mean BMI 32.5, mean age 32.4 years) were eliminated from the study.

Among the multigest and multipara, 7.2% had had previous GDM with 24% miscarriage and 4.3% late fetal death.

In the present pregnancy, the average gestational age at the time of diagnosis was 27 weeks and the mean HbA_1C was 4.3% (range 3.4–5.7%). Forty-one women (20.4%) required insulin treatment to maintain good metabolic control.

Complications of pregnancy included pregnancy-induced hypertension (8, 3.8%), pre-eclampsia (3, 1.4%), HELLP (3, 1.4%), placenta abruptio (3, 1.4%), thrombocytopenia (4, 1.9%), oligo/hydramnios (2, 0.9%), ACIU (2, 0.9%). There were no maternal or perinatal deaths.

Delivery was by cesarean section in 43.9% and by instrument delivery in 8.8% while for a control group of macrosomic babies of non-diabetic mothers these figures were 36.4% and 9.2%, respectively. The average birth weight at 38 weeks was 3121 g (SD 424 g) and length 48.55 cm (SD 1.77 cm).

Neonatal morbidities expressed in Table 8.1, compared to LGA neonates of non-diabetic mothers, were considerably better than in many series. Several points, though, need to be considered. The incidence of macrosomia [birth weight/gestational age (BW/GA) $>$ 90th centile] was identified in only six (2.9%), a figure that is just above that of our unselected population (2.8%). However, if PI is applied instead of BW/GA, the incidence rises to 31 (16.1%) of babies with PI $>$ 90th centile, especially with advancing gestational age (21.4% and 38.5% at 39 and 40 weeks, respectively), suggesting a population of short obese babies within our population of gestational diabetes in contrast to LGA neonates of non-diabetic mothers, which are large and long (Table 8.2). We would therefore consider PI to be a more accurate and true reflection of macrosomia than just BW/GA. Another area for concern is the high incidence of cesarean sections, which suggests labor-induced failure, because even correcting for PI, only 16.1% were macrosomic newborns, questioning the current practice of elective induction at 38 weeks' gestation. The proportion of small for gestational age within our diabetic population (10.3% vs. 13.64 % in our general population), suggests an adequate metabolic control.

Although there were very few cases of RDS in our neonates, mostly due to the paucity of very small, extremely preterm infants, we observed that of those with respiratory problems, more than one-half were pulmonary adaptation syndromes in neonates delivered by cesarean section at 37 weeks' gestation.

In summary, even within perinatal centers, although maternal and peri(neo)natal adverse results can be greatly improved, GDM remains a public health problem of considerable proportions.

Table 8.1 Comparative neonatal morbidities of IDM and LGA

Morbidity	IDM n	%	LGA N	%	χ^2 (P)
Fractured clavicles	4	2	9	5.4	0.79
Brachial plexus palsy	1	0.5	2	1.2	0.47

Why does it happen?

In a theoretical model, according to Freinkel's concept of pregnancy as a tissue culture experience, the whole pathogenesis and spectrum of fetal and neonatal mortality and morbidity could primarily be attributed to the excessive transferal of glucose from mother to fetus, inducing fetal hyperglycemia, leading to fetal pancreatic islet hypertrophy and β-cell hyperplasia with a consequent rise in insulin secretion.[81] Chronic fetal hyperinsulinism results in raised metabolic rates and oxygen consumption causing fetal hypoxemia, which, in turn, would be responsible for the increased rate of stillbirths and birth asphyxia as well as for the excessive erythropoietin production and polycythemia.[68–70,82,83] In addition, fetal hyperinsulinism would be responsible for increased fetal substrate intake, leading to fat synthesis, with the resulting adiposity, macrosomia and visceromegaly. Furthermore, fetal hyperinsulinism may also be responsible for the development of respiratory distress syndrome at birth by either inhibiting or decreasing lung surfactant synthesis.[45–50] Neonatal hypoglycemia may be a combination of several factors including sustained hyperinsulinism and lack of counter-regulatory hormonal responses impairing hepatic glucose production, deficient lipolysis and increasing peripheral glucose uptake.[84–86] It would seem, therefore, that uncontrolled maternal hyperglycemia could start the whole spectrum of diabetic embryofetopathy (Figure 8.1). It is quite possible, however, that other metabolic fuels, either besides or in association with glucose, from lipids to

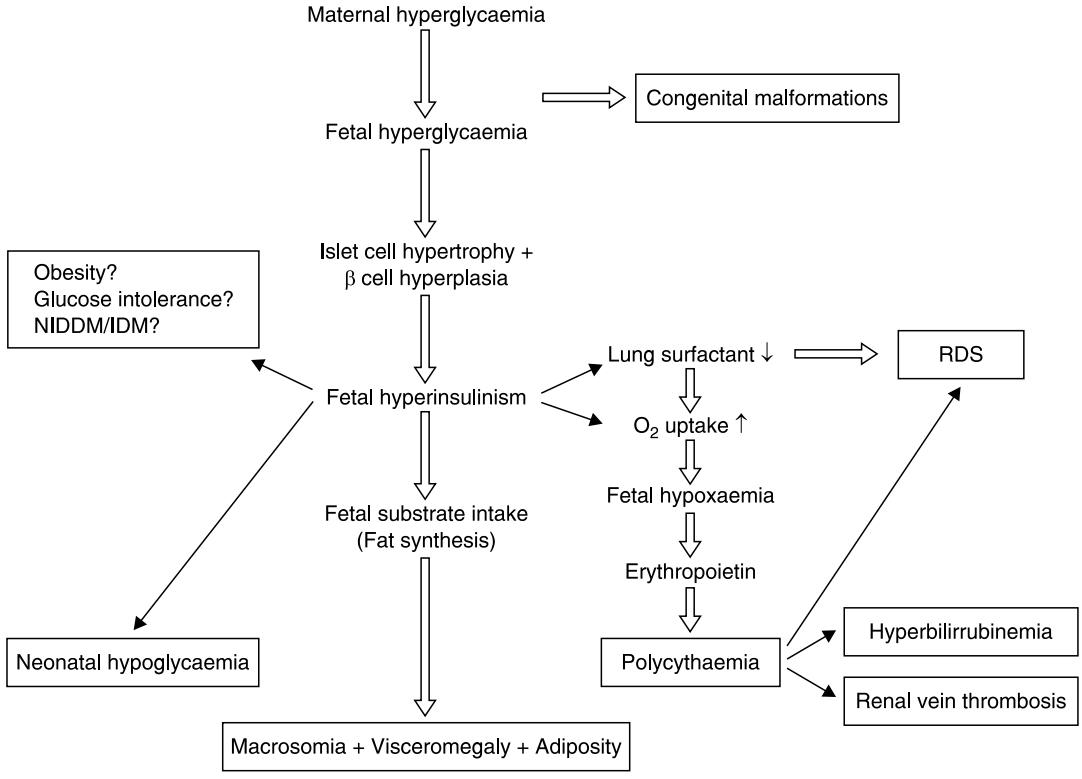

Figure 8.1 Diabetic embryofetopathy.

amino acids, may also cross the placenta in a concentration gradient inversely proportional to insulin availability, further contributing to the abnormal fetal milieu.[70,71,87] Depending on the timing of gestation, during critical developmental stages, the same metabolic fuels would have different effects on the fetus. Over the last 15 years there has been increasing evidence from animal and human studies to support the theory that in addition to sugars (glucose, galactose and mannose) other metabolic fuels, from ketones to deranged lipid peroxidation, may be responsible for the pathomechanisms of congenital malformations provided that they are present at certain (high) levels for a reasonable amount of time and especially at crucial 'developmental windows'.[88–91] Dietary supplementation of deficient substracts (arachidonic acid and myo-inositol), free oxygen radical scavenging enzymes and antioxidants have been shown *in vivo* and *in vitro* to reduce the rate of malformation in the offspring of diabetic animals.[92–95] Whether such strategies might be applicable to clinical practice remains a promising but open question.

Similarly, the same general principles of multifactorial pathomechanisms have been postulated for macrosomia, including and ranging from ketone bodies to free fatty acids, 'selected' amino acids and with a conspicuous role for IGF-1 and IGF-2 at the local level. Maternal insulin antibodies and insulin counter-regulatory hormones may, in addition, further contribute to the resulting macrosomia.[96–101]

Toward the end of the second trimester, at a time of increasing cerebral cortical differentiation and maturation, it is quite conceivable that a metabolic insult may result in altered neurological or intellectual behavior[102–106] and, during the third trimester, proliferation of fetal adipocytes, muscle cells and pancreatic β-cells may then be responsible for 'programming' the later development of several adult disorders.[107–111]

What is the outcome?

Neonatal complications of the IDM, in spite of the high morbidities involved, are now quite well managed with intensive neonatal care. It is questionable whether these babies are more prone to developing neurological, behavioral and learning disabilities and, if so, whether they are due to an unfavorable intrauterine metabolic environment or to other perinatal and early life events operating on different fetal determinants. Most of the early reports of severe brain damage are, reassuringly, now of historical interest.[112,113] Nevertheless, well-documented evidence points to mild to moderate psychomotor and psychosocial impairment in the offspring of these mothers. While it is quite possible that early neonatal events may play a role, available data also place a suspicious emphasis on intrauterine life.[102–105]

The long-term outcome, on the other hand, poses several questions. Some studies point to a higher

incidence of childhood obesity in the offspring of these mothers while others fail to find such correlations. Conflicting results might be the result of the different methodologies involved, including different definitions and very often small numbers, without adequate control populations.[114–116]

Finally, a major issue is whether some adult diseases of metabolic and vascular disorders may have had a fetal origin. In recent years, there has been accumulating evidence, both from animal studies and from epidemiological data, to suggest that fetal β-cell hyperplasia and hyperinsulinism may induce irreversible changes leading to obesity, glucose intolerance and even overt non-insulin-dependent diabetes and, perhaps, a protective effect against type 1 diabetes later in life – a model very much in line with the 'Barker Hypothesis' of the fetal origins of adult disease.[107–111,117,118]. What might be the relative weight of genetics vs. intrauterine events remains to be confirmed[119,120] but it is quite interesting that at least in experimental models the prevention of hyperglycemia in pregnancy significantly reduces the prevalence of diabetes in the next generations.[111]

What can be done?

Based on the assumption that poor maternal homeostasis is at the core of the problem and that tight metabolic control might change the outcome of a diabetic pregnancy to normal, why then are such poor results being reported even in developed countries? Admittedly, most of these bad performances are for pre-GDM. But, even allowing for different data collection, lack of uniform criteria in definitions and case identification,[121–123] the fact remains that overall results are far from satisfactory. It can be argued that they are due to poor medical and social care – and they most probably are. It can also be argued that poor metabolic control has not been achieved or that 'good' is not necessarily 'optimal'. Alternatively, it can be put forward that there might be an abnormal genetic background contribution (evidence is pretty scanty) or that there might be other metabolic fuels besides glucose operating at different developmental stages of pregnancy, thus accounting for the etiopathogenesis of the whole syndrome. It is quite possible that some, or all, of these metabolic fuels may, *per se* or in synergie, play a significant role in the whole metabolic disturbance and it is quite conceivable that besides the classical approach to strict glucose control, other dietary manipulations with supplementation or replacement of deficient substracts might hold a promise for the near future. For the moment, however, priority should focus on intensive prenatal care for diabetic women and the identification of women for the development of GDM and, once diagnosed, placing them on a strict glycemic control throughout pregnancy. The cost-efficiency of screening all women for GDM is often discussed and, likewise, whether many of these women are overtreated unnecessarily. Argument, however, should concentrate not just on the immediate effects of GDM but on the long-term consequences for both the mother and her offspring.

Acknowledgment

The authors gratefully acknowledge the antenatal data on diabetic mothers supplied by Dr. Célia Araújo.

9 Neonatal seizures

A. Beke and Z. Papp

Definition

Seizures have been defined as abnormal, paroxysmal, stereotypical clinical events that are initiated by the hypersynchronous activity of neurons in the brain.[1] They represent rapid alteration in the function of the nervous system by which the motor, behavioral or autonomic functions (or all of these) are clinically affected. Seizures are far commoner in the first month of life than at any other time. Neonatal seizures have been described in both clinical and electrical terms. Clinical seizures have been described as occurring in close association with electroencephalograph (EEG) seizure activity (epileptic in origin), and without accompanying EEG seizure activity (presumably non-epileptic in origin). All the clinical seizures described indicate the presence of significant central nervous system dysfunction. In this regard, the findings of EEG monitoring studies do not change a fundamental concept concerning seizures of the newborn: each newly diagnosed neonatal seizure represents a neurological emergency.[2]

Incidence

Conventionally, the neonatal period is limited to the first 4 weeks of life. However, some authors[3,4] define neonatal seizures as those that occur up to 44 weeks of postmenstrual age, to take into account premature birth. Although convulsive phenomena are the most frequent among the major neurological disorders in the neonatal period, their precise frequency is unknown because many of the subtle manifestations of neonatal convulsions may escape recognition. Conversely, jittery and tremulous movements, common at this period, are often mistaken for convulsive seizures, although their significance is completely different. The true incidence of neonatal seizures varies in different series from 0.15% to 1.4%.[5–10] Scher *et al.*[11] found that the incidence of seizures among all neonates admitted to the intensive care unit was 2.3%, and the group of preterm neonates of <30 weeks of gestational age had a seizure frequency of 3.9%, which was significantly higher than that of older preterm or full-term neonates. The very high incidence (up to 22.7%) reported in premature infants by Bergman *et al.*[6] is probably due to the frequency of non-epileptic events in this group.[1] Seay and Bray[12] reported seizures in 20% of infants admitted to the intensive care unit, weighing 2500 g or below. In general, an incidence of neonatal seizures of between 4 and 6 per 1000 infants seems to be a realistic figure. This figure is much higher among the most immature infants. Neonatal seizures appear to be associated with major morbidities and surgical interventions in very low-birth-weight infants. Continuous electroencephalographic monitoring could be warranted in infants following surgical treatment.[13]

Pathophysiology

The site of paroxysmal activity may arise from previously normal neurons. This fire due to a trigger and abnormal conduction occurs through neighboring neurons. Alternatively, the neuronal focus may be inherently abnormal and fires repetitively. Seizures in infants and children may be due to either or both mechanisms.[10] Seizures indicate the presence of a central nervous system dysfunction and may contribute to additional brain injury.[14–16]

Brain maturation progresses rapidly during the last weeks of gestation and in the postnatal period. Structural and functional development of the central nervous system is reflected in the rapidly changing bioelectrical activity and behavior of the brain. This has been extensively documented during the past decades in studies of various mammalian species[17,18] and human preterm and newborn infants.[19–21] In the term newborn, the archicortex (i.e. diencephalon and brain stem) is at a relatively more advanced stage of development than is the neocortex. A significant percentage of paroxysmal electrical discharges in the newborn brain, which arise from subcortical gray matter, might not be identified by EEG scalp recordings. Two possible explanations exist for clinical seizures without an electrographic signature:[22]

(1) Tonic posturing and motor automatism are epileptic but are generated in the brain stem, and the paroxysmal electrical epileptic activity is not manifested at the scalp and not recorded by surface EEG electrodes.
(2) Tonic posturing and motor automatisms are generated and elaborated at a brain-stem level by a non-epileptic mechanism.

It has been suggested that the latter explanation is more plausible.[23,24] Although the lack of a close association to EEG seizure activity would only suggest that tonic posturing and motor automatisms are not epileptic in origin, it is these clinical characteristics of the behaviors that provide the evidence for a non-epileptic mechanism. Tonic posturing and motor automatism may be evoked by tactile stimulation; a graded increase occurs in the magnitude of the response proportional to an increase in the intensity of the stimulus at a single site (temporal summation) or an increase in the number of sites of stimulation (spatial summation). The response may spread to muscle groups other than those originally stimulated (irradiation of the response). Both provoked and spontaneous tonic posturing and motor automatism may be suppressed by restraint or repositioning of the body or affected limbs. All of these features are typical of reflex behaviors[25–27] and are not characteristic of epileptic seizures. On this basis, it has been proposed that tonic posturing and motor automatisms result from depression of forebrain function and the consequent disinhibition of the brain-stem centers that facilitate primitive reflex behaviors.[23,24] This hypothesis is based not only on clinical observations but also on the correlation of these findings with experimental studies of reflex physiology in animals.[24,28] Primitive reflex behaviors are normally mediated by spinal mechanisms and facilitated by centers within the brain stem. These centers are tonically inhibited by the forebrain and may be stimulated by proprioceptive and entroceptive pathways activated by limb and truncal manipulation. When the forebrain is depressed, brain-stem centers are disinhibited, and primitive reflexes may occur spontaneously or be evoked by stimulation. It has been proposed that these behaviors, as a group, be designated 'brain-stem release phenomena' rather than epileptic seizures.[26,29] Although neurons are in place by the time of birth, their axonal and dentritic ramifications and synaptic connections are still incompletely developed in the neonatal human brain,[30,31] and myelination is limited to a few pathways not including the main hemispheric commissures.[32] The *hyperexcitability* of the immature cortex is explained by the underdevelopment of the myelinization and the characteristic phenomena;[33–35] the *modification* of the shapes of spikes depends on the developmental stage of dendrites; the *propagation* of discharges is determined by the state of maturity of the cortical and subcortical and interhemispherial connections.[36]

Kolmodin and Meyerson[37] found the age-related variations of the potential stable and others observed the role of the enzymatic reactions.[38,39] In addition, synaptic connection and transport across synaptic membranes is much less efficient in the immature brain.[40] Both inhibitory [γ-amino butyric acid (GABA)-ergic] and excitatory receptors are present in the human newborn but are not fully developed or are not completely functional because of the incomplete development of the appropriate circuitry.[41,42] There is evidence that the inhibitory dopamine transmitters have a predominant effect over excitatory transmitters in the developing brain.[43] The neonatal brain appears uniquely susceptible to seizure because neonatal GABA receptors are excitatory, and are functionally more active than *N*-methyl-D-aspartate (NMDA) receptors at this time of life.[44] The absence of generalized tonic–clonic seizures probably reflects both the lack of a sufficient degree of cortical organization (which is necessary to propagate and sustain the electrical discharge) and the failure of interhemispheric transmission, resulting from commissural immaturity. Experimental data suggest that neonatal seizures may have a deleterious effect on the developing brain, depleting cerebral glucose, which may interfere with DNA synthesis, glial proliferation and differentiation and myelinization.[45–47] Younkin *et al.*,[48] using nuclear resonance spectroscopy, showed a marked depletion of brain phosphocreatine and adenosine triphosphate during a subtle seizure, which was reversed following phenobarbital therapy and seizure cessation. Animal studies have shown that seizures impair neurogenesis and derange neuronal structure, function and connectivity ('cells that fire together'). The hippocampus has been well studied because it is particularly susceptible to seizure-induced injury. Seizures cause synaptic reorganization with aberrant growth (sprouting) of the dentate granule cell (DGC) axons (i.e. the mossy fibers).[49] There is also apoptosis in the inner granule cell layer of the dentate hilus, and bilateral hippocampal sclerosis has been found at autopsy in human babies who suffered prolonged seizures. Seizures lead to a mismatch between energy supply and demand, and although there is a rise in cerebral flow this may not be sufficient to meet the requirement.[50] Neonates have a low cerebral metabolic rate and a fragmentary neuronal network, making them less vulnerable to neuronal damage and cell loss than adults and more resistant to the toxic effects of glutamate. However, seizures undoubtedly can inhibit brain growth, modify neuronal circuits and increase neuronal excitability. Recurrent seizures during early development have been shown to result in impairment of visual-spatial learning and memory.[51,52] Status epilepticus and recurrent seizures have also been shown to predispose the brain to seizures in later life.[53] Magnetic resonance spectroscopy studies show areas of cerebral metabolic dysfunction in babies with seizures.[54] Status epilepticus can result in

necrotic damage to the thalamus in immature rats.[55] The response of the developing brain to epileptic seizures and to status epilepticus is highly age specific. Neonates with their low cerebral metabolic rate and fragmentary neuronal networks can tolerate relatively prolonged seizures without suffering massive cell death, but severe seizures in experimental animals inhibit brain growth, modify neuronal circuits and can lead to behavioral deficits and to increases in neuronal excitability. Past infancy, the developing brain is characterized by a high metabolic rate, exuberant neuronal and synaptic networks and overexpression of receptors and enzymes involved in excitotoxic mechanisms. The outcome of seizures is highly model dependent. Status epilepticus may produce massive neuronal death, behavioral deficits, synaptic reorganization or chronic epilepsy in some models, and little damage in others. We now have some models that reliably lead to spontaneous seizures and chronic epilepsy in the vast majority of animals, demonstrating that seizure-induced epileptogenesis can occur in the developing brain. The mode of cell death from status epilepticus is largely (but not exclusively) necrotic in adult, while the incidence of apoptosis increases at younger ages. Seizure-induced necrosis has many of the biochemical features of apoptosis, with early cytochrome release from mitochondria and capsase activation. Wasterlain *et al.* speculate that this form of necrosis is associated with seizure-induced energy failure.[56] A recent finding is that neonatal seizures can permanently disrupt neuronal development, induce synaptic reorganization, alter plasticity and 'prime' the brain to increased damage from seizure later in life. This finding has led to a renewal of interest in the topic of neonatal seizures, particularly regarding treatment.[57]

Edwards *et al.* found that prenatal stress alters the seizure threshold and the development of kindled seizures in infant and adult rats. Their findings indicate that stress, particularly during the latter half of pregnancy, may play an important role in increasing vulnerability to seizures in the unborn offspring.[58] The idea that stem cells may play a role in the pathophysiology or potential treatment of specific epilepsy syndromes is relatively new.[59] Knowledge of the normal neurogenesis pathways in the mature brain has led to recent studies of neurogenesis in rodent models of acute seizures or epileptogenesis. Current evidence indicates that single brief or prolonged seizures, as well as repeated kindled seizures, increase DGC neurogenesis. Recent work also suggests that pilocarpine-induced status epilepticus increases rostral forebrain subventricular zone (SVZ) neurogenesis and caudal SVZ gliogenesis. These abnormalities include aberrant mossy fiber reorganization, persistence of immature DCG structure (e.g. basal dendrites) and abnormal migration of newborn neurons to ectopic sites in the dentate gyrus. Taken together, these findings suggest a proepileptogenic role of seizure- or injury-induced neurogenesis in the epileptic hippocampal formation. However, the induction of forebrain SVZ neurogenesis and directed migration to injury after seizures and other brain insults underscores the potential therapeutic use of neural stem cells as a source for neuronal replacement after injury.

Table 9.1 Electroclinical classification of neonatal seizures (from Younkin[2] with permission)

Clinical seizures with a consistent electrocortical signature

A. Focal clonic
   - Unifocal
   - Multifocal
     - Alternating
     - Migrating
   - Hemiconvulsive
   - Axial

B. Myoclonic
   - Generalized
   - Focal

C. Focal tonic
   - Asymmetric truncal
   - Eye deviation

Clinical seizures with no electrocortical signature

A. Motor automatisms
   - Oral–buccal–lingual movements
   - Ocular movements
   - Progression movements
     - Pedaling
     - Stepping
     - Rotary arm movements
   - Complex purposeless movements

B. Generalized tonic
   - Extensor
   - Flexor
   - Mixed extensor/flexor

C. Myoclonic
   - Generalized
   - Focal

The classification of neonatal seizures

Recently, neonatal seizures have been characterized and classified according to their presumed pathophysiology, with the suggestion that some neonatal seizures are epileptic in origin and others are not (Table 9.1).[2,60,61] Seizure recognition, characterization and classification create the foundation of care of the neonate who may be at risk for central nervous system dysfunction. For classification of neonatal seizures and for making a guide to clinical recognition a workshop was formed in the USA [participants: Subcommission on Classification and Terminology of Pediatric Epilepsy, Commission on Classification and Terminology, International League against Epilepsy (ILAE) and the Clinical Research

Centers for Neonatal Seizures, National Institute of Neurological Disorders and Stroke, National Institute of Health (NIH)]. The report of the newest classification was published by Mizrahi in 2004.[62] The classification system and the infants presented in the workshop are based on a prospective, clinical study of infants with seizures that have been documented by bedside, video-EEG monitoring. Each seizure was examined by all the investigators together, characterized and then classified by consensus.

Approximately 65% of neonatal seizures are not clearly associated with apparent cortical electrographic seizure activity on the basis of EEG recordings from surface electrodes.[24,63] Neonatal seizure types differ considerably from seizures observed commonly in older children, principally because the newborn infant is less able to sustain organized, generalized epileptiform discharges. The most widely accepted and most often clinically applied classification scheme is that proposed and recently updated by Mizrahi and Kellaway (Table 9.2). Some clinical seizures are characterized by just one type of movement. However, other seizures are more complex. They may begin with one type of movement, which is then followed by others in a sequence typical for that specific seizure. The most effective application of this classification is to use it as a basis to identify the individual components of a single seizure, rather than to classify an entire complex event.

Several seizure types frequently occur together in the same infant; subtle seizures are frequently associated with other types in the severely ill neonate.[5] In addition, various seizure types may be generated by different mechanisms – either epileptic or non-epileptic. The clinical characteristics of a specific seizure may designate its pathophysiology. Thus, the classification of a seizure may suggest a specific mechanism of generation, leading eventually to considerations of therapy and long-term prognosis.

Clonic seizures

Clonic seizures consist of rhythmic muscle jerking that can involve any part of the body and are often

Table 9.2 Classification of neonatal seizures (modified from Mizrahi[62])

I. Clonic
   A. Unifocal: (1) limb, (2) facial, (3) hemiconvulsive
   B. Multifocal: (1) alternating, (2) bilateral, asynchronous
   C. Axial: (1) abdominal, (2) diaphragmal

II. Tonic
   1. Focal: (1) ocular (sustained eye deviation), (2) limb posturing, (3) asymmetric
   2. Generalized: (1) symmetric – a. flexion, b. extension, c. mixed flexion–extension; (2) asymmetric

III. Myoclonic
   1. Generalized
   2. Focal
   3. Multifocal (fragmentary)

IV. Spasm (generalized)
   1. Flexion
   2. Extension
   3. Mixed extension–flexion

V. Motor automatisms
   A. Oral–buccal–lingual movements: (1) chewing, (2) sucking
   B. Ocular signs: (1) random eye movements, (2) blinking, rhythmic eye opening
   C. Limb (movements of progression): (1) pedaling, (2) swimming
   D. Complex purposeless movements

VI. Autonomic nervous system signs
   A. Respiratory: (1) tachypnea, (2) respiratory pause
   B. Cardiac: (1) tachycardia, (2) bradycardia
   C. Cardiovascular: (1) hypertension, (2) hypotension
   D. Vasomotor: (1) flushing, (2) pallor
   E. Pupillary dilatation
   F. Salivation
   G. Other

VII. No clinical signs – electrical seizure only

VIII. Unclassified

ILAE–NIH classification of neonatal seizures

associated with simultaneous epileptiform activity on EEG.[64] Two subtypes are recognized, focal clonic and multifocal.

Focal clonic seizures have limited, usually unilateral, involvement of the face, limbs or axial muscles and are often not associated with alterations of the level of consciousness. In many instances, there is an underlying focal lesion, e.g. focal cerebral infarction. However, it is important to realize that metabolic derangements, e.g. hypoglycemia, may present as focal seizures in the newborn.[16] Cockburn *et al.*[65] reported clonic seizures with late hypocalcemia.

Multifocal clonic seizures are observed more frequently in the term newborn, and are a relatively benign form. They involve non-synchronized clonic movements of the extremities, which differ from multifocal clonic seizures in older infants in that abnormal movements in newborns usually migrate in an unordered, non-Jacksonian fashion. For example, clonic movements of one hand may be followed by jerking of the opposite leg.[66] This particular seizure type may be explained by the immature stage of development of the cerebral cortex of the term infant. Thus, although there is sufficient interneuronal communication to permit sustained seizure activity, the immaturity of synaptic development and axonal myelination may prevent the organized spread of electrical impulses. Because of this, generalized tonic–clonic seizures, which are symmetric and synchronous, occur infrequently in the term newborn.[30]

Tonic seizures

Tonic seizures are most often generalized, featuring tonic extension of all limbs (which resembles 'decerebrate' posturing), or, occasionally, flexion of the upper limb with the extension of the legs (which resembles 'decorticate' posturing). Eye signs such as opening or closing movements of eyelids, staring, gaze deviation or the occurrence of a few clonic jerks may be a clue to their epileptic mechanism. Volpe[30] found tonic seizures to be particularly common among premature infants, and they accounted for 70% of fits seen in infants weighing 2500 g or less. This form of seizure occurs in infants with significant cerebral injury [e.g. massive intraventricular hemorrhage (IVH)] and is associated with a bad prognosis. In approximately 85% of cases, the abnormal posturing is accompanied by electrical seizure activity or autonomic phenomena and the response to anticonvulsant therapy is poor.[12,30] This observation gives rise to the possibility that such posturing represents abnormal brain-stem release phenomena as opposed to true epileptic seizures.[23,30,67] In these instances, although there is no corresponding electrical seizure activity, the interictal EEG is usually severely abnormal with marked voltage suppression.[29]

Myoclonic seizures

Myoclonic seizures, which may be focal, multifocal or generalized, are rare in the neonatal period. They may occur in infants of any gestational age and are associated with time-synchronized EEG discharges only in a minority of cases.[24] They are characterized by rapid, unilateral or bilateral, single or multiple flexion jerks of the upper extremities, but to a lesser extent. Myoclonic seizures often signify severe structural or metabolic cerebral disturbance. They often persist into infancy as more or less atypical infantile spasms.[68,69] A benign variety of neonatal myoclonus has been described, which occurs characteristically only during sleep. Focal and multifocal myoclonic activity may be observed, which is difficult to distinguish clinically from epileptic seizures. However, the correlation with the sleep state and the absence of associated EEG abnormalities may be helpful in this. It typically resolves spontaneously before 6 months of age.[70–72]

Spasms

Spasms may be flexor, extensor or mixed extensor and flexor, and may occur in clusters. Spasms cannot be provoked by stimulation or suppressed by restraint. Pathophysiology is epileptic.

Motor automatisms (subtle seizures)

Subtle seizures may be the most common type and are present to some degree in most term newborns with seizures. This category includes all paroxysmal steps of behavior in newborns that may be sustained, and that cannot be readily classified as myoclonic seizures. Subtle or minimal seizures are also termed 'motor automatisms' by some investigators.[73] The most common clinical manifestation is a variety of ocular movements, e.g. eye opening, tonic horizontal deviation of the eyes; orofacial movements, such as repetitive chewing, swallowing, drooling; rotatory limb movements or complex patterns, like pedaling, boxing, swimming or stepping, and autonomic disturbances, such as hyperpnea, vasomotor abnormalities, salivation or modification of the heart rate. Abnormal eye movements, especially in the horizontal plane are of special diagnostic value.[74,75] Unlike sustained eye deviation is typical of focal tonic seizure of epileptic origin; the ocular signs of motor automatisms are less well defined. They include random eye movements, eye opening and blinking.[62] Motor automatisms and generalized tonic posturing may coexist, since their pathophysiologic mechanisms are the same.

Autonomic nervous system signs are often combined with motor automatisms apneic seizures are common, sometimes in isolation,[76,77] but more often in association with ocular or other autonomic signs. Fenichel *et al.*[78] found that apneic seizures were not

accompanied by bradycardia, as opposed to the much more frequent non-epileptic apneas of the premature infant, which last 20 s or more. Other studies involving simultaneous video-EEG investigations demonstrated that subtle clinical phenomena are frequently accompanied by simultaneous electrical discharges in premature infants.[79] The EEG signs that are associated with subtle seizures occur commonly in the temporal leads,[64] which is not surprising as similar clinical features are frequently observed in older children in complex partial seizures, which originate in the temporal lobes. Alterations in the autonomic function as a seizure manifestation raise particular diagnostic problems. Thus, although apneic episodes in the premature infant may rarely be a manifestation of seizure activity,[79] they are much more likely to be related to other mechanisms. In contrast, apnea in the term newborn appears to be associated more commonly with electrical seizure activity. Recently, the apneic episodes have been observed and differentiated in newborns and especially in prematures with a new polygraphic computerized method (SLEEP Labor). We can also determine the type of apnea exactly: central, obstructive or mixed. Figure 9.1 shows a polygraphic investigation demonstrating a central apnea (cenA-) following the electrical activity change on the FP1 channel. There is no significant change in ECG (examination of the author). Infantile spasms and episodic apnea (associated with electroencephalographic seizure activity) may also occur as neonatal seizures, but they are rare and currently do not warrant major classifications.[3]

Isolated seizures are relatively uncommon in the neonatal period. The occurrence of at least a few attacks is the rule. However, neonatal seizures tend to be self-limited and to last 24–96 h,[80–82] which complicates the assessment of therapy further.

Neonatal status epilepticus has been defined by Dreyfus-Brisac and Monod[83,84] as the repetition of clinical and/or purely electrical seizures with the interictal persistence of an abnormal neurological status. Cukier *et al.*[82] redefined the term with greater precision as the occurrence of electrical seizure discharges, each lasting at least 10 s and repeated for several hours, in association with an abnormal neurological state and unconsciousness. Clinical seizures may or may not be present. The latter definition does not include repeated clinical seizures without ictal EEG concomitants such as those that may occur in neonates who have been convulsing for many hours.[85] The term serial seizures is perhaps preferable to that of status epilepticus in the neonatal period because it does not refer to an abnormal interictal neurological state, which may be impossible to assess reliably on account of the interference of drug treatment.[3] With prolonged convulsive episodes, there is a tendency for individual seizures to change from well-marked to poorly organized attacks, clinically as well as electrically.

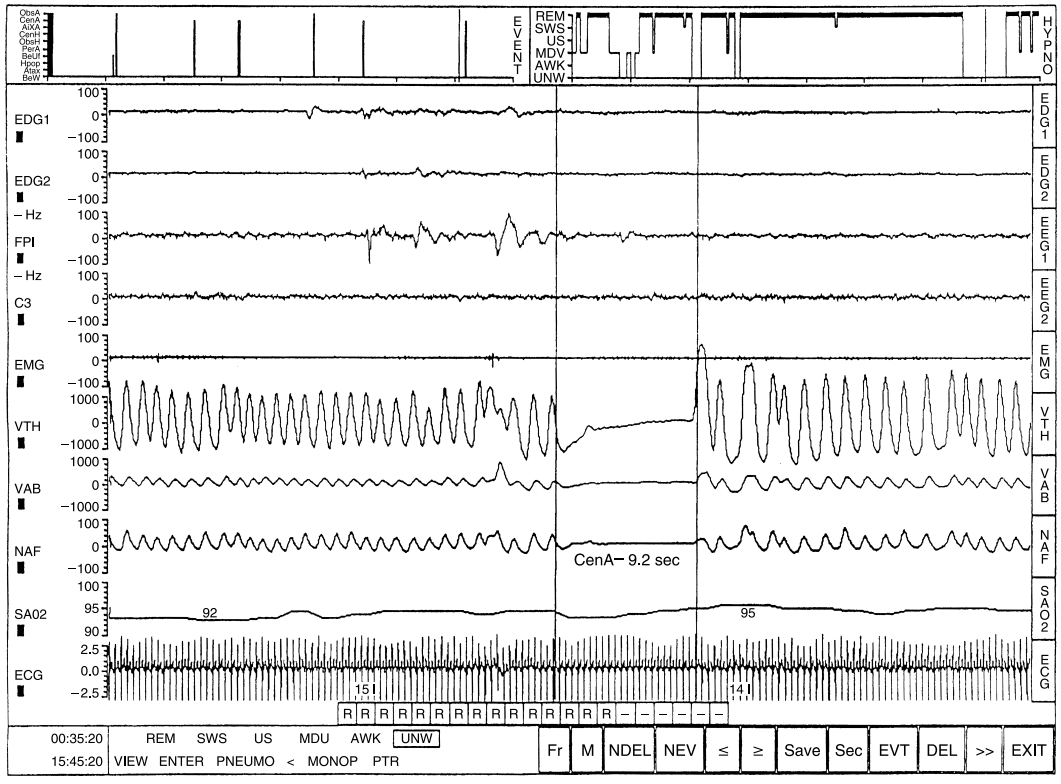

Figure 9.1 Central apnea demonstrated by polygraphy.

Etiology

Although the etiology of neonatal seizures is extremely diverse, most of them can be attributed to hypoxic-ischemic encephalopathy (about 65% of neonatal seizures), intracranial hemorrhage (about 15%), metabolic disturbances (hypoglycemia, hypocalcemia), intracranial infection and cerebral cortical dysgenesis. Table 9.3.

Hypoxic-ischemic encephalopathy is the most important cause of neonatal seizures in infants and in all gestational ages.[30] It has been estimated to account for approximately two-thirds of all cases. Seizures are a major manifestation of moderate or severe intrapartum hypoxic-ischemia encephalopathy in approximately 50% of affected term newborns and are associated with long-term neurological sequelae in at least 20–40% of cases.[30,86] Many cases are probably of prenatal origin, so a low weight for date and other signs of dysmaturity are common findings.[66] Postnatal respiratory insufficiency causes less than 10% of cases of hypoxic encephalopathy.[30] Ischemia is secondary to intrauterine asphyxia with cardiac insufficiency. Seizures begin most frequently during the first day of life,[87–89] and 60% of the patients with this condition have already had fits by 12 h.[30] The seizures are often isolated at the start. Of the cases of neonatal status epilepticus 75–85% have been attributed to hypoxic insult.[30] Seizures may be of any type and are often prolonged and refractory to anticonvulsant therapy. Brown[90] has pointed out that the seizures usually occur when infants show a transition in muscle tone. The interictal EEG is of the 'tracé paroxystique' or inactive tracing type in severe cases.[91] The convulsions may be extremely difficult to control by drugs. Levene *et al.*[92] have reported neonatal convulsions due to asphyxia to occur in 2 per 1000 full-term infants. Delivoria-Papadopoulos and Mishra studied the mechanism of cerebral hypoxia in the fetus and newborn that results in neonatal morbidity and mortality as well a long-term sequelae such as mental retardation, seizure disorders and cerebral palsy. Using electron spin resonance (ESR) spectroscopy they demonstrated that tissue hypoxia results in increased free-radical generation in the cortex of fetal guinea pigs and newborn piglets.[93] Normally, more than 80% of the oxygen consumed by the cell is completely reduced by cytochrome oxidase to reactions with the cytoplasm and mitochondria that produce a superoxide anion radical. To protect cells from the deleterious effects of free radicals, a number of enzymatic and non-enzymatic defenses such as catalase, superoxide dismutase, glutathione peroxidase, ascorbic acid and vitamin E are present in cells.

The hypoxia-induced increase in lipid peroxidation products was shown to be also associated with a decrease in cell membrane Na^+,K^+-ATPase activity. The direct demonstration of production of free radicals during hypoxia was documented by measuring the signal of spin adducts using ESR, which allows direct identification and characterization of free radicals.[94] The brain tissue hypoxia modified the NMDA receptor ion channel recognition and modulation sites. A higher increase in NMDA receptor agonist-dependent Ca^{2+} in synaptosomes was demonstrated. The increase in intracellular Ca^{2+} may activate several enzymatic pathways such as phospholipase A and metabolism of arachidonic acid by cyclooxygenase and lipoxygenase, conversion of xanthine dehydrogenase to xanthine oxidase by proteases and activation of nitric oxide synthase. In summary, studies demonstrated that cerebral tissue hypoxia results in increased free-radical generation that may lead to the oxidation of brain cell membrane lipids, membrane enzymes, receptor proteins as well as the nuclear DNA precipitating the hypoxic neuronal injury in the fetus and newborn.

Table 9.3 Correlation of time of onset of seizures and etiology (adapted from Hill and Volpe[73] with permission)

Most frequent time of onset	Etiology of seizures
< 48 h	Hypoxic-ischemic encephalopathy Intracranial hemorrhage Hypoglycemia Sepsis-meningitis Congenital viral infection Drug withdrawal Local anesthetic intoxication Pyridoxine dependency Non-ketotic hyperglycinemia Urea cycle disorders
48–72 h	Cerebral dysgenesis Cerebral infarction Ketotic hyperglycinemia Urea cycle disorders
> 7 days	Cerebral dysgenesis Organic acidopathies Amino acidopathies Urea cycle disorders Bacterial meningitis

Intracranial hemorrhage

This condition is often difficult to establish conclusively as a primary cause of seizure distinct from hypoxic-ischemic encephalopathy or traumatic injury, because of the frequent association of these conditions. There are three important types of hemorrhage according to localization:

Intraventricular hemorrhage is a very common lesion in extremely premature infants, but germinal matrix/IVH is associated relatively rarely with

seizures. However, large IVHs, especially if there is associated intraparenchymal hemorrhagic infarction (which accounts for approximately 15% of all examples of IVH), may occur together with generalized tonic seizures, most often as part of a catastrophic deterioration evolving to coma and respiratory arrest. This clinical setting and type of seizure signify an ominous prognosis.[30]

Subdural hemorrhage is most commonly associated with traumatic delivery or non-accidental shaking injury. The associated cerebral contusion frequently results in focal clonic and subtle seizures. Such seizures most commonly begin during the first 48 h of life.[95] Subdural hemorrhage occurring as a result of tentorial tears is not necessarily fatal and may have a relatively good prognosis.

Primary *subarachnoid hemorrhage*, especially of a minor degree, is a very common occurrence in newborns and is usually not of major clinical significance. When seizures occur secondary to the subarachnoid hemorrhage in the full-term infant, they occur most commonly on the second day of life.[96] During the interictal period, affected infants often appear remarkably healthy, leading to the descriptive term 'well baby with seizures'. Spanish authors have reported neonatal convulsions and subarachnoid hemorrhage after paroxetine treatment in the third trimester of pregnancy.[97]

Neonatal stroke

Billard et al.[98] reported eight infants presenting focal seizures between the age of 8 and 72 h and all had evidence of cerebral infarction on the computed tomography (CT) scan. Only three of these infants showed evidences of subsequent handicap. Venkataraman *et al.* studied 11 full-term babies with neonatal stroke. Seizure was the most common presenting sign, with paucity of other focal neurological deficits.[99]

The few days before and after birth are a time of special risk for stroke in both mother and infant, probably related to activation of coagulation mechanisms in this critical period. Arterial ischemic stroke around the time of birth is recognized in about 1 in 4000 full-term infants, and may present with neurological and systemic signs in the newborn.[100] Neonatal seizures are most commonly the clinical finding that triggers assessment. In other children, prenatal stroke is recognized only retrospectively, with emerging hemiparesis or seizure after the early month of life. Risk factors for perinatal stroke include hereditary or acquired thrombophilias and environmental factors. Perinatal stroke underlies an important share of congenital hemiplegic cerebral palsy, and probably some spastic quadriplegic cerebral palsy and seizure disorders. There is much to be learned about the natural history of perinatal stroke, and there are as yet no evidence-based strategies for prevention or treatment.

Intracranial infection

Both the bacterial and the non-bacterial types of intracranial infection are common causes of neonatal seizures. Seizures secondary to bacterial meningitis are most likely to occur after the first week of life. Like the common metabolic disturbances, they are of particular concern because definitive therapy is of primary importance. Of the bacterial infections, meningitides secondary to group B streptococci, *Listeria monocytogenes* and *Escherichia coli* are the most common. In addition to bacterial meningitis, meningo-encephalitis may occur due to herpes simplex, Coxackie and toxoplasmosis. In the latter case, toxoplasmosis may be acquired in early pregnancy and extensive brain damage may have occurred by the time of delivery. Cytomegalovirus and rubella infections acquired in early pregnancy may also present with neonatal fits, without any signs of other infections. Septicemic infants, without meningitis, may also develop seizures. The cause of this can be the complication associated with infection and hypoglycemia or hypotension. Diarrhea due to infection may cause disturbances in the sodium balance, which may also cause seizures. Herpes simplex virus type 1 (HSV-1) encephalitis is the most common cause of acquired epilepsy in human. Chen *et al.* studied *in vitro* HSV-1-infected organotypic hippocampal slice culture to elucidate the underlying mechanisms of HSV-1-associated acute seizure activity. The results suggest that a direct change in excitability of the hippocampal CA3 neuronal network and HSV-1-induced neuron loss resulting in subsequent mossy fiber reorganization may play an important role in the generation of epileptiform activity.[101]

Metabolic disturbances

Although different kinds of metabolic derangement and certain intoxications are associated with convulsive phenomena in newborn infants, abnormalities of glucose and divalent cation homeostasis are the most frequent.

Hypoglycemia is most common in infants who are small for their gestational age and in infants of mothers with diabetes or gestational diabetes.[102] The brain can use few sources of energy, glucose being the most important. Hypoglycemia may cause devastating neurological damage when the brain's energy reserves are exhausted. The most important determinant of the occurrence of neurological signs in neonatal hypoglycemia appears to be the duration of this. Monod *et al.*[103] observed that among the prematures, hypoglycemia may be very low, without any seizures. Neurological symptoms consist most commonly of jitteriness, stupor, hypotonia and apnea, as well as seizures. The onset of the seizures is usually early, often on the second postnatal day. In many instances hypoglycemia occurs in the context of hypoxic-ischemic encephalopathy, IVH or infection. Secondary

transient hypoglycemia may occur in association with meningitis or following exchange transfusion. Persistent hypoglycemia may be observed in certain inborn errors of metabolism, e.g. galactosemia, fructosemia, leucin sensitivity, glucos-6-phosphatase deficiency, etc. Other rare disorders that must be considered include the Beckwith–Wiedemann syndrome, pancreatic islet cell tumors and anterior pituitary hypoplasia. The importance of early diagnosis and treatment of hypoglycemia has become more critical. Recent data suggest that even moderate hypoglycemia in the premature newborn may be associated with poor outcome.[104]

Electrolyte disturbances

Divalent cations are regulators of the ion fluxes associated with membrane depolarization. Because of this, abnormalities in their homeostasis are more likely to result in electrical seizures than in the homeostasis in monovalent cations. However, both hyponatremia and hypernatremia have been associated with seizures because of derangements in cell volume. The most common cause of these disturbances is inappropriate fluid therapy. In infants with serious neurological or pulmonary disease, the syndrome of inappropriate secretion of antidiuretic hormone may result in severe hyponatremia and seizures.[30]

Hypocalcemia/hypomagnesemia

Infants with seizures due to hypocalcemia are usually alert between seizures and the seizures are often multifocal and migratory. Hypocalcemia occurs at two peak times in the newborn period. Early hypocalcemia, which occurs in the first 2–3 days of life, seems to be in association with other potential etiologic factors that appear to play a major role in the origin of the convulsions. The definition of hypocalcemia is taken to be serum calcium below 1.75 mmol/l (7 mg/dl). The ionized calcium is a more important predictor; unfortunately, this is a difficult measurement in clinical practice. Ionized calcium is responsible in part for axonal conduction as well as neuromuscular function. In addition, magnesium is an important comineral for the function of the neuromuscular junction.[10] Functional hypocalcemia can be diagnosed by assessing cardiac neuromuscular conduction on the electrocardiograph. Early-onset hypocalcemia is often observed in the context of hypoxic-ischemic encephalopathy, in newborns with low birth weight, in prematures with hyaline membrane disease and in infants of diabetic mothers. In rare cases, early severe hypocalcemia is due to parathyroid hypoplasia or aplasia. The commonest condition associated with absent parathyroid is Di George syndrome. An infusion of intravenous calcium may be useful for determining whether seizures are caused directly by the low calcium level. Late-onset hypocalcemia is relatively uncommon and presents as an isolated condition without other associated or underlying diseases. Classically, such hypocalcemic infants are large, term infants who have avidly consumed a milk preparation with a suboptimal ratio of phosphorus to calcium and phosphorus to magnesium, e.g. cow's milk. The neurological syndrome is consistent and distinctive, and it consists primarily of hyperactive tendon reflexes. Hypocalcemia fits are treated with intravenous 10% calcium gluconate and the seizures should stop soon after administration. Hypomagnesemia often coexists with hypocalcemia and convulsions are likely to occur at serum levels below 0.3 mmol/l. Giving magnesium alone to hypocalcemic infants caused both serum magnesium and calcium to rise.[65] Manzar mentioned a case of a newborn with late-onset seizure with hypocalcemia, hyperphosphatemia and raised parathyroid hormone. The infant did not have any stigmata of pseudohypoparathyroidism. The hypocalcemia was initially resistant to calcium therapy but responded to vitamin D analog therapy. Transient pseudohypoparathyroidism was entertained.[105]

Congenital abnormalities

Tables 9.4 and 9.5 list inborn errors of metabolism and neuronal storage diseases that may cause neonatal fits.[10]

Pyridoxine dependency is a rare, autosomal recessive disorder of the pyridoxine metabolism. Pyridoxine is a cofactor necessary for the synthesis of the inhibitory neurotransmitter GABA, a deficiency that may presumably produce severe neonatal seizures recalcitrant to all treatment except the administration

of large doses of pyridoxine.[106] Fewer than 100 patients have been reported, and only four reports have included examples of brain imaging findings.

Gospe *et al.* found in their patient progressive magnetic resonance changes – dilatation of the ventricular system, cortical and white matter atrophy. The abnormalities may be due to chronic excitotoxicity caused by an imbalance of cerebral levels of GABA and glutamic acid.[107]

Kernicterus

Bilirubin is a neurotoxic substance that may cause a clinical syndrome in severely jaundiced infants, referred to as kernicterus. The most severe form of this condition includes opisthotonus, sunsetting and neonatal tonic seizures.

Any abnormality in the cerebral development may cause neonatal seizures but disorders of neuronal migration are particularly likely to be associated with abnormal neurological behavior and fits. Seizures in these infants are usually very difficult to control. Genetically determined disorders such as Sturge–Weber syndrome, tuberose sclerosis and incontinentia pigmenti may also rarely cause neonatal convulsion.[10] Hennel *et al.* found in their case with incontinentia pigmenti evolution of acute microvascular hemorrhagic infarcts in the periventricular white matter in the first week of life. The associated magnetic resonance angiogram findings consisted of decreased branching and poor filling of intracerebral vessels.[108] Table 9.6 lists some congenital cerebral abnormalities that may be associated with neonatal convulsion.[10] Wada *et al.* show a female patient who has enlargement of lateral ventricles and atrophy of the brain associated with infantile spasms. The ventriculomegaly was documented *in utero* at as early as the 28th week of gestation with lactic acidosis due to deficiency of the pyruvate dehydrogenase E1 (alpha) subunit, demonstrating that the changes characteristic of this disease can occur antenatally. The mechanism of infantile spasms in this disease may be linked to mosaicism of the brain cells involving the normal enzyme and the mutant enzyme.[109]

Intoxications

Local anesthetics

Seizure may occur when local anesthetics are administered to the mother for episiotomy, or for other types of maternal analgesia. The major clinical features of toxicity include a very low Apgar score, apnea or severe hypoventilation, severe bradycardia and hypotonia and severe bradycardia. Seizures occur early and are commonly tonic in nature. These features are also seen in hypoxic-ischemic encephalopathy. There are two distinguishing features that aid in its differentiation from perinatal hypoxia: the absence of the pupillary response to light and the absence of eye movement with the oculocephalic (doll's eye) maneuver. The absence of these signs is unusual in hypoxic encephalopathy during the first 12 h of life. Management depends on prompt recognition. The half-life of the drug in the blood is approximately 8–10 h.

Methylxanthine

Both theophyllin and caffeine overdosage have resulted in seizures in the neonatal period.[8]

Drug withdrawal

Passive addiction of the newborn and drug withdrawal may be related to maternal ingestion of cocaine, narcotic-analgesics and sedative hypnotics. Many findings demonstrate that exposure to alcohol during brain development can permanently alter the physiology of the hippocampal formation, thus promoting epileptic activity, enhancing kindling and facilitating spreading depression.

Epileptic syndromes in the neonatal period

Subgroups can be recognized among the neonatal convulsions on the basis of the age at onset and/or characteristics of fits and associated neurological manifestations. Although there is some relationship between the age at the onset of seizures and the associated clinical manifestations on the one hand, and etiology and prognosis on the other, it is difficult to isolate well-defined 'epileptic syndromes' during the neonatal period. Most groupings are rather loose, and only familial seizures and a few rare syndromes such as neonatal myoclonic encephalopathy[110,111] stand out clearly.

Neonatal myoclonic encephalopathy[30] is a syndrome characterized clinically by the occurrence of erratic, fragmentary myoclonus of early onset, usually in association with other types of seizures and, from the EEG viewpoint, by a stable suppression–burst

pattern persisting after 2 weeks of age.[110,112,113] Seizures associated with the myoclonus include partial motor seizures, massive myoclonias and tonic spasms that are not usually observed before 4–5 months of age. The onset is in the neonatal period and all affected infants have severe neurological impairment; half of them die before the age of 6 months.[112] Familial cases are frequent; a recessive inheritance is probable in some of the cases. The syndrome may result from undetermined metabolic defects or from brain malformations.[114] The relationship of neonatal myoclonic encephalopathy with early infantile epileptic encephalopathy (Ohtahara's disease) is not entirely clear. The two conditions have several clinical and EEG characteristics in common, including the occurrence of tonic spasms and a suppression–burst pattern. Lombroso[115] accepts that early myoclonic encephalopathy is distinct from the Ohtahara syndrome but considers the latter only as a variant of infantile spasms.

Benign familial epilepsy

An autosomal dominant syndrome of neonatal seizures unrelated to recognized etiologies has been described.[116] The gene for this transient, primary epilepsy of infancy has been recently assigned to chromosome 20q.[117] The onset of the seizures is usually on the second or third postnatal day, and in the interictal period the infants appear remarkably well. Seizures may occur at a frequency of 10–20 per day or even more. The disorder is usually self-limiting. Neurological development is normal. Because of the benign course yet striking clinical presentation, the history of affected family members might easily be missed unless specifically sought.[118]

The 'fifth-day fits' syndrome is characterized by repeated seizures that occur between the third and the seventh days of life in full-term neonates without any abnormal gestational and obstetric antecedent and without any neurological abnormality during the first days of life. According to Dehan *et al.*,[119] the attacks are of two main types: clonic focal or multifocal convulsions and apneic spells. They last on an average 20 h. The interictal EEG shows preserved rhythms and a normal organization of sleep. Bursts of alternating delta-rhythms or 'théta pointu alternant' are observed in three-quarters of the patients. Dehan *et al.* and other authors have underlined the benignity of fifth-day fits when all the criteria of the syndrome were present.[119–121]

Intrauterine seizures have been suspected in several reports.[122,123] Movements identified by mothers as probably convulsive in nature occur mainly in the last days or weeks of gestation. Pyridoxine dependency is a possible cause of intrauterine convulsions,[122,124] but other causes, especially brain dysplasia, can be suspected.

Mulley *et al.* in their review describe the significant number of new gene associations with epilepsy syndromes that have emerged during the past year, together with additional mutations and new electrophysiological data relating to previously known gene associations. Idiopathic epilepsies are predominantly a family of channelopathies. The corresponding ion channel mutations show measurable *in vitro* abnormalities that are likely to affect transmission between neurons. In their paper autosomal dominant juvenile myoclonic epilepsy was demonstrated to be a channelopathy associated with a GABAa receptor, (alpha) 1 subunit mutation. Benign familial neonatal infantile seizures were delineated as another channelopathy of infancy, by molecular characterization of sodium channel, (alpha) 2 subunit defects. A sodium channel, (alpha) 2 subunit defect was previously found to be associated with generalized epilepsy with febrile seizure plus (GEFS+). Similarly, the clinical spectrum associated with potassium channel, KQT-like mutations was extended to include the channelopathy, myokymia and neonatal epilepsy. Mutations in the non-ion channel genes, leucin-rich, glioma inactivated 1 gene and Aristaless related homebox gene (causative gene in X-linked infantile spasms) have emerged as important causes of their specific syndromes, with mutations in the last gene frequently underlying X-linked mental retardation with epilepsy.

There are now nine ion channel subunit genes implicated in 10 syndromes of idiopathic epilepsy.

The boundaries between clinically defined 'idiopathic' and 'cryptogenic' epilepsies are being blurred by the demonstration of sodium channel mutation in the infantile syndrome of severe myoclonic epilepsy in infancy. Genetic heterogeneity has been so far proven for three of the syndromes: autosomal dominant frontal lobe epilepsy, benign familial neonatal seizure and GEFS+. Considerable phenotypic heterogeneity occurs in association with mutations in four of the genes described in GEFS+: sodium channel, (beta) 1 subunit (SCN1B); sodium channel, (alpha) 1 subunit (SCN1A); sodium channel, (alpha) 2 subunit (SCN2A) and GABAa receptor, (gamma) 2 subunit (GABRG2).

Whether progress toward understanding the genetic basis for the rare epilepsies will relate to the development of therapies for the common epilepsies remains to be established, but progress to date has provided remarkable insights into the neurobiology of the epilepsies.[125]

Diagnosis

First- and second-line investigations in infants with seizures are listed in Table 9.7.[10]

Diagnostic evaluation must begin with a careful history and physical examination. From the maternal history it is important to determine the possibility of drug abuse, intrauterine infection and genetic or metabolic disorders. Laboratory investigations should focus initially on treatable causes, such as metabolic

Table 9.7 First- and second-line investigations in infants with seizures (adapted from Levene[10] with permission)

Sugar chromatography for galactose
Pyridoxine infusion
Computer tomography or magnetic resonance scan

disorders and infection. Lumbar puncture or treatment with meningitic doses of antibiotics and acyclovir may be indicated. Rapid diagnosis of the underlying etiology is of major importance to enable the institution of specific and definitive therapy as well as for accurate prediction of the outcome. However, in such instances the diagnosis of a specific underlying disease may have important genetic implications for the family. The time of the onset of seizures may assist in determining an underlying etiology. If the initial screening investigations fail to confirm the etiology, additional studies may be obtained, e.g. CT, cranial ultrasonography, magnetic resonance imaging, serum amino acids, blood pyruvate and lactate, urine amino acids and organic acids, maternal and fetal titer of TORCH [toxoplasma, others, rubella, cytomegalovirus, herpes (hepatitis)] group and syphilis, and urinary drug screen.[30,126]

Differential diagnosis

Jitteriness is a common movement disorder of the newborn, which may be misinterpreted as epileptic seizures. The major features that distinguish jitteriness from seizures are summarized in Table 9.8.[118] The distinction between jitteriness and seizures may be difficult at times because both may occur in a similar context, e.g. hypoxic-ischemic encephalopathy, hypoglycemia, hypocalcemia. Drug withdrawal is another common cause of jitteriness.[127]

EEG in diagnosis

Despite advances in neuroimaging techniques over the past decades that have helped identifying structural lesions of the central nervous system, EEG continues to provide a valuable insight into brain function by demonstrating focal or diffuse background abnormalities and epileptiform abnormalities. It is an extremely valuable test in patients suspected of epilepsy and in patients with altered mental status and coma. Patterns in the EEG make it possible to clarify the seizure type; it is indispensable for the diagnosis of non-convulsive status epilepticus and for separating epileptic from other paroxysmal (non-epileptic) episodes. There are EEG patterns predictive of the cause of the encephalopathy (i.e. triphasic waves in metabolic encephalopathy) or the location of the lesion (i.e. focal polymorphic delta activity in lesions of the subcortical white matter). An EEG is most helpful in assessing normal or abnormal brain functioning in a newborn because of the serious limitation in performing an adequate neurological examination on the neonate who is intubated or paralyzed for ventilatory control. Under such circumstances, the EEG may be the only tool available to detect an encephalopathic process or the occurrence of epileptic seizures.[128] Neonatal EEG abnormalities may be transient and of benign significance, or may be persistent and severe, indicating neurological morbidity. The clinical usefulness of the EEG is enhanced by recording as soon as possible after the onset of symptoms of the suspected insult, although during the first day of life the stress of birth and the effect of anesthesia may complicate the interpretation of the tracing. If an EEG appears abnormal, recordings may be repeated in 48–72 h, and at weekly or biweekly intervals until discharge or normal patterns appear. Continuous EEG monitoring may be of value for the diagnosis of seizures in newborns that are treated with muscular paralysis to improve assisted ventilation.[129]

The major EEG correlates of neonatal seizures include focal or multifocal spikes or sharp waves and focal monorhythmic discharges. Care must be taken not to confuse epileptiform activity and normal sharp transients in recordings of premature newborns or 'tracé

alternant' patterns of quiet sleep in term newborns with seizures. Abnormal motor activity is associated with EEG abnormalities on routine surface recordings in only approximately one-third of the recordings.[126] Several modifications of electroencephalographic techniques have been developed recently to improve the quantification of the frequency and the duration of the seizure activity. These include serial or continuous EEG recordings, and simultaneous video-EEG recordings. Cerebral function monitoring (CFM) is widely used to detect neonatal seizure but comparing with video recording, the observer usually detects generalized seizures but approximately half of all focal neonatal seizures may be missed using CFM only. The CFM may thus be useful for long-term monitoring alone. The digital EEG technology can improve the accuracy of EEG interpretation and lead to more accurate recognition of electroencephalographic features and thereby improve the diagnostic utility of EEG.[130] Clinical interpretation of the EEG during this age-period is difficult because of its rapidly changing morphology. The main characteristics of EEG maturation in preterm infants were a progressive spatio-temporal differentiation, with an increase of rhythmic activities and a decrease of discontinuity. A strong relationship was found between the postmenstrual age of the infants and EEG maturity, but there were exceptions to this rule. A longer duration of extrauterine life had a small accelerating influence on EEG maturation. The relationship between EEG pattern types and behavioral states becomes more stable with increasing age.[131]

Clinically significant and common EEG abnormalities noted in the neonatal period are the next:[132]

Isoelectric pattern in the absence of hypothermia or acute systemic disorders indicates severe and diffuse cerebral dysfunction and is associated with a high incidence of neurological sequelae in survivors.

The paroxysmal pattern, which is characterized by suppression–burst activity, must be distinguished from the discontinuous pattern of the normal preterm, and consists of irregular bursts of abnormal activity on an isoelectric or markedly attenuated ground. The paroxysmal pattern is usually associated with neurological sequelae.

Excessively slow background pattern occurs most commonly in abnormal term newborns, who lack the usual spectrum of beta, delta and transients, are poorly reactive and are not associated with normal wake–sleep cycles; the incidence of neurological sequelae is high.

Persistent asymmetry of the background (reduced by 50%) is sometimes associated with underlying structural lesions, including intracranial hemorrhage.

Excessive interhemispheric asynchrony is commonly noted in association with other EEG abnormalities.

Positive rolandic sharp waves may occur in association with IVH in the newborn, and the positive component is of high amplitude, may be broad in configuration and may be followed by a lower-amplitude negative wave, as well as with other separate focal abnormalities. Positive rolandic sharp waves have also been recorded in neonatal infants with non-hemorrhagic disorders and in apparently normal preterm infants.

Electroencephalographic seizures in preterm and term newborns are associated with a combined mortality and neurological morbidity of approximately 30%; they appear as ictal, repetitive focal or generalized spiking, rhythmic focal or generalized delta and occasionally rhythmic alpha or theta-like activities. There are few specific pathologic EEG patterns associated with specific illnesses (neonatal herpes encephalitis, congenital malformations or Aicardi syndrome).

Patrizi *et al.* observed the characteristics of EEG ictal activity in preterm and full-term infants.[133] They investigated the trend for a closer relationship between behavioral changes during the electroencephalographic seizure when the background activity was normal or moderately abnormal than when background activity was severely abnormal. In both, preterm and full-term infants, the most common site of seizure origin was the temporal lobe. Full-term infants commonly had sharp waves, spikes, sharp and slow waves and spike and slow waves at the onset of the ictus while rhythmic delta activity was most common in the preterm infants. Preterm infants typically had a regional onset to the ictus whereas full-term infants most frequently had a focal onset. There was no clear relationship between onset, morphology, frequency or propagation of the ictal discharge in both age groups. The results demonstrate that while the type of ictal discharge is related to gestational age, there is a rich variety in the onset, morphology and frequency of the ictal discharges in both groups. Generally, neonatal ictal patterns lack a close correlation with the underlying pathology.

Therapy

The newborn exhibiting seizure activity should be treated on an urgent basis with adequate support ventilation and perfusion, correction of any underlying metabolic derangements and the use of anticonvulsant medication.

Treatment of neonatal seizures is directed toward minimizing physiological and metabolic derangements that are associated with the epileptic process and to prevent recurrence of seizures. The choice of anticonvulsants in the treatment of neonatal seizures should consider the unique characteristics of neonatal seizures and the efficacy, toxicity and pharmacologic appropriateness of the drug. All aspects of toxicity are to be considered, but two factors of immediate concern in neonates are changes in heart rate and effects on brain growth.[132] The generally used order of antiepileptic drugs and their doses are indicated in Table 9.9.

Table 9.9 Treatment of neonatal seizures (adapted from Younkin[2] with permission)

Initial therapy

1. Phenobarbital 20 mg/kg i.v.; if seizures continue, phenobarbital 10 mg/kg i.v. every 15–30 min to a total of 40 mg/kg or to a serum level of 40 μg/ml
2. Phenytoin 20 mg/kg i.v.; if seizures continue, phenytoin 10 mg/kg intravenously to a serum level of 20 μg/ml. If seizures continue
3. Diazepam 0.1–0.3 mg/kg i.v. repeated as necessary, or 0.7–2.75 mg/h continuous intravenous infusion
   Lorazepam 0.05–0.10 mg/kg i.v. repeated as necessary
   Paraldehyde 200–400 mg/kg i.v. over first hour, then 16 mg/kg/h; adjust infusion rate based on EEG response

Since clinical detection of seizures is frequently inaccurate, it is helpful to have continuous and video-EEG monitoring during the initiation of therapy. The EEG is especially helpful in making decisions regarding additional diazepam or lorazepam, or in adjusting the rate of paraldehyde infusion

Maintenance therapy

1. Phenobarbital 3–4 mg/kg/day i.v., i.m. or orally, starting 12 h after the loading dose
2. Phenytoin 3–4 mg/kg/day i.v. starting after the loading dose
3. Primidone 12–20 mg/kg/day

Phenobarbital continues to be the first-line drug for the treatment of neonatal seizures. A loading dose of up to 40 mg/kg achieves therapeutic levels in the serum within a short time. Therapeutic levels are 20–40 mg/l (80–160 μmol/l). Babies who are not artificially ventilated can be rendered apneic by a single loading dose of 40 mg/kg, and it is usual to give two separate doses of 20 mg/kg in this situation. If clinical and EEG-revealed seizures persist despite a phenobarbital concentration greater than 40 μ/ml, phenytoin should be added; approximately one-third to half the babies with seizure respond to phenobarbital, about 90% respond to a combination of phenobarbital and phenytoin. The dose of phenytoin is 15 mg/kg given as an intravenous 'push' at a rate no greater than 1 mg/kg/min. Phenytoin is probably the best choice as second-line treatment in babies who fail to respond to phenobarbital, but problems with hypotension and arrhythmias have been reported when there is hidden myocardial damage accompanying hypoxic-ischemic encephalopathy.

Most of the benzodiazepines have been tried in the newborn. The use of diazepam is controversial. Diazepam has a very long half-life in babies, of approximately 30–75 h, and because of the respiratory depressant effects that occur when the levels accumulate this drug is not suitable for prolonged infusion. Lorazepam and clonazepam are also given; the latter is traditionally given intravenously or as an infusion. Hypersalivation and increased bronchial secretion are frequent side effects. Midazolam is a newer benzodiazepine that has proved effective in treating status epilepticus. Midazolam has been reported to cause myoclonic jerking and dystonic posturing in preterm babies when it was used for sedation. The neurodevelopment outcome was better in a group of preterms sedated with morphine, than it was when midazolam was used.

There is very little published experience with any other antiepileptic drug in the newborn. Paraldehyde was popular during the 1970s and 1980s, but it is now difficult to obtain. Sodium valproate has hepatotoxicity. Vigabatrin is not available in an intravenous form, and there is a risk of incurring visual field effects, which cannot be monitored precisely in babies. There is virtually no neonatal experience with lamotrigine or carbamazepine, or with other, new antiepileptic drugs, like oxcarbazepine, gabapentin, topiramate. In animal models the acute and chronic effects of hypoxia can be prevented by pretreatment with topiramate. Topiramate was administered before the hypoxic insult and prevented the expression of the hypoxia-induced seizure.[134] Anticonvulsant therapy must be tailored to the individual needs of the child. Most neonatal seizures are secondary to an acute cerebral insult and thus tend to resolve within 2–4 days. If there has been status epilepticus or if seizures have not been controlled with phenobarbital alone, we continue anticonvulsants for at least 3 months.[2]

Specifics of the pharmacology of antiepileptic drugs in neonates

Binding profile

Painter *et al.*[135] found that there is significant correlation between phenobarbital and phenytoin *in vitro* binding and the total protein and albumin concentration.

Phenobarbital is exclusively but weakly albumin bound. The finding that *in vivo* phenobarbital binding was not significantly correlated with total protein or albumin may be explained by the influence of other factors known to affect albumin binding, such as bilirubin concentration, pH changes, the elevations of free fatty acid concentration and drugs administered to critically ill neonates.

Half-life

Morselli *et al.*[136] studied the influence of age on the half-life of diazepam. The metabolic pathway of diazepam develops only some time after birth, so premature babies show a significantly longer half-life than full-term infants. Carbamazepine autoinduces its own biotransformation, usually during the first 4–6 weeks of treatment. Beginning at a relatively low dose and progressively increasing the dose can avoid the fall in drug concentration.

Toxicity

Phenytoin toxicity is known to cause cardiac arrhythmias and exacerbate seizures. Elevated free concentrations of phenobarbital are known to cause hypotension and respiratory depression. Phenytoin has less of a sedative effect than phenobarbital and clonazepam, thus allowing a more reliable clinical assessment of improvement.[137] Interpatient variability of the various antiepileptic drugs is extensive in newborns, and intraindividual variation occurs in all premature and full-term newborns during the neonatal period. The extensive variability means that the therapy should begin with a relatively small dose, which is increased stepwise until either seizures are controlled or side effects occur.[138]

The effect of antiepileptic drugs on the EEG

Bell *et al.*[139] show a marked depressant effect of phenobarbitone and diazepam on the EEG in newborn babies. The effect of sedation on the maximum interburst interval was greater than expected, particularly when compared to reports on adults.[140] The authors suppose that the drugs are acting on subcortical generators, such as the thalamus and reticular formation, which play a major role in maintaining the background EEG in newborns. Determination of effectiveness of therapy is important in the management of neonatal seizures. With the antiepileptic treatment the clinical control of the convulsions was obtained in more them 80% of the cases, while control of the electrical convulsions was obtained only in 62.5%. There was a highly significant association between favorable response to treatment and normal neurological examination at hospital discharge and at 1 year of age. It is necessary to confirm by means of EEG record the neonatal clinical convulsion before and after having established the anticonvulsive treatment, as the control of electrical convulsion improves the neurological outcome.[141]

Table 9.10 Prognosis of neonatal seizures – relation to neurological disease (adapted from Volpe[30] with permission)

Neurological disease	Normal development (%)*
Hypoxic-ischemic encephalopathy	50
Intraventricular hemorrhage**	10
Primer subarachnoid hemorrhage	90
Hypocalcemia	
Early onset	50†
Late onset	100
Hypoglycemia	50
Bacterial meningitis	50
Development defect	0

Prognosis is for those cases with the stated neurological disease when seizures are a manifestation (thus, value usually will differ from the overall prognosis for the disease)
*Values are rounded off to the nearest 5%; **usually, severe intraventricular hemorrhage associated with major periventricular hemorrhagic infarction; † represents primarily that prognosis approaches later-onset hypocalcemia if no or only minor neurological illness is present

Long-term treatment

There is little agreement on how long to continue anticonvulsant therapy in the neonate. We agree with the opinion of Levene, who stops all drugs when the infant has had no seizure for 7 days as long as they show no neurological abnormality.[10] In those in whom seizures recur or who are neurologically abnormal, medication is continued for 3 months, when they are reviewed. Drugs are stopped if the infant appears to be neurologically normal.

Prognosis

Several factors may influence the neurological outcome of neonates who have clinical seizures. These include the nature and degree of the underlying neuropathologic process, the possible adverse effects of epileptic activity on the developing brain, the secondary effects of the seizures (for example, hypoventilation or hypoperfusion) and the potential adverse effects of antiepileptic drugs. Several studies, however, suggest that seizures associated with certain etiologic factors have a worse prognosis than others (Table 9.10). Normal outcomes occur with increasing frequency in each of the following: hypoxic-ischemic encephalopathy,

intracranial hemorrhage, hypoglycemia, unknown cause, hypocalcemia.[23] In monitored infants in whom outcome was assessed only at hospital discharge, the highest morbidity and mortality were associated with seizures due to hypoxic-ischemic encephalopathy and the lowest in infants with subarachnoid hemorrhage, hypoglycemia and hypocalcemia.[24,28] The outcome of neonatal seizures is mainly dependent on their cause. Newborns with seizure were three times more likely (16%) to develop cerebral palsy than were controls (6%). The adverse outcomes observed after neonatal encephalopathy included both cerebral palsy and global developmental delay without motor deficit. For years it has been held that intellectual difficulties can only accompany motor problems in the postasphyxia syndrome, and are not seen in isolation, but this view is now beginning to be challenged. Over the years the reported outcome of neonatal encephalopathy with seizures has been remarkably consistent, with about 25% adverse outcomes in babies with moderate encephalopathy and 66% adverse outcomes (33% dead, 33% disabled) in those with severe encephalopathy, usually defined as coma. The background electroencephalogram abnormality consistently performs best as an outcome predictor; babies with burst suppression or a markedly attenuated background pattern that persists for longer than 12 h after birth have an adverse outcome.[57]

The role of EEG and the clinical neurological status

The extreme ends of the spectrum of clinical neurological status during the newborn period are useful indicators of the outcome. Thus, infants with flaccid coma and seizures generally have an unfavorable outcome, whereas infants with consistently preserved consciousness, activity, reflexes and tone have a more favorable outcome.[96] Infants, who had non-epileptic seizures consisting of tonic posturing and motor automatisms most often had hypoxic-ischemic encephalopathy, interictal lethargy or obtundation, the nature of the abnormal EEG, and poor short-term outcome. In the infants who had epileptic seizures (focal-clonic or focal-tonic), an association was noted with focal structural lesions, subarachnoid hemorrhage and metabolic abnormalities; and with interictal alertness, normal background EEG activity and a relatively good short-term outcome. These clinical and electrographic features suggest a delimited process rather than diffuse injury, which is probably the important factor in the relatively good short-term outcome of these infants. Abnormal neurological examination on discharge was a good predictor of an unfavorable outcome and abnormal polysomnographic recording a moderate predictor.[142] Several investigators have demonstrated that the interictal EEG is a useful prognostic indicator in the term infants. In one large series, a normal interictal EEG was associated with an 86% chance of normal development at the age of 4 years.[96] In contrast, infants with flat, periodic or multifocal EEGs had only an 8% probability of a normal outcome. The burst–suppression pattern, which is included in this group of EEGs with a poor prognosis has a superficial resemblance to the tracé alternant pattern seen in quiet sleep in the normal term newborn. Moreover, 25–35% of term newborns with seizures will have EEGs that are borderline, or demonstrate less marked abnormalities associated with an uncertain prognosis. Bergman *et al.*[6] demonstrated that the outcome of neonates who had manifested seizures for more than 3 days was associated with moderate or severe neurological injury. Babies with normal clinical examination, cranial ultrasound, CT and EEG results at 7–14 days usually have a good prognosis. Estimates of the incidence of epilepsy in children with neonatal seizures vary from 15% to 20%.[96]

Maternal epilepsy

Risk of maternal seizure

Pregnancy in women with epilepsy is accompanied by increased maternal and fetal risk. During pregnancy, seizure can cause maternal and fetal hypoxia and acidosis. The increase in seizure has been reported to occur mostly during the first trimester[31] or evenly throughout pregnancy.[25,26] In animal studies, estrogen is generally proconvulsant; conversely, progesterone generally has an anticonvulsant effect.[46] Status epilepticus is an uncommon complication of pregnancy, but when it occurs it carries high maternal and fetal mortality rates (31% and 48%, respectively).[26] The effects of non-convulsive seizures on the developing fetus are not clear.

Antiepileptic drug pharmacokinetics during pregnancy and lactation

The ideal management of women with epilepsy during pregnancy and the postpartum period involves achieving an optimal balance between minimizing fetal and neonatal exposure to the deleterious influences both of antiepileptic drugs and of seizures.[143] During the past decade, consensus guidelines have emphasized minimizing the associated risk by optimizing a woman's antiepileptic drug regimen and initiating supplemental folic acid before conception, and high-dose folate supplementation prior to conception and during organogenesis. However, there are no current guidelines regarding the best management once a woman with epilepsy becomes pregnant. Because of large intraindividual and interindividual variability, some authors recommend at least monthly monitoring of antiepileptic drug concentration.[144] During mothers

taking the most antiepileptic drugs indicate extensive transplacental transfer and low to moderate excretion into breast milk, the breast milk/maternal plasma concentration ratios less than 1.

In the newborn special care should be given to congenital malformations, vitamin K supplementation and symptoms of neonatal withdrawal. Breast-feeding should be allowed for the most anticonvulsive drugs unless the infant becomes symptomatic.[145]

Fetal anticonvulsant syndrome

The cause of this syndrome is probably multifactorial, but recent studies have indicated that antiepileptic drugs are a major offending factor.[15,20,21] If women with epilepsy are in need of antiepileptic drugs for seizure control, then monotherapy at the lowest effective dose should be employed. Offspring are at increased risk of major congenital malformation, a rate of 4–7% (2–3% in normal population), including congenital heart disease, cleft lip/palate, neural tube defects and urogenital defects. The risk of malformations increases with the number of antiepileptic drugs to which the fetus is exposed during pregnancy[10,11] and possibly with the daily amount or peak concentration of individual drugs. Data for valproic acid are suggestive of a dose–response effect for the risk of neural tube defects.[9,12,14,15]

Results of studies investigating cognitive outcome report an increased risk of mental deficiency in 1.4–6% of children of women with epilepsy (including both seizures[17] and *in utero* exposure to antiepileptic drugs[18]), compared with 1% of controls. Unlike major malformations, exposure to antiepileptic drugs during the last trimester may actually be the most detrimental for cognitive outcome.[19]

10 Oxygen toxicity

R. Bracci

Introduction

Although the toxic effects of oxygen have been known since the end of the 19th century,[1] the first evidence of a relationship between oxygen toxicity and neonatal diseases emerged in the early 1950s when retinopathy (ROP) was observed in premature infants breathing high concentrations of oxygen.[2] At about the same time, the red cells of the newborns were demonstrated to have increased susceptibility to oxygen damage.[3] This made it clear that oxygen species were particularly toxic to neonatal red cells, which were damaged by exposure to H_2O_2 and substances producing H_2O_2.

Great advances in our understanding of the toxic effects of oxygen were made in the years that followed, when oxygen toxicity was recognized to be due to the development of reactive oxygen species (ROS). The main ROS are the superoxide anion ($O_2^{\bullet -}$), hydrogen peroxide (H_2O_2), lipid peroxide (LOOH), peroxyl radicals $RO_2^{\bullet -}$ and the hydroxyl radical ($OH^{\bullet}$). Other important radicals are the highly reactive electron delocalized phenoxyl radical ($C_6H_5O^{\bullet}$) and nitric oxide ($NO^{\bullet}$).[4–8]

The term ROS includes free radicals, which are atoms or molecules with one or more unpaired electrons. Free radicals may react with other radicals, the unpaired electrons forming a covalent bond. The resulting molecule may decompose other molecules into toxic products. Free radicals may react with non-radical molecules in free-radical chain reactions, which are stopped by antioxidant enzymes or protein reactions. $O_2^{\bullet -}$ is the precursor of most ROS and a mediator in oxidative chain reactions. Dismutation of $O_2^{\bullet -}$ by superoxide dismutase (SOD) produces H_2O_2, which in turn may be fully reduced to water by glutathione peroxidase (GSH-Px) and catalase (Cat) or partially reduced to $OH^{\cdot}$. The latter reaction is called the Fentonl-Haber–Weiss reaction and is catalyzed by reduced transition metals.[4–9] ROS are involved in the following reactions:

$$O_2^{\bullet -} \xrightarrow{SOD} H_2O_2$$

$$H_2O_2 + GSH \xrightarrow{GSH\bullet Px} H_2O + \text{Oxidized glutathione}$$

$$H_2O_2 \xrightarrow{Cat} H_2O + O_2$$

A deficiency of scavenging reduces the detoxification of H_2O_2 and $O_2^{\bullet -}$ and increases the formation of $OH^{\bullet}$ by metal activation following the Fenton reaction:[4–9]

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^{\bullet} + OH^{-}$$

There is no specific scavenger for this radical: once released, OH reacts with lipoproteins, cell membranes, lipids, proteins, DNA, amino acids and other molecules. $OH^{\bullet}$ is one of the strongest oxidants in nature and may damage tissues.

Oxidative tissue damage may be mediated by reactive nitroxide species.[9–11] The reaction product of $NO^{\bullet}$ and $O_2^{\bullet -}$ is the unstable molecule peroxynitrite ($ONOO^{-}$), which is regarded as highly reactive and hence destructive, although it seems to be trapped by cellular antioxidants and other factors at low concentration.[12–14]

It is important to remember that free-radical reactions are a normal occurrence in living organisms and ROS are not necessarily toxic. Vascular tone appears to be modulated by the contrasting effects of $NO^{\bullet}$ and $O_2^{\bullet -}$.[15] Production of $O_2^{\bullet -}$ by phagocytes is an important defense mechanism but extracellular release of free radicals by activated phagocytes is itself a mechanism of tissue damage during inflammation.[5,16] Oxidative balance, therefore, is an intriguing question, and much recent research has increased our knowledge of the relations between ROS and human diseases.

The oxidative stress

An excess of ROS, as well as reactive nitrogen species, in relation to detoxification capacity is called 'oxidative stress', a term used to describe imbalance between oxidants and antioxidants, which is a potential cause of damage. If oxidative stress is mild, cell defenses may increase by a complex mechanism, which generally involves enhanced gene expression of ROS scavenging activities.[6,17,18] Severe oxidative stress is generally followed by cell injury, which may proceed to necrosis or apoptosis.[4–6] The involvement of oxidative stress in the mechanism of apoptosis has been extensively studied.[19–22]

The pathological conditions leading to oxidative stress are extremely complex. It is therefore necessary

to identify the biochemical basis of oxidative stress in order to prevent or treat oxygen toxicity.[4–7,9,23]

ROS production

Two main sites have been recognized as sources of ROS: the extracellular compartment with phagocyte activation and the endogenous source with mitochondrial function.[13] Both these sites are important in the pathogenesis of fetal and neonatal diseases.

Intracellular and extracellular production of ROS is provided by activated phagocytes.[24] ROS released inside phagocytes during infection and cytokine production can also alter the extracellular oxidative balance and harm tissues, since the cells undergo an efflux of $O_2^{\bullet -}$.[25] However, opsonization and activation of phagocytes is also known to occur during the hypoxanthine–xanthine oxidase reaction, and therefore during hypoxia–reoxygenation.[26]

Mitochondria are the primary sources of superoxide and it has been demonstrated that mitochondrial dysfunction is responsible for increased superoxide release. The mitochondrial electron transport chain contains redox centers, which may leak electrons to oxygen, constituting the primary source of $O_2^{\bullet -}$ in most tissues.[9] Research into myocardial physiology has demonstrated that under normal conditions, mitochondrial electron transport reduces 95% of oxygen to H_2O by tetravalent reduction without any free-radical intermediates and the remaining 5% is reduced by the univalent pathway in which free radicals are produced.[27,28]

During acidosis and hypoxia ischemia, mitochondrial dysfunction occurs and ROS production increases, while antioxidant defenses are depleted and metal ions may play a role in generating $OH^{\bullet}$.[29] ROS production by mitochondria may increase during hypoxia ischemia as a result of dramatic increases in cytosolic calcium concentrations. Since mitochondrial enzymes, such as pyruvate dehydrogenase and α-oxyglutarate dehydrogenase, are normally regulated by Ca cycling across the inner mitochondrial membrane, when intracellular Ca increases, cycling may become excessive and lead to increased ROS production, while structural alterations to the inner mitochondrial membrane may be followed by mitochondrial respiratory chain disorganization with further increases in ROS.[30–33] During asphyxia, $OH^{\bullet}$ production also increases as a result of the release of iron from safe sites.[27] Acidosis may therefore enhance $OH^{\bullet}$-mediated tissue injury.[34]

When oxygen is restored to ischemic tissue, free-radical reperfusion injury occurs by several mechanisms including the xanthine–xanthine oxidase reaction.[27,35] Reperfusion injury is considered the major source of oxidative stress and has been reported in heart, kidney, liver lung and intestine, particularly in necrotizing enterocolitis (NEC).[27,36]

Hyperoxia has been demonstrated to be associated with increased mitochondrial production of $O_2^{\bullet -}$.[9] The rate of mitochondrial $O_2^{\bullet -}$ production increases linearly with increasing oxygen concentration.[37] Under normobaric hyperoxic conditions, the only organs affected by ROS formation are the lungs, since they are the only ones in direct contact with atmospheric oxygen.[9] However, under hyperbaric conditions other tissues become exposed to a hyperoxic environment and increased ROS formation has been found in other organs.[9] Other sources of ROS include catecholamines, prostaglandins and xenobiotics, previously reduced by certain enzymes.[4–6]

Endothelial dysfunction caused by oxidative stress and leading to vascular disease has been extensively investigated.[38–41] The endothelium is normally protected against ROS; however, overproduction may occur via mitochondrial reactions, xanthine–xanthine oxidase reaction, vascular as well as phagocytic NAD(P)H oxidases and toxin-induced reactions. There is also a growing body of evidence linking blood cell and endothelial cell interactions in the enhanced production of ROS.[38–42] Oxidative stress to endothelium may be due to ROS or reactive NO-mediated peroxynitrite.[11] $O_2^{\bullet -}$ therefore promotes tissue damage by reacting with NO, reducing NO bioavailability and producing toxic $ONOO^-$.[38–41] The presence of non-protein bound iron during acidosis, hypoxia and infections causes $OH^{\bullet}$ release and may exacerbate ROS-mediated tissue injury.[10,19,41,43] The resulting vascular endothelial dysfunction elicits a number of maladaptive phenomena that impair normal healthy blood vessels. The normal vascular environment is lost, exposing the lumen to the possibility of thrombosis, while the decrease in NO production and enhanced endothelin 1 production leads to vasoconstriction,[38] which also seems to be enhanced by inhibition of PGI.[43] Endothelial injury due to oxidative stress has been demonstrated to play a key role in coagulation disorders by enhancing procoagulant activity.[44,45]

Antioxidants

The antioxidant system can be classified into two major groups: enzyme activities and low-molecular-weight antioxidants.[13] The enzyme group is represented in the reactions mentioned above. Other important antioxidant enzymes are thioredoxin reductase and glutathione transferase (GSH-T). It is important that $O_2^{\bullet -}$ dismutation be associated with balanced H_2O_2 detoxification. It has been suggested that overexpression of SOD may lead to deleterious effects if not balanced by GSH-Px.[46,47] This observation underlines the key role of GSH in protecting against oxidative stress.[48] The enzyme-based antioxidant system includes extracellular SOD, the only extracellular scavenger of $O_2^{\bullet -}$, which also plays a key role in scavenging $O_2^{\bullet -}$ produced in the extracellular compartment by phagocytes, endothelium and other mechanisms.[49]

The low-molecular-weight antioxidant group contains a large number of compounds that are capable of preventing oxidative damage by direct or indirect interactions with ROS. The effects of these molecules are complex, since the same molecule may have pro-oxidant or antioxidant effects depending on the

bioavailability, metabolism and tissue properties as well as interactions between enzymic and non-enzymic antioxidants. Ascorbic acid may have pro-oxidant and antioxidant properties.[50] Coenzyme Q (CoQ) is a source of $O_2^{\bullet -}$ when partially reduced and an antioxidant when fully reduced.[51] One of the most studied antioxidants is α-tocopherol, but competition between different forms and their uptake and the synergistic or inhibitory role of other compounds are not yet understood. Furthermore, non-antioxidant effects of α-tocopherol have been demonstrated.[52] Iron-binding proteins have the major antioxidant activity, protecting against metal-induced $OH^{\bullet}$ production.[53]

ROS in fetus and neonate

Excessive oxidative stress and particularly $OH^{\bullet}$ can impair cell function and induce apoptosis in rapidly growing structures. An oxidized state can also be beneficial, since ROS may activate transcription factors and promote fetal development, but both of which are sensitive to uncontrolled oxidative stress.[54] The effects of ROS are secondary to its direct toxicity and indirect effects, such as vasoconstriction in the lung or systemic circulation.[55,56] Another important condition of oxidative stress produced by $O_2^{\bullet -}$ and NO-derived free radicals is impaired placental function, which may lead to fetal growth retardation.[57]

Oxidative stress in the fetus and the newborn may result from decreased antioxidants, increased ROS or both. The fetus has a lower antioxidant capacity than older babies and adults. Free-radical scavenger enzyme activities and many other components of the antioxidant system are low. Studies in various animals have shown that the main ROS-detoxifying enzymes, GSH-Px, Cat and SOD, increase during intrauterine life.[58,59] At least in the lungs and liver, detoxifying reactions ruled by SOD, GSH-Px and Cat are fully expressed only after birth.[58,59] Scavenger activities involving GSH-T have been studied in the fetus and newborn and seem to vary widely in different animal species.[60]

In the human newborn, the scavenger enzyme activities were first investigated in erythrocytes: Cat and GSH-Px were found deficient in most of the infants, and SOD only in some.[46,61,62] SOD activity is reported to increase in the lungs of the human fetus during intrauterine life.[63,64] Normal values of GSH-Px have been reported in leukocytes of full-term newborns.[65]

Non-enzyme antioxidant factors are reported to be lower in the fetus and newborn than in adults and older babies,[66–68] partly because of deficient placental transfer of some antioxidants.[54] However, antioxidant capacity of neonatal plasma is controversial since peroxy-radical trapping capacity and chain-breaking antioxidants, the same or higher than in adults, have been observed.[69,70] These differences can be ascribed to the study methods, the components of antioxidant capacity tested and the timing of blood sampling. Infant condition also plays a role since asphyxia and acidosis may reduce certain components of antioxidant power.[71] Plasma antioxidant capacity is not correlated with any neonatal pathology. On the contrary, other markers suggest ROS toxicity in neonates[70,72–74]. Irrespective of total antioxidant capacity, a deficiency in particular antioxidant factors, such as ceruloplasmin and transferrin, may play an important role in neonatal susceptibility to oxidative stress and particularly to metal-induced $OH^{\bullet}$ production.[75,76] Low concentrations of transferrin have been found in neonates, especially premature ones, and high plasma levels of ascorbic acid may create a condition of risk due to the pro-oxidant effect of iron. The finding of increased bleomycin-detectable iron in premature and some full-term infants is the evidence of the real risk of increased pro-oxidant effects of iron in neonates.[77] High saturation of transferrin is therefore probably a risk factor of oxidative stress. It is generally accepted that non-transferrin bound iron is a pathological manifestation and it is extremely rare in adults, in whom even the presence of non-protein-bound iron (NPBI) in iron overload is uncommon.[78] Levels of NPBI in the plasma of newborns are correlated with other markers of oxidative stress and high plasma NPBI has been found in hypoxic newborns with poor outcome.[79] Compensatory protection against oxidative stress in neonates is demonstrated by high activity of GSH reductase and high recycling of GSH in red cells.[80] However, several observations have shown that preterm infants have lower and age-related plasma concentrations of GSH and higher concentrations of GSSG than adults.[81] This is interesting since a low GSH/GSSG ratio is a reliable index of generalized oxidative stress.[82] Reliable markers, such as F2-isoprostanes, allantoin and the oxidized form of CoQ, provide further evidence of oxidative stress in neonates.[71,83,84] Oxidative stress in neonates has also been demonstrated by higher values of CoQ120 in those born by vaginal delivery than by elective cesarean section.[85]

Oxidative stress is involved in tissue damage induced by infection and sepsis. Although there is a general agreement that neonatal phagocytes, and, especially those of premature infants, have abnormalities of various functions,[86] active neonatal secretion of proinflammatory cytokines suggests a very complex situation in which oxidative stress following infection may be more dangerous in newborns, especially if premature, than in adults.[87]

The high levels of peroxides found in cord blood of fetuses with asphyxia are in line with the hypothesis of high ROS production in the placenta and umbilical structures during hypoxia.[88–90] However, it should be remembered that the oxidative balance of the fetus is not the same as that of the neonate because of the peroxidase content of the placenta.[91,92]

The first condition suspected to be responsible for increased oxygen toxicity, namely hyperoxia, has recently been demonstrated to cause the oxidative stress responsible for lung injury and possibly generalized tissue damage.[93] The definition of hyperoxia in

newborns is closely related to oxygen requirements during the first hours of life, when the baby is suddenly exposed to higher oxygen tension than in the uterus. The oxidative stress recorded in animal experiments with hyperoxia could occur in neonates with oxygen tensions lower than previously considered.[93]

Endothelial injury by ROS following asphyxia or infection may lead to vasoconstriction and coagulation disorders that are particularly harmful to newborns due to the procoagulative state of the fetus and neonate.[44]

Links between ROS and endothelial cell injury seem to play a role in the development of pre-eclampsia, since increased oxidative stress has been demonstrated in pre-eclamptic women.[94,95] Although the pathogenesis of pre-eclampisa is poorly understood, it seems that oxidative stress plays an important role.[96]

ROS are involved in many diseases of newborns and adults, such as NEC, renal failure and septic shock. Neonatal conditions of particular interest concern red cells, lung, retina and brain.

Red cells

Several observations in animal and human erythrocytes have demonstrated that release of free radicals inside red cells may affect membrane structure during oxidation of hemoglobin.[97,98] Membrane structure may also be damaged by ROS uptake from the extracellular medium, where they may arise from ischemia–reperfusion, phagocyte activation, endothelial metabolism, hyperoxia, lipoprotein peroxidation and other sources.[99,100] Uptake of free radicals by red cells can be regarded as a mechanism protecting the tissues from oxidative injury, since the high-antioxidant enzyme activities of erythrocytes can scavenge extracellular ROS. However, excessive oxidative stress leads to hemolysis followed by free iron and free-radical release, and possible tissue damage.[101] In newborns, antioxidant activities are generally lower than in adults, and seem to be even lower in premature infants.[61,62,–102,103,105] Activities, such as GSH-Px, increase rapidly in the first days, presumably as a result of increased exposure to ROS.[106,107] Exposure of red cells to ROS after birth is also demonstrated by a decrease in GSH-T in the first days of life in response to ROS production.[108] Very active GSH recycling occurs in normal newborns, but asphyxia and acidosis have been reported to depress it, as well as ATP.[80] GSH recycling also seems deficient in infants with RDS and chronic lung disease (CLD).[109] Chemiluminescence assays have demonstrated higher ROS production in newborns than in adults.[110] This observation is in line with the demonstration of high lipid peroxidation and decreased CoQ10.[111] The red cells of newborns appear to be more susceptible to the toxic effects of oxidative stress than those of adults.[112] Besides low scavenger enzyme activities, newborn red cells have other characteristics, such as lipid content and composition, which predispose them to oxidative stress.[112] Vitamin E levels are not only much lower in the neonatal than in the adult red cell, but requirements of the vitamin are also higher, as shown by increased recycling.[113] ROS are generated in red cells not only under pathological but also under normal conditions.[114,115] Animal studies have demonstrated the key role of oxidative stress caused by intraerythrocyte iron release in a reactive form and hydroxyl radical production in the development of membrane protein damage.[102] Oxidative cross-linking of membrane proteins can produce clustering of the major erythrocyte membrane spanning protein band 3.[116,117] The clusters provide recognition sites for antibodies against senescent cells and trigger their removal from circulation. In the absence of efficient protection by antioxidant factors, oxidative stress therefore appears to be responsible for the release of iron in a reactive form, predisposing red cells to hemolysis through the formation of senescence antigen.[117] Paradoxically, recent observations show that auto-oxidation of Hb may occur *in vitro* at low oxygen tension.[118]

Studies in newborns have shown interesting analogies between experimental and clinical observations. The free iron content of red cells of newborns is higher than that of adults and is significantly correlated with pH and base deficit as well as with plasma lipid peroxide products, expressed by malondialdehyde (MDA) concentrations.[119] Incubation of newborn and adult red cells *in vitro* showed higher iron release in the former under aerobic and anaerobic conditions. It is interesting that during anaerobic incubation, increased $O_2^{\bullet -}$ production, free iron release and senescence antigen production showed the highest significant differences between adults and neonates.[110,120] *In vitro* studies show that incubated neonatal red cells release iron in reactive form. This iron is recovered in the incubation medium at the end of incubation, apparently irrespective of hemolysis, demonstrating that reactive iron may be released by stressed red cells and diffuse outside the cell.[121] This finding suggests that oxidative stress in erythrocytes may be involved in the increase in NPBI in plasma of asphyxiated neonates. In conclusion, several reports suggest that acidosis and hypoxia may generate red cell damage via ROS.

Pulmonary oxygen toxicity

Oxygen toxicity is particularly harmful for the lungs. The mechanism of damage is complex. Lung injury may be caused directly by ROS production in response to hyperoxia or indirectly by ROS due to phagocyte activation and inflammation. The two mechanisms seem to be integrated.

CLD, a severe complication of prematurity, was long thought to be due to high concentrations of oxygen in inspired air and barotrauma. ROS are now generally accepted to be largely responsible for lung

injury in preterm infants since several studies using different methods have demonstrated products of ROS reactions in premature infants with CLD.[122–127] The particular toxicity of ROS in the immature lung is due to the low antioxidant capacity of premature infants, which does not increase rapidly as in the full-term lung, as well as to the possibly high toxicity of ROS in rapidly developing tissues.[128] Increased production of ROS under certain conditions may also play a role. The main sources of ROS production in the immature lung are ischemia–reperfusion, phagocytosis and increased mitochondrial activity, mainly due to hyperoxia. Mitochondrial oxidative stress following hyperoxia has been demonstrated by a decrease of intramitochondrial GSH/GSSG redox status.[129] High inspired oxygen fraction (FiO_2) may be responsible for lung injury and high lipid peroxidation, as demonstrated by high F2-isoprostane levels in the lungs of animals exposed to high oxygen concentrations.[130] Effects of hyperoxia in the lung and a close relationship between oxidative stress and inflammation have been demonstrated. Magnetic resonance studies have confirmed the previously reported experimental data on the consequences of hyperoxia in the lungs of premature newborn animals, namely, edema, congestion, immune cell infiltration and decreased number of alveoli per square meter.[131,132] Prolonged moderate hyperoxia induces airway hyper-responsiveness and histological changes similar to those of CLD.[133] Increased type IV collagenase in bronchoalveolar lavage suggests a role of this factor in lung damage and particularly in disruption of the extracelluar matrix. It is interesting that injury produced by oxidative stress involves matrix metalloproteinases (MMP) and tissue inhibitor of matrix metalloproteinase (TIMP), which are also involved in infections.[134] Increased MMP-8 and MMP-9 associated with decreased TIMP have been reported in amniotic fluid during infection and chorioamnionitis, a condition frequently associated with the development of CLD.[87] These findings are in line with reports of phagocyte activation and increased cytokine production. The finding of a large number of neutrophils and high concentrations of interleukin-8 and leukotrienes in bronchopulmonary lavage of infants with severe CLD demonstrates the role of inflammatory reactions and ROS production in the development of this disease.[135,136]

The toxic effects of ROS on the lungs appear to be due to iron-mediated $OH^{\bullet}$ release.[125] This radical alters surfactant composition and causes decreased surfactant production by injuring type II pneumocytes.[125,137] Peroxynitrate formation from $O_2^{\bullet -}$ and $NO^{\bullet}$ can also cause lung injury.[138] ROS can modify production of vasoactive substances by the endothelium, and this might be important in CLD since increased endothelin-1 has been demonstrated to be associated with inflammation and lung disease.[139] Oxidative stress has been studied in the lungs of premature rats and a complex orchestra of genes involved in inflammation, coagulation, fibrinolysis, extracellular matrix turnover, cell cycle, signal transduction and alveolar enlargement have been found to be affected by oxidative stress.[140] The combined effect of oxygen and inflammation on the origin of CLD also emerges from studies of bronchopulmonary lavage and tracheal aspirate in which increased levels of markers of oxidative stress, such as protein carbonyls and myeloperoxidase activity in neutrophils of premature infants who developed CLD, have been found.[141,142] Increased lipid peroxidation in plasma of premature infants with CLD and periventricular leukomalacia has been reported.[77] Conditions of oxidative stress possibly responsible for CLD and ROP have also been reported.[143] These observations suggest a combined effect of oxidative stress in the pathogenesis of CLD, brain damage and ROP.

Retinopathy

Although the origins of ROP are multifactorial (see Chapter 12), the role of oxygen toxicity, which was first detected half a century ago, has been confirmed by experimental and clinical studies. ROS have been recognized to play an important role, particularly in the first stage of eye injury when hyperoxia seems to affect the vascular endothelium arresting normal blood vessel development.[144] Hyperoxia also seems to inhibit vascular endothelium growth factor, and involvement of oxidative stress in vascular obliteration caused by apoptotic vascular endothelial cells has also been suggested.[144] The hypothesis of a complex mechanism of oxidative stress in the development of ROS is also suggested by observation of the role of iron intake,[145] decreased GSH/GSSG ratio[146] and NPBI[147] in patients with ROP. Morphological abnormalities of ROP, such as 'gap junctions', are an expression of lipoperoxidation, which has been demonstrated in the retina as a result of free-radical release.[148]

A relationship between free-radical release, induced retinal injury and cyclooxygenase pathway activity has been reported.[149] Abnormalities of retinal vasculature have demonstrated that reversal vasoconstriction by dilator prostaglandin during oxidative stress in newborns may facilitate neovascularization of the retina of premature animals.[150] The role of peroxides in inducing abnormal retinal vasculature has also been demonstrated by the marked vasoconstriction that these molecules produce in the retinal vasculature of premature animals.[151]

Brain injury

ROS may affect the brain by different interacting systems involving membrane damage, astrocyte dysfunction, abnormalities of *n*-methyl-D-aspartate receptors and, particularly, increased intracellular calcium and mitochondrial dysfunction.[152,153] ROS may also cause indirect injury by inducing cerebrovascular spasms.[154] Iron-induced $^{\bullet}OH$ production may occur

during brain injury because the low transferrin content of cerebrospinal fluid (CSF) is saturated by iron released from cells with a high iron content, and free and unbound iron becomes available for the Fenton reaction.[152]

The brain is low in Cat and has moderate amounts of SOD and GSH-Px; its membrane lipids are rich in polyunsaturated fatty acids, which are sensitive to oxidative stress.[152] In the fetus and newborn, protection against ROS seems to be even poorer than in adults, especially in the glia, and sensitivity to oxidative stress seems particularly high in the first hours of life.[152–157] The first mechanism of brain damage due to ROS to be investigated was that of ischemia–reperfusion and hypoxanthine–xanthine oxidase reaction.[158] The importance of this mechanism emerged from the finding of high concentrations of hypoxanthine in blood and CSF during hypoxia, and from experimental data demonstrating inhibition of ROS release by allopurinol, an inhibitor of xanthine oxidase.[159] However, Delivoria *et al.*[160] demonstrated that hypoxia results in brain cell membrane damage, as shown by increased membrane lipid peroxidation and decreased Na^+,K^+-ATPase activity, irrespective of reoxygenation. High levels of isoprostane-8, another marker of oxidative stress, also suggest the responsibility of ROS in brain damage during asphyxia,[161] while electron spin resonance spectroscopy has shown that tissue hypoxia results in increased free-radical generation in the cerebral cortex.[162] Levels of conjugated dienes and fluorescent compounds, markers of lipid peroxidation, have also been detected in the brain of newborn animals with asphyxia, particularly during recovery from single or repeated episodes.[163] Histochemical studies of brains of neonatal rats after hypoxic ischemic injury demonstrated that iron increases rapidly in the first 24 h in regions of ischemic injury, suggesting oxidative stress induced by $OH^\bullet$ produced via the Fenton reaction.[164] The effects of ROS are also due to brain hypoxia-induced generation of NO free radicals; peroxynitrite is formed when $O_2^{\bullet -}$ predominates over the scavenger system and NO increases as an effect of increased NOS.[153]

However, during ischemia, a number of metabolic changes occur and prostaglandin metabolism and dopamine oxidation have been found to have a role in the release of ROS.[165] The recent availability of reliable markers of oxidative stress, such as isoprostanes and particularly F2-isoprostane and 8-isoprostane, has provided evidence of involvement of oxidative stress in the development of cerebral white matter injury, since these compounds were detected in the CSF of premature infants with white matter damage.[161] Further confirmation of this involvement was the finding of increased carbonyls, a marker of protein oxidation in the CSF of these neonates.[161] It is interesting that none of the observed infants had infections and their CSF, unlike in meningitis, did not contain chlorotyrosine, a marker of leukocyte oxidant activity.[166] Indirect evidence of the responsibility of ROS in brain damage of asphyxiated infants comes from the observation of NPBI in CSF.[167] Increased NPBI resulting from asphyxia or hemorrhage has an important role in the development of brain injury, one reason being that early differentiating oligodendroglia is poor in ROS detoxification systems and enables peroxide accumulation and $OH^\bullet$ generation by the Fenton reaction.[152,168]

Several observations also suggest ROS involvement in brain injury during hyperoxia.[169,170] Decreases in cerebral blood flow in response to O_2 administration have been detected in human studies[170] and reduced blood flow was observed in premature newborns treated with high O_2 concentrations.[171] However, animals kept in hyperoxia showed a reduction in blood flow, which was not statistically significant.[172]

Considering the interaction between ROS and inflammatory mediators, oxidative stress to the endothelium may play an important role in the development of brain damage.[173]

Relationships between ROS and brain damage are suggested by the link between increased markers of oxidative stress and clinical observations.

Oxidative stress in premature and full-term newborns with asphyxia is demonstrated by high plasma levels of lipid hydroperoxides and evidence of the MDA reaction.[174,175] Markers of oxidative stress, such as HPLC determinations of MDA, 4-hydroxynonenal, total hydroperoxide and carbonyl groups, are significantly higher in asphyxiated babies.[174–177] It is interesting that markers of oxidative stress, such as total hydroperoxides, remain high for weeks in sick babies.[177] Isoprostanes, a reliable marker of oxidative stress, have been reported to be higher in cases of fetal distress.[178]

High levels of NPBI in plasma of the asphyxiated newborn are evidence of a role of ROS in the development of brain injury in hypoxia ischemia. The reports of Dorrepal *et al.*[179] indicated that this occurrence, which is peculiar to neonates, is associated with severe brain damage. Buonocore *et al.*[180] recently tested the predictivity of traditional indicators of brain damage in relation to neurodevelopmental outcome. They demonstrated that plasma NPBI is the most reliable marker of severe outcome in asphyxiated newborns.[180]

The markers of oxidative stress

If oxidative damage contributes significantly to neonatal pathology, it is essential to be able to accurately measure oxidative stress. Two basic approaches have been suggested: (1) attempting to trap ROS and measure levels of trapped molecules and (2) measuring the oxidative damage done by ROS.[181] Other frequently used approaches are inaccurate.[181] Erythrocyte enzyme activities, which were the first indication of the low antioxidant resistance of newborns, are not fully reliable since the enzyme activities of red cells are age

dependent and values may be an expression of young or old red cell populations.[181] Measurement of total antioxidants usually involves major contributions from urate, ascorbate, bilirubin and albumin-SH groups, which are variable and may not accurately reflect antioxidant power.[181] However, plasma antioxidants, if measured in conjunction with other parameters, may be useful in the detection of imbalance between free radicals and antioxidants. Chromatographic profiles of antioxidants in human plasma can provide indications of single-component deficiencies, which may be useful to distinguish particular deficiencies or increased consumption of a factor involved in a particular disease.[182]

Lipid oxidation is a complex process and commonly used methods, such as thiobarbituric acid (TBA), are questionable. The TBA test should not be used because most TBA-reactive material in the human body is not related to lipid peroxidation.[181] Measurement of MDA by HPLC is more indicative of lipid peroxidation, although MDA is only one of the many aldehydes formed during this process.[181] It is more logical to measure 4-hydroxynonenal.[181] The best biomarker of lipid peroxidation is isoprostane, which is a specific end product of peroxidation of polyunsatured fatty acids.[181,183] Most work has been done with F2-isoprostane, which arises from arachidonic acid peroxidation. Neuroprostane or F4-isoprostane has also been measured.[183] They are best measured by mass spectrometry.[184] It is important to remember that isoprostanes are rapidly metabolized, so that increased values may indicate slower metabolism and not increased production.[181]

Measurement of ethane and pentane in expired air was among the first methods of detecting oxidative stress in asphyxiated neonates.[185] These assays have the advantage of being non-invasive and independent of the complex matrix of blood.[186] However, variations in the methods make it difficult to compare populations.[187] Simultaneous measurement of pentane and MDA has been carried out to assess oxidative stress. In studies on human hyperoxia, increased values of both the markers were found, but no correlation between pentane and MDA was observed, probably because they are metabolized differently.[188]

Profiles of aldehydes pentanal, hexanal, 2-hexanal, heptanal, 2-heptanal, 2-octenal, 2-nonenal and 4-hydroxy-nonenal formed during autoxidation of fatty acids, such as oleic, linoleic, α-linoleic, γ-linoleic and arachidonic, seem to improve the sensitivity of detection.[189]

Determination of protein carbonyl concentrations provides information regarding protein involvement in ROS reactions. The carbonyl assay as applied to tissues and body fluids measures the average extent of protein modification.[181] The use of proteomics to identify specifically oxidized proteins appears to be a promising method.[190] Research on plasma of newborns has shown interesting selectively oxidized proteins during asphyxia.[191]

Total hydroperoxides represent a measure of overall oxidative stress, given that they are the intermediate oxidative products of lipids, peptides and amino acids.[176]

Percentages of oxidized forms of CoQ10 have also been used to demonstrate oxidative stress in asphyxiated newborns.[71]

A major marker of oxidative stress is the GSH/GSSG ratio, which directly reflects alteration of intracellular redox status.[192] GSH is a cofactor of GSH-Px and also has the antioxidant effect of binding Cu^{2+}, contributing to delivery of copper to the apoprotein of copper enzymes and decreasing free metal available for the Fenton reaction. Filomeni *et al.*[192] showed a relationship between intracellular GSH levels and mitochondrial-dependent apoptotic pathways. Under oxidative stress, GSSG may be produced at a high rate and extruded from cells into the extracellular milieu.[192] Since blood glutathione may reflect GSH status in other less accessible tissues, measurement of GSH and GSSG in blood has been considered an essential index of overall oxidative status and a useful indicator of risk of disease.

The GSH/GSSG ratio has been used as a measure of oxidative stress in neonates. Decreased ratios were observed in premature infants with severe RDS and newborns resuscitated with 100% O_2.[193,194] Lower GSH/GSSG ratios were found in very low-birth weight (LBW) infants even when they were breathing room air.[195]

Levels of nitrotyrosine have been reported to be a marker of $ONOO^-$ production resulting from phagocyte activation in inflammatory processes.[196] Therefore, nitrotyrosine can also be used as a marker of oxidative stress, since total nitration is consistent with amplified cell levels of $O_2^{\bullet -}$ in the presence of NO and CO_2.[197]

Allantoin can be measured in body fluids and its plasma levels are high under conditions of oxidative stress.[198] Assays in urine give reliable results.[199]

8-Hydroxydeoxyguanosine has been reported to be a reliable marker of oxidative stress. This molecule can be assayed in urine and has been done in newborns. While no differences in relation to gestational age have been reported by some authors,[200] others[201] observed a negative correlation between 8-OHdG and gestational age, confirming that premature infants are more subject to oxidative stress.

Plasma levels of NPBI appear to be a reliable marker of oxidative stress and close relationships between these levels and plasma carbonyls have been reported.[197] At least in neonates, both assays can be regarded as markers of potential risk of pathology due to oxygen toxicity.

Isolevuglandins (structural isomers and stereoisomers of cyclooxygenase-generated levoglandins) may be formed via free-radical-mediated pathways and have been proposed as a sensor of lipid peroxidation initiated by myeloperoxidase.[202]

Prevention and therapy

Avoiding oxidative stress

ROS are normally produced in living organisms. Their properties and complex role in the development of diseases make prevention and antioxidant therapy very difficult in newborns as well as in adults. Obviously, avoidance of conditions, such as asphyxia, hyperoxia and retinal light exposure, under which excessive free-radical release occurs, are the best defense against development of imbalances in pro-oxidant and antioxidant factors in the neonate. It is also important to remember that infections and particularly sepsis may be a severe source of oxidative stress. Frequent reports of NPBI in plasma of neonates suggest that indiscriminate iron supplementation should be avoided.

The concept of optimal oxygenation of newborns has recently been revised in order to clarify whether the optimal oxygen saturation unanimously accepted for normal infants and adults is also the best for sick neonates, especially if premature. The relationship between Hb oxygen saturation, risk of oxidative stress and oxygen toxicity, is still a problem. Even a recent Cochrane review failed to define the target range for maintaining blood oxygen levels in preterm/LBW infants.[203] This is presumably due to the complex mechanism of oxygen toxicity, which may be expressed at different percentages of O_2 saturation under different conditions. Conventional indications suggest that optimal oxygen tension should be maintained between 50 and 70 mmHg.[204] High O_2 saturation seems to be necessary for infants with CLD and infants with prethreshold ROP.[205] However, in view of susceptibility of some neonates to oxidative stress, it has been suggested that oxygen saturation maintained within physiological limits could result in moderate hyperoxia that could generate an excess of ROS. Experimental studies in animals in the first 24 h of life demonstrated a threshold of oxygen-restricted metabolism at $PaO_2 = 40$ Torr.[206] Shulze *et al.*[207] did not observe signs of mismatch between systemic oxygen delivery and demand in LBW infants kept at O_2 93–96% and 89–92% saturation. A significant decrease in CLD and ROP without any differences in mortality were observed in extremely low-birthweight (ELBW) infants kept at less than 95% O_2 saturation compared to those kept at more than 95%.[208] Important indications on the use of oxygen were recently reported by Cow *et al.*[209] in a 5-year study in a tertiary neonatal center, where oxygen therapy was adjusted to optimize neonatal care and decrease the incidence of ROP. They recommended avoidance of repeated increase and decrease in FiO_2 in response to the oxygen saturation monitor and maintenance of oxygen saturation within 'acceptable' limits. They also recommended an alarm setting for oxygen saturation below 85% and above 93% for the newborns under 32 weeks of age. More recently, comparison of two populations of high-risk newborns kept at O_2 saturations of 88–98% and 70–90% showed a significant reduction in ROP in the group at lower O_2 saturation, but no differences in mortality or poor outcome.[210,211]

Hyperoxia and oxidative stress may occur during neonatal resuscitation. In an attempt to avoid the risk of tissue damage caused by ROS in the first hours of life, when susceptibility to oxidative stress is particularly high, the effects of reduction of O_2 were investigated. Some animal studies demonstrated identical outcome variables, including blood pressure, lung hemodynamics, acid–base status, cerebral blood flow and brain oxygenation whether resuscitation was done with room air or 100% oxygen.[212] In other experiments with animals subjected to ischemia and hypoxia, reoxygenation with 100% oxygen was followed by better restoration of microcirculation, but no difference in biochemical markers of brain injury.[213] Comparison of short and long duration of oxygen treatment after cerebral asphyxia in newborn piglets confirmed the efficacy of reoxygenation with room air.[214] Potential risks associated with resuscitation with 100% oxygen are suggested by the observation of increased production of ROS with respect to room air.[215,216] Clinical studies have demonstrated that there were no differences in short-term outcome between newborns resuscitated with room air and 100% oxygen.[217,218] The same results were observed in a follow-up at 18 and 24 months.[219] Vento *et al.*[194] demonstrated that room air resuscitation was associated with significantly less oxidative stress. It is important to note that increased oxidative stress following resuscitation with 100% oxygen was demonstrated by the sensitive GSH/GSSG ratio, which is a marker of generalized oxidative stress.[192] The satisfactory results of room air resuscitation in terms of outcome and avoidance of oxidative stress were recently confirmed by the same authors.[220] A reduction in mortality and no evidence of harm were described in a Cochrane review.[221] However, the authors concluded that there is insufficient evidence on which to recommend a policy of using room air over 100% oxygen or vice versa for resuscitation of newborns.[221] Although the guidelines do not discourage high FiO_2, it seems reasonable to conclude that 100% oxygen should not be used routinely.

Antioxidants

Much research has recently been carried out to find substances with antioxidant activity.[222] These substances can be divided into those decompartmentalizing metal complexes, those limiting ROS production, those modifying antiradical defenses and enhancing intracellular or extracellular antioxidant levels, those incorporating lipophilic antioxidant into membranes and those scavenging superoxide.[222]

Substances inhibiting phagocyte activation or xanthine oxidase and arachidonic acid metabolism, or decompartmentalizing free iron and making it available for the Fenton reaction, have also been investigated, together with those scavenging ROS directly

or repairing ROS-induced membrane injury, like calcium antagonists and β-blockers.

On the whole, the results obtained in newborns have been uncertain. Although substances such as ascorbate are considered to be antioxidants *in vitro* and *in vivo*, they may act as pro-oxidant factors by causing metal-induced release of ROS.[223] Several other antioxidant substances have been used in newborn animals and humans in an attempt to improve the worst prognosis of damage, presumed to be due to ROS. Many, such as SOD, showed the same disadvantages in newborns as in adults.[224] Other drugs, such as allopurinol, have shown good results in animals,[225] but no advantages in human newborns, especially those with hypoxic ischemic encephalopathy.[226] Indomethacin, which has been shown to have antioxidant effects in humans, reduces the incidence and severity of intraventricular hemorrhage, but it is not known whether this effect is due to antioxidant activity.[227] Involvement of metal-induced ROS in brain damage suggested treatment with chelating agents. Desferrioxamine seemed to have a protective effect in animals, which has not yet been demonstrated in humans.[228] No definite results have been obtained by retinol supplementation.[229] Among the antioxidants, melatonin has a special place since it has been reported to have several interesting effects, such as enhancement of antioxidant enzyme activities and neutralization of H_2O_2 singlet oxygen and peroxynitrite.[230] Melatonin also appears to scavenge $OH^{\bullet}$.[231] Administration of melatonin to neonates with RDS has been reported to lower concentrations of proinflammatory cytokines.[232] In septic newborns, melatonin also lowers levels of oxidative markers, such as MDA and 4-hydroxylalkenals, and improves prognosis.[233]

Some drugs commonly used in neonatology, such as aminophylline, are reported to have antioxidant properties.[234] Vitamin E is a powerful, widely tested antioxidant and although no definite agreement has been reached on its use, interesting results have been reported even in human newborns. Analysis of nine randomized controlled trials of prophylactic use of vitamin E supplementation in very LBW infants showed no statistically significant reduction in the incidence of ROP and hemorrhage confined to the germinal matrix, although a significant reduction in the incidence of intraventricular hemorrhage was found.[235] Some formulations of vitamin E are poorly absorbed[236] and the metabolism and membrane distribution of the vitamin is uncertain; apart from this, there is no doubt about the effectiveness of α-tocopherol in protecting membranes and plasma lipoproteins from lipoperoxidation. In view of the potential activity of α-tocopherol and its proven deficiency in newborns, administration of vitamin E at the commonly recommended doses should be considered in any high-risk neonates.[237,238] Doses from 10 to 25 mg/kg/day in the first 3 days of life should protect premature infants in the first weeks.[239] Serum levels should be monitored in order to avoid levels exceeding 3 mg/dl. Subsequently, human milk or formula should be sufficient to maintain adequate vitamin levels.[239] Conclusions of a recent Cochrane review are that vitamin E supplementation to preterm infants reduces the risk of intracranial hemorrhage, but increases the risk of sepsis; in very LBW infants it seems to reduce the risk of ROP and blindness.[240] There is no evidence to support the use of vitamin E at high doses or the aim of keeping serum tocopherol levels above 3.5 mg/dl.[240]

Peroxidation products in stored lipid emulsions have been shown to increase lipid peroxidation *in vivo* in newborns and adults.[241] Since parenteral nutrition has been associated with increased formation of ROS, it is necessary to protect intralipids from light and add vitamins.[242] However, adaptation to factors responsible for oxidative stress has been demonstrated by Pitkanen *et al.*,[242] who found attenuated lipid peroxidation in preterm infants after repeated doses of intravenous lipids.

Micronutrients also play a role in protection against oxidative stress. Selenium is a part of the GSH-Px molecule, and a close correlation exists between selenium and GSH-Px.[243] Very severe RDS has been reported in selenium-deficient human babies.[244] However, while the deficiency of GSH-Px has been demonstrated in premature infants deficient in selenium,[245] the quantity of selenium supplementation to premature infants has yet to be established.[246]

Finally, the protective effects of bilirubin against ROS have been conclusively proved.[247,248] Although hyperbilirubinemia can be regarded as a natural antioxidant factor, the risk of brain damage due to high plasma levels of this molecule, particularly in premature babies, should not be underestimated.

11 Pathology of the neonate

B. Hargitai, T. Marton and Z. Papp

Introduction

Obstetrical care of high-standard and regular ultrasound scanning usually leads to prenatal diagnosis of developmental abnormalities and often prevents perinatal pathologists from encountering those in term, or near-term neonates. Therefore, dysmorphology and congenital abnormalities are more and more the subject of the fetopathology while growth abnormalities, hypoxic injuries, preterm birth and infection remain a major problem in neonatal medicine. Congenital tumor and genetic metabolic disease are rare in general, but may have a great impact on the life of the family, especially when they are part of a syndrome and have a high risk of recurrence. Stillbirth and early neonatal death rates, due to birth-related events, have significantly decreased in the last 40 years (from 7.9 to 0.5 per 1000 total births) in the UK[1] and a similar trend can be observed in many other European countries. The number of litigation cases following intrapartum neonatal death is increasing, and thus potentially the postmortem report has medico-legal importance. It is highly recommended for obstetricians to ask for a postmortem examination and to encourage the parents to give permission for a full autopsy. It is a good practice to have regular discussions with the perinatal pathologist and to provide the pathologist with detailed clinical information prior to postmortem examination.

Growth abnormalities and intrauterine growth restriction (IUGR). Assessment of IUGR during perinatal postmortem examination

Massive cell division and differentiation take place in the developing fetus and result in a linear growth until the 38th week of gestation. Any failure of the complicated biochemical routes and control system, shortfall in nutritional agents or oxygen supply, may lead to growth abnormalities. In obstetric practice, ultrasonographic assessment of biparietal diameter (BPD), femur length and other fetal measurements was found to be useful to date the pregnancy.[2] To estimate the duration of the pregnancy, the most frequently used method is to count the gestational weeks from the first day of the mother's menstrual period. Although many charts of fetal and neonatal measurements are available in textbooks, most of these were created decades ago.[3–5] Perinatal pathology centers have to update these data, especially to reflect characteristics of a given geographical and ethnical population.

During perinatal necropsy the appropriate measurements of the body (weight, crown–rump length, crown–heel length, foot length and head circumference) and organ weight always have to be taken and should be compared with the normal values, apt for the counted gestational age.

Neonates, born between the 37th and 41st gestational weeks are term neonates and those born before the 37th week are preterm neonates, expressing signs of prematurity. Both term and preterm babies can be of appropriate weight for the gestational age or may weigh less than the expected normal value. Babies who weigh 2500 g or less are called low-birth-weight neonates and those under 1500 g are designated as very low-birth-weight. Small-for-date or small-for-gestational-age infants measure less than the 3rd, 5th, or 10th centile or less than two standard deviations below the mean. Small-for-date infants are not necessarily growth restricted and babies suffering from IUGR are not always small-for-date.

IUGR is usually detected during the third trimester of pregnancy. In case of an early-onset growth restriction, the fetal organs are smaller but proportionally developed. The serial BPD measurements are lower and parallel with the normal values from the early pregnancy. This type of IUGR is usually associated with intrauterine infections, chromosome abnormalities – e.g. Down's syndrome – and many other malformation syndromes. Triploidy (Figure 11.4) is an example of early onset asymmetrical growth restriction. Late-onset IUGR is usually caused by environmental factors, such as malnutrition due to placental dysfunction or maternal undernutrition, reduced uteroplacental perfusion related to maternal hypertension, pre-eclampsia, diabetes mellitus or maternal smoking. In late-onset IUGR the infant's body is disproportional, the head circumference is relatively large and the brain weight/liver weight ratio is elevated.

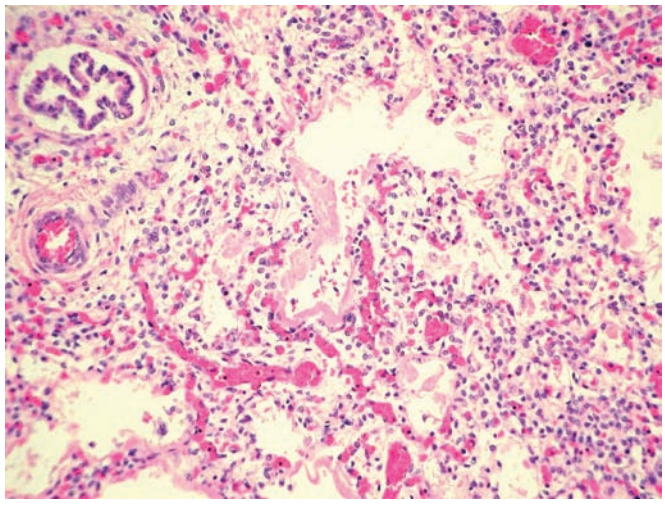

Figure 11.1 Eosinophilic membrane lines the inner surface of the airway.

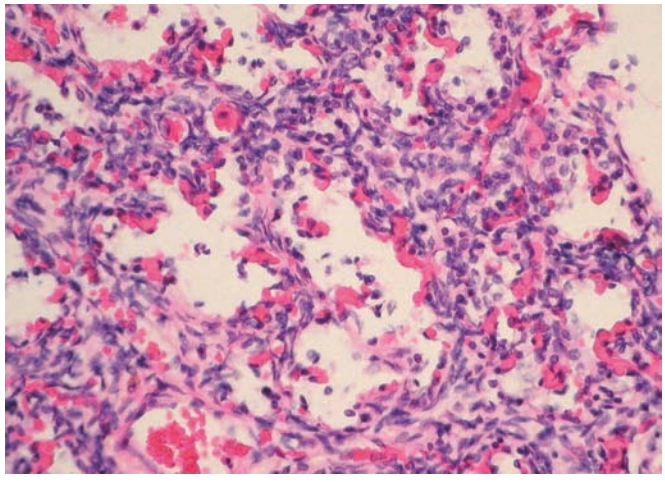

Figure 11.2 Simplified airways, widened interalveolar septa are present in chronic lung disease.

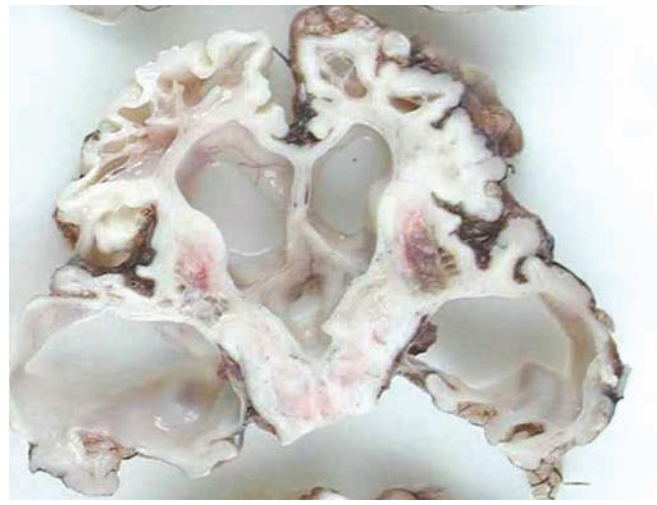

Figure 11.3 Postischemic change in the brain. The ventricles are dilated, and there are multiple cysts in the white matter (postnecrotic porencephaly).

Pathological and histological assessment of IUGR requires accurate measurement of body weight, crown–heel length, crown–rump length, head circumference, foot length, organ weights, and microscopic examination of the parenchymal organs. Elevated brain weight/liver weight ratio [mean 2.8 (range 1.7–4.1)],[6,7] lower crown–rump length than head circumference, immature brain gyral pattern,[8] decreased nephron counts and presence of nephrogenic zone of the kidney after the 36th week of gestation,[9] bone growth plate abnormalities and specific placental findings are sensitive markers of IUGR.[10]

Infants who weigh more than the normal value for a particular gestational age are called heavy-for-date babies. This condition can be constitutional and usually is associated with high maternal body weight or higher parity. Maternal diabetes mellitus and gestational diabetes are often complicated with increased somatic size (macrosomia) when the diabetes of the mother is not sufficiently controlled. Macrosomia, unilateral hyperplasia or single organ overgrowth can be seen in so-called overgrowth syndromes. This group includes Beckwith–Wiedermann syndrome, characterized by hemihyperplasia, macroglossia, omphalocele and increased risk of pediatric neoplasms, most frequently Wilm's tumor. Simpson–Golabi–Bernel syndrome, an X-chromosome-linked disorder, is associated with macrosomia, congenital heart defects among other abnormalities.[11] Perlman syndrome, autosomal recessive, is characterized by macrosomia at birth, cardiac malformation, hypertrophy of the islets of Langerhans, bilateral renal hamartomas and sometimes nephroblastomatosis.[12] Weaver syndrome is characterized by accelerated growth and osseous maturation, bears considerable overlap with Soto's syndrome, both of them associated with congenital heart defects and higher risk of malignancy.[13]

Pathological sequels of intrauterine asphyxia

Intrauterine asphyxia is a common cause of fetal death and may lead to severe organ failure, such as long-term neurodevelopmental injuries, in the surviving infant. During the last two decades it has become evident that only a minority of cases of cerebral palsy and severe neurological damage begin at labor. In contrast, chronic or subacute intrauterine asphyxia is responsible for about 80% of cases.[14,15] In case of acute intrauterine asphyxia, pathological events lead to fetal demise or major damage within 24 h, while in chronic intrauterine asphyxia the estimated time course is 3 weeks or more. Specific causes of intrauterine asphyxia and associated pathological events can be identified in 50–80% of stillbirth cases.[16] Clinical data and pathological examination

Figure 11.4 Triploidy: note the relatively large head and atrophic body, small jaw and low-set ear of this fetus.

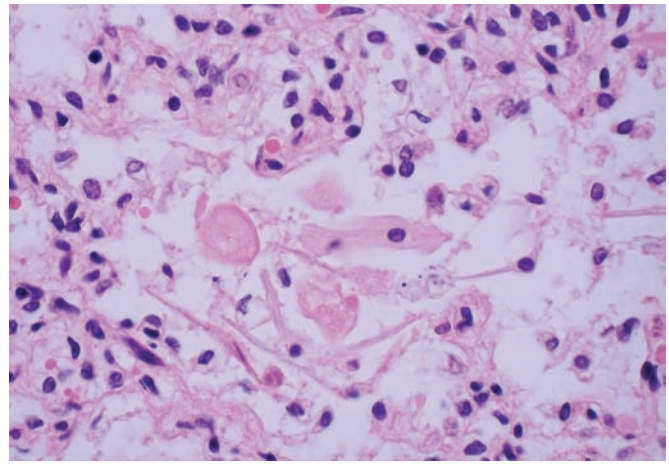

Figure 11.5 Squamous cells in the alveoli of a stillborn fetus.

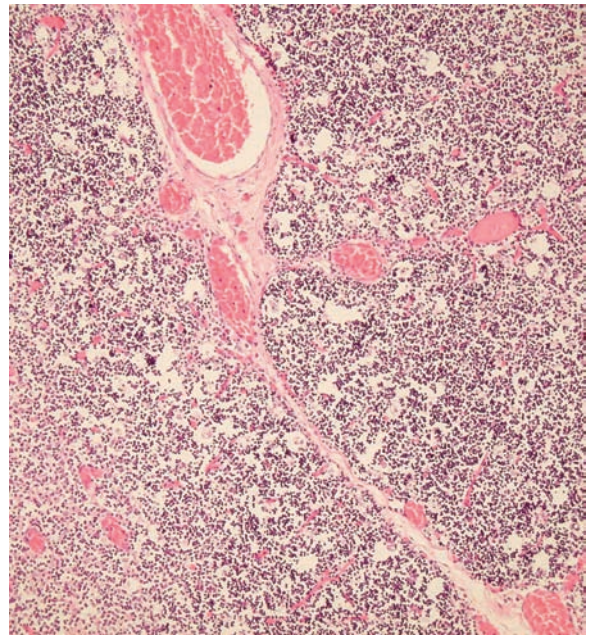

Figure 11.6 Starry sky reaction in the thymus of a neonate. The whitish small areas represent missing thymocytes as a result of subacute stress.

may help to clarify the mechanism of damage and reveal maternal, placental or fetal causes, such as maternal disease, hemorrhage, placental malfunction, fetal malformation, second trimester loss of a twin in monochorionic pregnancy or infection.

During the course of the postmortem examination of a fetus or a neonate, which underwent intrauterine asphyxia, a combination of features associated with the predisposing causes as well as symptoms related to intrauterine hypoxic stress can be seen.

Acute intrauterine asphyxia is characterized by petechial hemorrhages on the epicardium along coronary arteries and at the base of the aorta and pulmonary trunk, visceral pleura, meconium in the airways, massive intrapulmonary hemorrhage, subcapsular hemorrhage of the liver, interstitial corticomedullary hemorrhage of the kidney and subcapsular hematoma of the adrenal glands. Microscopic examination reveals aspirated meconium, squames in the airways (Figure 11.5.), myocardial contraction band changes, cortical histiocytosis in the thymus and cystic degeneration of the adult cortical zone in the adrenals.

There are usually no petechial hemorrhages in subacute asphyxia/hypoxia. Microscopical shrinking of the cortex, prominent Hassal's corpuscles and histiocytosis can be observed in the thymus; with lymphocytolysis. The depletion of lymphocytes results in a typical 'starry sky' pattern. (Figure 11.6.) In the adrenals, lipid depletion and reaccumulation occur in the middle fetal cortex. (Figure 11.7.)

Chronic intrauterine hypoxia leads to fetal growth retardation with an asymmetric or disproportionate pattern, reduced muscle and subcutaneous fat. Microscopically, reaccumulation of lipid and fatty change in the outer fetal cortex of the adrenal gland is characteristic. The thymus shows severe involutional changes with thin or diminished cortex and crowding of Hassal's corpuscles. (Figure 11.8.) In the enchondral growth plate of the bones irregular costo-chondral junction can be observed.

Intrauterine hypoxia leads to congestion in the central nervous system. Grossly, flattening of the gyri and compression of lateral ventricles can be seen. Microscopically, different stages of neuronal degeneration, necrosis and apoptosis are typical for hypoxic-ischemic changes in thalamus, midbrain, pons, hippocampus and basal ganglia. Angulation of the neurons, karyorrhexis and karyopicnosis are characteristic signs of neuronal apoptosis. (Figure 11.9.) Late consequences

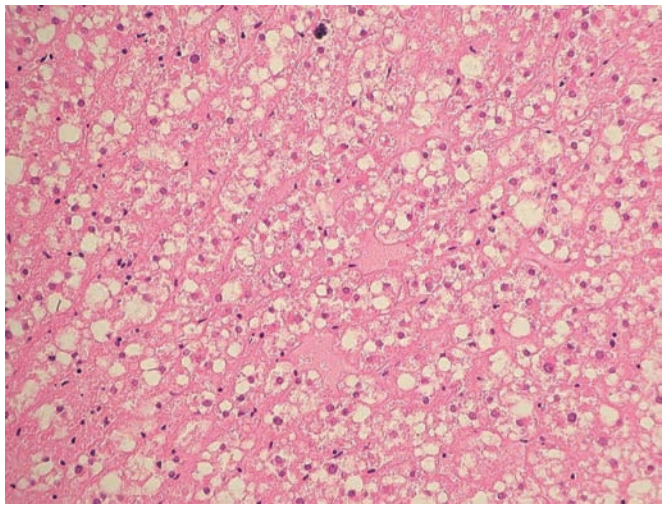

Figure 11.7 Severe lipid reaccumulation in the adrenal cortex.

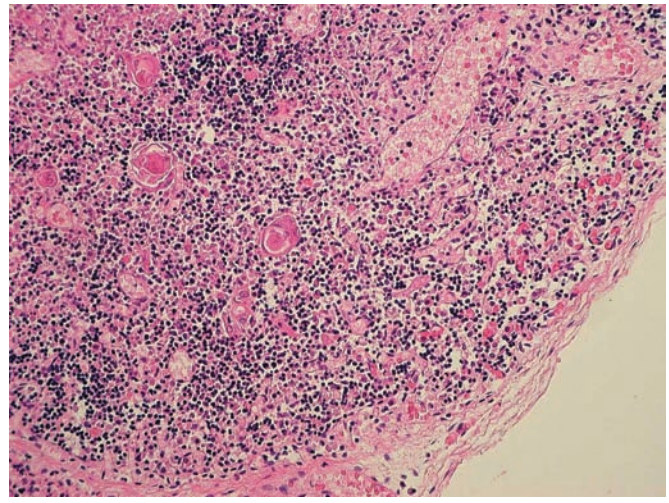

Figure 11.8 Atrophic cortex of the thymus, prominent Hassal's corpuscles.

of hypoxic-ischemic brain damage may include massive loss of brain tissue causing porencephaly, hydrocephaly, cystic changes and subsequent microcephaly.

Prematurity, immaturity

Neonates, delivering before 37 completed weeks of gestation are called preterm neonates. The direct causes of preterm labor are not entirely understood, although many associated pathological events have been studied, such as maternal diseases, socio-economic factors, previous reproductive events, effect of twinning and fetal factors. Structural and functional immaturity of preterm babies causes major problems in postnatal life during adaptation. Hypoglycemia, hypothermia, high blood potassium level and anemia are frequent complications. The pathological appearance of organ-specific alterations has been changed due to technical development of neonatal intensive care and new therapeutic methods.

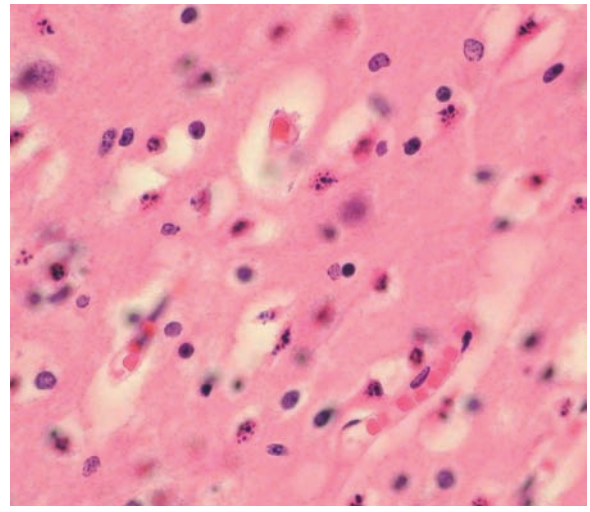

Figure 11.9 High number of apoptotic figures in the hippocampus of a neonate with hypoxic-ischemic encephalopathy.

Pathology of the respiratory system in premature infants

Infantile respiratory distress syndrome (IRDS) and hyaline membrane disease (HMD)

IRDS is a frequent condition in preterm infants and is characterized by a well-defined clinical picture: rapid increase in oxygen requirement and demand for ventilation, cyanosis, tachypnoe, intercostal and sternal recession, increasing expiratory pressure and a typical grunting noise at expiration. Radiological staging is possible but not always consistent with the degree of respiratory failure. In an advanced stage the picture of 'white lungs' appears on x-ray.

The underlying cause behind the acute respiratory failure of preterm neonates is the functional and structural immaturity of the lung. The reduced number and incomplete formation of airways, inefficient production of surfactant factor and lack of antioxidant defense lead to a number of immunopathological processes similar to diffuse alveolar damage syndromes. The exact mechanism of the initial epithelial injury is not known but ischemia, volu- and barotrauma and oxygen toxicity are likely to play a major role.[17] Most babies survive IRDS, and in about 50% of the cases there are no significant complications in the respiratory system. The outcome is less favorable with younger gestational age. The incidence is higher in males, and symptoms can be more severe in infants of diabetic mothers, in multiple pregnancies and after intrauterine asphyxia.[18]

In pretem babies who die in the first week of life with symptoms of IRDS, the lungs are heavy, purple colored and have a liver-like texture due to atelectasia. Microscopically, most airways are collapsed, but terminal airways are distended, the bronchial epithelial

lining is necrotic. As soon as 1 h after birth, the hyaline membrane starts to develop lining the primitive airways, which consists of nuclear debris of epithelial cells as well as necrotic cell mass and exudates from inflammatory cells. A few hours later polymorphonuclears and macrophages migrate into the septae and after 2 days regenerative changes in the epithelium become visible. The hyaline membrane (Figure 11.1.) is strongly associated with IRDS, but can be present in acute asphyxia, in some infections (e.g. group B streptococcus infection) and in pulmonary hemorrhage.

The incidence of IRDS and HMD has been significantly reduced with surfactant administration and, especially the preventive use of natural surfactant has proved to be useful. Steroid administration before preterm labor is a common practice, the benefits and complications of which are still being investigated.[19,20]

Changing morphology of chronic lung disease (CLD)

Clinical definition of chronic lung disease requires a demand for assisted or supported ventilation after 28 days of life, radiological signs and previous acute respiratory failure of the infant, most frequently IRDS–HMD. The classical morphology of chronic lung injury has changed and is rarely seen today. Therefore, the term 'bronchopulmonary dysplasia' is not appropriate for the majority of the cases and 'CLD' is preferred currently.

Traditionally, three stages could be distinguished in BPD based on the histology of the lung.

- In the acute exudative early reparative stage (1–9 days) persisting hyaline membrane, lack of type II pneumocytes, bronchiolar epithelial necrosis, obliterative bronchiolitis, interstitial edema, congestion and initial septal fibrosis can be seen.
- In the subacute fibroproliferative stage (10–30 days) increasing interstitial and perialveolar fibrosis, necrotizing tracheobronchitis, smooth muscle proliferation, dilated bronchioli and terminal airways are present.
- In the late stage (after 1 month) prominent septal fibrosis, reduced number and anatomical distortion of terminal airways, metaplastic changes in bronchial epithelium, pulmonary hypertensive changes in pulmonary arterioles are typical findings.

The changing morphology of chronic lung disease might be a result of the longer survival time of the very immature, very low-birth-weight preterm infants and the technical improvement of intensive care, especially ventilation. Characteristic morphological changes include less exudative–fibroproliferative signs, but a dramatic fall in the number of airways and gas exchange surfaces. (Figure 11.2.) The proximal airways are collapsed and in contrast, the terminal structures are dilated. Patchy fibrosis may be present, but is not dominant. Inflammatory morphological changes are not common, although a significant inflammatory response is associated with CLD and there is an increased level of inflammatory cytokines. It is suggested that the current morphology of chronic lung disease might be the consequence of an alveolar developmental abnormality due to the lack of physiological signal during lung remodeling in the highly immature infants.[21,22]

Pulmonary air leak and pulmonary hemorrhage

Positive pressure ventilation may result in alveolar overdistension and rupture. The air can be pressed into the pleural cavities leading to pneumothorax. Air leakage into the pulmonary tissues results in pulmonary interstitial emphysema. Pneumopericardium is usually associated with other air leaks and is a severe complication with the risk of pericardial tamponade. Systemic air embolism is a very rare complication of ventilation and may lead to sudden death.

Intra-alveolar and interstitial hemorrhage is frequently associated with HMD. Massive hemorrhage is occasionally a terminal event, while alveolar and subpleural hemorrhage are rather associated with acute asphyxia.

Pathology of the central nervous system in premature infants (germinal matrix hemorrhage, intraventricular hemorrhage and periventricular leukomalacia)

A reasonable improved prognosis has been documented in the last decade; the incidence of intracerebral hemorrhage and ischemic white matter damage in preterm infants is still high and may be responsible for long-term neurodevelopmental sequels, such as hydrocephalus, spastic diplegia, hemiplegia, quadriplegia, learning difficulties and behavioral problems.[23,24]

The pattern of neuropathological changes in preterm brain differs from those that can be found in term neonates. Most frequent pathological findings in preterms are germinal matrix/intraventricular hemorrhage and periventricular leukomalacia, and in contrast with the term brain, the most vulnerable areas are the periventricular germinal matrix and white matter. Although basal ganglia are far more frequently affected in term babies, pontosubicular necrosis has been observed in a high ratio of preterm infants.[25] The fetal brain is characterized by an active neurogenesis, dense aggregation of precursor cells in the subependymal germinal layer and a paucity of myelin. Neuronal precursors migrate from the germinal layer into the cortex, where later glial cells are also produced, and by the 36th week of gestation only residual foci of the germinal matrix can be seen. The germinal matrix bears a delicate vascular pattern, consisting of vulnerable capillaries, having no muscular wall. Sudden changes in the blood pressure, disturbed autoregulation, higher fibrinolytic activity and increased permeability of vessel walls, caused by hypoxia, contribute to the

pathogenesis of germinal matrix hemorrhage. Bleeding may occur in one focus but can be multiple, unilateral or bilateral. According to Papile's grading system, bleeding restricted to the germinal matrix represents grade 1; hemorrhage breaking into the lateral ventricle is regarded as grade 2; in more severe cases, dilatation of ventricles follows the hemorrhage, which is grade 3 and parenchymal damage (grade 4) can be observed in about 10% of the cases.[26] Germinal matrix and intraventricular hemorrhage usually develop in the first 3 days of life. High-grade intraventricular hemorrhage, associated with RDS, is a leading cause of death, and grades 1–4 hemorrhage is present in as many as 83% of very low-birth-weight preterm infants in our postmortem examinations. On histology, extravasation of red blood cells, tissue damage and a few days later many hemosiderin-laden macrophages and petrified neurons can be seen.

Periventricular leukomalacia is related to a sudden drop in the blood pressure and the most vulnerable sites are the vascular watershed areas, where the decreased perfusion leads to ischemia.[27] Recent studies have revealed a relationship between intrauterine infection, acute high-grade chorioamnionitis–funisitis and white matter injuries.[28,29] On macroscopical examination whitish–yellowish foci can be seen with a chalk-white rim, usually within the paraventricular white matter, in the temporal lobe and in the tapetum. The lesion tends to be multifocal and bilateral. Histologically, signs of coagulative necrosis, microglial and astrocytic reaction, groups of macrophages and mineralized neurons can be present. In the later stage, cystic changes develop in the injured sites leading to the typical picture of multicystic periventricular leukomalacia (Figure 11.3).

Necrotizing enterocolitis (NEC)

The onset of the NEC is usually during the first 2 weeks for preterm infants. Although the exact initial cause is not known, alimentary and iatrogenic aspects are investigated. Immaturity is strongly associated with this condition, but the etiological role of early enteral feeding is now challenged.[30,31] In contrast, perinatal asphyxia and RDS were not among the risk factors in the study of Kanto,[32] but umbilical cord catheterization increased the chance of NEC.[33] An infectious component has also been suspected by many investigators, but no pathogenic organism has been found yet.[34,35] Breast milk proved to have a protective role.[36]

The clinical picture of NEC is characterized by lethargy, pale skin tone, abdominal distension, bloody stools and vomitting. Radiology shows distended, gas-containing bowels and occasionally gas perforation into the abdominal cavity. The outcome is less favorable for very low-birth-weight infants, and for cases complicated by perforation, peritonitis, sepsis and intravascular coagulopathy.

Postmortem or postoperative examination of the bowels reveals a distended, thin or paper-like bowel wall, sites of perforation, greenish–brownish exudate on the visceral peritoneum. The number of villi of the small intestine is diminished and the wall shows different degrees of edema, hemorrhagic necrosis and gangrenous inflammation. The picture can be similar in the lower part of the intestinal tract.

Retinopathy of prematurity and other pathological conditions associated with prematurity

Retinopathy of preterm infants was described in the early 1940s, and was regarded as retrolental fibroplasia (Terry 1942). The frequency dropped when the adverse effect of concentrated oxygen was recognized, but rose again with the increasing survival time of very low-birth-weight infants. According to the current practice, high-risk babies (less than 1500 g and/or born before the 32nd week of gestation) are monitored in order to prevent retinal detachment and blindness, total retinal detachment being the most severe stage of this condition.[37] The site of the changes is the junction of the vascularized and avascular retina, where demarcation, fibrovascularization and neovascularization develop as a pathological reaction of the immature tissue for angiogenetic signals. The detailed pathway of this procedure is not yet fully understood.

There are other clinically important consequences of the altered metabolic functions, which do not have characteristic morphological appearance, such as hypothermia, hypoglycemia and higher blood potassium level. Anemia of preterm infants presents with extensive extramedullary hemopoiesis and occasionally fatty changes of the adrenal cortex.

The risk of sudden infant death syndrome is higher for preterm babies.

Preterm birth is very frequently complicated by perinatal infections, which are discussed in the next section.

Perinatal infections

Frequent pathological sequels of intrauterine infections

The incidence of the intrauterine infection reaches a peak in the second trimester. The two most frequent mechanisms are the ascending genital tract infections and the transplacental hematogenous spread. The pathogenesis of the intra-amniotic infections and the most common pathogenic agents are summarized in Table 11.1.

The consequences of intrauterine infection include early, spontaneous, preterm labor and premature rupture of membranes,[38] and occasionally generalized fetal infection. Developmental abnormalities and other clinical features related to particular intrauterine infections are well described in pediatric pathology.[4] Cytomegalovirus (CMV) infection is known to be

Table 11.1 Mechanism and common pathogens of intrauterine infections

	Virus	Bacteria	Fungi	Protozoa
Transcervical	Herpes simplex or genitalis, HIV-1 (infection during labor)	Group B streptococcus, *E. coli* and *H. influenzae*	*C. albicans*	
Transplacental	CMV, parvovirus, rubella and HIV-1	Group B streptococcus and *L. monocytogenes*		*Toxoplasma*, *Chlamydia psittaci*, *Treponema p.* and *Borrelia*

Table 11.2 Typical macroscopic and microscopic features of intrauterine infections in the fetus and in the placenta

	Macroscopic signs	Microscopic signs
Bacterial infection		
Placenta	Opaque or greenish–brownish membranes in transcervical infection Placental abscesses in case of transplacental spreading	Transcervical infection Acute, high-grade chorioamnionitis, fetal chorionic vessel vasculitis and funisitis Transplacental infection Acute villitis, deciduitis Microabscesses, microgranulomas, e.g. in listeriosis
Fetus	Macroscopic features of septic shock Leptomeningeal purulent exudate and congestion in meningitis Occasionally periventricular leukomalatia	Intrauterine pneumonia, infiltration with polymorphonuclear leukocytes in the airways, interstitial inflammatory reaction Microabscesses of the parenchymal organs
Viral infection		
Placenta		Subacute or chronic villitis, specific virus inclusions, e.g. parvovirus B19, CMV
Fetus	Hepatosplenomegaly Icterus, petechiae Hydrops IUGR Developmental malformation	Specific virus inclusions, e.g. parvovirus B19, CMV, HSV Hemolysis – hemosiderin deposition Focal necrosis, dystrophic calcification, e.g. HSV

associated with severe central nervous system damage, microcephaly with multifocal calcification, chorioretinitis, hearing loss and neonatal hepatitis, while rubella infection may lead to cardiac malformation, deafness and eye defects. The incidence of syphilis infection is very low and the vertical transmission rate for HIV showed a decreasing trend in the industrialized countries in recent years.[39,40] The statistics is less favorable in the developing countries.[41]

The patho-morphological signs of intrauterine infection have to be carefully looked for in case of stillbirth or neonatal death. Symmetric type of IUGR is a common association. Frequent macroscopic and microscopic features of viral and bacterial infections are summarized in Table 11.2.

Neonatal infection

Neonatal infection is frequent in preterm infants, with a higher risk and worse prognosis for low-birth-weight infants.

Sepsis occurring in the first 3 days of life, called early-onset neonatal sepsis, can be a devastating neonatal problem with a high mortality rate. Although neonatal sepsis is not very frequent (2–4 per 1000 live births) in developed countries, the rate increases for

preterm infants and those born to mothers with infections or prolonged rupture of the fetal membranes. Group B streptococci and enterobacteriaceae are the main causes of early-onset sepsis in more developed countries.[42]

Late-onset neonatal sepsis (> 72 h) is usually caused by Gram-positive agents, especially coagulase-negative staphylococci.[43,44]

Rarely, other streptococci, *Haemophilus influenzae, Serratia marcescens, Malassezia furfur, Salmonella, Pseudomonas aeruginosa, Campylobacter* and *Listeria monocytogenes* lead to neonatal infection. *Candida albicans* is the most common among fungal infections, which often colonizes the baby from birth, and sometimes causes pneumonia in infants treated with antibiotics.

The costs and benefits of intrapartum antibiotic prophylaxis therapy should be carefully evaluated and the therapeutic policies reconsidered in the light of the new data on increasing frequency of nosocomial infections.[45,46]

The most severe complications of early- and late-onset infections are pneumonia and meningitis, but enteral and urogenital infections, conjunctivitis and skin rashes may be also present. Pathological signs are frequently poor and non-specific. Macroscopically, skin rashes, congestion of the parenchymal organs, petechiae, adrenal hemorrhage, rarely leptomeningeal purulent exudates can be observed. Microscopically, inflammatory infiltrate of the airways is present in the congested, edematous lung tissue with interstitial reaction. Special stains may help to visualize the fungi. Samples for microbiological laboratory tests should be taken during postmortem examination.

Congenital tumors and tumor-like lesions

Epidemiology, biological behavior and etiology of congenital tumors

Neonatal tumors (including congenital tumors) occurring within the first 28 days of life represent an age-specific group of neoplastic lesions. The reported incidence (2003) ranged between 1 per 12,500 and 27,500 live births in the UK and the USA and varied from 17 to 121 per million births worldwide.[47]

Abnormal tissue swellings and masses present at birth are often regarded as congenital tumors, although many types of them do not fulfill the criteria of true neoplasias. These tumor-like lesions, traditionally called hamartomas and choristomas, are probably due to tissue developmental abnormalities, differentiation and migration defect of cells, resulting in a pathological architecture.

Benign and tumor-like lesions are reasonably frequent and usually harmless – such as infantile hemangioma, the smallest congenital nevi – but occasionally bear more clinical significance and complications, e.g. Kaposiform hemangioendothelioma associated with Kasabach–Merrit syndrome and fetal hydrops.[48] The biological behavior of neonatal tumors cannot always be predicted based on their morphological appearance. Benign congenital lesions may have a risk of malignant transformation, e.g. malignant melanoma can develop in giant congenital nevus.[49–51] Infantile hemangioma may show spontaneous regression; however, lesions of large size may cause cardiac failure or consumptional coagulopathy. The histologically benign cardiac fibroma or cardiac rhabdomyoma may represent a poor prognosis for its unfavorable location. In contrast, some tumors of malignant histological appearance tend to show a significantly better prognosis in early life, e.g. neuroblastoma, hereditary retinoblastoma and congenital fibrosarcoma.

A unique group of true congenital neoplasias are regarded as embryonal tumors. These are characterized by a uniformly primitive histological picture resembling the embryonal–fetal appearance of the organ in which they arise. This group includes neuroblastoma, nephroblastoma (Wilm's tumor), hepatoblastoma, retinoblastoma, embryonal rhabdomyosarcoma and medulloblastoma. Some embryonal tumors are familial, such as 40% of retinoblastomas and familial Wilm's tumors, while others associate with inherited syndromes, e.g. glycogenosis type I and hepatocellular carcinoma, or α-1 antitripsin deficiency and hepatoblastoma.

In a few sporadic malformation syndromes there is a higher risk of neonatal tumors, for example, in Beckwith–Wiedermann syndrome, where a higher risk of nephroblastoma, hepatoblastoma and adrenal cancer can be observed, or in Hirschsprung's disease, which is occasionally associated with neuroblastoma. There is a long list of many other inherited syndromes, including metabolic disorders, phacomatoses, DNA repair defects, immune deficiency syndromes, carrying a higher risk of different malignant tumors, but most of these develop only in later childhood.

Neonates with structural chromosomal anomalies may present with congenital tumors, trisomy 18 and 13 can be associated with teratomas, trisomy 18 with nephroblastoma and hepatoblastoma.[52] Acute megakaryocytic leukemia is a well-known complication of Down's syndrome in early neonatal age.[53]

On the other hand, the frequency of congenital abnormalities – spina bifida, abnormalities of ribs and eyes – was higher in children with solid tumors (Wilm's tumor, Ewing sarcoma, hepatoblastoma) than in population-based controls. This observation directs future studies in underlying gene disorders.[54]

Environmental factors including ionizing radiation, particular drugs taken during pregnancy and maternal CMV, varicella, influenza and HIV virus infections have been implicated in the etiology of neonatal (and pediatric) tumors.[55–57]

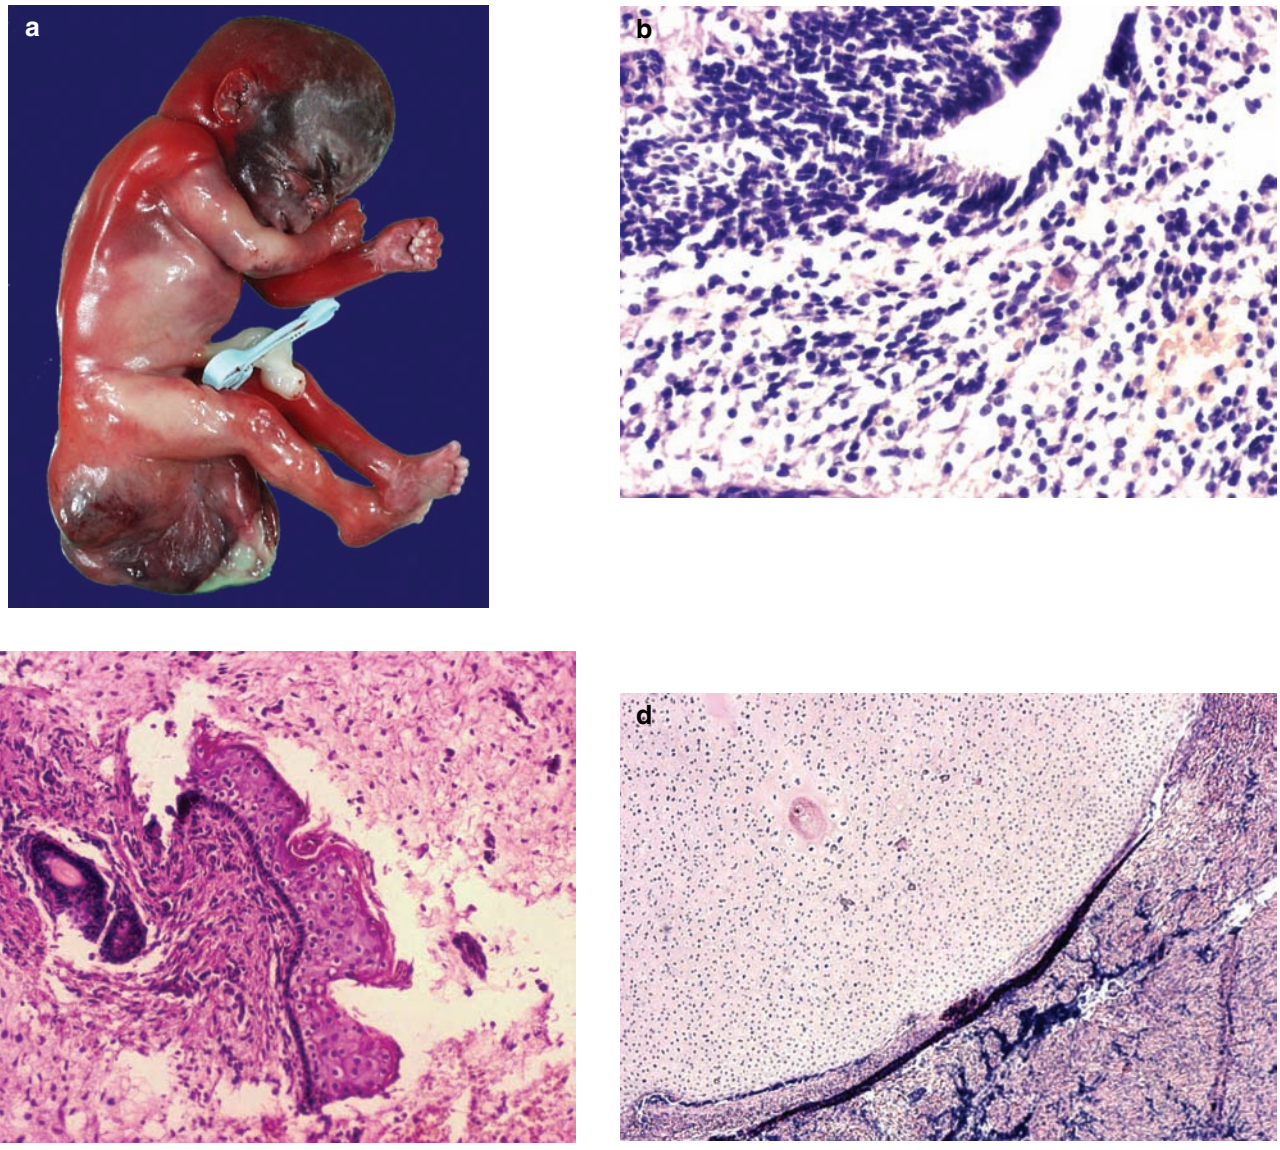

Figure 11.10 Sacrococcygeal teratoma in a fetus of 23 weeks of gestation. (a) Macroscopic picture of the large, mainly presacral tumor. (b, c and d) Microscopic examination reveals immature neural elements, squamous epithelium with a hair follicle, hyaline cartilage tissue.

Common types of solid neonatal tumors

The incidence of neonatal tumors is similar in different reports: teratoma and neuroblastoma, being the most common, followed by soft tissue tumors, renal and CNS tumors and leukemias.[47]

Congenital and neonatal teratoma

Fetal and neonatal germ cell tumors have a different clinical course and morphology from those occurring in older children or adults. Congenital teratoma has been described in numerous sites, most frequently in sacrococcygeal location, but ovarial, testicular, mediastinal, cervico-facial, retroperitoneal, abdominal and intracranial location have also been documented (Figure 11.10a–d). There are published cases of teratoma developing in the placenta or umbilical cord. Prenatal diagnosis, recognition of risk factors and intrauterine therapeutic interventions improved the outcome, although maternal complications, polyhydramnios, fetal cardiac failure, fetal hydrops and tumor rupture were not uncommon.[58–60]

Macroscopically, teratoma presents as a solid and cystic mass, potentially containing well-formed organoid structures. The traditional histological definition requires the presence of tissues from all three germ layers and most teratomas fulfill these criteria. Immature tissue is usually present in 20–50% of cases[4,61] and the histological grading is based on the amount of immature tissue;[62] however, immature neural elements do not indicate malignancy in this age group. True malignant tumors, most frequently yolk sac tumor, were present in 5.8% of teratomas, with

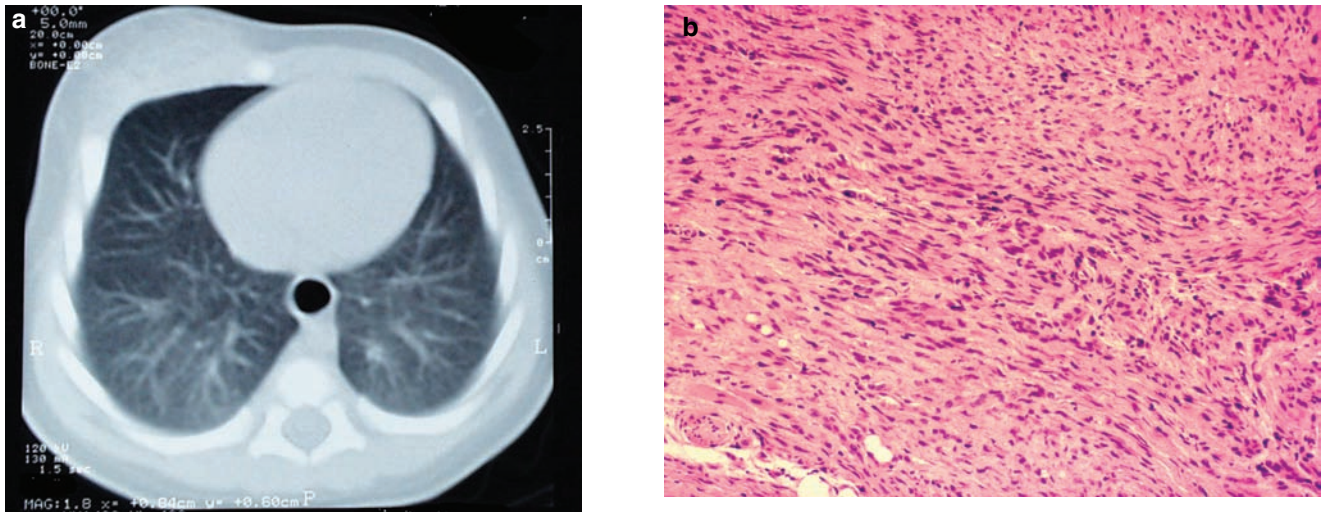

Figure 11.11 Soliter infantile myofibromatosis in a term baby. (a) CT scan shows soft tissue swelling around the second rib, on the right, suggesting infiltrative growth. (b) Characteristic microscopic appearance, with bindles of spindle cells, and small round primitive-looking cells. The soliter lesion bears an excellent prognosis.

the highest incidence (10%) in sacrococcygeal teratoma, and a tumor recurrence rate of 5% was reported in a recent review.[61]

Presacral sacrococcygeal teratoma has a worse prognosis than those in postsacral location, gastric teratoma has a good prognosis, while the outcome of the intracranial teratomas is poor with a few exceptions.[63–66] The main prognostic factors of fetal and neonatal teratoma are the size and the location, the completeness of surgical excision and the presence of malignant tumor (yolk sac tumor).

Congenital neuroblastoma

The incidence of congenital neuroblastoma is similar to that of teratoma; thus, it is the most frequent malignant tumor of the neonatal period. Ultrasonographic features of the tumor have been described and prenatal diagnosis gives an opportunity for appropriate planning and management.[67,68]

Congenital neuroblastoma usually presents with an abdominal or adrenal mass but extra-adrenal location, disseminated form, massive liver involvement and metastasis of the skin and placenta can occur.[69–72]

The morphological features are not different from those in older children, and the same histological criteria are used for classification.[73] Immunohistochemistry and electron microscopy confirm the histological diagnosis. Molecular genetics is a useful aid to detect prognostic factors. N-myc amplification, expression of bcl-2, an apoptosis suppressing protein, is associated with unfavorable histology and a bad prognosis.[74] The outcome of congenital neuroblastoma is generally favorable. A special pattern, characterized by a small primary tumor, disseminated spreading and low N-myc copy numbers, is termed as Stage IV-S neuroblastoma. Spontaneous regression is not an uncommon finding in this stage.[75–77] Only a small proportion of congenital neuroblastomas require aggressive therapy. Life-threatening respiratory complication might be related to massive hepatomegaly.

Soft tissue tumors

Fibromatosis This is a unique group of tumors with diverse clinicopathologic features.

The histological picture varies according to the specific types, but shares common features like the presence of intersecting bands of spindle cells in variably collagenized stroma. The lesions might be more cellular than the similar adult-type alterations and show an aggressive growth. In contrast with the occasionally formidable picture, the outlook is favorable. Spontaneous regression is not uncommon, although local recurrence may occur.[78]

Congenital myofibromatosis may present as a solitary lump and show spontaneous regression, while in its generalized form it carries a poor prognosis due to visceral involvement (Figure 11.11a and b). Fibromatosis colli is a palpable mass in the sternocleidomastoid muscle and occurs in young infants, while infantile digital fibromatosis may be present on the fingers and toes. Cranial fascitis and fibrous hamartoma of infancy are both rapidly growing lesions of the subcutaneous soft tissue, the former localized on the skull.

Sarcoma. Congenital infantile fibrosarcoma is a fibroblastic–myofibroblastic proliferation, a rapidly growing lesion resulting in a massive tumor. The histological appearance is sarcoma-like, but the prognosis is good, with a 5-year survival of more than 90%, and metastases are very rare.[78] Some cases have a characteristic chromosomal translocation with t(12;15)(p13;q25) and an *ETV6–NTRK3* gene fusion or *ETV6* gene rearrangement.[79] Embryonal rhabdomyosarcoma shares similar features in young infants and

children, having a 5-year survival of 66%. Embryonal rhabdomyosarcoma displays loss of heterozygosity on chromosome 11p15.5, a tumor-related locus at 11q, numerical abnormalities, trisomy 8 and other abnormalities. However, these findings do not, as yet, have diagnostic or prognostic significance.[80,81]

Neural/neuroectodermal tumors

Neural tumors in young infants are usually associated with neurofibromatosis type 1 (NF1). Plexiform neurofibromas are histologically benign lesions with premalignant potential as in about 10% of the NF1 patients malignant peripheral nerve-sheath tumor develops from it. Congenital peripheral/primitive neuroectodermal tumor (PNET) has been reported in several sites.[82–84] PNET and Ewing sarcoma are now considered the same entity, based on their shared genetic abnormalities, being consistently associated with chromosomal translocation and functional fusion of the *EWS* gene to any of several structurally related transcription factor genes (*EWS-FLI-1*, *EWS-ERG*, *EWS-ETV1*, *EWS-E1AF*, etc.).[85]

Adipose tumors of the neonate

Lipoblastoma, a typical benign tumor of fat tissue in early childhood, occasionally may be present at birth. The circumscribed type is more common, with superficial location, while the diffuse type (lipoblastomatosis) originates from deep soft tissue, has an infiltrative growth pattern and recurs more frequently. Characteristic clonal karyotypic changes can be demonstrated and help to distinguish it from childhood and adult lipomas as well as from myxoid liposarcoma.[86]

Intracranial tumors

The most frequently diagnosed intracranial tumor is teratoma, PNET, medulloblastoma, astrocytoma, glioblastoma multiforme and ependymoma. Plexus choroideus papilloma, ganglioglioma and low-grade astrocytoma have the best prognosis, but the overall survival rate of perinatal brain tumors was only 28% in a recent review. Stillbirth is frequent and hydrocephalus-macrocephaly is often diagnosed prenatally.[87–90]

Congenital tumors of the kidney

Congenital mesoblastic nephroma is a benign tumor, and occasionally leads to fetal hydrops and polyhydramnios. Although the tumor mass can be huge and extends beyond the kidney, surgical treatment is usually curative. Histologically, the tumor consists of spindle cells of myofibroblastic origin. A more cellular variant is known that carries the same t(12;15)(p13;q25) and *ETV6–NTRK3* gene fusion as infantile fibrosarcoma.[91]

Rhabdoid tumor of the kidney is an aggressive tumor with bad prognosis and distinct morphological features. It is characterized by deletion of the *hSNF5/INI1* gene, which links it to other rhabdoid tumors of infancy that arise in the soft tissue and brain.[92]

Congenital and infantile Wilm's tumor is rare and shows a strong association with the presence of nephrogenic rests (persistent metanephric blastema) in the kidney.[93] Recent molecular genetic findings suggest a multistep model of the pathogenesis in Wilm's tumor and support the precursor role of nephrogenic rests.[94] Nephrogenic rest as well as nephroblastoma may be present in bilateral location. Nephroblastoma of early infancy has a good prognosis.[95,96]

12 Ethics: An essential dimension of perinatal medicine

F. A. Chervenak and L. B. McCullough

Introduction

Ethics is an essential dimension of perinatal medicine.[1–3] In this chapter, we develop a framework for clinical judgment and decision making about the ethical dimensions of perinatal medicine. We will emphasize a preventive ethics approach that anticipates the potential for ethical conflict and adopts ethically justified strategies to prevent those conflicts from occurring. Preventive ethics in perinatal medicine helps to build and sustain a strong physician–patient relationship.

This chapter has five parts. First, we define ethics, medical ethics, and the fundamental ethical principles of medical ethics: beneficence and respect for autonomy. Second, we show how these two principles should interact in perinatal medicine with emphasis on the clinical ethical concept of the fetus as a patient. Third, we describe different concepts of the ethical principles of justice. Fourth, we examine ethical issues in managed care with particular attention to the virtues of the physician as a professional. Fifth, we describe a new formal tool for critically appraising the literature of medical ethics, including perinatal ethics.

Ethics and medical ethics

Ethics is understood to be the disciplined study of morality. Medical ethics is therefore the disciplined study of morality in medicine, and concerns the obligations of physicians and health care organizations to patients, as well as the obligations of patients.[4] Medical ethics should be distinguished from the many sources of morality in pluralistic societies. These include law, our political heritage as free people, the world's religions, ethnic and cultural traditions, families, the traditions and practices of medicine (including medical education and training), and personal experience. Medical ethics since the 18th century European and American enlightenments has been secular.[5] It makes no reference to God or revealed tradition, but to what rational philosophical discourse produces. Therefore, ethical principles and virtues should be understood to apply to all physicians, regardless of their personal, religious, and spiritual beliefs.[6]

The traditions and practices of medicine constitute an important source of morality for physicians because they are based on the obligation to protect and promote the health-related interests of the patient. This obligation tells physicians what morality in medicine ought to be in very general and abstract terms. Providing a detailed and clinically applicable account of that obligation is the central task of medical ethics, using ethical principles.[4]

Ethical principles

The principle of beneficence

The ethical principle of beneficence requires one to act in a way that is expected reliably to produce the greater balance of benefits over harms in the lives of others.[6] Putting this principle into clinical practice requires a reliable account of the benefits and harms relevant to the care of the patient and how those benefits and harms should be reasonably balanced against each other, when not all of them can be achieved in a particular clinical situation. In medicine, the principle of beneficence requires the physician to act in a way that is reliably expected to produce a greater balance of clinical benefits, over clinical harms, for the patient.[4]

Beneficence-based clinical judgment has an ancient pedigree with its first expression found in the Hippocratic Oath and accompanying texts.[7] Beneficence-based clinical judgment aims to interpret reliably the health-related interests of the patient from a rigorous clinical perspective, which is provided by accumulated scientific research, clinical experience, and reasoned responses to uncertainty. Such a rigorous clinical perspective is thus not the function of the individual clinical perspective of any particular physician, and therefore should not be based merely on the clinical impression or intuition of an individual physician.

On the basis of this rigorous clinical perspective, which should be based on the best-available evidence, beneficence-based clinical judgment identifies the clinical benefits that can be achieved based on the competencies of medicine. The benefits that medicine is competent to seek for patients are the prevention and management of disease, injury, handicap, unnecessary pain, and suffering, and the prevention of premature or unnecessary death. Pain and suffering become unnecessary when they do not result in achieving the other benefits of medical care, e.g. allowing a woman to labor without effective analgesia.[4] Non-maleficence means that the physician should not, on balance, cause harm, and is best understood as expressing the limits of beneficence. This is also known as '*Primum non nocere*' or 'first do no harm'. This commonly invoked dogma is really a Latinized misinterpretation of the Hippocratic texts, which emphasized beneficence, while avoiding harm when approaching the limits of medicine.[4] There is an inherent risk of paternalism in beneficence-based clinical judgment. By this we mean that beneficence-based clinical judgment, if it is mistakenly taken by the physician to be the sole source of moral responsibility, and therefore moral authority in medical care, invites the unwary physician to conclude that beneficence-based judgments can be imposed on the patient irrespective of her autonomy. Paternalism is a dehumanizing response to the patient and therefore should be avoided in the practice of perinatal medicine.

The preventive ethics response to paternalism is for the physician to explain the diagnostic, therapeutic, and prognostic reasoning that leads to his or her clinical judgment about what is in the interest of the patient and her pregnancy, so that the patient can assess that clinical judgment for herself. The physician should first explain to the patient the major factors of this reasoning process, including matters of uncertainty. In neither medical law nor medical ethics does this require that the patient be provided with a complete medical education.[8] The physician should then explain how and why other clinicians might reasonably differ from his or her clinical judgment. The physician should then present a well-reasoned response to this critique. The outcome of this process should be that beneficence-based clinical judgments take on a rigor, which they sometimes lack, and the process of their formulation includes explaining them to the patient. In complex areas, such as perinatal medicine, beneficence-based clinical judgment will frequently result in the identification of a continuum of clinical strategies, which protect and promote health-related interests. Awareness of this feature of beneficence-based clinical judgment provides an important preventive ethics antidote to paternalism by increasing the likelihood that one or more of these medically reasonable, evidence-based alternatives will be acceptable to the patient. This feature of beneficence-based clinical judgment also provides a preventive ethics antidote to 'gag' rules that restrict physician's communications with the managed care patient.[9] All beneficence-based alternatives must be identified and explained to all patients, regardless of how the physician is paid, especially those who are well established in evidence-based perinatal medicine.

One advantage for the physician in carrying out this approach to communicating with the patient would be, we believe, to increase the likelihood of compliance.[10] This is an especially pertinent consideration in perinatal medicine, e.g. self-observation for unusual weight gain, bleeding, or signs of premature labor. Another advantage would be to provide the patient with a better-informed opportunity to make a decision about whether to seek a second opinion. The approach outlined above should make a decision less threatening to her physician, who has already shared with the patient the limitations of clinical judgment.

The principle of respect for autonomy

To complement the principle of beneficence, there is emphasis in the literature of medical ethics on the principle of respect for autonomy.[6] This principle requires one to always acknowledge and carry out the value-based preferences of the adult, competent patient, unless there is compelling ethical justification for not doing so, e.g. prescribing antibiotics for viral respiratory infections. The pregnant patient increasingly brings to her medical care her own perspective on what is in her and her pregnancy's interest. The principle of respect for autonomy translates this into autonomy-based clinical judgment. Because each patient's perspective on her interests is a function of her values and beliefs, it is impossible to specify in advance the benefits and harms of the patient's autonomy-based clinical judgment. Indeed, it would be inappropriate for the physician to do so, because the definition of her benefits and harms and their balancing are the prerogative of the patient. Autonomy-based clinical judgment is strongly antipaternalistic in nature.[4]

The responsible practice of perinatal medicine depends on an operationalized concept of autonomy to make it relevant to clinical practice. We therefore identify three sequential autonomy-based behaviors on the part of the patient: (1) absorbing and retaining information about her condition and alternative diagnostic and therapeutic responses to it, (2) understanding that information (i.e. evaluating and rank-ordering those responses and appreciating that she could experience the risks of treatment), and (3) expressing a value-based preference. The physician has a role to play in each of these. They are, respectively, (1) to recognize the capacity of each pregnant patient to deal with medical information (and not to underestimate that capacity), provide information (i.e. disclose and explain all medically reasonable alternatives, that is,

supported in beneficence-based clinical judgment), and recognize the validity of the values and beliefs of the patient; (2) not to interfere with, but, when necessary, to assist the patient in her evaluation and ranking of diagnostic and therapeutic alternatives for managing her condition; and (3) to elicit and implement the patient's value-based preference.[4]

Beneficence and respect for autonomy in perinatal practice

The ethical principles of beneficence and respect for autonomy play a central role in perinatal practice. There are obviously beneficence-based and autonomy-based obligations to the pregnant patient: the physician's perspective on the pregnant woman's health-related interests provides the basis for the physician's beneficence-based obligations to her. Her own perspective on those interests provides the basis for the physician's autonomy-based obligations to her. Because of an insufficiently developed central nervous system, the fetus cannot meaningfully be said to possess values and beliefs. Thus, there is no basis for saying that a fetus has a perspective on its interests. Hence, there can be no autonomy-based obligations to any fetus. The language of fetal rights has no meaning and therefore no application to the fetus in perinatal clinical judgment and practice, despite its popularity in public and political discourse in the United States and other countries. The physician does have a perspective on the fetus's health-related interests, and the physician can have beneficence-based obligations to the fetus, 'but only when the fetus is a patient'.[4]

Clinical ethical concept of the fetus as a patient

The clinical ethical concept of the fetus as a patient is essential to perinatal clinical judgment and practice. Developments in fetal diagnosis and perinatal management strategies to optimize fetal outcome have become widely accepted, encouraging the development of this concept. This concept has considerable clinical significance, because when the fetus is a patient, directive counseling, that is, recommending clinical management for fetal benefit, is appropriate, and when the fetus is not a patient, non-directive counseling, that is, offering, but not recommending, a form of management for fetal benefit, is appropriate. However, these seemingly straightforward roles for directive and non-directive counseling are often difficult to apply in actual perinatal practice, because of uncertainty about when the fetus is a patient. This concerns moral status, i.e. whether others have an ethical obligation to the fetus to protect and promote its interests.

One prominent approach for establishing whether or not the fetus has the moral status of being a patient has involved attempts to show whether or not the fetus has independent moral status. Independent moral status for the fetus means that one or more characteristics that the fetus possesses in and of itself, and therefore independently of the pregnant woman or any other factor, generate and therefore ground clinical obligations to the fetus on the part of the pregnant woman and her physician.

Many fetal characteristics have been proposed as the basis for such independent moral status, including moment of conception, implantation, central nervous system development, quickening, and the moment of birth. It should come as no surprise that there is considerable variation among ethical arguments about when the fetus acquires independent moral status. Some take the view that the fetus has independent moral status from the moment of conception or implantation. Others believe that independent moral status is acquired in degrees, thus resulting in 'graded' moral status. Still others hold, at least by implication, that the fetus never has independent moral status so long as it is *in utero*.[11,12]

Despite an enormous amount of theological and philosophical literature on this subject, there has been no closure on a single authoritative account of the independent moral status of the fetus. This outcome should be expected because, given the absence of a single method that would be authoritative for all of the markedly diverse theological and philosophical schools of thought involved in this sometimes acrimonious debate, closure is impossible. For closure ever to be possible, debates about such a final authority within and between theological and philosophical traditions would have to be resolved in a way satisfactory to all, an inconceivable intellectual and cultural event. Claims about the independent moral status of the fetus, as the basis for claims about the fetus as a patient, have no stable or clinically applicable meaning. We therefore abandon these futile attempts to understand the fetus as a patient in terms of independent moral status of the fetus and turn to an alternative approach.

Our analysis of the clinical ethical concept of the fetus as a patient starts with the recognition that being a patient does not require that one possess independent moral status. Rather, being a patient means that one can benefit from the applications of the clinical skills of the physician. More precisely stated, a human being is properly regarded as a patient when two conditions are met: (1) the human being is presented to the physician and (2) there exist clinical interventions that are reliably expected to be efficacious, in that they are reliably expected to result in a greater balance of clinical benefits over harms for the human being in question.[13] We call this the dependent moral status of the fetus as a patient.

The authors have argued elsewhere that beneficence-based obligations to the fetus exist when the fetus is reliably expected later to achieve independent moral status

as a child and a person. The fetus is a patient when the fetus is presented for medical interventions, whether diagnostic or therapeutic, that reasonably can be expected to result in a greater balance of benefits over harms for the child and person the fetus can *later* become during early childhood.[4] The clinical ethical significance of the concept of the fetus as a patient, therefore, depends on the links that can be established between the fetus and its later achieving independent moral status.

The viable fetus as a patient

One such link is viability. Viability is not an intrinsic property of the fetus because viability should be understood in terms of both biological and technological factors. It is only by virtue of both factors that a viable fetus can exist *ex utero* and thus achieve independent moral status. It is important to appreciate that these two factors do not exist as a function of the autonomy of the pregnant woman. When a fetus is viable, that is, when it is of sufficient maturity so that it can survive into the neonatal period and achieve independent moral status, given the availability of the requisite technological support, and when it is presented to the physician, the fetus is a patient.

Viability exists as a function of biomedical and technological capacities. These differ in different parts of the world. As a consequence, there is no worldwide, uniform gestational age to define viability. In the USA, we believe viability presently occurs at approximately 24 weeks of gestational age.[14]

When the fetus is a patient, directive counseling for fetal benefit is ethically justified. In perinatal practice, directive counseling for fetal benefit involves recommending against termination of pregnancy, recommending against non-aggressive management, or recommending aggressive management. Aggressive obstetric management includes interventions, such as fetal surveillance, tocolysis, cesarean delivery, or delivery in a tertiary care center when indicated. Non-aggressive obstetric management excludes such interventions. Directive counseling for fetal benefit, however, must always take account of the presence and severity of fetal anomalies, extreme prematurity, and obligations to the pregnant woman.

The strength of directive counseling for fetal benefit justifiably varies according to the presence and severity of anomalies. As a rule, the more severe the fetal anomaly, the less directive counseling should be for fetal benefit. In particular, when lethal anomalies, such as anencephaly, can be diagnosed with certainty, there are no beneficence-based obligations to provide aggressive management. Such fetuses are dying patients, and the counseling, therefore, should be non-directive in recommending between non-aggressive management and termination of pregnancy, but directive in recommending against aggressive management for the sake of maternal benefit.[15] By contrast, third-trimester abortion for Down's syndrome or achondroplasia is not ethically justifiable, because the future child with high probability will have the capacity to grow and develop as a human being.[16,17]

Directive counseling for fetal benefit in cases of extreme prematurity of viable fetuses is appropriate. In particular, this is the case for what we term just-viable fetuses, those with a gestational age of 24–26 weeks, for which there are significant rates of survival, but high rates of mortality and morbidity. These rates of morbidity and mortality can be increased by non-aggressive obstetric management, whereas aggressive obstetric management may favorably influence outcome. Thus, it appears that there are substantial beneficence-based obligations to just-viable fetuses to provide aggressive obstetric management. This is all the more the case in pregnancies beyond 26 weeks of gestational age. Directive counseling for fetal benefit is therefore justified in all cases of extreme prematurity of viable fetuses. Of course, such directive counseling is appropriate only when it is based on documented efficacy of aggressive obstetric management for each fetal indication. For example, such efficacy has not been demonstrated for routine cesarean delivery to manage extreme prematurity.

All directive counseling for fetal benefit must occur in the context of balancing beneficence-based obligations to the fetal patient against beneficence-based and autonomy-based obligations to the pregnant woman. Any such balancing must recognize that a pregnant woman is obligated only to take reasonable risks of perinatal interventions that are reliably expected to benefit the viable fetus or child later. A unique feature of perinatal ethics is that the pregnant woman's autonomy influences whether, in a particular case, the viable fetus ought to be regarded as presented to the physician.

Obviously, any strategy for directive counseling for fetal benefit that takes account of obligations to the pregnant woman must anticipate the possibility of conflict between the physician's recommendation and the pregnant woman's autonomous decision to the contrary. Such conflict should be managed preventively through the use of the informed consent process as an ongoing dialog throughout a woman's pregnancy, augmented as necessary by negotiation and respectful persuasion.[18]

The previable fetus as a patient

The only possible link between the previable fetus and the child it can become is the pregnant woman's autonomy, because technological factors cannot result in the previable fetus becoming a child. The link, therefore, between a previable fetus and the child it can become can be established only by the pregnant woman's decision to confer the status of being a patient on her previable fetus. The previable fetus has no claim to the status of being a patient independently of the

pregnant woman's autonomy. The pregnant woman is therefore free to withhold, confer, or, having once conferred, withdraw the status of being a patient on or from her previable fetus, according to her own values and beliefs. The previable fetus is presented to the physician as a function of the pregnant woman's autonomy.[4]

Counseling the pregnant woman regarding the management of her pregnancy when the fetus is previable should be non-directive in terms of continuing the pregnancy or having an abortion if she refuses to confer the status of being a patient on her fetus. If she does confer such status in a settled way, at that point beneficence-based obligations to her fetus come into existence, and directive counseling for fetal benefit becomes appropriate for these previable fetuses. Just as for viable fetuses, such counseling must take account of the presence and severity of fetal anomalies, extreme prematurity, and beneficence-based and autonomy-based obligations to the pregnant woman.

For pregnancies in which the woman is uncertain about whether to confer such status, the authors propose that the fetus be 'provisionally' regarded as a patient. This justifies directive counseling against behavior that can harm a fetus in significant and irreversible ways, e.g. substance abuse, especially alcohol, until the woman settles on whether to confer the status of being a patient on the fetus.

In particular, non-directive counseling is appropriate in cases of what we term near-viable fetuses, that is, those that are 22–23 weeks of gestational age, for which there are anecdotal reports of survival. In our view, aggressive obstetric and neonatal management should be regarded as clinical investigation (i.e. a form of medical experimentation), not a standard of care.[14] There is no clinical obligation on the part of any pregnant woman to confer the status of being a patient on a near-viable fetus, because the efficacy of aggressive obstetric and neonatal management has yet to be proven.

The *in vitro* embryo as a patient

A subset of previable fetuses as patients concerns the *in vitro* embryo.[19] It might seem that the *in vitro* embryo is a patient, because such an embryo is presented to the physician. However, for beneficence-based obligations to a human being to exist, it must also be the case that medical interventions are reliably expected to be efficacious.

Whether the fetus is a patient depends on the links that can be established between the fetus and its eventual independent moral status. Therefore, whether medical interventions on the *in vitro* embryo should be reliably expected to be efficacious for the child later depends on whether that embryo later becomes viable. Otherwise, no benefit of such intervention can meaningfully be said to result. An *in vitro* embryo becomes viable only when it survives *in vitro* cell division, transfer, implantation, and subsequent gestation to such a time that it becomes viable. The process of achieving viability occurs only *in vivo* and is therefore entirely dependent on the woman's decision regarding the status of the fetus(es) as a patient, should assisted conception successfully result in the gestation of the previable fetus(es). Whether an *in vitro* embryo will become a viable fetus, and whether medical intervention on such an embryo will benefit the fetus and future child, are both functions of the pregnant woman's autonomous decision to withhold, confer, or, having once conferred, withdraw the moral status of being a patient on or from the previable fetus(es) that might result from assisted conception.

It therefore is appropriate to regard the *in vitro* embryo as a previable fetus rather than as a viable fetus. As a consequence, any *in vitro* embryo(s) should be regarded as a patient only when the woman into whose reproductive tract the embryo(s) will be transferred confers that status. Thus, counseling about preimplantation diagnosis should therefore be non-directive, just as it should be for previability counseling. One additional justification is that the woman may elect not to implant abnormal embryos. These embryos will not become patients, and so there is no basis for directive counseling regarding them. Information should be presented about prognosis for a successful pregnancy and the possibility of confronting a decision about selective reduction, depending on the number of embryos transferred. Counseling about how many *in vitro* embryos should be transferred should be rigorously evidence based.[20]

Justice and perinatal medicine

Ethical concerns about justice arise when economic, clinical, or other resources are scarce. Justice requires that in the distribution of resources, each should receive what is due to him or her. Different concepts of justice define 'due' in different ways. Each strives to result in a fair distribution of benefits, i.e. access to resources, and burdens, the risks that could follow from lack of such access.

Utilitarianism is a theory of justice that makes central the obligation to produce the greatest good for the greatest number in the management of scarce resources. To be successful in guiding practical, day-to-day decisions about the allocation of resources, utilitarianism requires an account of the greatest good. For society overall, it has been difficult, if not impossible, to define what the greatest good is. The value of utilitarianism is the balance it seeks to achieve among benefits and burdens of scarce resources, so that inequalities do not become inequities, i.e. unfair. Critics of utilitarians have pointed out that sometimes utilitarianism results in inequities, i.e. shared distributions of benefits and burdens.[21]

Two other concepts of justice have been developed to address this problem. The first of these is a libertarian concept of justice. This concept of justice was

developed to correct for tyrannical burdens that pure utilitarianism could create. In particular, libertarianism was developed to give priority to individual freedom and property rights, as correctives to the potential excesses of utilitarianism and, in the political realm, of state power. Libertarians argue that in a market that places different values on different services and products, and in which there is an equal opportunity to develop one's talents, those who provide more highly valued services rightly earn more than those who provide less valued (though not necessarily less intrinsically valuable) services. Everyone should get to keep what he or she earns through these marketplace exchanges, reflecting the strong emphasis of the libertarian concept of justice on property rights. Libertarian theories emphasize fairness of process, rather than equality of outcomes.

The other concept of justice that has been developed is an egalitarian concept of justice. This concept was developed to protect vulnerable and disadvantaged members of society, who may lose out in a utilitarian distribution of scarce resources. This concept of justice corrects for unfair outcomes in the form of undue burdens on those least able to protect themselves.

These three and other concepts of justice remain in unresolved competition in ethics generally, in medical ethics,[22] and in perinatal ethics. It is fair to say that the medical ethics literature is strongly influenced by a concept of justice that calls for fair equality of opportunity (an element of libertarian justice) and protection of the least well-off (an element of egalitarian justice). However, it is also fair to say that no single concept of justice shapes health care policy in the United States. This lack of a conceptually coherent health care policy is a long-standing feature of American health care policy. In particular, unlike many other developed countries, the United States has yet to create a universal right to health care, though there are selective entitlements.

Managed care and the professional virtues

The practice of perinatal medicine is coming under managed care, which involves a set of strategies used by both private and public payers to control the cost of medical care. Two main business tools are used to achieve this goal: (1) creating conflicts of interests in how physicians are paid, diplomatically called 'sharing economic risk', and (2) increasingly strict control of clinical judgment and practice through such means as practice guidelines, critical pathways, physician report cards, and retrospective chart reviews. These business tools generate ethical challenges to perinatologists who seriously threaten the virtues that define the fiduciary character of medicine as a profession.[23]

In medicine, the physician is the patient's fiduciary. The physician should be competent and use clinical competence as a matter of routine and habit primarily to protect and promote patients' interests rather than pursue his or her own interests. Virtues are those traits and habits of character that routinely focus the concern and behavior of an individual on the interests of others and thereby habitually blunt the motivation to act on self-interest one's primary consideration. We believe that four virtues constitute the physician–patient relationship based on the physician as fiduciary.[4]

The first virtue is *self-effacement.* This professional virtue requires the physician not to act on the basis of potential differences between the patient and the physician, such as race, religion, national origin, gender, sexual orientation, manners, socioeconomic status, or proficiency in speaking English. Self-effacement prevents biases and prejudices from arising from these differences that could adversely impact on the plan of care for the patient.

The second professional virtue is *self-sacrifice.* This requires physicians to accept reasonable risks to themselves. As an example, perinatologists manifest this virtue in their willingness to perform a cesarean delivery for an HIV+ patient, following accepted standards. In both fee-for-service and managed care, the professional virtue of self-sacrifice obligates the physician to blunt economic self-interest and focus on the patient's need for relief, when the two are in conflict.

The third professional virtue, *compassion,* motivates the physician to recognize and seek to alleviate the stress, discomfort, pain, and suffering associated with the patient's disease and illness. Self-effacement, self-sacrifice, and compassion provide the basis for a powerful ethical response to the business tool of conflicts of interest by the physician.

This response is strengthened by the fourth professional virtue, *integrity.* This virtue imposes an intellectual discipline on the physician's clinical judgments about the patient's problems and how to address them. Integrity prescribes rigor in the formation of clinical judgment. Clinical judgment is rigorous when it is based on the best available scientific information or, when such information is lacking, on consensus clinical judgment and on careful thought processes of an individual physician that can withstand peer review. Integrity is thus an antidote to the pitfalls of bias, subjective clinical impressions, and unexamined clinical 'common sense' that can undermine evidence-based practice. Integrity provides the basis for the physician's ethical response to the business tool of control of clinical judgment and practice.

None of these four virtues is absolute in its ethical demands. The task of medical ethics is to identify both the application and the limits of these four virtues. The concept of legitimate self-interest provides the basis for these limits. Legitimate self-interest includes protecting the conditions for practicing medicine well, fulfilling obligations to persons in the physician's life other than the patient, and protecting activities outside the practice of medicine that the physician finds deeply fulfilling.

Managed care and the physician as fiduciary

The fee-for-service practice of medicine unconstrained by fiduciary obligations could and did in the past lead to harm to patients from non-indicated overutilization of resources. It is a violation of the standard of care to subject patients to unnecessary active intervention in order to achieve personal economic gain. Managed care unconstrained by fiduciary obligations puts patients at risk of harm by denying access to the standard of care. This will occur if patients are subjected to unnecessary risk from withholding appropriate care and intervention in order to achieve reduced cost.[23,24]

Financial incentives to the physician and supervision of clinician decision making with strict controls over utilization are the business tools managed care uses. Forms of payment by managed care plans, such as capitation and withhold, deliberately impose an economic conflict of interest on the physician.[25] Every time the physician uses a resource, e.g. consultation, diagnostic testing, or surgical procedures, the physician pays an economic penalty. The ethical challenge occurs when the patient's interests are subordinated to the pursuit of financial rewards and are thereby harmed by this underutilization.

The professional virtue of self-sacrifice prohibits the physician from making the avoidance of such financial risk, the *primary* consideration. Avoiding financial risk as one's primary consideration involves an ethically pathologic process that leads naturally and quickly to the abandonment of self-effacement (economically driven managed care for some patients, but not for others), compassion (patients' health-related concerns do not matter but are only a means to maximize revenues), and integrity (the standard of care is sacrificed to maximize revenues). Importantly, physicians are not sanctioned by society to engage in the destruction of medicine as a fiduciary profession, because it is a public trust, not a private fiefdom.

Physicians should not assume that managed care organizations (MCOs) are unwilling to negotiate contracts to reduce the severity of economic conflicts of interest. Physicians should therefore make a good faith effort to negotiate these matters. If the MCO refuses to negotiate and the economic risk of not signing the contract is very significant, then the physician should voluntarily accept the ethical responsibility to be alert to and manage these conflicts of interest well. First, integrity requires that the physician avoid the self-deception of underestimating any potential influence on clinical judgment and practice by the conflict of interest. Second, once these contracts are signed, the professional virtues add an important dimension to total quality management: diligent monitoring of conflicts of interest to prevent them from resulting in substandard care should be among the physician's 'accountabilities'. Third, the realities of managed care mean that, for the near term at least, increasing financial sacrifice may be required to protect the integrity of medicine as a fiduciary profession. Fourth, in group practice, there should be a fair sharing of economic self-sacrifice. In particular, individual efforts to tune the system to one's economic advantage in a group, for example, avoiding the care of high-risk pregnancies, and to the disadvantage of colleagues should be avoided.

The second business tool of managed care, increasingly strict control of clinical judgment and practice, is a heterogenous phenomenon. Some managed care plans are poorly capitalized and poorly managed. They compete by price, with little or no attention given to the quality of their services. A 'bottom line' mentality dominates with economic savings and net revenue maximization the overriding values. These poorly managed companies have little or no understanding of or interest in the fiduciary nature of medicine, and so their controls of clinical judgment and practice are driven almost entirely by economic considerations.

Physicians subject to management controls by such companies face the very difficult challenge of trying to get such companies to constrain their economic interests by their fiduciary obligations, a daunting task but not, we believe, impossible. The concerns of ethics, especially to protect the integrity of the fiduciary enterprise, may frequently be swept aside when they are not ignored altogether. However, as the fiduciaries of patients, physicians in such MCOs are the ultimate bulwark on which patients and society must be able to rely at the present time to protect patients from management's unbridled pursuit of economic self-interest. Physicians, therefore, should strenuously resist and seek to change management controls driven solely by economic considerations. Adhering to evidence-based medicine of perinatal practice becomes a powerful tool for achieving this goal. If physicians refused to cooperate with such poorly managed companies, systematic dissociation would result in a loss of market share or, more optimistically, better management.

Being physician controlled does not provide the MCO immunization against the ethical challenges of the business tools of managed care. These new physician-owned provider entities will not provide a solution in and of themselves to the ethical threats of conflict of interest and control of clinical judgment and practice. The virtue-based arguments we have made will apply to these new entities without exception.

There is no conclusive evidence that preserving medicine as a fiduciary profession is impossible, even given the enormous economic power of MCOs. Ethics teaches us that business and economic power are not absolute and should always be called to account for their consequences. Society has not given MCOs the moral authority or permission to destroy the fiduciary character of medicine as a consequence of the pursuit of economic interest and power. Nor has society given physicians the moral authority or permission to cooperate willfully in this destruction. Quite the

opposite, society counts on physicians because ultimately society can count on no one else to preserve and advocate for the fiduciary character of the medical profession.

Argument-based ethics

Before turning to the presentation of a formal tool[26] for critically appraising the ethics literature, it is important to distinguish descriptive from normative medical ethics. The proposed formal tool is designed to be applied to the latter. Descriptive medical ethics uses empirical methods to obtain data that describe the actual ethical judgments, practices, and policies of physicians and health care organizations, of patients and their families, and of the larger society. These articles also report the results of ethically justified interventions for their clinical effects. Descriptive ethics articles use accepted methods of empirical research, such as interviews analyzed with qualitative methods and questionnaire research analyzed with quantitative methods.[27,28] Such empirical studies are common in the medical literature and should be critically appraised using appropriate methodology that has already been well described.[29–37]

The literature of normative medical ethics is argument based. It therefore uses the tools of ethical analysis and argument to explore the implications of ethical concepts for what clinical practice and organizational and health care policy ought to be, as we did above with respect to the clinical ethical concept of the fetus as a patient. Normative ethics scholarship offers reasoned conclusions about what clinical judgment, decision making, and behavior ought to be, rather than empirically based descriptions of what these are.

Formal assessment tool

The new critical appraisal tool presented here is adapted from recent work on critical appraisal of the medical literature reporting the results of qualitative research[26] (see Figure 12.1).

Does the article address a focused ethics question?

Normative ethics articles in perinatal medicine should have a clear, well-defined focus. This focus should be reflected in the title and made explicit in the introductory section of the paper. There are a number of possible domains for the focus of normative ethics literature, including theoretical issues (such as whether the fetus is a patient or a person), clinical issues for a specific patient population (the management of pregnancy in a diabetic patient), research issues for a specific population (surgical management of fetal spina bifida), organizational management issues (quality improvement and cost control of IVF services), and public policy issues (partial-birth abortion).

The importance of the issue should be explained, which can be theoretical or clinical. The issue may be important for research or for organizational and public policy. The importance of the issue should be justified. It is important that the article should identify the perspective from which importance of the issue is claimed, whether that of physicians, scientific investigators, patients, patient's families and other support networks, payers, health care organization leadership, and scholars and public officials concerned with health policy. The target audience for the article should be made clear.

Are the arguments that support the results of the article valid?

This question concerns whether the results of the article, i.e. the conclusions that it draws about what morality in medicine ought to be, are supported by high-quality ethical analysis and argument. The literature of normative ethics in perinatal medicine is now quite extensive, making it increasingly unlikely that

there is no prior relevant literature that should be considered. Relevant literature should be cited and analysis and arguments from this literature should be presented clearly and accurately. In the basic and clinical science literature, investigators are increasingly expected to elucidate the search strategies, including keywords, databases, bibliographies, and other sources used. The same standard should begin to be met by the normative ethics literature. In assessing the search of an article, the critical reader should first ask, how adequate is the article's search strategy? In as much as all are major forms of scholarship in bioethics, are articles, book chapters, and books cited?

Is the literature carefully reviewed? By this we mean that the major positions on the issue should be presented in a clear and unbiased fashion. How these positions have developed and their critical interaction should be explained, so that the reader is provided with a reliable account of the best thinking on the subject. Major positions should be critically appraised for their strengths and weaknesses and how well they have responded to criticisms that advanced against them.

What is the quality of the paper's analysis and argument? Quality turns on both validity and soundness. Validity concerns the formal qualities of ethical analysis and argument. Are relevant clinical and other facts clearly identified and supported? Are key concepts and ethical appeals clearly stated and reasonably related to clinical information? Are these concepts and appeals used with consistent meaning throughout the argument? Do the reasons given for the position, the premises of the argument, fit together into a coherent whole? Is the conclusion that follows from those premises clearly stated? Normative ethics in perinatal medicine is not an 'ivory tower' enterprise; it concerns issues of vital importance in clinical practice and research and in organizational management and health policy. Physician readers are therefore entitled to expect authors of normative medical ethics scholarship to take a clinically relevant and applicable stand that is supported by the argument presented.[4,41]

Soundness concerns the substance of the ethical analysis and argument, including especially whether the conclusion should be regarded as reliable, i.e. one on which the physician can act with confidence that patient care will be improved as a result. Reliable arguments are those in which a clear warrant of defense is given for each premise or reason offered in support of the conclusion.

In preventing readers' bias,[42] it is helpful to identify the disciplines represented among the authors. The normative medical ethics literature is distinctive in that work of high quality by non-clinicians should influence the clinical judgment and decision making of physicians, just as a work on infectious diseases of the reproductive tract by microbiologists or on pharmacokinetics of gynecologic cancer chemotherapy by pharmacologists rightly influences clinical judgment and practice. Normative ethics work, therefore, should not be dismissed when only some, or even none, of the authors are physicians.

At the same time, the reader should beware of positive or negative bias toward an article, based on the reputation of the author(s) or of the journal. Just as in the basic and clinical sciences, the standing of authors in journals in obstetrics and gynecology or in the field of bioethics is no guarantee of quality in normative medical ethics.

What are the results?

The results of normative ethics are the conclusions of ethical analysis and argument. These conclusions should be clearly stated and easy to find in the article.

Will the results help me in clinical practice?

The results of normative ethics articles and books can be helpful in at least three ways. First, they may have important practical implications, especially if the paper incorporates evidence to support the clinical utility of acting on the conclusions of the paper. The quality of the empirical evidence cited should be assessed in the same way as evidence should be assessed in any medical or scientific article.[29–37] The results for clinical practice, research, organizational management, or policy should be assessed as well. Second, they may have important theoretical implications, which do not depend on whether an intervention was performed and evaluated. Identifying such theoretical implications results in critical assessment and revision of ethical frameworks and appeals based on them. Finally, readers of the normative ethics literature should ask themselves how they should change their thinking (clinical judgment and reasoning), attitudes (toward patients, their families, and legal institutions), clinical practice, or organizational policies. This is a crucial step in the literature on evidence-based medicine and is similarly crucial here.

Conclusion

In this chapter we have provided a general ethical framework for perinatal clinical judgment and practice. Implementing this framework on a daily basis is essential to creating and sustaining a professional physician–patient relationship in perinatal medicine. This framework emphasizes preventive ethics, i.e. the recognition that the potential for ethical conflict is built into clinical practice and the use of such clinical tools as informed consent and negotiation to prevent such conflict from occurring. This framework comprehensively appeals to the ethical principles of beneficence, respect for autonomy, and justice, and the professional virtues of self-effacement, self-sacrifice, compassion, and integrity. Finally, a formal tool can now be used to critically evaluate the literature of ethics in perinatal medicine.

13 Ethical committees

J. G. Schenker

In the last two decades, ethical issues in medicine have come to the forefront of public consciousness, with concern focusing on several important areas. Advances in scientific and technological knowledge have created ethical dilemmas about what is right and wrong, about life and death issues, as well as issues of equality, justice, and personal preferences. Biomedical ethics also raised issues on patients' rights, which required steps to be taken to protect the patient's welfare and to promote the patients' autonomy.

Society's concern for ethical issues in medical practice has led to a growing need for the medical profession to become fully aware of the public view not only on individual patient–physician relationships, but also on how medical developments affect social structure and health policies. Health policy makers as well must examine the ethical basis of decision making, prioritization, and conflicts of interest as they influence health care locally, nationally, and internationally.

Biomedical ethical issues, guidelines, principles and regulations cut across national boundaries and often have universal implications. Although cultures differ, certain values are common to all. In this context, the most important is respect for human dignity, and this should not be negotiable. The establishment of international and interdisciplinary forums in which scientists and lay people can exchange views on topics of immediate concern, unhampered by administrative, political, or other considerations was needed. They are intended especially for the discussion of the scientific and technical bases of advances in biology and medicine and other related areas and their social, economic, ethical, administrative, and legal implications.

The range of ethical questions raised by new scientific achievements in the life science and methods of taking care of women's health, especially assisted reproduction, have been debated by international political and professional bodies. Within international committees, diverse geographic, ethnic, cultural, linguistic, and religious backgrounds are represented.

The Nuremberg Code

The first international code of ethics for research involving human subjects – the Nuremberg Code – was a response to the atrocities committed by Nazi research physicians that were revealed at the Nuremberg War Crimes Trials. Many of their experiments had entailed the deliberate killing of, or infliction of grievous injuries on, prisoners whose rights to consent or refuse were ignored. Thus, it was to prevent repetition by physicians of such attacks on the rights and welfare of human beings that human-research ethics came into being. The Nuremberg Code, issued in 1947,[1] laid down the standards for carrying out human experimentation, emphasizing the subject's voluntary consent:

(1) The voluntary consent of the human subject is essential. This means that the person involved should have legal capacity to give consent; should be so situated as to be able to exercise free power of choice without the intervention of any element of force, fraud, deceit, duress, overreaching, or other ulterior form of constraint or coercion; and should have sufficient knowledge and comprehension of the elements of the subject matter involved so as to enable him to make an understanding and enlightened decision. This latter element requires that before the acceptance of an affirmative decision by the experimental subject there should be made known to him the nature, duration, and purpose of the experiment; the method and means by which it is to be conducted; all inconveniences and hazards reasonably to be expected; and the effects upon his health or person that may possibly come from his participation in the experiment. The duty and responsibility for ascertaining the quality of the consent rests upon each individual who initiates, directs, or engages in the experiment. It is a personal duty and responsibility that may not be delegated to another with impunity.

(2) The experiment should be such as to yield fruitful results for the good of society, unprocurable by other methods or means of study, and not random and unnecessary in nature.

(3) The experiment should be so designed and based on the results of animal experimentation and knowledge of the natural history of the disease or other problem under study that the

anticipated results will justify the performance of the experiment.

(4) The experiment should be so conducted as to avoid all unnecessary physical and mental suffering and injury.

(5) No experiment should be conducted where there is an *a priori* reason to believe that death or disabling injury will occur, except, perhaps, in experiments where the experimental physicians also serve as subjects.

(6) The degree of risk to be taken should never exceed that determined by the humanitarian importance of the problem to be solved by the experiment.

(7) Proper preparations should be made and adequate facilities provided to protect the experimental subject against even remote possibilities of injury, disability, or death.

(8) The experiment should be conducted only by scientifically qualified persons. The highest degree of skill and care is required through all stages of the experiment of those who conduct or engage in the experiment.

(9) During the course of the experiment, the human subject should be at liberty to bring the experiment to an end if he has reached the physical or mental state where continuation of the experiment seems to him to be impossible.

(10) During the course of the experiment, the scientist in charge must be prepared to terminate the experiment at any stage if he has probable cause to believe, in the exercise of the good faith, superior skill, and careful judgment required of him, that a continuation of the experiment is likely to result in injury or death to the experimental subject. All research involving human subjects should be conducted in accordance with three basic ethical principles, namely, respect for persons, beneficence, and justice.

The Nuremberg Code document was criticized because it does not distinguish between different types of biomedical experimentation. The Nuremberg Code makes the subject's legal capacity to consent a prerequisite to experimentation, thus excluding from participating in research many people who might benefit from the results obtained, including children, the mentally ill, and others who are unable to give legal consent.

UNESCO – The United Nations Educational, Scientific and Cultural Organization

The United Nations Educational, Scientific and Cultural Organization (UNESCO) was established on November 16, 1945.[2] The main objective of UNESCO is to contribute to peace and security in the world by promoting collaboration among nations through education, science, culture, and communication to further universal respect for justice, for the rule of law, and for the human rights and fundamental freedoms that are affirmed for the peoples of the world without distinction of race, sex, language, or religion. At the international level, UNESCO has been one of the principal promoters of the reflection on ethics of living. In 1993, UNESCO created the International Bioethics Committee (IBC). The IBC[3] is a forum for debate and reflection and for the elaboration of UNESCO's normative actions, particularly with regard to the implementation of the Universal Declaration on the Human Genome and Human Rights. It is up to the IBC to keep up with progress in genetics while taking care to ensure respect for the values of human dignity and freedom in view of the potential risks of irresponsible attitudes in biomedical research. The IBC has drafted statutes and published reports on the ethical aspects of human embryonic stem cell research and its use in therapeutic research; ethical issues on genetic screening and the testing, treatment, storage, and use of genetic data on genetic screening; and human gene therapy.

WHO – World Health Organization

The Health Organization of the League of Nations was set up in Geneva in 1919. In 1945, the United Nations Conference on International Organization established a new, autonomous, international health organization – the World Health Organization (WHO). The objective of the WHO is the attainment by all peoples of the highest possible level of health.[4]

The WHO's constitution affirms fundamental ethical principles, such as the equality of rights and the unalienable dignity of all human beings. The WHO has set technical standards and proposed guidelines and codes of good practice in virtually all its fields of activity, including the widely publicized areas of organ transplantation, breast-milk substitutes, essential drugs, the marketing of pharmaceuticals, and, more recently, reproductive health, environmental health, and emerging diseases. The WHO also contributes to harmonizing legislation and terminology and fosters the dissemination and exchange of information on these subjects. Ethics continues to provide the basis for the WHO's activities and functions. Several WHO programs have their own ethical review committees; additional activities are carried by consultation on ethics and health at the global level.

The Declaration of Helsinki

The Declaration of Helsinki, promulgated in 1964 by the World Medical Association, is the fundamental document in the field of ethics in biomedical research

and has had considerable influence on the formulation of international, regional, and national legislation and codes of conduct. The Declaration, revised in Tokyo in 1975, in Venice in 1983, and again in Hong Kong in 1989,[5] is a comprehensive international statement of the ethics of research involving human subjects. It is the mission of the physician to safeguard the health of the people. The physician's knowledge and conscience are dedicated to the fulfillment of this mission. Medical progress is based on research that ultimately must rest in part on experimentation involving human subjects. In current medical practice, most diagnostic, therapeutic, or prophylactic procedures involve hazards.

The purpose of biomedical research involving human subjects must be to improve diagnostic, therapeutic, and prophylactic procedures and the understanding of the etiology and pathogenesis of disease. In the field of biomedical research, a fundamental distinction must be recognized between medical research in which the aim is essentially diagnostic or therapeutic for a patient and medical research the essential object of which is purely scientific and without implying direct diagnostic or therapeutic value to the person subjected to the research.

In 1992, International Ethical Guidelines for Biomedical Research Involving Human Subjects were introduced by The Council for International Organizations of Medical Sciences and WHO based on ethical principles.[6] All research involving human subjects should be conducted in accordance with three basic ethical principles: respect for persons, beneficence, and justice. Respect for persons incorporates at least two fundamental ethical considerations: (1) respect for autonomy, which requires that those who are capable of deliberation about their personal choices should be treated with respect for their capacity for self-determination and (2) protection of persons with impaired or diminished autonomy, which requires that those who are dependent or vulnerable be afforded security against harm or abuse.

For all biomedical and clinical research involving human subjects, the investigator must obtain the informed consent of the prospective subject. Informed consent is based on the principle that competent individuals are entitled to choose freely whether to participate in research. Informed consent protects the individual's freedom of choice and respects the individual's autonomy. In the case of an individual who is not capable of giving informed consent (e.g. a fetus, a newborn, or a small child), the proxy consent of a properly authorized representative should be obtained. In all human research, ethical guidelines have differentiated between beneficial (therapeutic) and non-beneficial (non-therapeutic) research. The therapeutic research subject stands to gain as much from the research, whether it be a procedure or a drug, as to lose from it. In the non-therapeutic research, the subject cannot possibly benefit himself, and any benefits can therefore only add to others. The risks of a non-beneficial research fall solely on the research subject, whereas the benefits may extend beyond the research subject to the population as a whole.

The spirit of the Declaration of Helsinki is that, in medical research, the interests of science and society should never take precedence over considerations related to the well-being of the subject. Only a minimal level of risk may be allowed for volunteers to subject themselves for the benefit of others. However, it remains a problem to decide what sorts of levels of risk are acceptable in the case of pregnant women and where the subjects of non-therapeutic research are not autonomous (e.g. premature and newborn babies).

It is generally accepted that pregnant and nursing women are not suitable subjects of clinical trials other than those that are designed to respond to the health needs of such women or their fetuses or nursing infants. Clinical trials for conditions associated with or aggravated by pregnancy and to test the safety and efficacy of drugs, methods, and devices for detecting fetal abnormalities and well-being are of primary importance in the medical field of perinatology. The justification for the participation of pregnant women in clinical trials is that they should not be deprived arbitrarily of the opportunity to benefit from investigational drugs, vaccines, or other agents that promise therapeutic or preventive benefit. In all cases, risks to pregnant women, fetuses, and newborns should be minimized, as far as sound research design permits. As a general rule, pregnant or nursing women should not be the subjects of clinical trials except when such trials are designed to protect or advance the health of pregnant or nursing women or fetuses or nursing infants and for which women who are not pregnant or nursing would not be suitable subjects.

Some therapeutic research on fetuses *in utero* must be allowed. It contributes to the discovery of new methods for treating fetal health problems. There is a consensus that research on fetuses *in utero* should be treated as human subjects research, and governed by the policies for human subjects research. Because fetuses *in utero* and pregnant women are linked to each other, research on one may affect the other. Such research may have a differential impact on the pregnant woman and the fetus, with one benefiting while the other does not, and may be harmful to the other. At the extreme, the research that is beneficial to the one may actually be harmful to the other. The fundamental presupposition of all ethical policies is that the independent review process for human subjects research must consider the interests and rights of both parties in reviewing research protocols. Most guidelines have also imposed additional requirements on the acceptable level of risk to the fetuses involved in the research protocol. It is assumed that fetuses have some moral standing so that some concern must be devoted to their interests and rights.

Sir John Peel's report, published in 1972,[7] presented governmental guidelines concerning the ethics of fetal research. The recommendations were as follows:

- Viable fetuses should not be subjected to non-beneficial research.
- Research is permitted on the whole alive previable fetus, dead fetus, or its organs.
- Dead fetuses or tissues may be used in accordance with the provisions of the Human Tissue Act, which governs the postmortem use of human tissue.
- Parental informed consent should be obtained.
- The validity of the research should be assured.

The National Commission for the Protection of Human Subjects in Biomedical and Behavioral Research was established in July 1974[8] and issued its recommendations. The guidelines have certain things in common with the British guidelines but differ on some grounds. The common points are that dead fetuses and their tissues are to be afforded the respect of other dead human bodies and tissues. Fetuses with a chance of survival are to be treated like children. Willful damage to the fetus *in utero* may not be caused, presumably lest a mother change her mind about abortion. Significant differences are that in the United States, regulations fathers can veto the research, whereas in the British guidelines there is no such specific provision. In Britain it is proposed that non-beneficial research is to be done on the fetus *in utero* or on the viable fetus, whereas in the United States it may be done if there is minimal risk.

Council of Europe

In 1985, the Council of Europe created a multidisciplinary body with experts appointed by each member country. This committee has already produced documents on reproduction research on human subjects, prenatal diagnosis and screening, and genetic testing. Once the Committee of Ministers approves these documents, they become recommendations for the national parliaments, which may or may not decide to follow them. The European assembly and other committees have also issued reports related to bioethical problems. The Council of Europe, which represents all the democratic countries of Europe, has organized a European Convention on Bioethics. The Committee published protocols regarding human experiments and organ transplantation.[9]

FIGO Committee for the Study of Ethical Aspects of Human Reproduction

In 1985, the FIGO Committee for the Study of Ethical Aspects of Human Reproduction was established.[10] Its main objectives were the recording and study of general ethical problems emanating from the research and practice of human reproductive medicine, with the aim of providing guidelines for the attention of physicians and the public in developed and developing countries.

From its inception this committee was not intended to solve these ethical dilemmas, but rather to raise discussion by suggesting the perspectives that this group of health professionals, lawyers, and ethicists arrived at after carefully crafted analysis and debate over these issues. Given the rich field of ethical issues in women's health that derive from not only the reproductive life cycle, but also the economic and political status of women internationally – this committee will always confront new issues and even new aspects of old issues that challenge ethical perspectives and practice. There are continual variations on themes the committee has raised in the past through new medical developments. The social status of women, the constraints on health care dollars, and the health status of women have also increased the need for the committee to address the broader set of rights and economic issues that directly influence the health of women and the ethical setting of their care.

The committee was composed of a range of international members who represented developing and developed countries and had a significant interest and expertise in medical ethics. The members of the FIGO Committee are obstetricians, gynecologists, oncologists, lawyers, and public health workers, all of whom represent diverse geographic, ethnic, cultural, linguistic, and religious backgrounds. Among the 14 members, 13 were chairs of leading obstetric and gynecologic departments.

The initial task of the FIGO Committee for the Study of Ethical Aspects of Human Reproduction was to identify and study the important ethical problems confronting health care practitioners in human reproduction. The ethical problems identified were to be brought to the attention of physicians and the public in the developed and developing countries to provide ethical guidelines where appropriate. This task has assumed greater importance with the continuing challenge of ensuring that women are granted human and reproductive rights worldwide. Furthermore, the complexity of incorporating the many ethical aspects of reproductive issues in different societies, for issues such as cloning, or patenting of the human genome, argues for the need for such a consensus body.

There is no other body internationally that confronts these issues with a view toward the impact on the health care of women. Because of this, the opinions of the committee are used by women's health practitioners internationally to assist them in setting national or local standards, to expand the depth of discussion of these issues locally, and to support their advocacy for improvements in the health and status of women internationally. In the face of rapid cultural and scientific change, this is a critical role of ever-greater need. Women are clearly vulnerable in countries where their health care rights are either non-existent or threatened,

and thus, these guidelines can be a powerful force to support the rights of women.

The work of the Committee: In its first Congress as a standing committee, the Ethics Committee presented three seminars: on medical ethics and medically assisted reproduction, on AIDS with emphasis on ethical aspects, and on refusal of obstetrical care (maternal health, fetal health, and neonatal health), which were published in the proceedings of the Rio Congress.

The early focus of the Committee, from 1985 to 1991, was clearly in areas central to obstetrics and gynecology practice, with a focus on such areas as sterilization, research on pre-embryo, and elective reduction of multiple pregnancies. In the same time period, however, the committee began to explore what the ethical responsibilities of societies of gynecology and obstetrics were for the broader issues of provision of reproductive health care and women's health in general. This led to a seminar during the FIGO Singapore Congress focusing on issues such as:

- How much are mothers worth?
- Distribution of resources between primary and tertiary reproductive care.
- Availability of resources for newborn care.
- Macroethical issues in obstetrics and gynecology.

This key seminar was chaired by Profs. Sureau and Schenker, and marked an important expansion of the thinking of the Committee beyond that of the common bioethical analysis of the time, which focused on principles such as benefit (beneficence), harm (maleficence), and patient autonomy in the area of human rights and justice. During this time, the Committee also began to align its meetings with regional meetings that paralleled the focus of the committee on ethical aspects of human reproduction. The first of these took place in Cairo in 1991 and focused on bioethics in human reproduction research in the Muslim World. The committee meeting foreshadowed an area of ongoing controversy in medicine – that of transplantation. At that time the group considered whether research on pre-embryos was required in order to broaden our knowledge of the developmental process, to improve the treatment of infertility and the control of reproduction, and to permit genetic screening with its potential for the prevention and treatment of birth defects. The Committee recognized and tried to incorporate the diverse spectrum of ethical, cultural, and religious values regarding the status of the pre-embryo. However, agreement was reached on some key areas even with these divergent views:

(1) First, research on pre-embryos is only ethically acceptable when its purpose is for the benefit of human health and only if animal models would not suffice.
(2) The Committee felt that no developing human pre-embryo might be kept alive beyond 14 days after fertilization (not including any time during which the embryo had been frozen).
(3) Research projects on pre-embryos should be authorized by ethical and/or other appropriate bodies in the country and, if allowed, appropriate informed consent must be obtained before undertaking research on pre-embryos, normally from both gamete donors. Furthermore, provision of gametes and pre-embryos should not be subject of commercial profit.
(4) The Committee was unable to reach a consensus as to whether research should be limited to surplus pre-embryos or should also include pre-embryos specifically generated for research, a debate that continues worldwide. The discussion over this issue established the precedent that committee statements required consensus, and where that was not possible, debates were either not included or included with the caveat that there was no consensus.

The deliberations are made public through committee statements published in scientific journals and in specific reports. The FIGO Committee has discussed and provided guidelines on general issues in women's health and advocacy, issues on genetics, embryo research, contraception, abortion, and reproductive endocrinology issues regarding pregnancy, maternal–fetal health, and neonates. The first bound publication of the collated Issues and Guidelines appeared in 1994, 1997, and 2000, and by 2003 had grown to a body of work that, with the translations into Spanish and French, covers 232 pages.[11]

The method of analysis adopted by the committee evolved early on and consisted of position papers on a topic identified by the committee that were circulated prior to committee meetings in the working language of the committee, English.

These research papers explicated the problem, the present status of knowledge, and the various ethical stances or issues that were identified in the literature. At times, the committee invited outside experts in areas where there was not felt to be adequate depth of expertise or where there were other FIGO committees working on the medical or rights aspects of the same issue. The papers were presented at the meeting and a consensus about the important background and ethical issues was identified.

Depending on the issues, further work on synthesizing these into a set of reflections or guidelines might take place at the meeting or over several meetings, until every word of each document was reviewed, read, and revised by all the members of the committee. Proposed statements were read line by line and edited by the entire committee to assure that not only the content was acceptable to the committee, but that the translations to French and Spanish would not contain errors because of the likely translation from English.

The committee statements and opinion are independent from FIGO member societies or the executive board. The documents represent the result of that carefully researched and considered discussion. This independence has been particularly helpful to FIGO in providing ethical guidance regarding the relationship of the federation to industry, initially formulated as internal 'Guidelines for Relations between Industry and FIGO' in 1991. The committee collaborates with international organizations – such as the WHO – on various aspects of women's health to ensure that the ethical aspects are fully covered.

The committee members represent a wide spectrum of religions and countries, and numerous members have co-coordinated with multiple international committees to encourage and ensure inclusion of these ethical aspects in regular and extraordinary meetings.

WAPM – World Association of Perinatal Medicine

In 1999, the World Association of Perinatal Medicine established an Ethical Committee. The main objectives of the committee are:[12]

- To study the ethical problems that emanate from practice and research in perinatal medicine.
- To provide guidelines for the practice of obstetrics and neonatology.
- To bring the ethical issues to the attention of physicians, nurses, paramedical staff, and the public.

National Ethics Committees

National ethics committees are set up by governments to advise on regulations or proposed legislation concerning moral bioethical programs that raise controversy among professionals and the public. National committees were originally created due to an increasing demand among doctors and researchers for some authoritative guidance as to what was permissible in issues where no law exists. The nature of the membership of such committees is of even greater importance. The chairman must be unrelated to the medical or research profession. The members of national ethics committees must represent a broad range of values and professional expertise in the fields of medicine, law, administration, media, economics, public policy, and moral philosophy. Within committees dealing with reproductive health, for example, at least 50% of the members must be women. Governmental or nongovernmental bodies have issued reports on ethical and legal aspects, especially in the fields of perinatal care, assisted reproduction technologies, and human experimentation. Scientific progress is ahead of what society is willing to accept, and the reports of the bioethical committees protect the public by monitoring and, when necessary, regulating scientific practice. There is no single solution to a moral problem. A committee must incorporate a number of different moral ideals and reach a workable compromise. The law that these committees create must be in step with moral beliefs, or it will not be implemented. It is the task of the ethics committee to try to produce some consensus, based on all considerations, and to recommend it for practice. Several problems arise in the setup of the committees. Who should make moral decisions in controversial public issues? How is the committee's membership to be determined? In a pluralistic, mainly secular society there are no moral experts *per se*. Committees who serve public morality must conform to certain specifications of expertise. The committee members must be capable of understanding the scientific background of the subject matter of the issue. They must be acquainted with moral philosophy and understand the nature of ethics. The members must be intelligent and creative and not dogmatic. It is imperative that people who hold particular moral or religious views that make them impervious to the language of consensus are not included in the committee's team. They may be incapable of sympathy and flexibility and thus not be of use. The members must also be readily available to perform this extremely time-consuming task. One major disadvantage of these committees is that sometimes the advent of new technologies is ahead of committee deliberations. If a previous committee decision was opposed to specific new advances, their use may be delayed until the committee changes its original decision. In most Western countries, committees are set up ad hoc to address specific subjects of public bioethical concern. The Warnock Committee on Human Fertilization and Embryology (1984) had a great influence on subsequent legislation in the United Kingdom.[13] In the United States, legislation that seems to reinforce ethical conduct may actually replace the exercise of ethical judgment with unreflective obedience to law. The Belmont Report (1979) identified the basic ethical principles that should emphasize the conduct of biomedical and behavioral research involving human subjects and developed guidelines that should be followed to ensure that such research is conducted in accordance with those principles.[14] The guidelines provided by national committees are usually converted into laws by legislation that introduces criminal punishment for violation. The experience of Assisted Reproductive Technology (ART) practice demonstrated that countries with voluntary guidelines seem to enjoy public confidence, and public pressure for a change seems minimal. Countries with legislative surveillance seem to agree that it works well, although there are understandable complaints about the slowness of the legislative process and the difficulty of having regulations changed once they are in place, and thus, not be of use.

Summary

The range of ethical questions raised by new scientific achievements in the life science, and methods of taking care of women's health especially, has been debated by international political and professional bodies. Biomedical ethical issues, guidelines, principles, and regulations cut across national boundaries and often have universal implications. Although cultures differ, certain values are common to all. In this context, the most important value is respect for human dignity, and this should not be negotiable. The establishment of international and interdisciplinary forums in which scientists and lay people can exchange views on topics of immediate concern, unhampered by administrative, political, or other considerations, was needed. They are intended especially for the discussion of the scientific and technical bases of advances in biology and medicine and other related areas and their social, economic, ethical, administrative, and legal implications. Commissions appointed by institutions, governments, and international bodies serve to relieve the medical profession from making ethical decisions and to protect human subjects from any harm. The deliberations of these committees are usually followed by guidelines of operation, which in many cases have become abiding law. For these committees to be of full advantage, they must convene promptly as issues arise so as not to delay medical advances from being implemented.

14 Education in perinatal ethics

G. M. Stirrat

Introduction

Amazing advances, in genetics, reproductive technologies, and perinatal medicine occurred in the latter part of the 20th century. As Radcliffe-Richards[1] has said, 'Science keeps on throwing up new situations which, in some ways resemble familiar ones but in others are utterly unlike them; and we try to solve the resulting problems by stretching our old familiar categories to fit, but with ever increasing strains and cracks appearing everywhere'. Those of us who practice perinatal medicine are required to consider a wide range of ethical questions, sometimes on a daily basis. Some of them relate to our specialty while others are generic (e.g. consent, confidentiality and resource allocation). The problems can be complex and true dilemmas where the choices are between equally undesirable alternatives. Over 30 years ago, Campbell[2] wrote, 'moral dilemmas will continue to occur in medicine as long as choices have to be made which involve putting one set of values against another'. Unfortunately, ready-made answers cannot be found in textbooks (not even this one!), because the situations in which the problems arise and the stories of the people involved are all different from any other. The desired goals may also be different. For example, the prevention of disease and health promotion tends to raise different issues and require different solutions than the relief of symptoms, pain and suffering, or the cure of disease.

The 21st century will bring further advances in what can be done, but the prevailing ethical climate suggests that there will continue to be much less critical consideration of what 'ought' to be done. How then can we as individuals and as a community of physicians reduce the risk of Radcliffe-Richards's 'strains and cracks' causing the edifice of our professional practice to crumble around us? If you ask an architect, builder or constructional engineer that question, their answer will be 'Get the foundations right!'.[3] Would it not, therefore, seem prudent that those training to be perinatal physicians be properly grounded in the theories and principles behind the increasingly complex ethical decisions in which they will inevitably be closely involved in their subsequent career?

This chapter is based on several fundamental premises:

(1) Each one of us is required to think ethically and act morally (i.e., we are all 'moral agents'). This is not an optional extra.

(2) Ethics is about individuals living and working in community.[4] It is not just about 'me' and 'mine'. As Campbell[5] states, 'there can be no possibility of freedom for any one individual if that person acts without reference to all other moral agents'.

(3) Medical ethics is not solely a matter of moral theory, it is 'an ethics of relation and practice'.[4] Thus, ethics is *for* something and must be translatable into moral action. It has to work in real life.

(4) The dominant individualistic version of autonomous choice is fundamentally (and, in the long run, potentially fatally) flawed.[6,7] Stirrat and Gill,[7] among others, have suggested a principled version of patient autonomy that involves the provision of sufficient and understandable information and space for a patient, who has the capacity to make a settled choice about medical interventions on himself/herself and to do so responsibly in a manner considerate to others. A lifetime in clinical practice strongly suggests that this model best fits the optimal patient–doctor relationship in which there is a mutual, unspoken agreement between the parties that recognizes the duties and obligations each to the other with bilateral trust at the heart of this relationship. This is discussed further below.

(5) The discipline of medical ethics is *not* qualitatively different from ethics in general. The fundamental ethical principles underpinning medical practice should be shared by society in general. However, by virtue of being a profession, we clearly have special obligations to the patients we serve. In the United Kingdom the 'Duties of a Doctor' are clearly laid down by the General Medical Council (GMC)[8], whose primary roles are 'To protect the public by setting standards for professional practice, overseeing medical education, keeping a register of qualified doctors and

Table 14.1 Duties of a doctor (UK GMC)[8]

'Patients must be able to trust doctors with their lives and well-being. To justify that trust, we as a profession have a duty to maintain a good standard of practice and care and to show respect for human life'

As a doctor you must

- Make the care of your patient your first concern
- Treat every patient politely and considerately
- Respect patients' dignity and privacy
- Listen to patients and respect their views
- Give patients information in a way they can understand
- Respect the rights of patients to be fully informed in decisions about their care
- Keep your professional knowledge up-to-date
- Recognize the limits of your professional competence
- Be honest and trustworthy
- Respect and protect confidential information
- Make sure that your personal beliefs do not prejudice your patients' care.
- Act quickly to protect patients from risk if you have good reason to believe that you or a colleague may not be fit to practice
- Avoid abusing your position as a doctor
- Work with colleagues in the ways that best serve patients' interests

In all these matters you must never discriminate unfairly against your patients or colleagues. And you must always be prepared to justify your actions to them

Table 14.2 American Medical Association 'Principles of Medical Ethics'[9]

Preamble

The medical profession has long subscribed to a body of ethical statements developed primarily for the benefit of the patient. As a member of this profession, a physician must recognize responsibility not only to patients, but also to society, to other health professionals, and to self. The following Principles adopted by the American Medical Association are not laws, but standards of conduct which define the essentials of honorable behavior for the physician.

I. A physician shall be dedicated to providing competent medical service with compassion and respect for human dignity.

II. A physician shall deal honestly with patients and colleagues, and strive to expose those physicians deficient in character or competence, or who engage in fraud or deception.

III. A physician shall respect the law and also recognize a responsibility to seek changes in those requirements which are contrary to the best interests of the patient.

IV. A physician shall respect the rights of patients, of colleagues, and of other health professionals, and shall safeguard patient confidences within the constraints of the law.

V. A physician shall continue to study, apply and advance scientific knowledge, make relevant information available to patients, colleagues, and the public, obtain consultation, and use the talents of other health professionals when indicated.

VI. A physician shall, in the provision of appropriate patient care, except in emergencies, be free to choose whom to serve, with whom to associate, and the environment in which to provide medical services.

VII. A physician shall recognize a responsibility to participate in activities contributing to an improved community.

taking action when a doctor's fitness to practice is in doubt'. Table 14.1 outlines the duties of a doctor as set down by the GMC.[8] The Code of Medical Ethics of the American Medical Association (AMA)[9] states, 'a physician must recognize responsibility not only to patients, but also to society, to other health professionals, and to self'. The two main items on the agenda of the first meeting of the Association in 1847 were the establishment of a code of ethics and the creation of minimum requirements for medical education and training. Table 14.2 shows the principles adopted by the AMA as 'standards of conduct which define the essentials of honorable behavior for the physician'.

(6) Ethics is a necessary part of good clinical practice. Ethical judgments must take full account of all the circumstances of the case and be based on sound principles. Decisions must be consistent, free from contradiction and clinically relevant. Exercise by physicians of their clinical judgment is frequently attacked as paternalism. While, in some instances, this can be so, it may also be the doctor fulfilling his or her duty to the

patient by exercising his or her own autonomy, and as such, may be entirely justified. Indeed, there will be some occasions, particularly in perinatal medicine, when acquiescence to a requested intervention against one's clinical or ethical judgment will be abrogation of one's duty as a doctor!

(7) The patient–physician covenant relationship depends totally on the trust of the former that the latter will act at all times with the highest ethical standards. Indeed, not only is trust 'the fundamental virtue at the heart of being a good doctor', it also allows us all to function socially as individuals in a complex society,[10] and 'every genuine moral community is built on the trust that its members will look beyond personal interests and individual concerns towards a truly common good'.[11] The words 'trust' or 'trustworthy' can be found on several occasions in the GMC's 'Duties of a Doctor' (Table 14.1) and it is implicit in the AMA's 'Code of Ethics' (Table 14.2). (Among other authors, Draper and Sorell[12] argue that the patient has reciprocal duties, but it is not appropriate to discuss this further here.)

The Basis for Ethics

Since at least the time of Socrates (470–399 B.C.), people have asked questions like 'How do we know what is good?' 'How should I live?' 'How can we know which decision is right?' and 'What is justice?'. Ethics or moral philosophy addresses these fundamental questions in order to establish a basis for moral judgments. Morals are the specific judgments, codes or beliefs of particular groups or societies and the actions that follow from these.

The relationship between ethics and morals has been compared to that between DNA and cell proteins.[13] Within the DNA (ethics) lies the fundamental information for the cell to function. The proteins (morals) produced by the cell interpreting and following that information do two things – they express both the nature and character of the cell and also perform its specific function. In addition, cells must work together within and among bodily structures and organs. The cell that expresses its individuality at the expense of its neighbors is 'neoplastic' and may become malignant, ultimately causing the demise of the body. What this might suggest about the long-term consequences of the dominance of the primacy of the individual – 'I', 'me' and 'mine' – in today's society is among the factors that leads to my concern about the potentially fatal flaw in this view of autonomy.

Diversity of moral theory

In 1972, Campbell[2] wrote, 'The essence of morality is that there is uncertainty'. As a young obstetrician wrestling with a whole series of ethical dilemmas at that time, I found this very threatening. I was like Montaigne who said, 'Tell me of your certainties; I have doubts enough of my own'. Indeed, I venture to suggest that we all find uncertainty difficult to deal with. We would much prefer 'meanings that are completely clear' and 'truths that are completely certain'.[14] Campbell[2] stated:

> Many people seek to handle situations of uncertainty by elevating their personal convictions to the status of inherent and all-embracing rules, which must apply to every situation, whatever its complexities and ambiguities. Others try to reduce all moral dilemmas to questions of technical skill.

He considered that both of these reactions were commonly found among physicians and nurses, 'many of whom may feel that there is little to be argued about in medical ethics, either because they do not themselves see any moral ambiguities in their professional practice or because they consider all the decisions taken to be purely matters of clinical judgment'. Personal experience suggests that although such individuals still exist, the vast majority of health care professionals are anxious to learn how to make more reflective and consistent ethical judgments in the face of the problems that they face from day to day.

Of course, 'moral philosophy does not attempt to "solve" moral dilemmas'.[2] Rather, 'it attempts to provide a rational framework for understanding the complexities of moral judgment'.[2] It is entirely appropriate that we try to make sense out of uncertainty, and we do so by classification and codification of what we think we know. We need frameworks as reference points to allow us to progress through our lives as individuals in society, much as a ship traveling across the ocean. Indeed, Jonsen[15] suggests:

> … moral principles are not unlike the sky-marks used in celestial navigation: a position is determined and a course marked by continual reference to fixed points – sun, stars, and planets. At the same time the navigator must look not only to the sky-marks but also to any visible landmarks and to the wind and waves. Thus while principles provide an indispensable general guiding direction, other features of the problem must be taken into consideration as the passage from moral question to moral answer is navigated.

It is, perhaps, not only inevitable, but also appropriate that a multiplicity of theoretical approaches to ethics should have arisen. Campbell has suggested, 'The diversity of ethical theories is about as wide as the diversity of ways of understanding the relationship between man and his environment'.[2]

The first of the two main theories is *deontology* or 'duties in action'. The best example is found in the

writing of the philosopher Immanuel Kant in the 18th century. The essence of Kant's ethics is:

- Certain kinds of acts are intrinsically right and others intrinsically wrong determined by a set of rules.
- The rules must be universally applicable, coherent (i.e. not contradictory) within what Kant called 'a rational system of nature' and capable of being freely adopted by 'a community of rational beings'.
- Among the rules are 'do not kill, cause pain, disable, deprive of freedom or pleasure' and 'do not deceive, break promises, cheat, break laws, or neglect one's duty'.
- Each of us has a set of duties to our fellow men and women. One of the most important duties is to 'act so that you treat humanity, whether in your own person or in that of any other, always as an end, and never as a means only'. It is this maxim that has, for example, contributed to concerns about so-called 'savior sibling' procedures in which a child is conceived with the primary intention of being a source of compatible tissue for a seriously ill sibling.
- An action should not be judged to have been right or wrong by its consequences in individual situations.

No theory is without problems, and the main difficulties with this theory are defining the meaning of 'rational' and agreeing on universally applicable rules.

The second main theory, developed in the 19th century by Jeremy Bentham and John Stuart Mill, is *consequentialism*, in which the rightness or wrongness of an action is based solely on consequences.[16] They named their theory *utilitarianism*, and argued that the maximization of pleasure or happiness was what made acts right. This has been summarized as 'The greatest happiness of the greatest number'. Consequentialist theories can be further divided. *Act consequentialism* states that the right action is the one that produces the most good. In *rule consequentialism* the test is whether an action accords with a set of rules whose general acceptance would result in the most good. In each case, 'good' is determined solely by the beneficial consequences. The problem with consequentialism is that, although consequences are undoubtedly important in moral judgments and actions, happiness is highly subjective, and what is good (let alone the greatest good) is not always easy to determine. Moreover, benefiting the majority could result in ignoring vulnerable minorities. Where do the seriously disadvantaged in our society, such as the very preterm infant, the severely disabled child, the terminally ill or the elderly with dementia fit with this philosophy? A rule to protect the vulnerable could be set aside if it did not promote general happiness.

Clearly, these theories are not, of themselves, sufficient for the resolution of clinical problems in real life and several other views have been developed to try to deal with their inherent problems. The *Four Principle Approach*, otherwise known as 'principlism', shown in Table 14.3 (and see Beauchamp[17]), was formulated as a basis for working out practical solutions for problems in medical ethics.

Table 14.3 The Four Principles ('principlism')[17]

Principle	The obligation/duty
Beneficence	• To do what is in the patient's best interests • To provide benefits balanced against risks
Non-maleficence	• Not to cause harm and, indeed, seek to prevent it
Autonomy ('self-rule')	• To respect the right of the individual to make choices about her own life *in the context of equal respect for everyone else involved*
Justice	• To treat patients fairly and without unfair discrimination • Fairness in the distribution of benefits and risks

Critics say, with some justification, that these are merely a checklist without an underlying theory, are often in conflict with one another (with no internal resolution) and do not deal with emotional aspects or relationships. In particular, as has already been noted, the concept of autonomy is widely misunderstood. It does not necessarily mean doing what someone requests or demands at one point in time. It implies a settled view of the individual reached by deliberation as to what is in his or her own long-term best interests. It is also to be balanced with the autonomy of others, including, in this context, medical staff. Regrettably, the four principles are all too often used as a mantra to be applied by the lazy to every ethical issue without thought or discrimination. If, however, one recognizes their shortcomings and incorporates some other insights such as those discussed below, the four principles can provide a useful framework for analyzing ethical problems (see Table 14.4a).

Other useful perspectives can be found:

Narrative ethics:[18] This takes account of the patient's and the physician's context, emotions and relationships. Indeed, whatever one's approach, the patient's story must be part of the ethical relationship and one's own feelings are relevant to the moral choices. It is important that the latter be recognized, if only to ensure that one's feelings do not inappropriately influence the choice of the patient.

Virtue ethics: Instead of asking 'How should I act?' this asks 'How should I live?'.[19] This system tried to define excellence of character or behavior to which individuals or groups should aspire. One aspect is caring about someone, rather than just caring for him

Table 14.4 Making ethical judgments

(a) Analysis

Define the problem(s)

Analyze the problem(s)

- What are its elements? – e.g. medical, ethical, legal, etc.
- What parties are involved? – such as the patient, her family, one or more fetuses, statutory authorities (e.g. social workers, police), health care professionals, etc.
    - Who is the appropriate advocate for the fetus?
- How do their perspectives fit together or conflict with each other, and in the latter case, what are the appropriate mechanisms for resolution?
- What is its context? – e.g., social, ethnic, economic (within this may be issues about rationing)

Consider the underlying principles involved

- It may be useful to start with the four principles (beneficence, do no harm, autonomy and justice).[17]
    - What is in the patient's best interests?
    - How can I balance this with the avoidance of harm?
    - Is the patient competent? If so
        - Is she expressing her settled view on what she wants?
        - Am I respecting her right to make choices about her own life?
        - Does this conflict with the autonomy of others, and if so, how is this to be resolved?
    - If she is not competent (e.g. a minor or an unconscious adult), or if this is open to question (e.g. a child aged 12–13 years), how is this to be dealt with?
    - Are there any issues of justice? e.g.
        - Is the patient being unfairly discriminated against?
        - Is there any conflict between what I consider to be in the patient's best interest and what can be provided?
- What other perspectives could assist in resolution?
    - Have the patient's social context, emotions and relationships been adequately considered?
    - Am I sure that I am treating the patient as a person?
    - Are we both caring for and caring about the patient?

(b) Action

Move towards recommending actions that best meet the above criteria

- What are the proposed objectives? e.g. cure, relief of symptoms (e.g. pain and suffering) or prevention of disease?
    - Which objectives are essential and which desirable?
    - What alternatives are available (including doing nothing)?
    - What are the risks of acting (or failing to act) and what is their probability and severity?
    - Do the expected benefits outweigh the potential risks?
        - Has the patient been properly informed of the available options?
    - Is she competent to give consent?
        - If so, has the consent been obtained properly?
        - If yes, put chosen option into effect.
    - If she is not competent whom, if anyone, can legally give consent?

Dealing with potential or actual conflict

This difficult area cannot be dealt with comprehensively here, but examples include the following:

- The patient refuses to accept the recommended interventions.
    - If competent, she has the right to do so, even if it leads to harm of herself (or the unborn child). Do not coerce her. Among the things to do are:
        - If junior, inform more senior colleagues; if senior, seek advice through clinical governance channels.
        - Make sure that full contemporaneous notes are made.

(Continued)

Table 14.4 (Continued)

- She requests intervention that informed medical opinion suggests is not justified or in her best interests.
  - You are not bound to do as she asks, particularly if it is contrary to your principles.
  - Offer referral for another opinion or, if needs be, transfer care to another team. (In the United Kingdom, if the patient is requesting termination of pregnancy, you are obliged to refer to another practitioner.)
  - (Then as above.)
- Another party tries to intervene inappropriately, e.g.
  - The family or another third party asks for confidential information.
    - The presumption is that confidentiality must be kept.
    - Any breach can be justified only in exceptional circumstances.
      - It is preferable that this be with the knowledge of the patient.
      - However, if, for example, it is judged that the patient would be seriously harmed by knowing that her illness is terminal, but that it would be in her best interests that a close relative should know about it, information may be divulged without consent.
  - The family asks that the patient not be told the truth about her illness.
    - The assumption (possibly rebuttable with good grounds – see example above) must be to tell the truth at all times.
    - Not to do so can have regrettable consequences, e.g. who is she to trust when she discovers any deception?
    - *Remember that your primary duty of care is to your patient and not her family.*

Good communication skills in general, and knowing how to impart bad news in particular, are central to being a good doctor
Review the outcome

- Ethical issues do not lend themselves easily to audit, but it may be useful to record and review major cases from time to time.
- In individual cases, remember that a good or bad outcome does not necessarily mean that the intervention was right or wrong

or her, and it can provide a useful perspective in, for example, those faced with chronic and/or serious illness or disability.

Feminist approaches to ethics:[20] One form of feminist ethics attempts to balance the dominant masculine ethos of traditional ethics with a more feminine perspective. The ethics is one of caring for individuals and although caring resolutions may be different in their outcomes, they are linked by personal regard and respect given to individuals.

However, 'formal frameworks, for all their value, need to be supplemented with other ethical approaches, based more on interpretation and judgment than on formal deduction or algorithm'[18] and 'any particular theory, when applied deductively, is shown to be inadequate sooner or later'.[21]

Sherwin[22] suggests, 'No moral theory can do the work normally expected of it, because none provides reliable grounds for resolving all moral complexities through deductive application of its central principles' and 'Doing bioethics well requires appeal to the insights provided by multiple theories'. Ethical reflection depends on having a set of core ethical beliefs that describe clear cases of morally objectionable or praiseworthy behavior, which contribute the prototypes of ethical deliberation. Rather than trying to force us to choose a single, comprehensive theory to apply to all cases, she finds it preferable to view different theoretical perspectives as providing alternative 'frameworks' or 'templates' for different sorts of approaches to problems. She suggests that we use competing theories as a set of lenses through which we can get a clearer view of complex moral problems. Some lenses will provide a clearer understanding than others.

Dunstan's[4] criteria for the practice of ethics in medicine are good moral theories, the elucidation of principles to which implicit or explicit appeal can be made, the discipline of logic for the framing of good arguments and the exposure of bad ones, learning the 'art of moral reasoning', discipline in the use of words without clichés and 'wisdom above all'.

Making ethical judgments

There are two main ways in which ethical issues arise. The first is while dealing with patients and their clinical problems. The second is when faced with an issue in abstract (e.g. 'What do you think of cloning?'). Dealing with the former tends to inform one's approach to the latter and, incidentally, provides valuable insights not given to the non-clinician.

How then do we go about making ethical judgments in the clinical context? McCullough and Chervenak[21] advocate five individually necessary and jointly sufficient criteria for rigorous analysis:

- *Clarity*: terms and concepts must have precise meaning.
- *Consistency*: those terms must always be used with that precise meaning and reasoning must be free of contradiction.
- *Coherence*: ethical deliberations must be internally consistent and non-contradictory.
- *Applicability*: the results of ethical deliberations can be applied in the clinical and research settings.
- *Adequacy*: the judgments allow ethical conflicts to be identified, managed or, preferably, prevented.

It has to be emphasized that there is no magic formula and, indeed, Dan Callahan has suggested (personal communication, 2002) that 'ethical theory ultimately doesn't matter very much – 90 per cent is educated common sense'.

My own approach to making ethical judgments involves consideration of a series of questions under five task-oriented headings, as outlined in Table 14.4a and b, that move from ethical analysis to clinical action.

The purpose and process of education in ethics

If Callahan is correct that 90% of ethics is educated common sense, why should anyone need training in ethics? The key is in the qualifying adjective, 'educated'. I once bought a wooden plaque on Cape Cod that read, 'The one thing about common sense is that it is not so common!'. Josh Billings (the pen name of Henry Wheeler Shaw), the renowned 19th century humorist, said two wise things on the subject: 'Common sense is the knack of seeing things as they are, and doing things as they ought to be done' and 'Learning is the art of knowing how to use common sense to advantage'. Thomas Huxley's aphorism that 'Science is nothing but trained and organized common sense'[23] applies equally to ethics. He suggests that the former differs from common sense 'only as a veteran may differ from a raw recruit: and its methods differ from those of common sense only as far as the guardsman's cut and thrust differ from the manner in which a savage wields his club'. To change the metaphor, no one expects the child with an innate musical ability to sit down at the piano and immediately play Beethoven sonatas. The talent needs to be developed both by understanding the theory underpinning the music and also by practicing increasingly complex compositions. It must also be rewarding for the student! Thus it is with ethics.

I believe that far more is achieved if a teacher starts from where the students are and builds on their inherent abilities, rather than start from where the teacher is and expect the students to soak up facts and opinions that do not necessarily relate to their own experiences. In the United Kingdom the majority of students come to medical school from high school at about 18 years of age. Teaching of ethics in medicine in the University of Bristol begins shortly after the students commence their course and follows for several weeks, working with family practitioners meeting patients, learning about their problems and discerning the ethical issues involved. It subsequently runs as a vertical theme through all 5 years of the course. We never cease to be amazed at the maturity with which these talented young people address complex ethical issues often from their own experiences. This develops as the course progresses. They have the talent; it is our task to let it flourish.

Not long ago I had one of the most rewarding teaching experiences of my life at the other end of the age spectrum. I was asked to speak to an older women's group on a reproductive ethics topic. Instead of lecturing them on the subject (on which, if truth be told, I was not an expert), I had prepared four hypothetical cases of increasing ethical complexity. Members of the group presented each case, the facts of the matter were discussed and questions addressed. We then began to consider the ethics of each case. In a very short time, the key ethical issues had been raised and debated, and by the time the fourth case had been completed, we had discussed a range of issues that would not have disgraced a textbook of ethics. Of course we did not come up with many firm answers, but these women not only discovered that they could think (something their families had probably told them implicitly or explicitly that they could no longer do), but also that their opinions were meaningful. What is more, they were not only thinking ethics on that day, but had been doing so all their lives! They also learned that there were few absolute answers, but had derived the principles to address the dilemmas by their own efforts. It was gratifying to see their self-esteem rise as the session progressed, and they left rejoicing in the experience. Henry Brook Adams, the historian, wrote in 1907, 'a teacher affects eternity: he can never tell where his influence stops'. Our objective in education in ethics is no less!

Phases of Education in Ethics

The most effective way to achieve proper education in ethics is to begin early and build on it through school, college, medical school and continuing professional development:

(1) *Education in human relationships*: This should begin early in school and become a more formal study of ethics for all students in high school and college, where it should be part of the examined curriculum. The objective is for the student to learn how to think, not what to think.
(2) *Introduction to bioethics*: This should commence in medical school, concentrating on a patient-centered approach to medicine, and be part of the examined curriculum. This has been emphasized by the GMC

Table 14.5 Introduction to bioethics in medical school

Objective	Key issues
Increasing knowledge	• In ethics there are very few cut and dry solutions to problems. In part this is because the problems themselves are so varied • As a practical discipline, ethics involves fitting general principles to specific circumstances in a way that respects these variations, but this does not mean deciding arbitrarily or with prejudice • The course should cover the main principles of ethics in medicine (e.g. respect for autonomy, beneficence, justice) and ethical concepts to be used in making morally reasonable judgments (e.g. duty, rights, virtue, consequences) • The students should learn: o The relevant law and professional codes of conduct that determine specific obligations owed by doctors to patients, society and each other o How best to determine what is morally important and relevant in a given medical situation: without this moral understanding it is impossible to apply rules or concepts in a sensitive and constructive way o The centrality of the patient's narrative in determining what is important for her and her medical care
Developing skills	The course should aim to develop skills of analysis, judgment and rational argument about moral issues in medicine. The context should always be their relevance to the practice of medicine and good patient care
Improving attitudes	The student should be become aware of the wide variety of patients' attitudes to health, illness, doctors and society, the ways in which these impact on the medical relationship and the ways in which their own attitudes play a part in this relationship The ways in which ethical issues in medicine are not only about hard decisions for doctors, but about making decisions with patients in personal, social and institutional contexts should be explored This approach to patients' attitudes will inevitably involve the students confronting and rethinking their own, and this can be threatening for some Problematic attitudes should be identified, acknowledged by the student and, if possible, remedied

Based on the Ethics and Law in Medicine Vertical Theme Course in the University of Bristol Medical School, 2003–4

in 'Tomorrow's doctors – recommendations on undergraduate medical education'.[24] The focus should be not only on knowledge, but also on skills and attitudes, as shown in Table 14.5. Both clinical and research governance should be included. There is increasing emphasis on this course being interprofessional, involving students from a variety of health care professions. The confrontation of some issues will be traumatic for some students. Teachers must be sensitive to this. The earlier this is recognized and dealt with, the better. In addition, having been dean of a medical faculty, I realize that the problem of the failing student is more often a problem in attitude rather than ability. This too must be recognized early for remedial action to be instituted and, if necessary, the student encouraged to join an alternative course of study for which he or she is more suited. It is too late for this to be recognized for the first time after qualification, perhaps as a result of an event that resulted in harm to a patient.

(3) *A core generic course for health care professionals*: It is suggested that these practice-based modular courses be designed for doctors working in hospitals, family practice and public health, nurses, midwives, allied health professionals and health care managers. The courses would be an integral part of their continuous professional development. The design would have to recognize that not all participants are starting from the same point in their understanding of basic bioethics. A 'core and options' design would allow this to be the first part of a specialty-specific program (in our case perinatal medicine). Among the proposed objectives of these courses would be:

- To provide an introduction to (or revision of) basic theory in bioethics and to the relationship between ethics and the law.
- To develop consistent, critical and reflective attitudes to ethical decision making in the health care setting.

Table 14.6 Suggested basic bioethics modules for a core generic course for health care professionals, and indicative curriculum for a specific course in perinatal medicine

(a) Suggested basic bioethics modules

Module 1 Overview of bioethics – 'What ought I do?', dealing with uncertainty, etc.
Module 2 Competing theories, e.g. duties vs. consequences
Module 3 Other important concepts, e.g. principlism, virtue and narrative ethics, autonomy, paternalism
Module 4 Ethics and the law
Module 5 Ethics and the professions, e.g. confidentiality, informed consent and the vulnerable and failing doctor
Module 6 Making ethical judgments
Module 7 Methods of ethics support in practice

Among the suggested core topics might be

- Patients' rights, expectations and reality
- Consent, confidentiality, communication
- Legal framework in relevant countries
- Economics, to include resource allocation and prioritization
- Refusal of treatment
- Conflicts of interest, e.g.
  - Commercial enterprises in medical practice
- Clinical governance, e.g.
  - Managing and reducing risk, clinical error, poor performance, support structures
  - Clinical ethics committees
- Quality of life issues
- Decision making, to include:
  - Partnerships in decision making, e.g. interdisciplinary career perspectives, patient–parental perspectives
  - Dealing with uncertainty
  - 'Futile' treatment
  - Withdrawing or withholding treatment
  - Religious and secular influences on decision making
- Generic issues at the beginning and end of life
- Research governance, e.g.
  - Evidence based medicine
  - Properly informed consent
  - Innovative interventions
  - Fraud and misconduct
  - Research ethics committees

(b) Indicative curriculum for a specific course in perinatal medicine

- Human genetics
- Conception and birth
- New reproductive technologies; pre-embryo research; stem cells and cloning
- The law and perinatal medicine
- Screening, antenatal diagnosis and counseling
- Sex selection for medical and non-medical reasons
- Termination of pregnancy
- Feticide
- Non-selective embryo reduction
- The fetus as person and patient
- Patient choice and the maternal–fetal relationship
- Obstetric interventions 'on demand'
- Antepartum management of fetal anomalies
- Drug dependency in pregnancy
- Critical care obstetrics
- HIV infection in pregnancy
- Prematurity (particularly the very pre-term infant at or near the threshold of viability)
- Ethical aspects of the care of the newborn
- Ethical aspects of the care of the malformed or brain-damaged infant

Table 14.7 A guide to a bibliography for core ethical subjects and perinatal ethics

(a) Core ethical subjects

Medical Ethics Today
The BMA's handbook of ethics and law
BMJ Publishing Group, London, 2004
A comprehensive, concise and authoritative guide to medical ethics
Medical Ethics, 4th edn
Campbell A, Charlesworth M, Gillett G, Jones G
Oxford University Press, New York/Oxford, 1997
An invaluable primer for the subject accessible to the non-expert
Clinical Ethics, 5th edn
Jonsen AR, Siegler M, Winslade WJ
McGraw-Hill, New York, 2002
A 'must read' in this context. 'Facilitates solutions to everyday ethical problems'
Principles of Health Care Ethics
Edited by Gillon R
John Wiley, Chichester/New York, 1994
A detailed in-depth analysis of the field
Principles of Bio-medical Ethics, 5th edn
Beauchamp TL, Childress JF
Oxford University Press, New York/Oxford, 2001
Another excellent source book
Bioethics – An Introduction to the History, Methods and Practice
Jecker NS, Jonsen AR, Pearlman RA
Jones & Bartlett Publishers, Boston, 1997
It does as it says
Medical Ethics – A Case-Based Approach
Schwartz L, Preece PE, Hendry RA
Saunders, Edinburgh/New York, 2002
A useful guide
Medicine, Patients and the Law, 3rd edn
Brazier M
Penguin Books, London, 2003
A scholarly work by an eminent legal authority
Medical Ethics and the Law – The Core Curriculum
Hope T, Savulescu J, Hendrick J
Churchill Livingstone, Edinburgh/New York, 2003
A useful guide
Autonomy and Trust in Bioethics
O'Neill O
Cambridge University Press, Cambridge, England, 2002
A must for anyone who wishes to understand the true nature of autonomy
Three Methods of Ethics
Baron MW, Pettit P, Slote M
Blackwell Publishers, Oxford/Malden, MA, 1997
For those who wish to consider more deeply and contrast Kantian ethics, consequentialism and virtue ethics
The Health Care Professional as Friend and Healer
Edited by Thomasma DC, Kissell JL
Georgetown University Press, Washington, DC, 2000
This book builds on the work of Edmund Pellegrino. A 'must-read' in this context

(b) Perinatal ethics

Ethics and Perinatology
Edited by Goldworth A, Silverman W, Stevenson DK, Young EWD
Oxford University Press, New York/Oxford, 1995
A required text for this field
Ethics in Obstetrics and Gynecology
McCullough LB, Chervenak FA
Oxford University Press, New York/Oxford, 1994
Another valuable reference for this field
Ethics in Obstetrics and Gynecology
American College of Obstetricians and Gynecologists
ACOG, Washington, DC, 2002
A compilation of the subjects considered by the ACOG Ethics Committee and another invaluable source of material

(Continued)

Table 14.7 (Continued)

Recommendations on Ethical Issues in Obstetrics & Gynecology
The FIGO Committee for the Ethical Aspects of Human Reproduction and Women's Health
FIGO, 2000
A compilation of the subjects considered by the FIGO Ethics Committee and also an invaluable source of material
Ethical Issues in Maternal–Fetal Medicine
Edited by Dickenson DL
Cambridge University Press, Cambridge, England, 2002
Contains succinct but deep analyses of many relevant issues
Crucial Decisions at the Beginning of Life
McHaffie H
Radcliffe Medical Press, Oxford, 2001
A descriptive account of parents' experiences of treatment withdrawal from their infants
Should the Baby Live? The Problems of Handicapped Infants
Kuhse H, Singer PO
Oxford University Press, New York/Oxford, 1985
A controversial book that discusses issues that must be addressed in this context
Selective Non-treatment of Handicapped Newborns: Moral Dilemmas in Neonatal Medicine
Weir RF
Oxford University Press, New York/Oxford, 1988
A necessary source book in this context for understanding how better to deal with clinical and ethical dilemmas
The Worth of Child
Murray TH
University of California Press, Berkeley, CA, 1996
A deep and compassionate analysis of many of the relevant issues

- To increase awareness of ethical dilemmas faced in different health care settings.
- To understand better the ethical problems facing colleagues in different disciplines.
- To reinforce best practices in clinical and research governance.

The desired learning outcomes would include:

- A working knowledge of basic concepts and theories in clinical ethics.
- Greater confidence in confronting ethical issues encountered in clinical practice.
- A more consistent approach to dealing with similar ethical issues as they affect individual patients.
- A better understanding of the social and institutional context of decision making in health care.
- Improved interprofessional communication, learning and decision making.
- Improved communication of ethical issues with the patients and their families.

Table 14.6 outlines some suggested modules for such a course in basic bioethics. Formative and summary assessments would be incorporated and candidates could gain credits toward, for example, a master's degree in bioethics.

(4) *Specific course in perinatal medicine*: In this model, participants would have completed and gained credits in the generic course. This too could benefit from being interdisciplinary. Table 14.6b is a guide to the possible subjects to be included in the curriculum for such a course. Table 14.7a and b lists some suggested texts relevant to both the generic and the specific curriculum. It is for the users to adapt these suggestions to their requirements.

Does education in ethics make any difference?

It is not sufficient to assert that education in ethics is a good thing. Evaluation is required in support of the program to justify the commitment and expense, and to provide an evidence base for future work. But what outcomes can be used? Among those suggested are ethical sensitivity, attitudes, reasoning ability and decision making. There is some literature on promoting ethical sensitivity in modern medical practice,[25–30] but the main focus has been on medical students.[31,32] Although some attempts have been made to measure the general effectiveness of ethics training,[33–36] the work lacks substantial investigation and discussion of different methods of moral education. One study has attempted to evaluate the effects of an intensive ethics course on health care professionals, including physicians and nurses.[37] It was carried out during an open conference. Only about half of the participants provided direct patient care, and there were no data on the proportions of health care professionals taking part, so no real conclusions can be drawn from it. More rigorous work is required.

Summary

Ethics is the system of thought that analyzes and provides a rational framework for moral judgments. Among the key features of ethics are:

- It must be translatable into moral action.
- It is a public system rather than a private activity, and no one can act morally without reference to other individuals.
- The fundamental ethical principles underpinning medical ethics are those of society in general.
- Ethical analysis must be clear, internally consistent and free of contradiction.
- The judgments made must allow ethical conflicts to be identified, managed or, preferably, prevented.

The most effective way to achieve proper education in ethics is to begin early and build on it through school, college, medical school and continuing professional development. Among the purposes of education in ethics are the development of consistent, critical and reflective attitudes to ethical decision making, increasing awareness of ethical dilemmas in one's own practice and that of others and reinforcement of best practices in clinical and research governance.

15 Words matter: nomenclature and communication in perinatal medicine

L. de Crespigny

Language

The general public now accepts the importance of using appropriate language. Their acceptance is in contrast with the attitude of many doctors who are quick to dismiss the importance of word choice in treating patients. The goal of this chapter is, first, to demonstrate that word choice by professionals involved in prenatal diagnosis is important and, second, to consider ethically appropriate word choices in our specialty.

Sexist and discriminatory language is now recognized as unacceptable. This is because we are aware that such language impacts negatively on others. As long ago as 1977, the United States Department of Labor revised 3000 of its approximately 30,000 titles for occupations. Advertisers are well aware of the importance of language and spend huge resources choosing names for products and developing phrases to describe them. Language is also the tool of trade of politicians. When there was an outcry over the government's harsh treatment of asylum seekers, the Australian Prime Minister, John Howard, recently declared that his party was endeavoring to govern in the interests of the mainstream of the Australian community. Shortly afterward, when the majority of Australians believed that he should dismiss the Governor General who had failed to act on child sexual abuse claims, he indicated that he would not be succumbing to the clamor of the mob. In other words, when the majority of Australians agreed with him, they represented the 'mainstream', but when most disagreed, it was 'the mob' talking.[1]

People now take care to avoid sexist and discriminatory language. Racist language, in particular, is acknowledged as being offensive and inappropriate. It is hurtful to, and places stress on, other people. Nobody working in prenatal diagnosis could fail to be aware of the unique stresses placed on a couple who are given bad news following a prenatal test. Despite this, however, there is remarkably little literature analyzing what word choice in prenatal diagnosis leaves couples feeling most comfortable. The importance of language has had very little focus in medicine generally – indeed, discussions on word choice may be perceived as trivial.

Language, reality, and moral judgment

Language makers and users of language are in a position to influence reality; language is a vehicle for them to construct, reinforce, and reproduce their particular bias or view of reality.[2] People's language can influence opinion: for example, a group might be called 'freedom fighters' if we support their cause, others may call the same group 'terrorists' if they wish to present them as evil.[3]

Doctors performing prenatal diagnosis are language makers in their specialist field. By their language they can subtly influence how their patients perceive a problem. We know that doctors have the potential to influence a patient's decision of what to do when a fetal anomaly is diagnosed. They can do this both by their choice of what information to impart and in the way they impart it. One group found that the proportion of women choosing pregnancy termination following the diagnosis of a facial cleft was 50%. It dropped to 5% following the introduction of 'emergency counseling by the cleft team'.[4] Women feel vulnerable and are susceptible to influence from their doctor following the diagnosis of fetal abnormality. There are few, if any, areas of medicine in which the language used by doctors is more important than in communicating with women having prenatal testing. Women feel stressed and may need to make one of the biggest decisions of their lives – to consider whether to have an abortion if a major abnormality is found.

Loftus and Palmer,[5] who summarized their results as follows, demonstrated the impact of language on memory:

> Two experiments are reported in which subjects viewed films of automobile accidents and then answered questions about events occurring in the films. The question, "About how fast were the cars going when they smashed into each other?" elicited higher estimates of speed than questions which used the verbs *collided*, *bumped*, *contacted*, or *hit* in place of *smashed.* On a retest one week later, those subjects who received the verb *smashed* were more likely to say "yes" to the question, "Did you see any broken glass?" even though broken glass was not present in the film. These results are consistent with the view that the questions asked subsequent to an event can cause a reconstruction in one's memory of that event.

The unique emotive experience suffered by women given a diagnosis of fetal abnormality far exceeds that of people watching a film. It is reasonable to assume that the doctor's language would have at least as much impact on patients as did the wording of questions to watchers of the crash film. In prenatal diagnosis there is the added factor that the doctor is seen as 'the expert'. Following the diagnosis of fetal abnormality, patients will often ask their doctor what is the best course of action. They will even attempt to read into a doctor's words or manner whether he or she thinks an abortion is warranted. It is not the role of the doctor to make a moral judgment about what is best for any particular patient. However, patients may be highly influenced not only by what the doctor says, but also by inferences from the doctor's word choice. The use of words such as 'baby' and 'mother' when the doctor means 'fetus' and 'pregnant woman' may result in the patient thinking that her doctor considers that her fetus has the status of a baby and she is already a mother. It might be expected that such a word choice may influence the patient's decision about abortion. In the crash film the questioner's language influenced the subjects' perception. Following detection of a fetal abnormality, the doctor's language at the time of diagnosis could affect the woman's decision on abortion. If her doctor, either directly or by word choice, infers that the fetus is a baby, this might also impact in the woman's ultimate ability to come to terms with her decision.

Medical language

In a field closely allied to prenatal testing, Bowker[2] explores the level of gender insensitivity in specialist language in the field of infertility. She cites examples demonstrating that the language used for similar problems leading to male and female infertility is often gender insensitive. For example, 'sperm antibodies' are described as being present in a male, while a woman whose cervical mucus develops such antibodies is described as having 'hostile mucus'. She claims that the choices of language are not always innocent and may be determined by belief systems that underlie them. Language may attempt to portray men in a more positive light and women in a negative one. She also notes that the term 'expected date of confinement' suggests punishment and imprisonment reflecting the male doctor's control over the place of birth and birthing practices. The terms 'expected date of delivery' or 'due date' are more gender sensitive. Bowker concludes that even when a doctor claims not to have a bias against women, the language that he uses to communicate to patients may be based on such a bias and may therefore have a harmful effect, even in the absence of a malicious intent.

A detailed analysis of the terms commonly used in obstetrical ultrasound practice would be valuable. Some language is clearly gender insensitive, such as cervical incompetence and the labeling of a woman as a 'recurrent aborter'. Some language is simply insensitive, such as intrauterine growth retardation (instead of restriction, to avoid a perceived association with intellectual retardation) or a fetal anomaly scan (instead of a fetal normality scan, to focus on the normal).

Doctors also use terms that could lead to misconceptions in the eyes of colleagues as well as the public. It has been suggested that 'myocardial infarction' should be replaced by 'coronary occlusion' since the goal of current treatment is to prevent the myocardial death that follows coronary occlusion.[6] The same author also proposed replacing the term 'hypertension', which falsely suggests that the condition is related to tension or stress, and replacing 'cardiac failure' with 'cardiac insufficiency'.

The medical profession has been slow to acknowledge the importance of language, dismissing it as being 'politically correct'. The term 'political correctness' is now used as a slogan of opprobrium, referring to someone who is an ideological monster.[7] Doctors dislike linguistic change and find it threatening, suggesting that there is something more acceptable about their own linguistic preference.[7] Why is it that the Right to Life movement long ago learned to use 'killing of babies' instead of 'abortion', while doctors often still speak as if language is mere political correctness and does not impact on peoples' opinions?

Language in obstetrics

Although doctors are often dismissive of politically correct language, our journals have over time reduced discriminatory language. The use of 'husbands and

wives' when the author means 'men and women' would no longer be accepted, although these terms were used in a leading journal as recently as 1984.[8] Similarly, one would not now expect to find in a standard medical text a quote such as 'it has been said that bad girls get babies but good girls get myomata'.[9] While this may have been presented as a joke, it helps perpetuate sexism by suggesting 'good girls comply with the stereotypical portrayal of women as chaste and passive'.[10]

The RCOG Study Group on *Problems in Early Pregnancy: Advances in Diagnosis in Management*[11] has recommended that in early pregnancy loss, the term 'abortion' be replaced by 'miscarriage'. It is recommended that 'spontaneous miscarriage' replace 'spontaneous abortion', 'early embryonic demise' and 'fetal demise' replace 'blighted ovum' and 'missed abortion', respectively, and 'incomplete miscarriage' be used instead of 'incomplete abortion'.[12] The general community has long accepted that our language is important in influencing the way people see reality; this is also starting to be accepted in our specialty.

Language in prenatal diagnosis

Ethical dilemmas pervade the specialty of prenatal diagnosis. However, there has so far been little attempt to review the language we use and the impact it may have on other professionals, and even more importantly on our patients. It is time doctors were more considered and considerate in their word choice. The terms 'fetus' and 'pregnant woman' are grammatically more correct than 'baby' and 'mother'. The latter names are used by some (including antiabortionists) euphemistically with a more sinister motivation – namely, to blur reality. Antiabortionists use 'baby' and 'mother' as 'linguistic fig leaves' to suggest that abortion is wrong;[7] while the motivation of doctors using these terms is likely to differ from antiabortionists, it may be misinterpreted by patients.

How do we determine the most appropriate terminology for the language of our specialty? Should we survey our patients and let them decide terminology? One such survey showed pregnant women had a strong preference to be called 'patient' rather than 'mother', 'client', 'consumer', 'customer', 'lady', 'woman', or 'pregnant woman'.[13] Another study surveyed women in an antenatal clinic in an attempt to decide whether to use the term 'mother-to-be', 'pregnant woman', 'maternant', 'patient', 'client', or 'consumer'.[14] The authors concluded, 'Simple softer terms like mother-to-be please a vast majority'. While we do not know the gestation of these women, given that most women have healthy pregnancies, it must be assumed that most of these women believed they had, and in fact had, healthy pregnancies. How would their answers have changed if, immediately after filling out this questionnaire, their doctor had told them that their fetus had a major abnormality? The softer pleasing term of 'mother-to-be' suddenly seems inappropriate – the patient will probably choose not to be a mother this time. Would the doctor using the term 'mother-to-be' have an impact on their patient's decision whether or not to continue with the pregnancy? Would the patient think that the doctor is insinuating that since she is a mother-to-be and not a pregnant woman that the doctor therefore opposes an abortion? If the woman has an abortion, might her grief be prolonged because of her concern that the doctor had implied that she should have become a mother?

Mothers, and presumably mothers-to-be, do not kill their children/fetuses. Pregnant women, however, do have a right to abortion in some circumstances in most Western societies. We cannot expect patients in an outpatient survey to think through these issues. Sometimes word choice is better resolved by reflection and discussion, because the appropriate survey cannot be easily carried out. Word choice is not always best resolved by surveying patients – just as medical treatments are not. Doctors have a role in patient and community education.

Another study suggested that some patients preferred the term 'baby' to 'fetus'.[15] Researchers in Canada examined the results of a questionnaire sent to women who had been informed of ultrasound findings of 'serious anomalies', soft markers of aneuploidy, or obstetric complications. Approximately 900 patients were seen in the study year, the number who declined to participate was not recorded, but 117 agreed to participate in the survey. Surveys were returned by 65% of the 117. This shows the difficulty in both performing and analyzing the results of such a survey – questionnaires were analyzed from only 76 (8%) of the original approximately 900 eligible women.

More women felt strongly that they preferred to have their health care provider use the word 'baby' when giving them bad news. A smaller number felt it important to hear the word 'fetus'. There was a significant minority who considered the terms used to be unimportant. There was great diversity of opinion among the women.

It is not clear from this paper how many women had chosen pregnancy termination following diagnosis of a serious anomaly. It might be expected that many women who continue their pregnancy, who have made the decision that they are going to have a baby, would prefer the term baby to be used. This would apply particularly to the women in this study who completed the survey up to 9 months after their ultrasound visit, so would by then either have a baby or be very late in pregnancy.

In our use of language in the specialist field of prenatal testing we have a number of goals:

(1) *Maximize the information provided to pregnant women*. The words we use should be descriptive and easily understood by the majority of pregnant women.

(2) *Be respectful of women's choices*. While some have suggested that prenatal diagnosis is a 'select and destroy' mission, most support the concept of prenatal diagnosis enhancing autonomous choices of pregnant women. The enhancement of autonomy should apply not only to choice of tests, but also to what information they receive from these tests (does the woman wish to know 'everything' including all low-risk markers of aneuploidy?) and the decision whether to continue the pregnancy or have an abortion.[16]
(3) *Reduce risks of long-term psychological maladjustment*. Since we have few data on the impact of language on psychological adjustment to adverse pregnancy outcome, we must theorize on its impact. Surveying healthy women at an antenatal clinic does not answer this question.
(4) *Promote bonding in normal healthy pregnancies*. This is not only through our language, but also by the use of technology, for example, offering of three-dimensional (3D) and 4D ultrasound when available.

At times, points (3) and (4) may appear to be in conflict. In showing pregnant women ultrasound images, we may promote bonding only to discover later in the examination that there is a fetal abnormality. The bonding itself is not necessarily a problem if the patient later chooses pregnancy termination. Indeed, counselors go to great lengths to support bonding by offering photographs, footprints, etc. following termination for fetal abnormality, and such a policy is supported by patient groups. We should not shield women from the fact that the fetus they aborted looks human, but we can use language that indicates that even though it looks human, it does not have human characteristics such as a conscious life and an ability to plan. Careful use of language can support this message.

Rothman has coined the phrase 'tentative pregnancy'[17] to describe the state of limbo that women are in prior to completion of prenatal testing. Women cannot say with confidence that 'I am going to have a baby' until after the completion of prenatal testing. Those of us in prenatal diagnosis know that most women in whom a major fetal abnormality is diagnosed will choose pregnancy termination. Women who have had a previous pregnancy terminated because of fetal abnormality are uniquely aware of their 'tentative pregnancy'. Their relief and excitement at the completion of a normal midtrimester ultrasound examination are plainly visible. Women are increasingly aware that a midtrimester ultrasound examination is primarily for fetal anomaly detection and that a midtrimester scan is the final prenatal test. Although women anxiously await the results of any prenatal test, the defining moment for pregnant women has become the news of a normal midtrimester ultrasound examination. It is rare that subsequent events or testing cause a pregnant woman to rethink pregnancy termination.

Our language should support and enhance the autonomy of pregnant women.[18] It is a normal midtrimester ultrasound examination that indicates to most pregnant women that their fetuses will become babies. They will become mothers after the birth. They are now unlikely to request abortion – a fetal anomaly is now unlikely to be found. Our word choice should acknowledge that our language is focused on the woman, and not on the views of the doctor.

The *Oxford English Dictionary* defines 'mother' as a female parent, one who has borne a child. It is therefore grammatically incorrect to use the term 'mother' for a pregnant woman. Pregnant women and mothers have contrasting rights and responsibilities. Pregnant women have the right to abortion in certain circumstances in most Western countries, while it is illegal for a mother to kill or fail to care for her child.

The definitions of 'baby' are more variable. The *Oxford English Dictionary* includes both unborn and newly born human beings as a baby while the *Collins Dictionary* defines a baby as a child in the first year or two of life. It is proposed that 'fetal patient' (or the lay terms 'child' or 'baby') should be used when it is unlikely that termination of pregnancy would be requested.[18] For most women this is after normal results of prenatal testing. An exception is the woman who in early pregnancy clearly indicates that she would not consider termination of pregnancy for fetal abnormality; she has given the status of a fetal patient to her previable fetus. She is free to withdraw that status at any time.[18]

The goal should be to remain as neutral as possible in the choice of words prior to the completion of prenatal testing in an attempt to avoid inadvertent directive counseling. The term 'fetus' is neutral in that it does not imply the fetus has the status of a baby; it implies that pregnancy termination is still considered acceptable. Following completion of prenatal testing the term 'fetal patient' is advocated with 'child' or 'baby' as the analogous lay term.[18]

The term 'mother' is clearly defined, and should be used when grammatically correct. 'Mother' is appropriate when describing a woman who has borne a child and is inappropriate when describing a pregnant woman who has not borne a child.

What alternative proposals for word choice might be suggested?

(1) In an earlier paper the author argued that the terms 'pregnant woman' and 'fetus' should replace 'mother' and 'baby' throughout pregnancy.[19] Such language supports the claim that 'a pregnant woman … should have the right to make decisions about her own body up until the time of birth …. In a difficult decision, the woman's present right to bodily integrity should prevail over the rights of the potential person'.[20]

The law puts great emphasis on the moment of birth. Late abortion is legal in many parts of the

world, especially in the presence of a major fetal abnormality. In most Western countries late abortion is available for lethal abnormalities. Using the term 'fetus' throughout pregnancy supports the philosophy that women late in pregnancy may put their rights above those of the fetus in the unusual situation when these are in conflict.

There are good reasons for reserving the term 'baby' for after birth and 'fetus' for before birth. This word choice is consistent with the definition of baby in at least some dictionaries. It supports the autonomy of the pregnant woman throughout pregnancy.

On balance, however, the author suggests the use of 'baby' is preferred following completion of prenatal testing. A disadvantage of using the term 'fetus' late in pregnancy is that it might potentially prolong the 'tentative pregnancy' in the eyes of the pregnant woman. Women benefiting from modern obstetrical and neonatal care have good reason for being confident that 'they are going to have a baby' after completion of testing; it would be a pity if our language diminished that confidence. Very few women have reason to request abortion after standard tests are completed. There is little reason not to enhance such confidence by using the lay term 'baby' late in pregnancy.

(2) Those opposing abortion following potential fetal viability may argue that from viability the term 'baby' should be used. Given a normal midtrimester ultrasound examination, few women will have further prenatal tests in the few weeks prior to potential viability. Even fewer women suddenly change their mind at this late stage and decide that their apparently normal pregnancy is unwanted and they wish to have an abortion. To propose viability as being decisive in determining word choice would result in the doctor prolonging the tentative pregnancy to support his or her ethical position. For the patient, the completion of prenatal testing is the more critical time.

(3) Finally, even after reflection, some doctors may choose to call the fetus a 'baby' from conception. This is the position of the Right to Life movement, since it enhances their view that abortion is tantamount to killing babies. These doctors are using word choice to deliberately promote their personal views on the status of the fetus. Others may claim that they use the term 'baby' throughout pregnancy because it is more patient friendly – better understood by some women. However, the term 'fetus' is now widely used and understood in the lay context; few adults find this term confusing. Young children and some adults may be more comfortable with 'unborn baby' and 'mother-to-be' – these are acceptable alternatives to 'baby'.

Some might claim that the language proposed contradicts the language used by many pregnant women who prefer to think of their child as a baby. The doctor participating in such baby talk may please some pregnant women and may be preferred by many, or even most, women who will proceed to have a baby. However, the long-term interests of the patient may be better served by more neutral language, particularly if the outcome to the pregnancy is adverse. It would be unfortunate if patients interpreted the doctor's participation in baby talk as the euphemistic language of an antiabortionist.

It is important to consider the impact of our language on women continuing the pregnancies. But the life-long distress felt by many women following pregnancy loss means that this group deserves our special attention. These women are at greatest risk – and they will not have a baby. The critical issue is how language impacts on women who are considering pregnancy termination. The author's proposition is that by using neutral language, such as 'fetus' and 'pregnant woman', these terms are not only more accurate, but also assist in ensuring that the pregnant woman does not misinterpret the health care provider as having an antiabortion bias.

We need to be sensitive that women who give the status of a patient to the fetus, in other words women who have made a prior decision to continue the pregnancy, might prefer the use of 'baby' to 'fetus'. We should use whatever language is most supportive of our patients.

After a miscarriage or pregnancy termination, some couples like to think of and refer to their fetus as a baby. They may even name the fetus. Even women having a pregnancy termination may wish the fetus to be considered as a baby, and that preterm labor is being induced in the best interests of the baby. It is important that our language is supportive of our patients and flexible, so enhancing their best interests. No rigid framework is correct for all situations. This is not to say, however, that the doctor should support the 'baby talk' of a woman early in pregnancy, excited by the first images of her fetus on the ultrasound screen. Not all pregnant women appreciate that prenatal testing may mean that they withdraw the status of a baby from their fetus. We as professionals need to be aware that we should, in general, support neutral language, even when caring for excited couples early in pregnancy. Doctors would be less tempted to indulge in baby talk if they perceived there was any risk that this could result in more prolonged psychological sequelae for a woman who subsequently chose pregnancy termination in the presence of a fetal abnormality. The principle guiding the physician should be respect for the patient.

Our respect for the patient also extends to others in the family. The term 'father' should be avoided during pregnancy. A male partner or husband becomes an expectant father following normal prenatal test.[18] If

the partner is a woman, she becomes the expectant parent at that time.

Conclusion

The best interests of our patients are served by using language that supports patient autonomy and is neutral. While it remains a 'tentative' pregnancy, i.e. prior to the completion of normal prenatal tests, the term 'fetus' should be used. Following normal prenatal testing, only in rare situations will the pregnant woman request an abortion. It is appropriate that the term 'fetal patient', or lay terms 'child' or 'baby', be then used. To be a mother, however, one must have borne a child.

Our language should support the autonomous views of the patient. The language proposed is not intended to be rigidly adhered to in all situations, but rather is an appropriate starting point, after which we as health providers need to be responsive to the position of the pregnant woman. It is important to individualize language to accommodate the views of individual patients. It is, however, time for doctors to acknowledge that their language can influence reality, particularly since they are frequently considered experts, not only in prenatal diagnosis, but also in morality. Doctors' language has a powerful influence not only on the way patients think, but potentially also on the decisions that they make.

16 The beginning of human life – scientific and religious controversies

A. Kurjak and J. M. Carrera

One of the most controversial topics in modern bioethics, science, and philosophy is the beginning of individual human life. In the seemingly endless debate, strongly stimulated by recent technologic advances in human reproduction, a synthesis between scientific data and hypothesis, philosophical thought, and issues of humanities has become necessary to deal with ethical, juridical, and social problems.[1] Furthermore, in this field there is a temptation to ask science to choose between opinions and beliefs that tend to neutralize one another. Indeed, the question of when human life begins requires the essential aid of different forms of knowledge. Here, we become involved in the juncture between science and religion, which needs to be carefully explored.[2]

Obviously, the beginning of human life is seen differently by different individuals, groups, cultures, and religions. Fundamental to productive debate and reconciliation between minority and majority groups is an understanding of the ill-defined concept of 'the beginning of human life'.[3]

Entering this field, scientists have been remiss in failing to translate science into the terms that allow mankind to share their excitement of discovering life before birth. Regardless of the remarkable scientific development, curiosity, and speculations dating back to Hippocrates, life before birth still remains a big secret. Different kinds of intellectuals involved themselves in trying to contribute to the solution of the human life puzzle. They are led by the idea that each newborn child will only reach its full potential if its development *in utero* is free from any adverse influence, providing the best possible environment for the embryo/fetus. Considering the embryo/fetus, the amazing aspect of these parts of human life in which the pregnant woman and the embryo/fetus, although locked in the most intimate of relationships, are at all times two separate individuals should be always kept in mind. Accepting the embryo/fetus as a person opens a new set of questions about its personality and human rights.

The definition of life

Proper answers to the question of how to define human life are complicated. Nowadays, dilemmas consider the respect of human life from birth to death involving not just biology, but other sciences also. Philosophy, theology, psychology, sociology, law, and politics evaluate this topic from different points of view. Integration of all could result in a useful answer.

Some authors say that life as such does not exist – no one has ever seen it. Szent-Gyorgy says that the noun 'life' has no significance because there is no such thing as 'life'. Le Dantez holds that the expression 'to live' is too general, and that it is better to say a dog 'dogs' or a fish 'fishes' than 'a dog or a fish lives'.[4]

When defining life, it should be considered not just as it is today, but as it might have been in its primordial form and as it will be in the future. All present forms of life appear as something completely new. Life, then, is transferred and not conceived in each new generation. Furthermore, the phenomenon of life has existed on Earth for approximately 3.5 billion years. Consequently, although the genome of a new embryo is unique, the makeup of an embryo is not new. If life is observed through the cell, then every life (and human life also) is considered as a continuum. Human cells and mankind have existed on Earth continuously since the appearance of the first man. However, if the definition refers to a single human being or the present population, the statement that 'human life is a continuum' is not acceptable.[5]

'Life', in the true sense of the word, begins when the chemical matter gives rise, in a specific way, to an autonomous, self-regulating, and self-reproducing system. Life is connected with a living being, and it

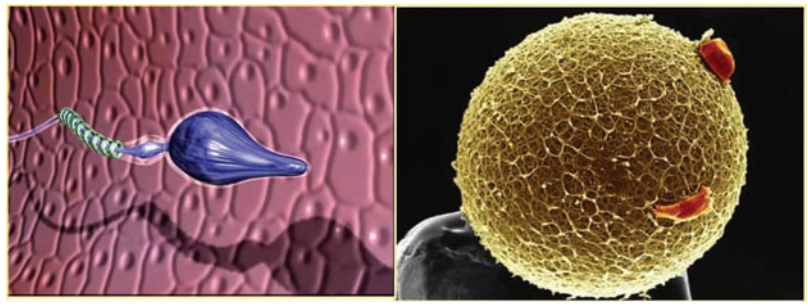

Figure 16.1 Schematic presentation of spermatozoa and oocyte.

creates its own system as an indivisible whole – it forms its individuality. One of the most important characteristics of living beings is reproduction.

Reproduction is a means of creating new life by transferring forms of an old one into a newly formed human being. Therefore, variability, individual development, and harmony characterize human beings. Individuality is the most essential characteristic of human beings consisting of new life. But also all human life forms through evolution, characterized by phenotype, behavior, and the capability to recognize and adapt. Human embryo and fetus gradually develop into these characteristics.

'Human life' poses a semantic problem. The placenta is 'human life', as is every individual cell or organ of the human body, but 'human life' is clearly not equivalent to 'human being'. It is therefore mandatory to differentiate between 'organic or vegetative human life' and 'potential personal human life'. The latter term allows various groups to identify a point of the continuum between abortion and birth to which they can ascribe appropriate values and rights.[3]

Although we should not forget that today's research is tomorrow's benefit,[6] concerning human life, conclusions should not be treated one-sidedly – from one perspective. This reality should be regarded in all its richness: the embryo gives the biologist and geneticist substance for consideration, but talking about the beginning of a human life requires philosophical/anthropological consideration, as well as theological and social sciences. In its protection, we have to include ethics and law. This approach leads to the conclusion that it is necessary to reject reductionism as well as integrism, and to find a 'golden middle' between these two methodologies.[1]

What does biology say?

Biology characterizes human beings by the dynamics of the system and its self-control (homeostasis), excitability (response to stimuli of different nature and origins), self-reproducibility, the heredity of the characters, and the evolutionary trend.[1] For biologists, it is important to specify which form of life phenomena we are referring to: cell, organism population, or species. The basic level of organization and the simplest form of life is the cell. Biologically speaking, human cellular life never stops – or if it did, the extinction of the human species would result – and is passed on from one generation to another. Human individual organismic life is defined within its life cycle, which is temporarily limited, i.e. it has a beginning and an end.[7] It is obvious that life is a highly dynamic phenomenon that could be described and explained through the careful study of life processes and interactions by the interdisciplinary approach. In human spermatozoa and oocyte, there are two essential cells involved in creating human life (Figures 16.1 and 16.2). It is clear that biologists are most qualified to render judgment on the structure and function of cells. To quote Scarpelli,[8] the very broad scope of biological science (from molecular to behavioral biology, and from unicellular to multisystem forms) brings with it the justifiable understanding that the biological scientist knows and is able to define the state of being 'alive' or 'life'. If not, the science fails.

The biological scientist, who may specialize within one or another domain of the broad scope, has particular and definitive knowledge and understanding of the living individual that is his specialty. If not, disorder will rise above failure.

Understanding of the beginning of human life and development of the embryo/fetus could provide definitive resolution. However, with the recent possibility of visualizing early human development virtually from conception, perinatologists should be those who by study, training, practice, and research are singularly qualified.[9]

While science provides us data about physical development of the human being, it does not provide information about its personality and personhood. These topics are philosophical rather than scientific.

Human embryogenesis

Only a proper understanding of the process of human embryogenesis enables answering scientifically the question of when the life cycle of a human individual

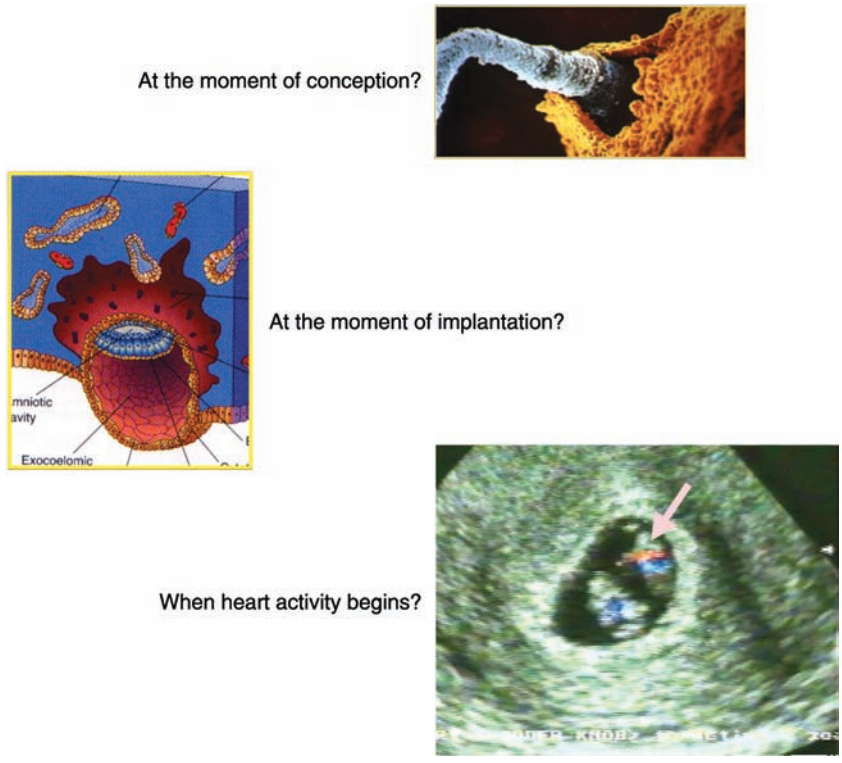

Figure 16.2 Some possible questions on the beginning of human life.

starts. Therefore, in the following text the main steps of the human developmental process are briefly described, primarily during the first 15 days following fertilization.

A human being originates from two living cells: the oocyte and the spermatozoon, transmitting the torch of life to the next generation. The oocyte is a cell approximately 120 μm in diameter with a thick membrane, known as the zona pellucida. The spermatozoon moves, using the flagellum or tail, and the total length of the spermatozoon including the tail is 60 μm.[10]

After syngamy, the zygote undergoes mitotic cell division as it moves down the fallopian tube toward the uterus. A series of mitotic divisions then leads to the development of the pre-embryo. The newly divided cells are called blastomeres. From 1 to 3 days after syngamy, there is a division into two cells, then four cells. Blastomeres form cellular aggregates of distinct, totipotent, undifferentiated cells that, during several early cell divisions, retain the capacity to develop independently into normal pre-embryos. As the blastocyst is in the process of attaching to the uterine wall, the cells increase in number and organize into two layers of cells. Implantation progresses as the outer cell layer of the blastocyst, the trophectoderm, invades the uterine wall and erodes blood vessels and glands. Having begun five or more days after fertilization with the attachment of the blastocyst to the endometrial lining of the uterus, implantation is completed when the blastocyst is fully embedded in the endometrium several days later. Even during these 5–6 days, modern medicine introduces the possibility of making preimplantation genetic diagnosis.

However, at this time, these cells are not yet totally differentiated in terms of their determination to specific cells or organs of the embryo. The term 'pre-embryo', then, includes the developmental stages from the first cell division of the zygote through the morula and the blastocyst. By approximately the 14th day after the end of the process of fertilization, all cells, depending on their position, will have become parts of the placenta and membranes or the embryo. The embryo stage, therefore, begins approximately 16 days after the beginning of the fertilization process and continues until the end of 8 weeks after fertilization, when organogenesis is complete.[11]

The pre-embryo is the structure that exists from the end of the process of fertilization until the appearance of a single primitive streak. Until the completion of implantation, the pre-embryo is capable of dividing into multiple entities, but does not contain enough genetic information to develop into an embryo; it lacks genetic material from maternal mitochondria and maternal and parental genetic messages in the form of messenger RNA or proteins. Therefore, during the pre-embryonic period it has not yet been determined with certainty that a biological individual will result, or would be one or more (forming of identical twins), so that the assignment of the full rights of an individual human person is inconsistent with biological reality.

One conclusion from this is that the pre-embryo requires the establishment of special rules in society: it

cannot claim absolute protection based on claims of personhood; although meriting respect, it does not have the same moral value that a human person has. Today, one largely accepted opinion is that until the 14th day from fertilization, or at least until implantation, the human embryo may not be considered, from the ontological point of view, as an individual.

Genetic uniqueness and singleness coincide only after implantation and restriction have completed, which is about 3 weeks after fertilization. Until that period, the zygote and its sequelae are in a fluid process, are not a physical individual, and therefore cannot be a person.

It is well known that high percentages of oocytes that have been penetrated never proceed on to further development, and that many oocytes that do are thwarted so early in their development that their presence is not even recognized. It is suggested that 30% of conceptions detected by positive reactions to human chorionic gonadotropin (HCG) tests abort spontaneously before these pregnancies are clinically verified.

The newly conceived pre-embryo presents itself as a biologically defined reality. However, the status of the pre-embryo as an individual remains a great mystery. In the present scientific scene, especially with the progress of ultrasound technologies, prenatal psychology and therapeutics have opened a window into the prenatal life of embryo and fetus confirming the evidence that the embryo/fetus is a true subject in itself.[12]

Personality

Defining personality is very complex. There is still no clear definition of personality. One dictionary offers 'what constitutes an individual as distinct person', but does not define what the 'what' is. Another dictionary asserts 'the state of existing as a thinking intelligent being'. This definition might lead to the inference that personality increases *pro rata* with intelligence, or that some people may not have a personality at all if we followed Bertrand Russell's dictum that 'most people would rather die than think and many, in fact, do!'. Kenneth Stallworthy's *Manual of Psychiatry* is more helpful with the definition that 'personality is the individual as a whole with everything about him which makes him different from other people', because we can certainly distinguish fetuses from each other and from other people. With the next sentence – 'personality is determined by what is born in the individual in the first place and by everything which subsequently happens to him in the second' – we are really in the field.[1,3]

Viewpoints on the nature of 'personhood' and what it means ethically and legally vary widely. In his proposed Life Protection Act, Sass acknowledges that a fetus with formed synapses is not a 'person' in the usual sense of the word, connoting consciousness and self-consciousness.[13] Veatch sees the problem as defining the life that has full moral standing,[14] while Knutson[15] has noted that 'those who employ spiritual or religious definitions of when life begins tend to place the beginning of life earlier than those who employ psychological, sociological, or cultural definitions'.

Led by the truism, 'No insignificant person was ever born', human beings should be valued from birth to natural death. It is hard to establish proper values and exact definitions. This becomes especially problematic when prenatal life is considered. The above-stated truism opens an important question: 'Is the person-unborn a person in the first place and, if so, is the person-unborn a "significant" person?'.[1]

Let us evaluate further present controversies. There is no doubt that the embryo and fetus *in utero* are biologically human individuals prior to birth. The child who is born is the same developing human individual that was in the mother's womb. Birth alone cannot confer natural personhood or human individuality. This is confirmed by preterm deliveries of babies who are as truly human and almost as viable as those whose gestation goes to full term. All the known evidence supports the human fetus being a true ontological human individual and consequently a human person in fact, if not in law. *A human person cannot begin before the appropriate brain structures are developed that are capable of sustaining awareness.* The same applies to a grossly malformed fetus. It would still be a human individual even if its human nature was not perfect or its functions quite normal. Nobody questions the humanity of a Down's syndrome fetus or child. A fetus or child with severe open spina bifida is not less of a human being. The same should be said for the live anencephalic fetus or infant with only brain stem functions. It is a human individual even if it lacks a complete brain and usually survives birth by only a few hours or a day.

'Person' and 'personhood' are the legally operational terms in the USA and many other countries. Alternatively, 'person' and 'personhood' are replaced by terms such as 'viable outside the uterus', 'a woman's right to privacy', and 'a woman's right to choose'. In each case, viable, privacy, and choice, the life-support provider may legally order transfer of the dependent individual into a morbid environment. For this group, dilemma (which includes the stem cell, abortion, and cloning debates) is abated, but not resolved.[3]

Human society created several standards in defining 'person' or 'human being' based on what is familiar and easy recognizable.[1] For example, a human speaks, understands, and laughs. Absence of these characteristics (mutism, autism, and stoicism) is not a disqualification. On the contrary, the conclusion is that the characteristics we have come to associate with being a person may not be applicable to each individual person. Therefore, it is necessary to establish criteria for a definition of 'person' in society and in time (Figures 16.3 and 16.4). Some prominent Italian professors[12] committed themselves to caring

Figure 16.3 Some questions about the definition of a person.

for the embryo in such a way, giving the same dignity to every patient, and the human conditions to grow and develop, to educate others inside and outside the specialty, and to carry out research involving all the components of society.

Embryo as a patient – bioethical aspects

The idea of the embryo/fetus as a miniaturized infant or adult is true to the extent that the embryonic/fetal physiologist must be able to apply knowledge of every system after birth, yet quite untrue in failing to recognize the many ways in which life before birth differs fundamentally from life after birth.[6] The newly conceived form presents itself as the biologically defined reality: it is an individual that is completely human in development, that autonomously, moment by moment without any discontinuity, actualizes its proper form in order to realize through intrinsic activity a design present in its own genome (Figures 16.5–16.10).[12] The embryo as a patient is best understood as the subset of the concept of the fetus as the patient. These two concepts opened a whole set of questions regarding ethical problems. The embryo as the patient is indivisible from its mother. However, balance is needed in protecting the interests of the embryo/fetus and the mother. One prominent approach to understanding the concept of the embryo/fetus as a patient has involved attempts to show whether or not the embryo/fetus has independent moral status, or personhood.[16–18] Independent moral status for the fetus would mean that one or more of the characteristics possessed either in or of the embryo/fetus itself, and therefore independently of the pregnant woman or any other factor, generate, and therefore ground, obligations to the embryo/fetus on the part of the pregnant woman and her physician.

A wide range of intrinsic characteristics have been considered for this role, e.g. moment of conception, implantation, central nervous system development, quickening, and moment of birth.[19] Given the variability of proposed characteristics, there are many

views about when the embryo/fetus does or does not acquire independent moral status. Some take the view that the embryo/fetus possesses independent moral status from the moment of conception or implantation. Others believe that the embryo/fetus acquires independent moral status in degrees, thus resulting in 'graded' moral status. Still others hold, at least implicitly, that the embryo/fetus never has independent moral status so long as it is *in utero*.[18]

Being a patient does not require that one possesses independent moral status.[20] Being a patient means that one can benefit from the application of the clinical skills of the physician.[21] Put more precisely, a human being without independent moral status is properly regarded as a patient when the following conditions are met: that a human being is presented to the physician for the purpose of applying clinical interventions that are reliably expected to be efficacious, in that they are reliably expected to result in a greater balance of benefits over harms in the future of the human being in question.[19] In other words, an individual is considered a patient when a physician has beneficence-based ethical obligations to that individual.

To clarify the concept of the embryo/fetus as the patient, beneficence-based obligation is necessary to

be provided. Beneficence-based obligations to the fetus and embryo exist when the fetus can later achieve independent moral status.[21] This leads to the conclusion that ethical significance of the unborn child is in direct link with the child to be born – the child it can become.

Legal status of the embryo

When discussing law, it should be always kept in mind that medicine is international, but law is not. Before the era of Aristotle, who taught that human life begins when the fetus is formed, human life was considered to begin at birth. Prior to birth, the fetus was not an independent human being but, like an organ, part of the mother.[22] Thus, the birth of a full-term infant has been used in the laws of various countries to signify the beginning of the human life that is to be protected.

Indeed, the status of the human embryo is not juridically defined and relies on the political, social, and religious influences in each country. Interestingly, nearly all countries of the Western world use the 12th week of pregnancy as the limit for legal abortion. It is not the end of the first trimester, which is 13.3 weeks, and there is no other particular biological event to justify this limit.

It is hard to answer the question when human life should be legally protected. At the time of conception? At the time of implantation? At the time of birth? (Figure 16.11). In all countries (except Ireland and Liechtenstein) juridical considerations are based on Roman law. Roman civil law says that the fetus has rights when it is born or if it is born-nasciterus.

Few countries agree with the definition of the beginning of human personality at the time of conception. The majority does not grant legal status to the human embryo *in vitro* (i.e. during the 14 days after fertilization). Thus, even in the absence of legal rights, there is no denying that the embryo constitutes the beginning of human life, a member of the human family. Therefore, whatever the attitude, every country has to examine which practices are compatible with the respect of that dignity and the security of human genetic material.[23]

Arguments for beginning of human life and human person at fertilization

The fundamental approaches of biomedical and social (secular) practice must begin with the understanding that the subject before birth is a person and that 'personhood' is conferred by successful fertilization of the egg. To hide from this in silence or ignorance should be unacceptable to all, as stressed by Scarpelli.[9]

The view that human life begins when sperm and eggs fuse to give rise to a single-cell human zygote, whose genetic individuality and uniqueness remain unchanged during normal development, is widely supported. Because the zygote has the capacity to become an adult human individual, it is thought it must be one already. The same zygote organizes itself into an embryo, a fetus, a child, and an adult. By this account, the zygote is an actual human individual and not simply a potential one, in much the same way as an infant is an actual human person with potential to develop to maturity and not just a potential person. As Scarpelli pointed out, outside the realm of religious dogma, there has been no one whose existence can be traced back to any entity other than the fertilized egg. The biological line of existence of each individual, without exception, begins precisely when fertilization of the egg is successful.[9]

The process of fertilization actually begins with conditioning of the spermatozoon in the male and female reproductive tracts. Thereafter, fertilization involves not only the egg itself, but also the various investments that surround the egg at the time it is released from the ovary follicle. Fertilization, therefore, is not an event, but a complex biochemical process requiring a minimum of 24 h to complete syngamy, that is, the formation of a diploid set of chromosomes. During this process, there is no commingling of maternal and paternal chromosomes within a single nuclear membrane (prezygote); after this process, the parental chromosomes material is commingled (zygote).

Among the many other activities of this new cell, most important is the recognition of the new genome, which represents the principal information center for the development of the new human being and for all its further activities. For the better understanding of the very nature of the zygote, two main features are to be at least mentioned here. The first feature is that the zygote exists and operates from syngamy on as a being, ontologically one, and with a precise identity. The second feature is that the zygote is intrinsically oriented and determined to a definite development. Both identity and orientation are due essentially to the genetic information with which it is endowed. That is why many do believe that this cell represents the exact point in time and space where a new human individual organism initiates its own life cycle.[1]

Arguments against the beginning of human life at fertilization

Today, one largely accepted opinion is that until the 14th day from fertilization – or at least, until implantation – the human embryo may not be considered, from the ontological point of view, as an individual. There are at least five main reasons in favor of this opinion:

(1) Before the formation of the embryonic disk, the embryo is 'a mass of cells, genetically human', 'a

cluster of distinct individual cells', which are each 'distinct ontological entities in simple contact with the others' (see Ref.[24], pp. 137–46). The genetically unique, newly developed DNA, a genome, is not established until 48 h after sperm penetration. The ovum and sperm lie side by side for more than 48 h before they finally merge. In biological terms, this renders conception as a process that occurs over time and not at a specific point in time.[3]

(2) Until approximately the 14th day after fertilization, all that happens is simply a preparation of the protective and nutritional systems required for the future needs of the embryo. Only when the entity called embryonic disk is formed can the embryo develop into a fetus.[25]

(3) The monozygotic twins phenomenon or chimeras can occur. In fact, this seems to be the strongest reason why the embryo is denied the quality of individuality, and proof that the zygote cannot be an ontologically human being. In approximately one-third of the cases the embryo divides at about the two-cell stage, and in the other two-thirds, the inner cell mass divides within the blastocyst from day 38. Occasionally, the division takes place from day 8 to day 12, but usually it is not complete, thereby forming conjoined identical twins or two-headed individuals.

The chimera, resulting from the recombination of two individua to become one individuum (and detectable through genetic testing) provides another argument against the equivalence of conception and the beginning of human life: no individuum has died, yet one has ceased to exist.

(4) Coexistence of the embryo with its mother is a necessary condition for an embryo belonging to the human species, and this condition can be obtained only at implantation.[18] However, there is evidence that development of a human embryo *in vitro* can continue well beyond the stage of implantation, and that mouse embryos implanted under the male renal capsule can reach the fetal stage. It is also argued, or at least implied, that so many human embryos die before or after implantation that it would be lacking in realism to accept that the human individual begins before implantation.

It is well known that high percentages of oocytes that have been penetrated never proceed on to further development, and that many oocytes that do are thwarted so early in their development that their presence is not even recognized. Up to 50% of ovulated eggs and zygotes recovered after operations were found so grossly abnormal that it would be very unlikely that they would result in viable pregnancies. It is also suggested that 30% of conceptions detected by positive reactions to HCG tests abort spontaneously before these pregnancies are clinically verified. The scientific literature is not unanimous on the incidence of natural wastage prior to, and during, implantation in humans, varying from 15% to as much as 50%. The vast majority of these losses are due to chromosomal defects caused during gametogenesis and fertilization.[26]

Genetic uniqueness and singleness coincide only after implantation and restriction have completed, which is about 3 weeks after fertilization. Until that period, the zygote and its sequelae are in a fluid process and are not a physical individual, and therefore cannot be a person.

Although in a set of twins one individuum can disappear, genetic and individual identities are now more or less equivalent. Many eminent Catholic writers, among them the Australian priest Norman Ford, author of *When Did I Begin?*, consider implantation to mark the beginning of human life; they maintain that the preembryo has only intrinsic potential and must be protected only from the time of implantation.[27]

(5) The product of fertilization may be a tumor, a hydatidiform mole, or chorioepithelioma. Though the mole is alive and of human origin, it is definitely not a human individual or human being. It lacks a true human nature from the start and has no natural potential to begin human development.

A teratoma is another clear instance of cells developing abnormally that results from the product of fertilization, but which could not be considered to be a true human individual with a human nature. It has no potential to develop into an entire fetus or infant. Clearly, the fetus with the teratoma would be a human individual, but not the attached teratoma itself. Obviously, not all the living cells that develop from the conceptus, the early embryo, or the fetus form an integral part of a developing human individual.[1]

Different religious teachings and historical aspects

The Catholic Church's teachings are clearly described in the Introduction of *Donum Vitae*: 'A human creature is to be respected and treated as a person from conception and therefore from that same time his (her) rights as a person must be recognized, among which in the first place is the invaluable right to life of each innocent human creature'.

In 1997 the Third Assembly of the Pontifical Academy for Life was held in Vatican City. It has been concluded that 'at the fusion of two gametes, a new real human individual initiates its own existence, or life cycle, during which – given all the necessary and sufficient conditions – it will autonomously realize all the potentialities with which he is intrinsically endowed'. The embryo, therefore, from the time the gametes fuse, is a real human individual, not a potential human individual. It was even added that recent findings of

human biological science recognize that in zygotes resulting from fertilization, the biological identity of a new human individual is already constituted.[28,29]

In Western Europe and in North and South America these opinions are mostly based on Judeo-Christian theology; in Arabian countries, in Africa, and in Asia the influences of the Islamic and Buddhist religions prevail. Although their approach to the beginning of human life is impressively similar, each of these religions has different attitudes to the problem of embryo research, infertility and its therapy. In fact, while the Jewish attitude toward infertility is expressed in the Talmud sayings and in the Bible (synthesized in the first commandment of God to Adam: 'Be fruitful and multiply'), the Christian point of view establishes no absolute right to parenthood. According to the Islamic views, attempts to cure infertility are not only permissible, but also a duty.

Islamic teaching is based on Prophet Mohammed's description:

> The creation of each of you in his mother's abdomen assumes a "nufta" [male and female semen drops] for 40 days, then becomes "alaga" for the same [duration], then a "mudgha" [like a chewed peace of meat] for the same, then God sends an angel to it with instructions. The angel is ordered to write the Sustenance, life span, deeds and whether eventually his lot is happiness or misery, then to blow the Spirit into him. (Human developments as described in the Khur'an and Sunnah; Moore *et al.* In *Some Evidence for the Truth of Islam*, 1981)

The summary of this poetic and sacred description is: 'Soul breathing "ensoulment" occurs at 120 days of gestation from conception'.

To make this religious principle applicable to the practice, the Islamic Jurisprudence Council wrote a fatwa in 1990 that said: 'Abortion is allowed in the first 120 days of conception if it is proven beyond doubt that the fetus is affected with a severe malformation that is not amenable to therapy, and if his life, after being born, will be a means of misery to both him and his family, and his parents agree', so that there is no difficulty for either the prenatal diagnosis, or for the possible termination of pregnancy within the exposed limits.

Buddhism has imposed strict ethics on priests, but it has relatively lenient attitudes toward lay people, so if medical treatment for infertility is available, people should make use of it.

For about 2000 years the opinions of Aristotle, the great Greek philosopher and naturalist, on the beginning of the human being were commonly held. He argued that the male semen had a special power residing in it, pneuma, to transform the menstrual blood, first into a living being with a vegetative soul after 7 days, and subsequently into one with a sensitive soul 40 days after contact with the male semen.[30]

Aquinas adopted Aristotle's theory, but specified that rational ensoulment took place through the creative act of God to transform the living creature into a human being once it had acquired a sensitive soul. The first conception took place over 7 days, while the second conception, or complete formation of the living individual with a complete human nature, lasted 40 days.[24]

Hippocrates believed that entrance of the soul into the male embryo occurred on the 30th day of intrauterine life. It entered into the female embryo on the 40th day. Actually, this idea was a considerable improvement on the scheme found in the *Book of Leviticus*, where it is suggested that the soul does not enter the female until 40 days after the conception.[31]

In short, the rational soul enables the matter to become a human being, an animated body, an embodied soul, a human person.

Harvey's experiments with deer in 1633 proved Aristotle's theory of human reproduction wrong, without finding a satisfactory explanation of human conception. After modern scientists discovered the process of fertilization, most people took it for granted that human beings, complete with a rational soul, began once fertilization had taken place.

It is clear that the answer to the question 'When has the human being actually come to life?' could only be given by combining the cognition of different religions, philosophies, and various biological scientific disciplines. There is a very fine line between the competence of science and that of metaphysics, and it greatly depends on the individual's philosophical principles. These two, more or less autonomous intellectual disciplines have very often tried dominating one another, or ignoring each other. It is only recently that the majority of scientists and some theologians have come to realize that the separate meanings of scientific and religious 'truths' complement each other, thus representing methodologically independent entities. Current science is not interested in what Nature is, but in the facts that could be stated regarding it, thus trying to explain the term, rather then inventing it. The main difference between science and religion can be seen in the fact that scientific 'truths', unlike religious postulates, can and must be experimentally verified and the methods of scientific cognition can be easily explained and learnt. Whereas religion favors irrationality, science prefers an entirely rational approach to matters of importance. Intellectual cognition, when scientifically expressed, usually is in the form of mathematical formulas and presented quantitatively. Contrarily, religion tends to keep its truths in the form of metaphoric expressions, preferring qualitative presentation. Today, there is a tendency, on a higher level, to reopen the dialog between science and religion, which was present at the very beginning of our culture. Religion had existed long before science came to life, but science is not to be thought of as a continuation of religion. Each discipline should preserve its principles, its separate interpretations, and

its own conclusions. In the end, both of them represent different components of the one and indivisible culture of mankind.

Clinical controversies

There are some clinical controversies pertinent in any discussion of when life begins. Spermatozoa are living cells. They present evidence that they are living by their motility. They are equipped with an effective mechanism for movement in the form of a tail that beats under the control of the cytoplasmic droplets within the head. These living cells, which have been manufactured in the testes, are released into the environment provided by the male reproductive tract. They are not yet capable of fertilization. The spermatozoon must first come under the influence of the male reproductive tract, where it acquires the ability to function in fertilization. Even after ejaculation, it is capable of penetrating the egg, and it is modified further by exposure to the female reproductive tract, taking on the ability or capacity to fertilize. The decision must be made as to whether the spermatozoon is a being (i.e. living and human with the potential for continued life once fertilization has occurred), albeit in another form, it is entitled to the right of protection as a person. Those who deny right for life to the spermatozoon might argue that it is not a complete human cell chromosomally – it contains only the haploid number of chromosomes. Paradoxically, those who take that point of view would insist that an individual born with fewer or more chromosomes than normal is human and entitled to all the rights of 'personhood'. As Mastroianni stressed, the decision to base the definition of 'human life' solely on the number of chromosomes in a given cell has far-reaching implications.[32]

Furthermore, life has been defined as being terminated when brain activity ends. If we were to say that life begins when brain activity starts, we would be admitting that the definition of the beginning of life is dependent on technology and not on ethics or morality.

Some suggested that the beginning of human life requires the neural fusion of the periphery with the center, as well as sufficient development of the brain itself.[33] Brody formulated the so-called symmetry concept: if the death of a human being requires the death of the brain, the beginning of human life shall correspond with the beginning of the life of the brain, considered to be at day 32 pc.[34] However, Sass has correctly pointed out that fusion is not established anatomically without neurons that form synapses, which would be expected from embryological development at 70 days (8 weeks) pc.[35]

In this light, let us take, for example, the accepted definition of birth, which some years ago was described as the complete expulsion of a fetus of 1000 g or 28 weeks of pregnancy. With advances in perinatal and neonatal intensive care, the line was drawn at 500 g, or approximately 22 weeks of gestation, some years later. This meant that a 20-week-old fetus was not born by definition, even if it was viable. This concept has changed. The same logic applies to a live fetus being accorded the term 'life', if we use such definitions as the beginning of brain activity or ultrasonic proof of heartbeat and movement. The establishment of each of these parameters is shifted to an earlier stage year by year by improving technological refinements in electronic and ultrasonic equipment. This leads us to the conclusion that to follow this line of reasoning means to give life, birth, and viability definitions determined by technology. The more advanced the technology, the earlier life begins.

In any consideration of the beginning of human life, it helps to think about when life ends. Let us consider the following. A 2-week-old newborn is hospitalized with massive brain injury suffered in an automobile accident. Despite all measures, no electrical or other brain activity can be detected during the next 2 days and the child is pronounced dead. Its body parts may survive after its death, as after the death of every person of whatever age. Hair and nails grow for days. Kidneys, heart, liver, and other organs may go on living for years if transplanted into another individual. Cells taken soon after death and cultured in a laboratory might live well beyond the 72 or more years this child might have lived, although the life of the infant has ended. The conclusion reached in this case – that death of the brain means the end of life – is generally accepted by physicians, courts, and the public.[4]

Returning to the question of when life begins, it is true that the DNA of the fertilized egg has the information necessary to form an individual, but so does virtually every other cell in the body. Nobody would claim full rights for the living cells of the infant killed in the accident, although each has a complete library of DNA. Nor would they for thousands of living skin cells we lose every time we wash our hands and face. Is there some stage in the development of the brain that is critical? Or is it the time at which the fetus can survive outside the womb, with or without the support of medical technology? Should we revert to a criterion used for many years, the time of quickening, when one can feel the fetus moving? These are questions still to be answered.

Visualization of early human development

Significant advances have been made in recent years in visualizing and analyzing the earliest human development. Most of them have been done by introduction of three-dimensional (3D) static and color Doppler and 4D sonography. Many new parameters about early human development are now studied directly by new ultrasound techniques.

A considerable number of biochemical, morphological, and vascular changes occur within the follicle during the process of ovulation and luteinization and most of them can be studied by transvaginal ultrasound with color Doppler and 3D facilities.[36] If the oocyte is fertilized, the embryo is transported into the uterus where, under favorable hormonal and environmental conditions, it will implant and develop into a new and unique individual. The introduction of transvaginal color Doppler improved the recognition of blood vessels enabling detailed examination of small vessels such as arteries supplying preovulatory follicle, corpus luteum, and endometrium.[25]

Perifollicular vascularization can help in identification of follicles containing high-quality oocytes, with a high probability of recuperating, fertilizing, cleaving, and implanting, while 3D ultrasound enables accurate morphological inspection and detection of cumulus oophorus. Follicles without visualization of the cumulus by multiplanar imaging are not likely to contain fertilizable oocytes. This information is especially useful in patients undergoing ovulation induction.

Following ovulation, the corpus luteum is formed as the result of many structural, functional, and vascular changes in the former follicular wall. Color Doppler studies of the luteal blood flow velocities enable evaluation of the corpus luteum function in the second phase of the menstrual cycle and in early pregnancy. When the placenta takes over the role of production of progesterone, the corpus luteum starts regressing.

After ovulation there is a short period during which the endometrial receptivity is maximal. During these few days a blastocyst can attach to the endometrium and provoke increased vascular permeability and vasodilatation at the implantation site. Trophoblast-produced proteolytic enzymes cause the penetration of the uterine mucosa and erode adjacent maternal capillaries. This results in the formation of the intercommunicating lacunar network – the intervillous space of the placenta. A small intradecidual gestational sac can be visualized by transvaginal sonography between 32 and 34 days.[37]

The secondary yolk sac is the earliest extraembryonic structure normally seen within the gestational sac in the beginning of the fifth gestational week (Figure 16.8). The yolk sac volume was found to increase from 5 to 10 weeks' gestation. When the yolk sac reaches its maximum volume at around 10 weeks, it has already started to degenerate, which can be indirectly proved by a significant reduction in visualization rates of the yolk sac vascularity.[24] Therefore, a combination of functional and volumetric studies by 3D power Doppler helps to identify some of the most important moments in early human development.

The embryonic heart begins beating on about days 22–23, accepting blood components from the yolk sac and pushing blood into the circulation. The embryonic blood begins circulating at the end of the fourth week of development.

The start of the embryo–chorionic circulation changes the source of nourishment to all intraembryonic tissues. The survival and further development of the embryo become dependent on the circulation of embryonic/fetal blood. If the embryo–chorionic circulation does not develop, or fails, the conceptus is aborted. The embryo cannot survive without the chorion (placenta) and the chorion will not survive without the embryo. Avascular degenerated chorionic villi constitute the hydatidiform mole.

Within the embryo, there are three distinct blood circulatory systems:[10]

(1) *Vitelline circulation* (from yolk sac to embryo)
(2) *Intraembryonic circulation*
(3) *Two umbilical arteries* (from embryo to placenta – fetoplacental circulation)

Figure 16.11 Another possible question about the beginning of human life.

Figure 16.12 Hand near face movement of the fetus at 16 weeks of gestation, as seen by 3D ultrasound.

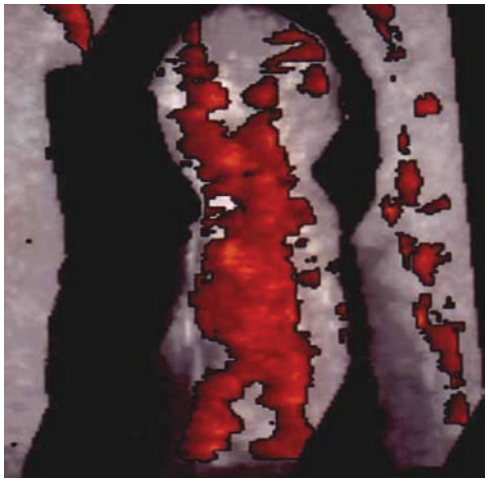

Figure 16.13 Early triplets clearly visualized by 3D sonography.

Figure 16.14 Illustrative example of the complex fetal movements recorded by 4D sonography at 12 weeks' gestation.

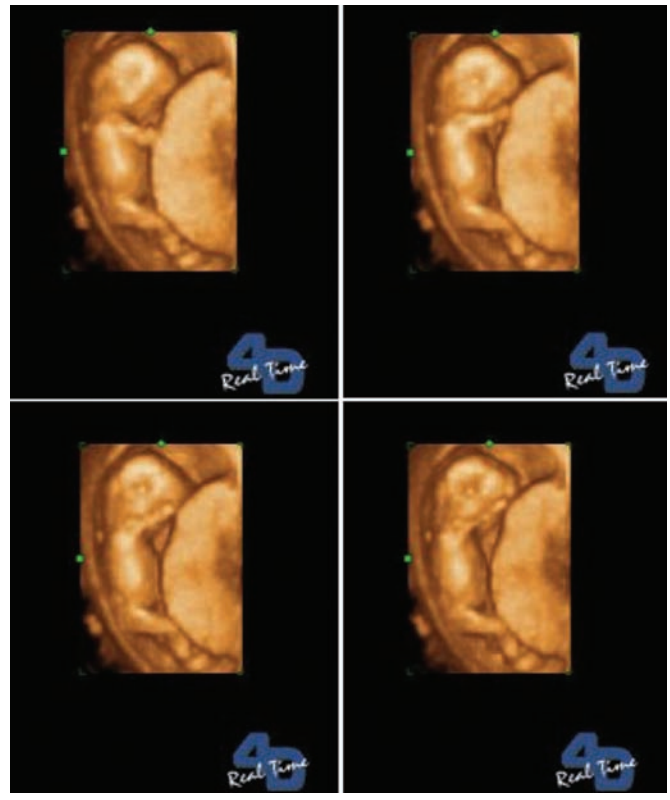

Figure 16.15 Fourteen-week fetus. Complete vascular anatomy of fetal and placental circulation shown by 3D power Doppler.

Figure 16.16 3D sonography visualization of the part of fallopian tube.

It is possible to visualize and assess them virtually from conception.[38–42]

At 5 weeks from the maternal side of the placenta, it is possible to obtain simultaneous 3D imaging of the developing intervillous circulation during the first trimester of pregnancy. 3D power Doppler reveals intensive vascular activity surrounding the chorionic shell starting from the first sonographic evidence of the developing pregnancy during the fifth week of gestation.

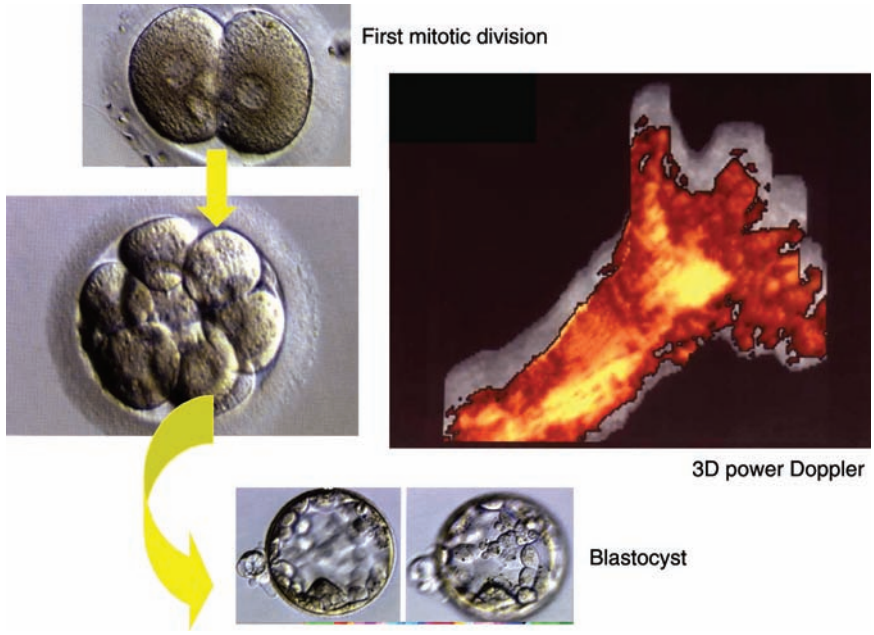

Figure 16.17 Visualization of the patency of fallopian tube by 3D power Doppler sonography, important for successful first mitotic division and transfer of early embryo to uterus.

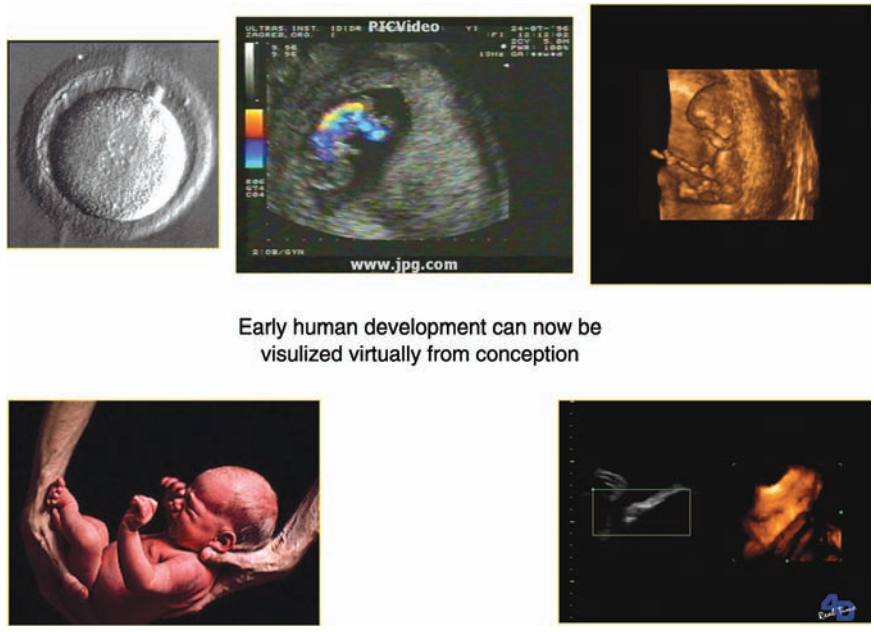

Figure 16.18 Illustrative example of the use of different medical methods to assess early human development.

At 7 weeks, 3D power Doppler images depict aortic and umbilical blood flow. Initial branches of umbilical vessels are visible at the placental umbilical insertion.

During the eighth and ninth weeks, the developing intestine is being herniated into the proximal umbilical cord.

At 9–10 weeks, herniation of the midgut is present. The arms with elbow and legs with knee are clearly visible, while feet can be seen approaching the midline.

At 11 weeks, 3D power Doppler imaging allows visualization of the entire fetal and placental circulation (Figures 16.6, 16.9, 16.10, and 16.12).

During the 11th and 12th week of pregnancy, development of the head and neck continues. Facial details such as nose, orbits, maxilla, and mandibles are often visible. Herniated midgut returns into the abdominal cavity.

New possibilities for studying embryonic movements and behavior

The latest development of 3D and 4D sonography enables the precise study of embryonic and fetal activity

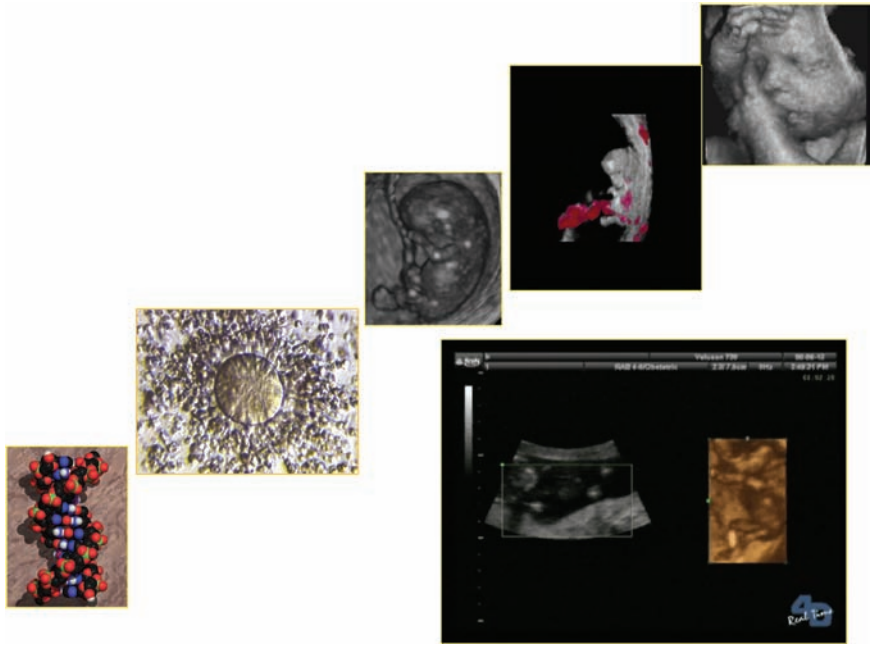

Figure 16.19 Integrated slide showing continuity of scientific visualization of the beginning of early human development from genetic material to oocyte, morphology of embryo, its vascularization, and fetal behavioral pattern assessed by 4D sonography.

and behavior (Figure 16.13).[43] With 4D ultrasound, movements of head, body, and all four limbs and extremities can be seen simultaneously in three dimensions.[44] Therefore, the earliest phases of the human anatomical and motor development can be visualized and studied simultaneously (Figures 16.11, 16.14, 16.18, and 16.19). It is clear that neurologic development – early fetal motor activity and behavior – needs to be re-evaluated by this new technique.[45–47] Our group studied the development of the complexity of spontaneous embryonic and fetal movements.[48] With the advancing of the gestational age, the movements become more and more complex. The increase in the number of axodendritic and axosomatic synapses between 8 and 10, and again between 12 and 15 weeks,[49] correlates with the periods of fetal movement differentiation and with the onset of general movements and complex activity patterns, such as swallowing, stretching, and yawning, seen easily by 4D technique. By 7–8 weeks of pregnancy, gross body movements appear. They consist of changing the position of the head toward the body. By 9–10 weeks of pregnancy, limb movements appear. They consist of changing the position of the extremities toward the body without the extension or flexion in elbow and knee. At 10–12 weeks of pregnancy, complex limb movements appear. They consist of changes in the position of limb segments toward each other, such as extension and flexion in elbow and knee (Figure 16.14).

Between 12 and 15 weeks of pregnancy, swallowing, stretching, and yawning activities appear. In addition to these activities, it is now feasible to study by 4D ultrasound a full range of facial expression including smiling, crying, and eyelid movement (Figure 16.15).

It is hoped that the new 4D technique will help us have a better understanding of both somatic and motoric development of the early embryo. It will also enable the reliable study of fetal and even parental behavior.[44]

Conclusion

The question of when a human life begins and how to define it could be answered only through the interconnecting pathways of history, philosophy, medical science, and religion (Figures 16.16–16.19). It has not been easy to determine where to draw the fine line between the competence of science and metaphysics in this delicate philosophical field. To a large extent the drawing of this line depends on one's fundamental philosophical outlook. To quote Beller:

> The point at which human life begins will always be seen differently by different individuals, groups, cultures, and religious faiths. In democracy there are always at least two sides, and the center holds only when the majority realizes that without a minority, democracy itself is lost. The minority in turn must realize its best chance lies in persuasion by reason and thoughtfulness rather than fanaticism.[3]

17 Preimplantation diagnosis

L. J. Nelson

Preimplantation genetic diagnosis (PGD) is a technique devised within the last 15 years used primarily to identify genetic disorders or defects in human embryos created by *in vitro* fertilization (IVF) prior to their implantation for gestation. The two dominant methods of PGD currently in use are polar body biopsy and blastomere biopsy on cleavage stage embryos, though fluorescence *in situ* hybridization has been used for PGD of common aneuploidies. PGD is an 'attractive means of preventing heritable genetic diseases', which, as an alternative to traditional prenatal genetic diagnosis following chorionic villus sampling (CVS) or amniocentesis, can avoid the need for selective abortion of the affected fetuses, even though it is strongly recommended that normality be confirmed by subsequent CVS or amniocentesis.[1] According to the National Society of Genetic Counselors, the primary reason for electing PGD over traditional prenatal diagnosis is the couple's objection to pregnancy termination.[2]

PGD is also used to detect aneuploidy (the major cause of inherited diseases) and to select chromosomally normal embryos for implantation, mostly in women of advanced maternal age undergoing IVF. The only known risk factor for aneuploidy is maternal age. While trisomies appear in 2% of recognized pregnancies of women 25 years old, this number increases up to 19% in women of 40 or more years of age.[3] One study found aneuploidy to be 52% in women aged 40–47 years.[4] PGD of aneuploidy has been shown to reduce the risk of children with trisomies, increase implantation rates, and decrease spontaneous abortions.[5]

Finally, in cases of parents who have children with bone marrow disorders, who are in need of human leukocyte antigen (HLA)-matched stem cell transplantation (e.g. acute lymphoid leukemia), and who wish to conceive another child to serve as a donor of stem cells, PGD can be employed to test embryos for causative gene mutations and simultaneously for HLA alleles with the goal of selecting and transferring only those unaffected embryos that are HLA matched to the sick child. A recent report documents this process as resulting in five singleton pregnancies and the birth of five HLA-matched healthy children.[6]

More than 1000 unaffected children have been born following PGD; this suggests that the procedure is both accurate and safe.[7] Even though PGD was described as experimental as recently as 1998,[8] it is now considered 'an established technique with specific and expanding applications for standard clinical practice', that is, 'a viable alternative to postconception diagnosis and pregnancy termination'.[1]

This chapter will review and comment on the central ethical issues raised by PGD. These fall into three major categories: (1) ethics and the provision of PGD, including the ethics of marketing PGD services, shared risk or refund programs, and disclosure and patient consent; (2) the moral status of the extracorporeal human embryo (those outside a woman's body) and its destruction following embryo selection; and (3) the ethically appropriate uses of PGD, including its use to prevent the birth of disabled persons and to select for sex and other traits for non-medical reasons. The last section examines the importance of each individual clinician making a personal decision, based on the exercise of an informed conscience, about the ethical propriety of his or her involvement in the provision of PGD services whether for the prevention of genetic disease and disability or for the selection of sex or some other trait unrelated to health.

Ethics and the provision of PGD

Marketing

Most of the utilization of IVF and, by implication, PGD, services is not covered by health insurance in the USA,[8] and this is likely true elsewhere in the world as well. Consequently, most individuals pay for these services directly out of their own private resources. With the average cost for an IVF cycle in the USA being $12,400,[9] the financial commitment for the individuals involved is substantial. Receiving direct payment from patients appeals to clinicians who are not required to wait weeks or months for insurer reimbursement, or to expend large amounts of time and effort in submitting reimbursement forms or obtaining pretreatment authorization. These factors

make the provision of IVF and PGD an attractive and potentially profitable form of professional practice. The utilization of PGD adds several thousands of dollars in cost over and above those incurred for IVF.

Clinics providing IVF, PGD, and other reproductive health services often advertise in the mass media and make other efforts to attract patients (e.g. free informational seminars and internet sites). While advertising health care services is by no means inherently unethical, the traditional professional values of beneficence and loyalty to the patients' interests indicate that the provision of medical services ought not to resemble a common commercial transaction between strangers. Clinicians are in a fiduciary relationship with their patients and are obligated to act so as to deserve and maintain the patient's trust and confidence that their wishes and best interests are being faithfully served. Consequently, the marketing of infertility services ought to place the good of patients above other interests (especially a clinician's or clinic's own economic interests), should not induce patients to accept excessive, unneeded, or unproven services, and should adhere to high standards of honesty and accuracy in the information provided to the prospective patients.[10]

For example, one infertility clinic that used advertisements to entice persons to undergo IVF with language suggesting that 'the dream of having a child might still come true for you' can be criticized as selling profitable services at the expense of vulnerable people suffering from the anguish and disappointment of childlessness. Another IVF clinic used chemical rather than clinical pregnancies in calculating its 'success' rate, a misleading number as only a relatively small portion of chemical pregnancies result in live birth.[10] The success, that is, healthy live birth, rate of IVF and PGD varies by center, and the staff of each is ethically obligated to be scrupulously careful in calculating and disclosing its rates of success – and its rates of error as well. This is particularly important as many PGD centers have not reported their experience, and there currently is no systematic approach to presenting errors. Informal reports suggest an error rate in the range of 1–10%, depending on the disease and assay being evaluated.[1] The European Society for Human Reproduction and Embryology PGD consortium has reported clinical pregnancies in 17% of cases after testing for structural chromosomal abnormalities, 16% after sexing, and 21% after testing for monogenic diseases, while the International Working Group of Preimplantation Genetics has reported a pregnancy rate of about 24%.[11] The former also noted an error rate of 2–3%.

Shared risk programs

In addition to traditional fee-for-service pricing, some assisted reproduction programs offer IVF on a shared risk basis by refunding the patient(s) a portion of, or even all, specified fees (pretreatment screening and drug costs are typically excluded from refund) if the patient does not have a live birth or achieve an ongoing pregnancy. However, patients electing shared risk pay a significantly higher initial fee. These alternative payment plans have been criticized as being 'exploitative, misleading, and contrary to long-standing professional norms against charging contingent fees for medical services'.[12] There is also the objection that shared risk plans create a conflict of interest in which the clinician is induced to take steps to achieve pregnancy regardless of the impact on the patient in order to avoid paying the refund. Assuming fair and adequate disclosure of terms, defenders of the practice point out that it is a legitimate alternative payment plan given the usual absence of insurance coverage, which addresses patient concerns about the high cost of many cycles of IVF that fail to achieve pregnancy, a not uncommon outcome.

The claim that all such programs are misleading or exploiting those who are desperate to have a genetically related child by inducing them to purchase a more expensive set of services is not persuasive. While persons contemplating the utilization of expensive IVF services may well suffer greatly from their infertility and may feel some degree of desperation in their efforts to conceive a child, it is wrong to assume that they are inherently unable to determine their own best interests and make decisions with significant economic consequences. The clinicians involved are, of course, obligated to provide patients with sufficient information to make an informed choice of a shared risk plan rather than fee-for-service. The shared risk plans reviewed by the American Society for Reproductive Medicine (ASRM) Ethics Committee were found to meet this standard.[12]

The objection to shared risk plans as an unethical contingency fee is likewise misplaced. The American Medical Association Code of Medical Ethics states that 'a physician's fee should not be made contingent on the successful outcome of medical treatment'.[13] First, this prohibition is primarily aimed at physicians treating patients who are seeking compensation for their injuries through the legal system. A contingent fee arrangement would strongly tend to bias the physician's opinion in favor of more treatment and more expensive treatment than might be warranted. This concern is absent in assisted reproduction. Second, the prohibition is aimed at dispelling the implication that a good outcome is guaranteed and avoiding unrealistic patient expectations that follow from it. However, shared risks plans are offered precisely because the outcome of the procedure is in serious doubt and the provider is willing to accept some of the financial risk of failure with the patient at the latter's own election.

The final objection based on conflict of interest focuses on the likelihood of a clinician preferring (1) utilization of egg stimulation procedures that will

not only produce more oocytes but also pose more risks to the woman's health and (2) transfer of a larger number of embryos in order to enhance the chances of pregnancy occurring but simultaneously increasing the chances of multiple gestation, which poses well-known risks to both offspring and parents. This objection has some merit. These dangers do exist, but they exist equally for IVF services provided on a fee-for-service basis. The solution is not to prohibit shared risk payment plans, but for clinicians both to carefully monitor their own behavior for strict conformance with the patient's best interests and to fully disclose to patients all of the risks and benefits, both to health and to wealth, of the different financing arrangements. Also, the ASRM Ethics Committee found no evidence that either danger mentioned here has actually materialized.[12]

Disclosure and informed consent

All clinicians should be scrupulous about the accuracy and the truthfulness of the methods they use to attract and secure patients who are dependent on professionals for knowledge about the health care services they receive. Likewise, all information provided by clinicians to patients wanting to utilize PGD should be complete, accurate, and devoid of ambiguity – in contrast with typical commercial information, which is often deliberately incomplete and ambiguous, and at least sometimes inaccurate. In particular, the risks, burdens, benefits, and probabilities of success, and the limits of PGD and IVF should be presented in a matter-of-fact manner and in terms easily accessible to persons unskilled in medical and scientific terminology. In particular, it is 'imperative that patients be aware of potential diagnostic errors and the possibility of currently unknown long-term consequences on the fetus [and subsequently born child] of the embryo biopsy procedure'.[1]

While the persons seeking PGD will almost certainly be competent adults with an above-average amount of education, they are also very likely to be struggling with the reproductive decisions they face and seriously worried about the outcomes. Clinicians providing PGD – and all other infertility and reproductive services – should be especially careful to avoid intentionally exploiting the anxiety and apprehension (or even desperation) of persons who know they are at risk of transmitting a genetic disease to their offspring.

Justice and ability to pay

Marked discrepancies in the use of prenatal genetic diagnosis already exist between affluent white women and other women in the USA.[8] As PGD becomes more available, this pattern will undoubtedly continue. It is certainly not inherently unethical for clinicians to offer health care services, such as cosmetic surgery, full body scans for detection of abnormalities, laser-assisted *in situ* keratomileusis (LASIK) vision correction, or PGD, which are available only to those who can afford to pay for them on their own. But the lack of broad availability of PGD for the less economically advantaged does becomes ethically problematic to the extent PGD satisfies fundamental human needs, but remains unavailable to them (like basic preventive and acute health care services) or produces additional social advantages for the well-to-do by enhancing their offspring, to which others cannot get access.[8] Insofar, as PGD can be legitimately considered as something owed as a matter of social justice to all persons in need, then it is the duty of the society in question to make PGD available to all. Finally, it is worth noting that it is seriously ethically questionable for public funds to be used in the development of PGD services when they are largely available only to persons of high socioeconomic status.

Moral status of the extracorporeal embryo

PGD is intended to result in the selective destruction (or the limbo of indefinite freezing) of extracorporeal human embryos following genetic analysis. Some consider PGD to be morally preferable to traditional prenatal genetic diagnosis because it precludes the need for an abortion to avoid the birth of a genetically abnormal child. This moral advantage to PGD can be understood in one of two ways. First, the woman who would have to undergo the abortion may find it morally preferable from her personal point of view to discard embryos prior to implantation rather than undergo a surgical or medical abortion with its attendant physical and psychological risks. Second, one could claim that discard is not morally wrong because extracorporeal embryos either lack moral status altogether or have less moral status than gestating embryos or fetuses, either of which makes destroying them *in utero* via abortion more morally problematic.

For many, the ethical acceptability of the destruction of human embryos turns much more on the inherent moral status or standing of the (gestating or extracorporeal) human embryo than on someone's moral preference for discard over abortion given that both end in the death of the human entity. If, as some contend, all human embryos have the same moral status as live-born persons,[14] then they are entitled to basic rights, including the right not to be killed arbitrarily or for the purpose of advancing the interests of other persons. In this view, PGD that resulted in the destruction of extracorporeal embryos, as well as abortion following traditional prenatal genetic diagnosis, would be seriously morally wrong. The opposing view would hold that embryos lack any moral status whatsoever as they lack any properties, such as sentience or other cognitive traits, that determine moral standing and hence can be destroyed at will.

Perhaps the more commonly held and the more ethically defensible position is that human embryos deserve some modest moral status because they are alive – embryos have some degree of potential to become human persons, and are in fact valued by moral agents whose views deserve at least some respect and deference from others, but they nevertheless do not possess the full and equal moral standing of persons because they lack interests and other moral claims to personhood. Having a modest level of moral status does not preclude the destruction of embryos for a morally serious reason or purpose, and the informed and conscientious choice of the persons who created the embryos to prevent the birth of a child with a serious genetic disease or abnormality is widely (though by no means universally) considered to be such a reason.

This ethical position roughly parallels that of current American constitutional law, which does not recognize embryos or fetuses as legal persons with rights (including the 14th Amendment rights not to be deprived of life, liberty, or property without due process of law and to have the equal protection of the laws), but recognizes considerable value in these entities through the State's substantial interest in preserving potential human life, an interest that becomes particularly compelling at viability.[15] This interpretation of constitutional personhood means that the State may ban postviability abortions (40 states have done so) unless an abortion is necessary to preserve the pregnant woman's life or health, but it may not totally ban previability abortions or otherwise place an undue burden on a woman's right to terminate her pregnancy.[16] In the absence of a state statute prohibiting the practice (and none exist at present), the discarding of embryos following PGD with the informed consent of the gamete sources cannot be considered a violation of the embryo's legal rights or be a form of criminal homicide in the USA. Whether the state could constitutionally ban PGD and IVF because they result in embryo discard is uncertain. Such a ban implicates not only the legal status of extracorporeal embryos, but also the constitutionally protected right of the persons whose gametes constitute the embryo to reproduce.[17]

However, the legal status of human embryos is not uniform around the world. Recently, the European Court of Human Rights ruled that the unborn are not human beings entitled to full human rights under applicable human rights conventions and that each national government must settle this legal issue for itself.[18] The legal status of embryos and the legal propriety of PGD vary in Europe. For example, PGD is currently illegal in Germany and Switzerland, although a recent study shows that a majority of Germans think the technique should be permitted for detecting genetic diseases.[19,20] The German Embryo Protection Law protects embryos from improper use and forbids genetic analysis of an embryo at the eight-cell stage or before.[21] One Austrian clinician has reported that the legal permissibility of PGD in Austria is unclear.[20] PGD has been authorized in France since 1994, but is strictly limited to cases in which there is a strong probability of the presence of a severe genetic disorder known to be incurable at the time of diagnosis.[22] The Human Fertilisation and Embryology Authority in the UK has licensed PGD for certain severe or life-threatening disorders at a limited number of clinics.[23] PGD is legally permitted in the Netherlands and Spain as well.[20]

Returning to the ethical analysis, the persons most humanly and ethically connected to human embryos are the individual men and women whose gametes wholly constitute the embryo. Almost all persons care deeply if their gametes or embryos are used for reproduction, and being a genetic parent is linked in profound ways to the individual's identity and the meaning he or she gives to life. Embryos ethically 'belong' to the people who created them, even if they are not property like inanimate objects.[24]

Consequently, even though embryos themselves have only a modest moral status, it is nonetheless seriously morally wrong to use the extracorporeal embryos of persons for any purpose without their informed consent. A corollary to this view is that the discarding of embryos secondary to PGD with the informed consent of the persons whose gametes created them is morally proper. In other words, the persons who created an embryo have the right of exclusive control over the disposition of those embryos, a right grounded in their interest in making the intimate, personal decision of when and how to reproduce. As no one else has a more significant moral connection to the embryos than the persons who created them, no one else has the moral authority to overrule their decision about the disposition of their embryos. Yet this right of disposition does not render embryos morally insignificant or allow them to be used for a morally trivial purpose; human embryos retain their modest moral status in any event.[24]

Ethics and the current uses of PGD

Before considering the ethics of the dominant use of PGD (the prevention of heritable genetic diseases), let us consider the other major uses mentioned previously: the identification (and discard) of chromosomally abnormal embryos in IVF and testing for HLA compatibility with an existing child. A moral objection to the former is actually an objection to the entire IVF process insofar as it results in the discard or indefinite cryopreservation of any human embryos, which have the moral status of persons with full and equal basic rights because this status would preclude their destruction or suspended animation. The objection to the intentional destruction of extracorporeal embryos for any purpose rests on the very controversial conclusion

that such immature human entities are entitled to the very same moral respect owed to born persons. Moreover, the objection considers the benefits to the parents of a child born free of a serious, even devastating, genetic disease and to the child herself to be morally irrelevant, a conclusion that seems myopic and incomplete.

The use of PGD for HLA testing and selection of embryos who, when born, can serve as stem cell donors for their seriously ill siblings is certainly more controversial than the use of PGD for the detection of aneuploidy. The most commonly heard objection here is that the child to be conceived is being used as a means to benefit the already existing diseased child and her parents, and is not being brought into the world for her own sake, a violation of the Kantian principle of respect for persons. For this same reason the parents' motives for conception of a child are considered ethically improper. Some critics would also claim that the child would be harmed psychologically, once she finds out that she was brought into the world for the purpose of saving a sibling.

The moral objection to the child being conceived as a means to an end really has force only if the parents actually have this specific intent and treat the child in a manner consistent with it by, for example, putting the child up for adoption immediately after stem cell harvesting or abandoning her. No public report that documents such a state of affairs could be located; in fact, the children born in this manner appear to be loved and valuable members of the family just as their ill sibling is. People conceive children for a wide variety of reasons and motives – to have help in their old age, to fulfill cultural expectations, to make grandparents of their parents, to honor a command of God, to fulfill their own dreams of parenthood, and so on – not all of which are morally admirable or accepted as legitimate by most persons. The real moral test is not the purity of parental motives, but the quality of their behavior during pregnancy and after birth, which should show love, concern, and dedication to their child. Moreover, as existing children can properly serve as bone marrow donors for sick siblings, it follows by analogy that it is ethically acceptable for parents to make a child who will serve in the same role, assuming all children involved are loved and not subjected to procedures that are clearly contrary to their best interests.[11] Finally, it is implausible to assume that psychological harm will come to children who serve as donors when they are as likely to benefit from knowing they assisted in preserving their sibling's life.

The most common utilization of PGD is by a particular woman who wishes to avoid bearing a child with a genetic disease or abnormality that she (and commonly a spouse or partner) finds unacceptable. Actually, the risk of bearing such a child is reduced, but not eliminated, because PGD can only detect diseases or conditions with an identified genetic basis (such as certain single-gene defects and translocations), and it has an estimated error rate in the range of 1–10%, depending on the particular disease and assay being evaluated.[1] Errors are particularly bothersome when testing autosomal recessive or dominant conditions due to the phenomenon of allele-specific dropout.[25]

While the key purpose of traditional, non-directive prenatal diagnosis is to provide persons with information about the genetic constitution of the pregnancy and not to render any opinion on its termination, the same cannot be said of PGD.

> The purpose of PGD is not simply to inform couples about the genetic nature of their embryos. The explicit purpose is also to transfer healthy embryos and to discard those destined to be affected. Once a couple has chosen PGD, nondirectiveness is no longer relevant.[8]

Therefore, the very purpose of PGD is to avoid the gestation and birth of a child who will have, or is likely to have, an identifiable genetic disease or disability of some sort. Nevertheless, clinicians remain ethically obligated not to impose on the prospective parents the values they bring to the assessment of a given embryo's genetic condition.

As a matter of general principle, prevention of the birth of a (genetically or otherwise) diseased or disabled child (such as one with profound mental retardation) is plainly a morally legitimate goal. If it were not, then it would make no sense to encourage pregnant (or prepregnant) women to avoid smoking tobacco or consuming large amounts of alcohol, to obtain competent prenatal care, or to take folic acid. But the prevention of such births is at least morally permissible, even if it is not morally obligatory.

There are two fundamental moral objections that can be levied at this particular goal: (1) the means taken to avoid the birth – the intentional discarding of embryos in the case of PGD – is morally wrong (this objection, based on the moral status of the embryo, was discussed above) and (2) the conception of 'disease or disability' being utilized by prospective parents and the clinicians assisting their reproduction is morally deficient. In addition, strong moral objections have been made to the use of PGD to determine conditions that cannot plausibly be called 'diseases', such as sex and the absence of desirable physical, mental, or social characteristics.

Disease and disability

Historically, medicine has offered prenatal diagnosis as a means of preventing the birth of children with the so-called serious inherited disorders, such as Tay Sachs, Trisomy 13, 18, and 21, cystic fibrosis, muscular dystrophy, Huntington's disease, Lesch–Nyhan, and neurofibromatosis. To one degree or another, each of these conditions may entail the imposition of pain,

suffering, shortened life span, and/or significant inability to engage in typical activities of daily living on the individual with the condition. They also may place personal and economic burdens of one degree or another on the individual's parents, family, and even the society in which they live. These considerations lead some individuals to conclude that they would rather not give birth to a child with such a disorder; they then turn to medical professionals, such as those who provide PGD, to assist them in effectuating this decision. Embryo selection then prevents disability by avoiding the gestation of individuals who would (or likely) be significantly disabled or diseased if born.

Recently, disability activists have strongly challenged what they deem to be the basic assumption underlying PGD and traditional prenatal diagnosis: reducing the incidence of disease and disability is an obvious and unambiguous good. They rightly criticize certain views that can, and frequently do, support this assumption: that the disabled's enjoyment of life is necessarily less than for non-disabled people, that raising a child with a disability is a wholly undesirable thing, and that selective embryo discard or abortion necessarily saves mothers from the heavy burdens of raising disabled children.[26] Not all disabled persons are barred from having a satisfying life by their disability (although the social disadvantages and discrimination they encounter do decrease their quality of life), nor is it the case that raising a disabled child is always terribly burdensome or unrewarding.

However, the ethical critique of the disability activists goes much deeper than this quite proper debunking of broadly drawn and inaccurate assumptions about life with any disability. First, they contend that the medical system tends to exaggerate the 'burden' associated with having a disability and underestimates the functional abilities of the disabled:

> Conditions receiving priority attention for prenatal [genetic testing] are Down's syndrome, spina bifida, cystic fibrosis, and Fragile X, whose clinical outcomes are usually mildly to moderately disabling. Individuals with these conditions can live good lives.[26]

The activists also point out how medical language reinforces the negativity associated with disability by using such terms as 'deformity' or 'defective embryo or fetus'.

Second, and more importantly, the disability activists claim that the promotion and use of PGD and traditional prenatal diagnosis 'sends a message' to the public which negatively affects existing disabled people and fosters an increase in the oppression and prejudice from which they regularly suffer. The so-called 'message' of PGD – that the birth of disabled persons who are defective or deformed ought to be prevented – 'may have the effect of triggering additional oppression, reinforcing the general public's perception that disability is a tragic mistake (that could and should have been avoided) and that disabled people are therefore justifiably marginalized'.[26]

Some commentators within the disability community acknowledge that disability itself is not inherently a neutral condition; it may limit some options and impose real health problems and diminished human capacities. But they also emphasize that 'oppressive social conditions have so distorted the public's perceptions [of disability and disabled persons], as well as how disabled individuals themselves might internalize these perceptions, that it is difficult to assess the true impact of disability on the individual's life experiences'.[26] In other words, the real negative impact of disability in and of itself is exceedingly difficult to isolate because of deep and pervasive social discrimination against disabled individuals and widely shared, strongly negative social views on the meaning and personal impact of disability.

Insofar as individual clinicians do, in fact, exaggerate the problems and burdens of living as an individual with a disability or of living with a disabled person as a parent or family member, they are doing a moral disservice to the people they are duty bound to be helping. Adults who wish to reproduce are ethically obligated to do so in a responsible manner, and this means (insofar as it is possible in a world about which we have imperfect knowledge) gathering and assessing fair and accurate information about what the future might hold for them and the child they might produce. Clinicians (especially genetic counselors) should endeavor to provide this kind of information, supplemented – if at all possible – by the first-hand information that comes from those who have actually lived with disabilities of various kinds, as parents of the disabled, or from the disabled individuals themselves. For example, it is certainly true that not all individuals with Down's syndrome or their parents live painful, frustrated, or tragically diminished lives. The same is true for individuals with spina bifida, cystic fibrosis, Fragile X, and other genetic disorders.

On the other hand, these conditions are simply not utterly benign or neutral as each may, and often does, involve what can fairly be described as an 'undesirable event, such as pain, repeated hospitalizations and operations, paralysis, a shortened life span, limited educational and job opportunities, limited independence, and so forth'.[27] Even though not all instances of such disorders will involve the experience of such problems, a significant risk that an individual may encounter them always exists. A prospective parent who chooses to act on his or her conclusion that it is better for a child not to have, or to be at significant risk of having, such serious disorders is acting reasonably. 'We do no one – not disabled individuals, not women, not families – a service by minimizing the physical, mental, and emotional burdens that may result from parenting children with disabilities'.[27]

The claim of certain disability advocates that those who utilize PGD as patients or who offer it as clinicians are necessarily 'sending a message' to the public that it is ethically right to oppress or discriminate against the disabled, or that the birth of any disabled child is a tragic mistake which ought to have been avoided, is simply untenable. 'From the fact that a couple wants to avoid the birth of a child with a disability, it just does not follow that they value less the lives of existing people with disabilities, any more than taking folic acid to avoid spina bifida indicates a devaluing of the lives of people with spina bifida.'[27] The attempt on the part of a prospective parent to avoid the conception and birth of a child with a disability through PGD (and it is always just an attempt as there are no guarantees) does not mean that he or she would surely reject or fail to love a child born with a disability – or show disrespect to an existing disabled person.

While it is morally permissible for a prospective parent to discard an embryo with a genetic disease, it would be seriously wrong for him or her to 'discard' or reject a live-born child with the same disease. Adults who reproduce must take moral and legal responsibility for their reproductive decisions, and this necessarily includes accepting the risk that the child born to them may not be 'perfect' or not as healthy as they would like. Unlike an embryo that has only modest moral status whose very existence can properly be controlled by the persons who created it, a live-born child is an independent individual with full and equal moral status who has now joined the human community and who cannot be arbitrarily discarded or destroyed by its parents without a serious moral wrong being done. Rejecting or not loving a child solely because he or she has a disability is reasonably considered morally arbitrary and wrong because the child has full and equal moral status, while an extracorporeal embryo does not.

Society does not utilize PGD or traditional prenatal diagnosis, whatever 'society's' views on disability might be. Individual persons utilize such services with the assistance of individual clinicians, and they do so in order to make deliberate choices about their personal reproduction and about their particular lives rather than leave these entirely to chance. A choice that each individual makes about his or her own reproduction has no moral implication for how a similar choice ought to be made by another person: a choice not to implant an embryo with the gene for cystic fibrosis, while morally permissible, does not (indeed cannot) mean that the opposite choice by a different person is morally wrong. Nor does such a choice mean that the individual must therefore devalue persons living with cystic fibrosis. However, some commentators have argued that under certain circumstances persons have a positive ethical duty not to reproduce.[28]

Suppose PGD reveals the presence of a genetic abnormality, Down's syndrome, in an embryo. Someone could say that an individual woman who chooses not to have that embryo transferred into her uterus is rejecting persons with Down's syndrome, but there is another, more plausible interpretation as well.

> What I would say is 'I do not want my child to be born with Down's syndrome', meaning 'if I have a choice, I want the person who will be my child to be born into a body without such potentially significant limitations ...'. That is all [I am expressing]. For a person with a disability to take this as a personal rejection seems unreasonable to me.[29]

The claim of the disability activists that the meaning of PGD must be that 'people like us will never be born' is unfounded: of course, 'they will [be born], they just won't have the disability'. To me, this objection only really makes sense if people with disabilities are their disabilities, which they are not.[29]

In sum, discrimination against persons with disabilities is just as morally repugnant as discrimination against persons based on race, religion, or sex, but it is not at all clear that PGD reinforces or contributes to this in any manner. Regardless of how society might change (as it surely *ought* to change) its attitudes and practices to decrease or, better, eliminate the socially created disadvantages wrongly placed on the disabled – and regardless of how individual persons might change their views on the prospect of knowingly having a child with a serious disability – other persons

> will prefer not to have a child with a serious disability, no matter how wonderful the social services, no matter how inclusive the society. [T]his is a perfectly acceptable attitude, one that does not impugn their ability to be good parents. This attitude does not imply a devaluing of the lives of existing people with disabilities, any more than do programs to vaccinate children against polio or ensure that pregnant women get enough folic acid.[27]

It is this individual choice that PGD preserves, although the clinicians who offer PGD have a moral obligation to explore their own and their patients' attitudes about, and understanding of, disability so these individual decisions can be made fairly and responsibly with accurate information about the real world of life with and without disability.

PGD and selection for sex and other desirable characteristics

Three methods for prepregnancy or prebirth sex selection are available: (1) prefertilization separation of X-bearing from Y-bearing sperm with selection of the desired sex for artificial insemination or IVF (Microsort), (2) PGD with transfer of embryos of the

desired sex, and (3) traditional prenatal diagnosis and selective abortion. However, given that IVF with PGD is expensive, technologically daunting, and imposes significant burdens on women, it has only limited usefulness as a method for sex selection, though it currently works much better than sperm sorting.[30] This may change as more reports of clinical experience with Microsort are made publicly available.

Interestingly, the Ethics Committee of the American Society for Reproductive Medicine has opined that 'policies to prohibit or condemn as unethical all uses of non-medically indicated preconception gender selection are not justified',[1] yet it has also held that

> ... initiation of IVF and PGD solely for sex selection holds even greater risk of unwarranted gender bias, social harm, and the diversion of medical resources from genuine medical need. It should therefore be discouraged.[31]

The National Society of Genetic Counselors has flatly stated that couples wanting 'sex selection for personal preference are not candidates for PGD'.[2] The primary ethical distinction between sperm sorting and PGD rests on the fact that the latter involves the creation and destruction of embryos, which have some moral status and are therefore entitled to some moral respect, while gametes have no moral status.

The selection of an embryo's sex via PGD is done for two basic reasons: (1) preventing the transmission of sex-linked genetic disorders, such as hemophilia A and B, Lesch–Nyhan syndrome, Duchenne–Becker muscular dystrophy, and Hunter syndrome and (2) choosing sex to achieve gender balance in a family with more than one child, to achieve a preferred order in the birth of children by sex, or to provide a parent with a child of the sex he or she prefers to raise.[31] While little extended ethical debate exists regarding the former, sex selection for the purpose of preventing the transmission of sex-linked genetic disease, the latter is the subject of heated ethical disagreement.

The ethical objections to sex selection for non-medical reasons can be grounded both in the very act of deliberately choosing one sex over the other and in the untoward consequences of sex selection, particularly if it is performed frequently. Sex selection can be considered inherently ethically objectionable because it makes sex a determinative reason to value one human being over another when it ought to be completely irrelevant: female and male children as such always ought to be valued equally and never differentially.

Sex selection can also be ethically criticized for the undesirable consequences it may generate. Choice by sex supports socially created assumptions about the relative value and meaning of 'male' and 'female' with the latter almost universally being considered seriously inferior to the former. By supporting assumptions that hold femaleness in lower social regard, sex selection enhances the likelihood that females will be the targets of infanticide, unfair discrimination, and damaging stereotypes. The experience in India and China indicates that sex selection is commonly used to ensure the birth of males over females.[32] At one point in China there were 153 boys for every 100 girls.[30] A more recent report indicates that in parts of China, there are 140 boys for every 100 girls (in contrast to the USA and world average of 105 boys for every 100 girls) and suggests that this will likely result in an increase in prostitution and the outright selling of women.[33] A preference for males as first-born could also disadvantage females, as research consistently shows that the first-born are more aggressive, more achieving, and of higher income and education than later-born children.[30]

Proponents of the ethical acceptability of sex selection would argue that the parents' desire for family balancing can be – and typically is – morally neutral. The defense of family balancing rests on the view that once a parent has a child of one sex, he or she can properly prefer to have a child of the other sex because the two genders are different and generate different parenting experiences.

To deny that the experience of parenting a boy is different from that of parenting a girl "seems breathtakingly simplistic, as if gender played no role either in a person's personality or relationships to others. Gender may be partly cultural (which does not make it less 'real'), but it probably is partly biological …. I see nothing wrong with wanting to have both the experiences".[30]

Thus, gender differences in fact exist and appear to be both cultural and biological in origin; actual physical and psychological differences exist between male and female children that affect parental child rearing experiences in important ways.[34] Even one noted feminist author has asserted that gender asimilarity and complementarity are morally acceptable reasons for wanting a child of a certain sex.[35]

The defender of sex selection for family balancing can also point out that parents who desire this different experience can do so without believing or acting as if one sex is better than the other and without imposing harmful gender roles (e.g. females are emotional, not rational) upon their children. As persons having such a preference may do so without believing that one sex is superior to another and with respect for the equal rights and status of females, proponents would argue that their preference should be respected incident to the exercise of their right to reproduce, especially in the absence of empirical evidence showing that the practice of sex selection actually harms females. Moreover, it can be argued that the modest moral respect due to embryos is not offended by a parental choice made on the basis of sex.

It also seems very unlikely that sex selection would significantly skew the male–female balance in the U.S. population or that of other developed Western nations. One U.S. study has shown that among the

respondents who would use sex selection, 81% of the women and 94% of the men would want their first-born to be a boy, which would result in more males receiving the advantage of being first-born. But given that this same study found that only 25% of all respondents would use sex selection methods, it appears unlikely that this would dramatically add to the number of first-born males.

> Nevertheless, if sex selection became widely available, it might change the American family, making older sisters to younger brothers somewhat less common than they otherwise would be. Whether this change would be harmful enough to justify constraining choice [of sex], however, remains hard to say.[30]

Overall, the predictions of potential bad consequences due to sex selection seem too speculative to be determinative of its moral propriety.[31]

An opponent of sex selection for family balancing can argue that good parents, whether prospective or actual, ought never to prefer, favor, or give more love to a child of one sex over the other. For example, a morally good and admirable parent would never love a male child more than a female child, give the male more privileges than a female, or give a female more material things than a male simply because of sex or beliefs about the child's 'proper' gender. A virtuous and conscientious parent, then, ought not to think that, or behave as if, a child of one sex is better than one of the other sex, nor should a good parent believe or act as if, at bottom, girls are really different from boys in the ways that truly matter.

The argument in favor of sex selection for family balancing has to assume that gender and gender roles exist and matter in the lived world. For if they did not, then no reason would exist to differentiate the experience of parenting a male child from that of a female child. However, it is precisely the reliance on this assumption to which the opponent of sex selection objects: accepting – and perpetuating – gender roles inevitably both harms and wrongs both males and females, although females clearly suffer much more from them than males. While some gender roles or expectations are innocuous (e.g. men do not like asking for directions), the overwhelming majority (e.g. males are – and should be – aggressive, women are – and should be – self-sacrificing) are not. Consequently, given that sex selection is inevitably gendered and most gender roles and expectations restrict the freedom of persons to be who they wish to be regardless of gender, sex selection is at least strongly ethically suspect, if not outright wrong.

Some would claim that choosing the sex of our children is not the most morally worrisome application of PGD or other forms of medical intervention in reproduction; it is rather the prospect of our ability to choose the characteristics of our offspring. '[T]he real threat comes from the identification of an increasing number of genetic markers associated with conditions that are not life-threatening, but impairing or socially undesirable, such as hyperactivity, homosexuality, and obesity'.[36] Botkin notes that the moral reluctance to discard an embryo or abort a fetus for a less than serious medical condition already conflicts with the value of honoring parental autonomy 'in this most intimate of enterprises'.[8]

This conflict will be 'exacerbated by the rapid increase in genetic tests for a wide range of conditions, including late-onset conditions, conditions with a limited impact on health, and, possibly, behavioral or physical characteristics that fall within the normal range'.[8] Despite the apparent falsity of strict genetic determinism,

> … we may only need a popular *perception* of genetic determinism, fueled by creative marketing and weak regulation, to move poorly predictive tests from the lab into the clinic … [T]hese tests need not be very predictive to be adopted by some couples who want the very best that their sperm, eggs, and money can buy.[8]

In this regard, it is also worth recalling the ASRM's characterization of PGD as 'an established technique with specific and *expanding* applications for standard clinical practice'[34] (emphasis added).

Sex selection by PGD or traditional prenatal diagnosis is already available, although one recent study shows that a majority of physicians who offer PGD are not willing to do so for sex selection.[37] The existence of genetic tests linked (even tenuously) to certain desirable or undesirable social, psychological, or behavioral characteristics is highly likely to generate at least some demand from people who will pay the going rate for such tests up front in cash and who will be more than capable of giving informed consent to the procedure. The critical ethical question will be: should medical professionals provide any such tests (or sex selection for that matter) on request or, more likely, on demand?

The role of the individual clinician's conscience

It is quite common for bioethicists to call for a 'social' resolution of thorny questions like this that arise in medicine.[8,38] One type of social resolution comes from the law. However, an answer to the ethical and practical question of which genetic tests clinicians should offer will almost surely not come from the law, which is (at least in the USA) a typically politically charged, slow (it is consistently behind developments in science), expensive (for both lobbying and litigation), uncertain, and cumbersome method for regulating what physicians and other clinicians do, especially when it comes to human reproduction. A true social consensus about matters involving embryo destruction is even

less likely, as witnessed by the current debate over therapeutic cloning and stem cell research, not to mention abortion. Some semblance of an answer may come from professional medical organizations in the form of 'recommendations' or 'guidelines', but they probably will be quite general and in need of interpretation and application to specific cases. Professional guidelines may also be intentionally ambiguously worded in order not to create a standard of care that could be legally enforced through civil lawsuits.

What then is a clinician involved in PGD to do? Should she perform PGD for sex selection for non-medical reasons or for roughly determining, say, IQ (which probably has some genetic basis)? There undoubtedly will be coherent and serious ethical arguments on both sides of the question, as the brief review of the debate over sex selection (above) indicates. Thoughtful and conscientious clinicians will undoubtedly disagree, but this is the same situation with other controversial areas in medicine, such as futility, the propriety of treatment in the absence of 'medical indications', physician-assisted suicide, and physician-performed euthanasia.[39]

Little true consensus exists regarding when physicians and other clinicians ought to refuse to do certain interventions because they do not benefit patients, harm patients or others, are inconsistent with the healing nature of medicine, disrespect the value of human life, or are outside the legitimate scope of medicine which should be devoted to promoting human health, not human happiness or simple human preference. As a result of this variability in ethical interpretation, each individual clinician has to make a personal decision, in light of his or her own conscience and understanding of the ethical requirements of responsible professional practice, about which genetic tests he will and will not perform incident to PGD.

Conscience is a form of self-reflection on, and a judgment about, whether a particular act (or omission) is morally right or wrong, good or bad, but it is never self-certifying from the moral point of view.[40] Conscience has to be properly informed by the pertinent moral principles and rules as well as relevant professional values. But conscience must, at some point or other, lead the individual to take a stand on pressing ethical issues – like which genetic tests of offer incident to PGD. And the stand must at least sometimes be '*this* I will *not* do'. The very meaning and integrity of an individual as a moral agent turns on this: the good things any person does can be made complete only by the things she refuses to do.[39]

When conscientiously refusing to do PGD for sex or a new marker associated with homosexuality or increased height, a clinician is not necessarily adopting the position that it is unethical for any other clinician to act in this manner, although she may believe this to be so and may attempt to persuade others to exercise their consciences in the same manner. An individual clinician who refuses to perform PGD for some specific purpose is primarily making a judgment about the ethical importance of acting in a way that preserves her *personal* moral integrity and expresses her need to assume personal moral responsibility for her actions. Clinicians cannot control the behavior of other professionals in their field, but they can and should choose to conform their own behavior to the ethical standards they personally embrace, even if the field as a whole has not taken a firm stand on the relevant issue.

Each and every clinician involved in assisted reproductive medicine (whether physician, nurse, genetic counselor, or technician) should practice as a responsible individual moral agent who has developed an informed conscience and not as a vending machine of professional services operated on patient demand. Every clinician should recognize that not all of her colleagues may come to the same conclusion as she and that her professional organizations may waffle on certain issues and issue only vague or ambiguous ethical exhortations. But the lack of agreement or consensus on ethical issues does not permit a morally conscientious individual to follow the path of least resistance and simply do whatever can technologically be done and whatever a willing patient will pay for.

Conclusion

PGD is a valuable addition to the repertoire of reproductive medicine as it gives individuals with a documented history of a genetic disorder the opportunity to begin a wanted pregnancy with little or even possibly no fear that they are transmitting this disorder to their offspring. An outstanding example of this is the recent report of PGD being successfully used to avoid the conception of a child that could have inherited a predisposition to early-onset Alzheimer disease.[41] But, if this service becomes embroiled in the detection of conditions having little or nothing to do with health and disease in order to satisfy patient demand or be a profitable business, its practitioners will get, and deserve, serious ethical criticism.

18 Genetic counseling

Á. Csaba and Z. Papp

In the past decades, genetic counseling has assumed an increasingly significant role in medical science. Deep changes in societal expectations coupled with the transforming social structure have led a growing number of married couples to make use of services offered by genetic counseling. Whereas, at the time of Semmelweis, the saving of mothers' lives had constituted a breakthrough in obstetrical practice, the 20th century development of neonatology and perinatology leading to improved survival chances in fetuses and newborn babies, brought further significant progress. As birthrates decreased and families tended to be founded at older age, more and more pregnant women chose to take advantage of genetics. It became a more important, if not the most important, objective to enable families burdened with inheritable and accumulating problems to have healthy children. The natural selection process that works on a large scale was no longer acceptable for families desiring to have one or two children; therefore, the demand emerged in developed countries for the safest possible pregnancy care. As part of this development, genetic counseling developed and continues to assume an increasingly significant role. The recent, explosive progress in genetic research has made people believe that now every hereditary disease can be screened in time and prevented, that is, the birth of a sick baby can be avoided with absolute certainty. The requirement of living up to this expectation more comprehensively has led to establishing and launching genetic counseling centers, which have become an integral part of the maternity care system. It has become virtually the first priority for families to expect the health care system to prepare and inform them, and thus make it possible for them to accept pregnancy as a result of a well-informed and well-considered decision. Society has also recognized that for a number of reasons (healing, psychological, financial, societal, etc.) it is preferable to prevent diseases than treat them after their emergence.

The roots of genetic counseling go back a long time in history. The correction of the undesirable qualities of the human race and the curing of its diseases has preoccupied us since prehistoric times. In one of his works, *The State*, Plato (427–347 B.C.) described a way to improve people by 'selective breeding'. The English scientist Francis Galton was the first to be engaged more thoroughly and seriously in eugenics. (It was he who introduced the word eugenics in 1883.) In a book written in 1869 (*Hereditary Genius*), he proposed that outstanding men be married by a plan to well-to-do women for a talented race to emerge. In the first half of the 20th century, certain forces disgracefully used the science of genetics and its achievements as a distorted means of eugenics to underpin their racial theories (for the extinction of Jews, blacks, and homosexuals), and also in the early 20th century this culminated in political dictatorships ordering sterilization for individuals with high genetic risk. As a result, the application of genetic achievements was long stigmatized and it had a hard time regaining the appreciation it deserves.

Before discovering genetic rules, genetic counseling was based on empirical observations. In this process it was important to recognize that certain diagnoses were more frequent in certain couples' descendents.

The 20th century witnessed revolutionary progress in the science of genetics that coincided with increasing societal demands and therefore became an integral part of modern genetic counseling. In the beginning, in the age of 'classic genetic counseling', our means were quite limited. Genetic diseases were Mendelian disorders or diseases that were inheritable through one gene. Then, counseling extended merely to clarifying the genetic, i.e. hereditable nature of a certain disease and informing the patients about the risk of recurrence. This was the time when society's demand for the prevention of diseases emerged, but our scientific and technical possibilities were still rather restricted. Regrettably, we were in no position to offer a reassuring 'alternative' to the couples who approached us with their problems. Those asking for advice had to make do with mere information, the rigid percentage numbers of the risk of repetition, on the basis of which they could make their decision on whether to have a child. In many cases, however, the high risk of occurrence and/or recurrence communicated by the physician forever deterred the couple from having another child. To be sure, in other cases it was useful for the couple to know that with the knowledge about

the heredity of the given problem, they could safely have another pregnancy without having to dread the recurrence of the disease that they had feared. In that period, there could occur such a situation (due to a lack of assisted reproduction techniques) when genetic counseling shed light on a disease inherited in a recessive manner, which might have led the couple to the conclusion that their descendents were exposed to a heightened risk. This could, unfortunately, result in the deterioration of the relationship, and even in their divorce, so that they both could increase their respective chances of having a healthy child. At last, the physician performing genetic counseling was also in a difficult position, since in many cases he was aware that he could not give the assistance that was needed, and he must have sensed the tension generated by the puzzlement of the couple seeking advice. (In certain cases, this feeling has, unfortunately, remained known to physicians providing genetic counseling.)

Theoretical and practical means of genetic counseling

Genetic counseling is centered on close interactive communication between those requesting and those giving advice. Genetic counseling centers operate in numerous countries of the world. Their task everywhere is to give information about hereditary diseases, to let patients know about the possible cures, and not the least to define the method of heredity. Knowing the type of heredity is indispensable for figuring out the risk of occurrence and/or recurrence, which is the most frequently asked and most important question for pregnant women or couples wanting babies, and therefore seeking counseling. Thus, genetic counseling can basically be divided into two major branches:

(a) Finding out if the disease of a newborn baby, older child, or adult is hereditary, making a diagnosis, and providing information about the possible treatment.
(b) Counseling during pregnancy concerning the occurrence and/or recurrence of hereditary (genetically determined) diseases in a family or those materializing in pregnancy, using prenatal diagnostic tools with the aim of ensuring the birth of healthy offspring.

Although the two branches obviously focus on the same diseases, they require different approaches. All over the world, genetic counseling is primarily done by biologists, geneticists, and various medical specialists, mainly pediatricians and obstetricians.[1–3] Pregnant women and their partners facing various genetic problems can base their decision on information and advice made available by these professionals' knowledge and expertise.[4] Counseling can follow two principles: the more widely used *non-directive* genetic counseling and the so-called *directive* genetic counseling.[5] Because the current era is dominated by legal claims against physicians, the non-directive method is more acceptable and more easily defendable, even though in many cases patients expect and demand a decision-shaping process closely guided by the physicians. When applying the non-directive method, the genetic counselor is ready to share information in a non-directive manner without committing to any potential alternative. It is very important that having thoroughly described the disease in question, the consultant should also inform the patient about the risk of occurrence and/or recurrence. After that, diagnostic alternatives should be described and offered – if there are any. This has to be done in a fashion so that the patients seeking counseling can understand the basic facts, and it may vary with the given circumstances. The patient's fear and anxiety must not be worsened by giving an opinion expressed in mystical, complicated sentences that are incomprehensible to ordinary people. By this point, the couples have already started the decision-making process. The physician leaves it to the patients to use the intensive interactive process to arrive at their final decision. Various prenatal screening and diagnostic methods have demonstrated revolutionary progress and have been made indispensable parts and means of modern genetic counseling.

Often screening tests could at least lower the excitement and nervousness, but it was prenatal diagnostics that made the real breakthrough in the practice of genetic counseling. At this point during counseling, one has to mention the inevitable necessity of explaining the differences between screening tests and diagnostic tests. Society mistakenly confuses the two examinations and attributes to them equal importance. In daily practice, this can result in erroneous decisions because many regard the reassuring results of the screening tests as a safe diagnosis. Too often, we can hear the following statement from a 40-year-old pregnant woman and her 50-year-old husband:

> As the biochemical markers (triple–quadro test) are normal, and the genetic ultrasound examination has not detected any visible abnormalities either, we can rest assured for we cannot have a child with chromosome abnormalities. We do not want amniocentesis.

Screening tests are performed to help us detect and 'take out' those who face a higher than average risk of certain pathological conditions of concern. Some procedures may serve a screening purpose in some cases, while they can have a diagnostic value in association with another disease. Sonography is one of these procedures, but it is only of a screening nature in the case of Down's syndrome, while it has a diagnostic value in the case of anencephaly, spina bifida, and hydrocephalus.

Among prenatal diagnostic tools we distinguish between *non-invasive* and *invasive* methods. Sonography,

one of the most frequently and widely used, dynamically developing examination procedure belongs to the first group. In the non-invasive group, we also have the tests using maternal blood, of which tests with fetal cells obtained from maternal circulation deserve more attention. The arsenal of invasive prenatal diagnostics is also steadily broadening, but those applied first in the practice of genetic counseling remain its most frequent procedures. These are genetic amniocentesis and *chorionic villus sampling* (CVS). Invasive procedures, unfortunately, carry certain risks for the fetus and the pregnant woman. Their complications have a considerable influence on the patients' decision, since in many cases they perceive their situation as a choice between bad and worse. In this context, it is understandable that the essential factor on which they base their decision is the intention to opt for the less risky examination if they are given a choice. The pain and tension caused by the examination also appear as a problem in invasive examination, but this does not have a decisive influence when making the final choice. While these procedures are not painless, the pain is not extensive either.

This strong inter-relatedness between genetic counseling and prenatal diagnostics is largely determined and driven by ultrasound examinations that, as a result of rapid technological advancements, allow the physician to follow more closely the life of the embryo and the fetus.[6–8] Ultrasound is biologically harmless, so undergoing an ultrasound examination cannot pose a serious dilemma for pregnant women. However, despite the accumulation of an increasingly significant amount of expertise and knowledge, it is often difficult to evaluate and interpret the results of the examination. Modern medical examination equipment with largely improved detection capabilities makes even tiny 'suspicious signs' recognizable.[9] Nevertheless, these signs can lead to differing interpretations, thereby causing unwarranted concern among patients. The sonograph can record even tiny divergences from normal conditions that cannot be ignored, because written documents can later serve as legal evidence. Frequently, we are in no position to perform further non-invasive examinations to reassure the patients. This often renders invasive examinations advisable, potentially putting the patients in a difficult decision-making situation. Patients can become anxious or even fearful, because they are apt to treat machine-made images virtually as facts, and to interpret them as serious threats to the fetus. It is then a daunting task to dispel anxiety or fear because the patients tend to believe the 'objective' computer. Here too, the non-directive method is advisable, and it is important to point out not only the possible pathologic conditions, but also the possibility of a reassuring outcome. For this reason, it is essential to follow closely any abnormalities detected during ultrasound examinations in later stages of the pregnancy and after delivery. This approach can lead us to a stage when images currently interpreted as suspicious signs will not result in groundless tension and fears for the pregnant woman.

Practice standards regarding ultrasound examinations during pregnancy vary from country to country. In some countries, one or two examinations are deemed sufficient without providing much detail as to how these should be timed. Nearly a decade ago, we introduced in Hungary a carefully designed system that pays due consideration to the interests of pregnant women and to professional rationality. Our protocol advises four plus one examinations for the pregnant woman, with the first taking place during the first call (usually in the fifth to eighth weeks), the others later in the 10th to 12th, 18th to 20th, 28th to 30th, and 36th to 38th weeks. If necessary, we advise an intrauterine examination of the fetuses' heart (echocardiography).[10] The pregnant woman must understand that these examinations are part of a series of screening tests meant to check on the intrauterine development of the fetus. Countries advising or performing fewer examinations partly cite high costs and question the efficiency of the examinations. There are also skeptical opinions about whether ultrasound examinations can significantly improve morbidity and mortality indicators.[11] Some others, arguing against ultrasound examinations, also point to the misleading, wrongly reassuring effects of 'false-negative' diagnoses. Well-elaborated and organized sonographic training can, however, minimize such risks. It is imperative that examinations be carried out and interpreted by trained and experienced professionals.

Such invasive genetic examinations as amniocentesis, CVS, and fetal blood sampling have become indispensable means of prenatal diagnostics and genetic counseling. These examinations allow us to obtain genetic information, leading to major breakthroughs in the development of genetic counseling. Samples obtained during invasive procedures are helpful in performing several examinations, and the number of diseases that can be detected this way is steadily increasing. Beyond detecting chromosome irregularities, these are now important means of diagnosing monogenic inheritable diseases (Mendelian inheritance) as well. From the samples, we can also perform microbiological and serological examinations. The newest molecular genetic techniques are opening a previously unhoped-for dimension in prenatal diagnostics. Beyond the dangers arising from the invasive nature of such examinations (due to the higher risk of miscarriage), their more widespread use has raised numerous ethical questions as well. Even when we face increased risks of genetic, inheritable diseases, we must try our best to make sure that no sick children are born, while giving couples a realistic chance to have a healthy newborn. Here, we have a reverse situation: contrary to ultrasound examinations, in this case the interpretation of examination results leaves very few questions owing to diagnostic accuracy from the principle of methods applied. In these cases, however,

the examination carries dangers that create significant tension, concern, and complicated decision situations. There can emerge a peculiar and difficult contradiction because the patients would like to have a healthy child, but the examination necessary to make this happen might endanger the further development of the fetus. When the woman makes this decision, the physician must stick with non-directive counseling, which allows him to inform patients about the benefits and drawbacks, but has him answer any further question about what decision to make in a non-directive fashion. The final decision has to come from the woman. The genetic counselor must not assume a 'divine role' and cannot be familiar with all relevant aspects of another person's life. Even in cases that seem identical, the final decisions can be different. A 37-year-old couple who already have three healthy children and where the woman can conceive without difficulty is likely to request karyotyping, whereas a couple having tried in vain to conceive a child for 15 years can be very concerned about the threat of miscarriage and may choose not to have such an invasive act performed.

During genetic counseling, certain 'semi-invasive' examinations can also be of assistance; these are widely used in screening because of their minimal level of invasiveness. Nevertheless, as a result of their being a screening test, they can produce false-positive results, generating serious concern in pregnant women. Biochemical marker tests done from samples of the mother's blood (AFP, BHCG, E2, PAPP-A, Inhibin) constitute one sort of genetic screening examination. Besides false-positive results, there are some false-negative test results as well, which makes it essential to explain to patients that screening examinations do not provide the basis for establishing a diagnosis. In view of the existing risk factors of invasive examinations, one has to aim at putting together as reliable a screening examination protocol as possible. There are ongoing efforts to examine an increasing number of serum markers that can be combined with ultrasound examinations (e.g. nuchal translucency) to improve results. Because of fears of being held accountable and exposed to malpractice claims, the drawing of the point will regrettably increase the number of false-positive cases, which, in turn, will demand a larger capacity for intrauterine chromosome analysis.

Decision making: rights and responsibilities

Physicians who have provided genetic counseling for an anxious married couple have faced their distress and feelings of defenselessness. The very uncertainty shadowing the health of their desired offspring puts a considerable burden on the expectant woman and her spouse. Add to that the further risk of various other special circumstances, and the result can be an effectively unbearable load. Those couples seeking genetic counseling almost always carry the 'extra burden', that being the very reason why their physician sends them to consult a specialist.

Many decision-making situations crop up during genetic counseling. In certain cases, the first question to answer is whether or not the patient is ready for pregnancy, knowing the genetic risk. The individual seeking counseling must decide if she wants to have the proffered diagnostic test. Another decision may have to be made with regard to the patient's wish to carry on with or terminate the pregnancy in the case of a positive result (indicating disease).[2,12,13]

The diverse nature of genetic problems necessitates separating the following branches in order to better understand decision-making mechanisms:

(a) Those cases requiring invasive, high-risk intervention (chromosome defects).
(b) Monogenic diseases with a high risk of occurrence and/or recurrence.
(c) Low-risk genetic situations (taking medicine, diagnostic x-ray examinations).
(d) Uncertain conditions for which diagnostics are limited (certain infections and anatomical defects detectable by serology or ultrasound where the outcome cannot be predicted).

One important consideration is whether the available means can result in a rock-solid diagnosis, or the problem in hand cannot be diagnosed during pregnancy, although certain results may indicate pathological conditions. The decision-making mechanism seems to be affected by a couple of factors, including risk of recurrence, seriousness of the disease, risk of the procedure, maternal age, previous pathological pregnancies (malformations, miscarriages), number of healthy offspring, level of education, religious faith, and convictions of conscience.

The kind of genetic counseling we prefer lets the patients have the final word. Neither the right to make a decision nor the responsibility resulting from that decision can rest with the genetic counselor. This point is important because it makes many legal claims avoidable. The non-directive counseling process can be easily violated, because the patients can be manipulated by carefully determining the sequence of sentences. It must be our objective to be as neutral as possible, while providing comprehensive and honest information to patients. Our words ought not to give away which decision we might favor. Although it is true that we cannot exist without having certain ideals, values, and views, and that we are bound to form an opinion about what we say in a counseling situation, the patients should not sense that we might disagree with their decision or that we might judge them negatively as a result. For the pregnant woman and her partner to accurately feel the weight of their decision, it is necessary to stress that they can choose

freely from the alternatives described to them. They have to see clearly the consequences of whatever decision they opt for.

It would be very difficult to conceive of any other counseling mechanism and decision-making process in democratic states where the wide-ranging rights of the individual are safeguarded. In democratic systems, however, one should not forget about obligations and responsibilities. Systems that exclusively emphasize rights, but not obligations, are moving toward anarchy. This anarchy would obviously apply to the field of genetic counseling as well. For free choice to be preserved, it is crucial that the decision made by the patients in no way influences further pregnancy care, and that the physicians continue to provide the broadest range of services possible.

The weight of the decision requires that pregnant women be given sufficient time to ponder the various dimensions of their choices. In most cases, the pregnant woman finds it reassuring to discuss her situation with her partner or physician and to seek the advice of her family before committing to one of the alternatives. It is highly possible that the patient and the counselor will have to see each other more than once.

During counseling, the physician should be understanding and patient – one cannot overemphasize the role empathy plays in the process. Dramatic statements, gestures, and other forms of non-verbal communication are equally impermissible during non-directive genetic counseling. A written report must be prepared about the counseling session and the patient's decision.

The complex nature of genetic counseling and its relatively short history are bound to raise several moral and ethical questions. Although there is an emerging consensus on the older problems, the new possibilities and achievements have caused significant rifts among physicians and scientists. These developments are increasingly prevalent in our everyday life, and their divisive effects can be felt in the society as well. When it comes to genetics and our endeavors to influence heredity, society tends to be sharply divided. In these situations, the individual's freedom and need to decide are at play simultaneously.

The counselor is not in an easy situation either. In these complicated and often very difficult decision-making situations the consultant's room for maneuver is rather limited due to the non-directive principle of counseling. One can feel every now and then that the advice seeker counts on the consultant's help when making her decision. Limited though the consultant's opportunities may be, he is still able to help by supplying clear and direct information relevant to the case. He is not to use either verbal or metacommunicative means, which might suggest that he is taking a firm stand on either side of the dilemma. At the same time, the verbal and metacommunicative behavior he does perform must not contradict each other, because that may confuse the other party. He must be patient and compassionate, but focused on the issues in hand, and should not let the advice seeker's attention wander. He must dissipate fears raised by 'rumors' and 'horror stories', but must never gloss over or retouch actual facts and dangers. The consultant must always be prepared and set forth possible alternatives along with their advantages, drawbacks, and consequences.[14] In many cases, the counselor is aware of the problem's serious and occasionally hopeless prognosis. The recurrence of this mental burden can pose a serious challenge for the physician. In cases of possible abortion, the genetic counselor's role goes beyond merely sharing information. From the moment that patients are confronted with the problem, we have to provide them with support. Besides the bare facts, we also need to point out the potential remedies. We must convey positive messages to the couple so that they can more easily deal with a tragedy. The description of the problem is never meant to deter; therefore, calm, a human voice, and compassion are the most important qualities of a genetic counselor. We stand a much better chance of achieving cooperation if, instead of telling the facts in a cold, matter-of-fact manner, we act kindly, and do not conceal the problem. The patients must never sense frustration and exhaustion on the part of the genetic counselor.

It is essential that the decision possibly reflects the common will of the couple, but at a minimum be preceded by a consultation between the partners. The couple frequently wishes to request the advice of the woman's gynecologist before making the final decision. This reinforces the strong bond of confidence that develops between the pregnant woman and her physician. This is especially true when genetic counseling is done by an obstetrician/gynecologist who may also be in charge of the patient's pregnancy.

The woman usually desires the most comprehensive information possible so that she can make an educated final decision. Questions like 'How would you decide in my place?' are often put to the genetic counselor. When responding, one has to follow the rules of non-directive counseling and accordingly give information about how the majority of other couples decide in similar situations. It needs to be pointed out to the patients that every individual's and every family's life is different, and therefore it is impossible to give a generalized answer. The decision is influenced, among other factors, by whether the family already has a healthy child, how many pregnancies the woman has had, how old the couple are, and how long they have been trying to conceive a child. Religion and beliefs certainly also play an important role. After the final decision is made, the couple must be given assistance to be able to deal with the consequences as smoothly as possible. A guilty conscience and the shadow of an irresponsible decision are difficult to dispel in a family, but proficiently executed counseling can prevent them from developing.

Ethical and moral aspects of genetic counseling

The diagnostics of monogenic diseases [heterozygote screening, Human Genome Project (HGP), eugenics]

The molecular genetic research brought to a high stage of development in the last years of the 20th century resulted in an even more detailed knowledge of the human genetic material. The HGP has established that the sequence of 3.1 billion letters of DNA shows that humans are made up of about 30,000–40,000 genes.[15,16] This may generate erroneous beliefs in society, because many think that any hereditary gene defect can be detected today, and therefore any given disease can be screened in the embryonic stage. True, more and more monogenic diseases may be diagnosed by polymerase chain reaction (PCR) or other molecular genetic techniques, but science has yet to enable us to detect every genetic defect. These examinations, combined with assisted reproduction techniques, in certain cases, make possible the detection of diseases in the pre-embryo conceived by *in vitro* fertilization (IVF). This doubtlessly important fact can be a strong propaganda factor for the unconditional supporters of this method and can contribute to solidifying it in practice and making its application more widespread by pushing its disadvantages into the background and making use of the media's help. Given that these are costly examinations, it is necessary to bring about a well-established international network of research. If the disease in question is serious, every effort is morally justifiable to organize prenatal diagnostics and make them available. However, HGP and our ever-deepening knowledge also mean that the genetic background of more and more 'conditions' can be examined, which conceals ethical dangers. Does humankind not try to implement positive eugenics when unearthing the genetic (hereditary) background of intelligence and physical features? Is there not a strange 'preordination', 'innate predestination', or 'special selection' for those who, because of their financial status, are able to take the opportunity provided by science however costly it may be in the beginning? Will it be possible to acquire or 'purchase' favored social status even before childbirth? Will these sayings come true: my child was born to be a banker, a doctor, a lawyer, a teacher or an athlete, an artist? Utopian as this assertion may seem, it is not unimaginable.

Let us play with the idea, and assume that the genetic code of every human disease and human quality, including physical and mental endowments as well as appearance, has become detectable through the HGP. In the present social environment, science and technology provide for the possibility of choosing and creating the socially most 'competitive', healthy descendants. If at the beginning it can be done through costly procedures, we have already reached the eugenics envisioned by Plato and Sir Francis Galton. Further, there could emerge in society castes firmly embedded for several generations, for with the help of genetic advantages, the descendants of the wealthier would become the leading stratum, while those with no access to these advantages would constitute the stratum of the subordinates and the employees. Would it be 'healthy', socially useful, or beneficial if everybody wished to be endowed with Einstein's IQ and Schwarzenegger's or Marylin Monroe's appearance? In our view, this vast acceleration of evolution's long and slow process could lead to unforeseeable tragic consequences.

A more delicate and much more topical aspect of this line of thinking is very much alive today: What are the pathological conditions that justify the induction of premature delivery as they exhaust its scope of indication? Who is to decide on these? If certain conditions (e.g. depression, rheumatoid arthritis, schizophrenia, arteriosclerosis, certain tumors, and autoimmune diseases) are proven to be inherited monogenically, is the pregnancy to be terminated if the fetus carries the faulty gene(s) and there is no known therapy? It is of paramount importance that the scope of therapy be extended so that more and more detected diseases can be treated. In order to prevent this, it is urgently necessary to create the proper legal framework of regulations and to introduce rational restrictions instead of outright prohibitions. Historical examples show that whatever can conceivably be done by man will be created sooner or later. We, therefore, cannot lull ourselves into illusions that mere prohibitions can prevent human cloning or that irrational restrictions can prevent the above vision from materializing.

Presymptomatic diagnostics (confidentiality of genetic data – relatives, insurance companies, employers, the family, and the individual)

Presymptomatic diagnostics and so-called 'susceptibility testing' are gaining increasing salience with reference to an increasing number of diseases.[17] *Presymptomatic testing* refers to identification of healthy individuals who may have inherited a gene for a late-onset disease, and if so will develop the disorder if they live long enough (e.g. Huntington disease). *Susceptibility (predictive) testing* identifies healthy individuals who may have inherited a genetic predisposition that puts them at increased risk of developing a multifactorial disease (e.g. heart disease, Alzheimer disease, or cancer), but who may never develop the disease in question. Do we have the right to inform the patient about the existence of untreatable diseases before symptoms appear? Is it necessary to do so? Are we obliged to do that? Is this individual ill at all? Can or need populations be screened for certain diseases? Indeed, the development of some diseases might be slowed down if changes in lifestyle were implemented. The knowledge, however, that the development of a serious disease is inevitable in a

later stage of one's life could put a heavy burden on his everyday existence and might even change an individual's personality. Surviving in the knowledge that one is to expect to develop a malignant tumor by the age of 30–40 years is difficult. By the same token, possessing the relevant information might result in more careful diagnostic examinations, which should have a substantial effect on the life expectancy.

At the same time, this raises the question of who is entitled to know the information, i.e. *confidentiality*,[18,19] the individual affected and his relatives? One might think that only the individual affected should, but with the disease in question being a genetic one, are the relatives not affected, too? Do they not have the right to know their risk? Is the parent obliged to tell his or her child? Can the child request the performance of a predictive test? Can the parent make a decision on whether the examination should be performed for her minor child?[20] Presymptomatic and susceptibility testing in the absence of therapeutic options should be available if certain conditions are met. It is important that the individual be provided thorough information about the limits of testing, and the information contribute to enhancing the pathography and informing the family because, in many cases, it is impossible to predict the onset and seriousness of a particular disease and its symptoms. Awareness of susceptibility could induce a change in the lifestyle that could prevent or prolong the development of a disease. If a disease is inevitable, the individual will have the chance of planning for his or her short life, as in the case of Huntington disease. Such genetic information can influence plans for marriage and having children. Preimplantation genetics could possibly prevent the development of a particular disease in their children. But the basic question remains: Is it good or useful to know what for millennia mankind has had no way of knowing – the ultimate end of life, the number of years, the sequence of probable diseases? Is society prepared for this? Is the human soul strong enough to carry this burden? Do such examinations make sense as long as we lack adequate therapies? Do we have to do everything just because we can? The problem is further complicated by the shortcomings of available predictive genetic tests that still carry a factor of serious uncertainty about whether a disease will develop, and if it does, when exactly and to what extent. Given the onus of this information, if there is no medical advantage concerning prevention or treatment, these examinations can best be postponed until adulthood, when the individual is able to make decisions on crucial aspects of his own life.

Stigmatization, discrimination

Society tends to single out 'other-than-average' individuals, in many cases stigmatizing them. Given the sensitive nature of issues, such as reproduction, heredity, child-rearing skills, and the fact that society considers calculable and predictable health defects a serious drawback, exposing information about such issues is unethical. It is for the individual to decide whether or not his genetic profile ought to be made public. Employers, insurance companies, government administrations, and schools are prone to gather the widest possible spectrum of information about their associates.[21–23] The results of presymptomatic and susceptibility tests are beginning to become central issues for these institutions. These organizations would like to have unrestricted access to these data. The individual is essentially interested in the opposite, since the insurance company would surely demand a higher premium if it is ready to offer insurance at all.

Similarly, an employer would be disinclined to employ someone of whom it is known that in a few years he or she cannot do his or her job. At the same time, the fear of insurers and employers is also understandable, because the individual can also abuse such genetic information. Those declared 'healthy', who will not have to reckon with the development of a serious disease in the course of their lives, would not pay for insurance, and even the 'ill' would wait almost until the likely development of the disease before they would buy insurance. This could generate unmanageable burdens for insurance companies and could lead to the total collapse of the insurance system. Environmental or occupational (e.g. miners and chemical industry workers, pilots) hazards can play a significant role in the development of certain conditions (e.g. asthma, allergies, heart disease, or cancers); therefore, by applying for such jobs, people jeopardize their own health, which can become starting points of future lawsuits. (The employer could propose that the individual should work in a different department, since the desired job could accelerate the development of the disease. If the employee would still choose the job not recommended, which he should have a right to do, then he or she would lose his or her right to sue his company on these grounds.)

Considering the likely rapid dissemination of predictive tests, there is an urgent need to develop a well-thought-out, detailed legal framework. Prohibition cannot be allowed because it would deprive the individual of rather important information. The proper regulation would eliminate the situation of diametrically opposed interests among the parties and would make them interested in wide-ranging examinations. (For instance, at birth everyone should be genetically screened for 'susceptibility' and the resulting information should be made available to those concerned, but at the same time, discrimination and the possibility of abuse by the examined individual should be prohibited; emphasis should be placed on prevention, and adequate sets of incentives should be elaborated). Apparently, avoiding stigmatization and discrimination makes a very important goal, but the problem itself is highly complex. It is unacceptable to discriminate against anybody at school, work, or when taking out an

insurance policy because of one's genetic background. It must not be allowed either that individuals misuse this information. Therefore, it is crucial to bring about well-considered, detailed regulation and legislative background. At present, the individual's and the family's personal rights must not suffer damage, and genetic information may be made public only with their consent.

Sex selection and sex determination

Both the prenatal and the preimplantation diagnostic procedures are suitable for the *determination of the sex* of the pre-embryo/embryo or the fetus. The majority of society does not prefer one sex to the other. In certain communities, however, the offsprings' sex is very important; therefore, sex determination presents itself as a problem in this controversial moral field. Many civilized societies do not allow carrying out invasive genetic examinations merely to select or determine sex, but loopholes exist in many countries. Where a pregnancy may be terminated at the married couple's request, the decision to do so is often made in the knowledge of the fetus' sex (as a result of karyotyping or an ultrasound examination). In these cases, we speak of sex determination done for non-medical reasons. Those in favor of this try to rely on demographic/statistical data arguing that in certain cases it would be favorable to permit it. There are certain research groups and countries where sex determination is permitted if a couple already has a child, and would like the next one to be of the other sex. Some claim that in countries with decreasing populations this could even become an instrument in stopping the declining numbers. In other countries (in Asia), this possibility is seen as one of the factors slowing down population growth.[24,25] They point out previous European experience when the selection of the descendant's sex was possible on the basis of the sperms, and practice showed that this did not change the proportion of the sexes in the population. In 2001, The American Society for Reproductive Medicine ruled that it is proper and ethical to help couples to choose the sex of their babies.[26]

By the same token, sex determination done for non-medical reasons also has several opponents. The most frequently heard argument against the use of preimplantation genetic diagnosis for non-medical sexing is that a medical method should not be used for non-medical reasons.[27] We are even more concerned that by legalizing this kind of sex determination, we will cross the Rubicon, for it would be classifying the sex of an individual as 'an abnormality'. This would be the first step toward the above-described, apparently utopian human interventions that on the surface would be 'done for genetic reasons', but in reality would serve a manipulated selection of human qualities. At a later point, this logic could have us argue that the decreasing population could be expanded if legal regulations allowed selection on the basis of intelligence or physique, or where the opposite is needed, the high-quality, efficient, and productive descendants could just as well slow down population growth.

In our view, to avoid abusing information about sex revealed by carrying out karyotyping for other reasons, careful regulation is needed, which effectively makes it impossible to terminate pregnancy just because the fetus belongs to one or the other sex.[28] Individual (personal) rights must be curtailed, and those uncritically embracing them should not ignore the rights of the fetus. Individualism is not identical to exemption from obeying rules and laws.

Today, sex determination may be justifiably indicated only if a family is affected by a hereditary disease connected to a sex chromosome, and when special molecular diagnostic tools making use of genetic engineering are not yet available. In such a case, if the test reveals that the fetus is male, the couple has the right to ask for the termination of pregnancy so that the disease will be avoided. In this case, we speak of sex determination done for medical reasons. If the preferred method of conception is IVF–ET and the disease in question is an X-determined, recessive one, the so-called preimplantation diagnostics is a possible option, which may ensure that only healthy female preembryos get implanted.[29]

The definition of illness and health

Differentiating between illness and health presents an increasingly complex problem. According to the World Health Organization's (WHO's) definition, health is a state of complete physical, mental, and social well-being, and is not merely the absence of disease or infirmity.[30] Holding the assertion that the absence of disease (an organic, physical decrease in or failure of function) does not in itself constitute health makes it difficult to define the conditions that ought to be regarded as healthy. Late-onset diseases, deviations from the statistical norm, and increased susceptibility to cancers are questionable states. These men and women are not ill for a long time, but they are handicapped from a certain point of view. Shall we or shall we not treat these states as diseases until we are able to cure already detected genetic predispositions? At the same time, millions of people live happy lives with certain diseases (blindness, absence of fingers, color blindness, deafness) presuming they are healthy. A number of geniuses would not have been born had they fallen victim to procured abortion because of conditions considered by society as illnesses.

There is another serious ethical challenge here. Do parents have the right to decide whether or not an obvious infirmity they carry is one that needs screening that might help avoid it in their children? And if they do not, who can decide? If it is left to the parents to make decisions, then strange situations should be

expected. A good example is reported by Green.[31] A deaf–mute couple sought genetic counseling, their disease's nature being monogenically hereditary. Having been informed about their prospects, they asked for a molecular genetic diagnosis to be made on the 13-week-old fetus. To the pleasure of their consultant, the result was homozygote recessive, meaning they could expect a healthy offspring. Surprisingly, however, the couple was disappointed by the result, indicating:

We can't carry on with the pregnancy. How could we bring up a child totally alien to us, able to hear and communicate, while our friends and we live in a different way? We aren't capable of establishing the appropriate circumstances.

Terminating pregnancy because of genetic indications

The most challenging moments of genetic counseling arise when a decision has to be made on the disposition of a pregnancy. From the consultant's point of view, those situations are the most difficult when the problem is so severe and the prognosis is so bad that termination on a genetic basis may be proffered. Even in this case, the goal of non-directive counseling is to inform the patient about this option. The woman is about to resolve one of the most difficult situations of her life. The weight of the decision depends on the gestational age of the pregnancy and other factors. Decisions on serious conditions detected in the first trimester are made easier. Given that most diagnoses are made in the second trimester, when the fetus has already made its first movement, a very close relationship has sometimes developed between the fetus and the expectant mother by decision time. She may have seen its face during an ultrasound examination, and she may even know her offspring's sex. Realizing her widening waistline, the people around her may learn about the pregnancy, and this knowledge and having to wait, make it even more difficult for her to cope. The necessity to make a decision presents a major state of crisis, the extent of which depends, among other things, on the obstetrical anamnesis.

In such a case, the task is to give the relevant facts, help the patient to consider them thoughtfully and calmly, and encourage her to develop positive prospects for the future. It is important to outline the possible short-term and long-term consequences of the decisions, the risk of the defect being recurrent, and the details of its heredity. If the woman opts to continue her pregnancy, she needs to be briefed on what sort of aid she can rely on from the fields of medicine and social services, as well as family care. Those deciding to terminate the pregnancy must be informed about the procedure to relieve tension and distress. In any case, this should ease the anxiety regarding the operation itself. It must be stressed that if the couple opts to terminate the pregnancy, the procedure must be initiated as early as possible. The methods used for midterm abortions vary from country to country. Regardless of the method, the objective is to get the procedure over within the shortest possible time and in the least intrusive way. The patient ought to get back to her home as soon as possible to be able to deal with the tragedy with her loved ones. Access must be made available to post-termination counseling.

The woman's and partner's freedom of choice and representing the fetus' and the newborn's interest: considerations relating to faith and religion

One basic feature of modern genetic counseling is that the final decision is always made by those seeking assistance.[1] The justification for this appeals to individual rights of freedom and people's right to decide issues affecting their own lives. Obstetrics and genetics, however, are fields where a decision often has to do with another individual (i.e. the embryo, fetus, or newborn); therefore, it must not be practiced without limitations and relevant regulation. The problems of fetal life have often been put in the center of debates, not only in professional circles, but also as a political issue. The rigid attitude of the Roman Catholic Church is well known and stirs a lot of debates even within that faith community. The church turns a deaf ear to the issue of termination and does not accept contraception as a legitimate option (with a few exceptions). Thus, it is difficult to provide the opportunities offered by the achievements of prenatal diagnosis to Catholics. In some liberal circles' view, parents must be assured of having the widest possible sphere of authority. This cannot be readily accepted by a physician or an obstetrician-geneticist. In the USA, it is legally possible that termination be carried out until the 24th week of pregnancy at the request of the patient and without any medical indication. The test is whether an individual physician accepts the pregnant woman's decision to terminate her pregnancy.

The WHO's position is that after the 24th week, an end to pregnancy has to be considered as childbirth and as such, everything has to be done to save the life of the premature infant. Therefore, there are cases where several doctors and nurses make superhuman efforts for weeks to rescue a 490-g premature baby born after the 24th week, whereas the life of another baby, perhaps with a little better initial life expectancy, perhaps even weighing a little more, is taken in minutes because the parents changed their mind 'at the last minute'. Our era is burdened with lawsuits brought against thousands of doctors, and many tend to give in to patients' request as self-defense. There are cases of minor problems whose long-time prognosis is not known for certain. In such cases, the question is frequently asked, 'But surely our child will be healthy? You know we don't want a sick baby'. Well, this question is difficult to answer. One must not yield to pressure by irresponsibly allowing termination in such cases. The freedom of choice must be

kept in focus, but between reasonable boundaries, too. Regulation established to protect fetal life enables us to do our job, living up to the principles of modern medicine, and actually protect life and health.

Preimplantation diagnostics: gene therapy

Assisted reproductive techniques are becoming more and more sophisticated, contributing to the expertise that makes it possible to subject the fertilized egg to ever more detailed genetic examinations still outside the mother's body. In the course of the procedure, blastomer, blastocyst, and polar-body biopsy take place, while the genetic analysis is performed with two major molecular genetic techniques, PCR and fluorescence *in situ* hybridization. The high cost of practice and the low pregnancy rate achieved are still considered the two major drawbacks of this new procedure. As our knowledge of the genetic background of diseases expands, the number of those for whom these examinations may be indicated is also increased. In the future, IVF may become more widespread, because it would prevent numerous terminations from occurring: pre-embryos carrying disease would not be implanted in the first place. Regulation must not be neglected in this field, because within a short time, society would be confronted with a deluge of unwarranted examinations. The financial and moral burden of this would surely prove unbearable. Positive eugenics must not be allowed to be realized this way.

Currently, the number of gene therapy procedures is negligible, but intensive research may make some treatments possible soon. This will herald a new age of genetics and, indeed, the whole of medicine. On the one hand, many couples as yet unable to rear children will have the opportunity to do so; on the other hand, one or another of these therapeutic methods might become a way of retrieving health, indeed, a new lease of life for many people.

Financial considerations

Science is capable of much more today in the fields of genetics and prenatal diagnostics than the health care system is able to offer to society. It is those costly interventions that make the difference. When setting priorities, their social usefulness must always be kept in mind. The needs of the wide social strata must never be sacrificed for the sake of a relatively narrow stratum. This principle will be there to be confronted in the field of genetics and prenatal diagnostics for a long time, because the procedures that have been introduced recently are highly costly. A breakthrough in this field may also be expected, but only if efficient screening/diagnostic methods and treatments are available, which are advantageous to the masses of society and for which financial consequences (insurance, work, pensions) are beneficial. The cost–benefit principle may not be accepted without reservation, but it defines what sort of examinations can be routinely carried out in a health care system with a finite budget.

Summary

The basic and clinical science of genetics has made vast progress in a few decades. In accordance with this, genetic counseling has reached the limelight of public attention. Given the fact that the subject of counseling is of momentous consequences and has important effects for both the short and the long term, its ethical aspect is paramount. What was inconceivable just half a century ago has become a routine procedure, and for the majority of previously hopeless couples it is now possible to have healthy descendants. Visions articulated by Plato millennia ago have come close to being realized. While ancient Sparta used exposure of infants on Mount Taigetos as a means of creating a healthy society, today we try to prevent the birth of ill children by examining and improving tiny DNA spirals and base pairs. The question is indeed whether mankind is mature enough to use this knowledge for choosing the right way ahead and utilizing the achievements for society's benefit. It is crucial that the relevant regulation be designed. The center of the ethical questions is occupied by the treatment of important personal information and the method of its being made public. The way the problems are dealt with is always changing, just as society is in a constant process of change. It is important, however, that we always be ready to offer proper help to those in need when they need it.

19 Selective reduction

M. I. Evans, D. W. Britt, D. Ciorica and J. C. Fletcher†

Introduction

Millions of babies have been born benefiting from infertility therapies including more than 1 million *in vitro* fertilization (IVF) babies over the past 25 years. These fulfilling outcomes, however, have been accompanied by serious side effects. The twin pregnancy rate has doubled to more than 1 in 45. Multiple pregnancies have continually risen. Prematurity and related sequelae closely correlate with fetal number (Figure 19.1, Table 19.1).[1] Infertility treatments have become so pervasive that more than 70% of all twins and 99% of higher-order multiples are initiated by them (Table 19.2). With increasing public and professional attention, some of the very high-order multiples have diminished, particularly secondary to lower transfer numbers of embryos in IVF. There are some suggestions that the incidence of triplets and higher is slowly diminishing, but the incidence is still very high.

Perceived pregnancy losses in multiple pregnancies are mostly correlated to how early in pregnancy one establishes the denominator.[2,3] Some perinatal reports are overly optimistic because these physicians do not start counting until they begin to see patients at nearly 20 weeks, at which time most losses have already occurred.[3,4] Many other articles have addressed these issues, which will not be repeated here.[4–6]

In the 1980s, about 75% of multifetal pregnancy patients seeking reduction had pregnancies initiated with ovulation induction agents such as Pergonal.[7] However, even with the first month of the lowest dose of Clomid, quintuplets have occurred. Over the years, cases induced by assisted reproductive technologies (ARTs), such as IVF, have become increasingly common. Currently, about 70% of patients we see seeking reduction have pregnancies generated by ARTs.[8]

Despite the increased utilization of ARTs,[8] the proportion of cases significantly hyperstimulated, and resulting in quintuplets or more, has dramatically decreased to less than 10% of all cases seen by us. Regardless, the 2000 report of the Society of Assisted Reproductive Technologies (SART) suggested that, of all pregnancies achieved by ARTs, in the USA 58.5% are singletons, 28% twins, 7.5% triplets or higher, and 5.9% were unknown.[9,10] In our experience with referred cases of ovulation stimulation, the proportion of cases that are quintuplets or more has likewise fallen but not as remarkably.[11]

The vast majority of multifetal cases occur to physicians with the best of equipment and with the best of intentions who have an unfortunate and reasonably unpredictable or unpreventable mal-occurrence. Despite this, clearly some cases might have been prevented if increased vigilance had been used.[11–13]

Patient issues

The demographics of patients considering multifetal pregnancy reduction (MFPR) have evolved considerably over the past 10–15 years.[11,12] The most dramatic change has been the introduction of donor eggs, which has opened the door to 'older women'. Over

Births	Observed	Expected	Ratio
Twins	125,134	44,686	2.80:1
Triplets	6,898	496	13.9:1
Quadruplets	434	6	72.3:1
Quintuplets and higher multiples	69	0.07	985.7:1

Total births in 2002 – 4,021,726

Table 19.3 Maternal age and ART (SART data, 2001) (from Evans *et al.*[11])

All cases	81,915
Fresh non -donor	60,780
< 35	28,778
35–37	14,416
38–40	11,301
41–42	4,365
42+	2,190

10% of all patients seeking MFPR that we see are over 40 years of age; nearly half of them are using donor eggs. As a consequence of the shift to older patients, many of who already had previous relationships and children, there is an increased desire by these patients to have only one further child. The number of experienced centers willing to do two to one reductions is still very limited, but we believe it can be justified in the appropriate circumstances.[11,13] We expect the proportion of all patients with multiples reducing to a singleton to continually rise.

For patients who are 'older', particularly using their own eggs, the issue of genetic diagnosis comes into play. By 2001, more than 50% of patients in the USA having ART cycles were over 35 (Table 19.3).[1,9,10,14] In the 1980s and early 1990s, the most common approach was to offer amniocentesis at 16–17 weeks on the remaining twins. A 1995 paper suggested a 11% loss rate in these cases, which caused considerable concern.[15] However, the issue was settled by a much larger collaborative series in 1998 that showed that loss rates were no higher than comparable controls of MFPR patients who did not have amniocentesis.[16] The collaborative data demonstrate a loss rate of 5%, which was certainly no higher than the group of patients post-MFPR who did not have genetic studies.

As the centers with the most MFPR experience also happened to be the ones that also had the same accomplishments with chorionic villus sampling (CVS), combinations of the procedures were very logical. There are two main schools of thought as to the best approach to first trimester genetic diagnosis, i.e. should it be before or after the performance of MFPR? Published data in the early 1990s on doing the CVS first followed by reductions suggested a 1–2% error rate as to which fetus was which, particularly if the entire karyotype is obtained before going on to reduction.[17] Therefore, for the first 10–15 years, the approach we used was to generally do the reduction first at approximately 10.5 weeks in patients reducing down to twins or triplets, followed by CVS approximately 1 week later.[11,14] However, in patients going to a singleton pregnancy, essentially putting 'all of their eggs in one basket', we believed the best approach was to know what was in the basket before reducing the other embryos.[11,12] In these cases we performed a CVS on usually all the fetuses or one more than the intended stopping number, and performed a fluorescent *in situ*

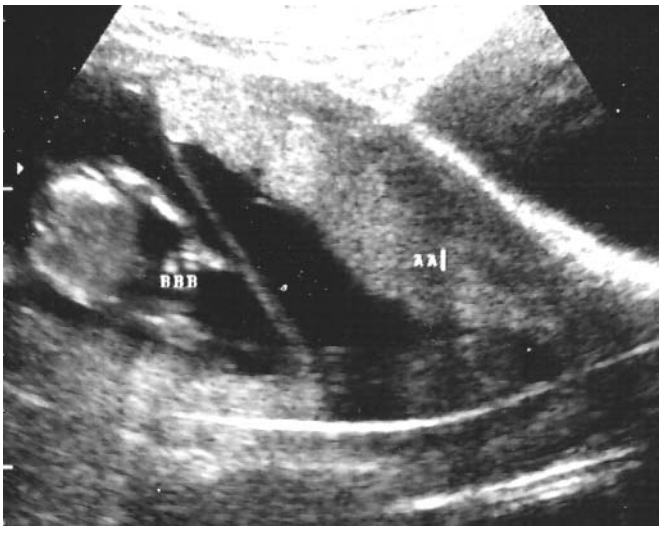

Figure 19.2 Transcervical CVS being performed on posterior placenta. For this patient, anterior placenta can be reached either transcervically or transabdominally.

hybridization (FISH) analysis with probes for chromosomes 13, 18, 21, X, and Y (Figure 19.2). Whereas about 30% of overall anomalies seen on karyotype would not be detectable by FISH with these probes,[18] there is always residual risk.[19] The absolute risk given both a normal FISH and a normal ultrasound including nuchal translucency[20] is only about 1/500. We believe that risk is lower than the increased risk from the 2-week wait necessary to get the full karyotype. We have now commonly extended this approach to all patients who are appropriate candidates for prenatal diagnosis regardless of the fetal number. Over the past few years, more than half our patients have combined CVS and MFPR procedures. With data now suggesting increased risks of chromosomal and other anomalies in patients conceiving by IVF and especially with intracytoplasmic sperm injection (ICSI), the utilization of prenatal diagnosis will likely increase even further.[21–26]

The other approach used by another group was to perform the CVS and complete karyotype first and have the patient come back for the reduction. Although 'mistakes' were common 10 years ago, the chance of error has been considerably reduced, and they believed the benefits of the full karyotype justified the wait. The issue as to the better of these two approaches is currently unsettled and would require a very large series to differentiate among small risks.

Procedures

MFPR is a clinical procedure developed in the 1980s when a small number of centers in both the USA and Europe attempted to reduce the usual and tremendously adverse sequelae of multifetal pregnancies by selectively terminating or reducing the number of fetuses to a more manageable number. The first European reports by Dumez,[27] and the first American report by Evans *et al.*,[28] followed by a further report by Berkowitz *et al.*,[29] and later Wapner *et al.*[30] described a surgical approach to improve the outcome in such cases.

Even these early reports appreciated the ethical dilemma faced by couples and physicians under such difficult circumstances.[13] In the mid-1980s, needles were inserted transabdominally and maneuvered into the thorax for the injection of KCl or mechanical disruption of the fetus by mechanical destruction, air embolization, or potassium chloride injections despite relatively mediocre ultrasound visualization. Transcervical aspirations were also initially tried, but with little success. Some centers also used transvaginal mechanical disruption, but data suggested a significantly higher loss rate than with the transabdominal route.[31] Today, virtually all experienced operators perform the procedure inserting needles transabdominally under ultrasound guidance.

Outcome

Several centers with the world's largest experience have, for more than a decade, collaborated to leverage the power of their data. In 1993, the first collaborative report showed a 16% pregnancy loss rate through 24 completed weeks.[17] While by today's standards, that was not a very satisfactory number, it did represent a major improvement for higher-order multiple pregnancies. Further collaborative papers have shown continued dramatic improvements in the overall outcomes of such pregnancies (Table 19.4).[11] The 2001 collaborative data demonstrated that the triplets reduced to twins and quadruplets reduced to twins now perform essentially as if they had started as twins.[11] Even with the tremendous advances in neonatal care for premature babies, the 95% take-home baby rate for triplets and the 92% take-home baby rate for quadruplets clearly represent dramatic improvements over natural statistics. Not only has the pregnancy loss rate been substantially lowered, but so has the rate of very dangerous early prematurity. Both continue to be correlated with the starting number. Data from the past few years show that the improvements are, not surprisingly, greatest from the higher starting numbers (Figure 19.3).

The lowest pregnancy loss rates are for those cases reduced to twins with increasing losses for singletons followed by triplets. However, the rate of early premature delivery has been, not surprisingly, highest with triplets followed by twins and lowest with singletons. Mean gestational age at delivery was also lower for higher-order cases. Birth weights following MFPR decreased with starting and finishing numbers reflecting increasing prematurity.[32]

While data in the literature are conflicting, our experiences suggest that triplets reduced to twins do

Table 19.4 Multifetal pregnancy reduction – percentage of losses and deliveries by years (from Evans *et al.*[11])

		Losses (weeks)			Deliveries (weeks)		
	Total	**% < 24**	**% > 24**	**% 25–28**	**% 29–32**	**% 33–36**	**% 37+**
1986–1990	508	13.2	4.5	10.0	21.1	15.7	35.4
1991–1994	724	9.4	0.3	2.8	5.4	21.1	61.0
1995–1998	1356	6.4	0.2	4.3	10.2	31.5	47.4

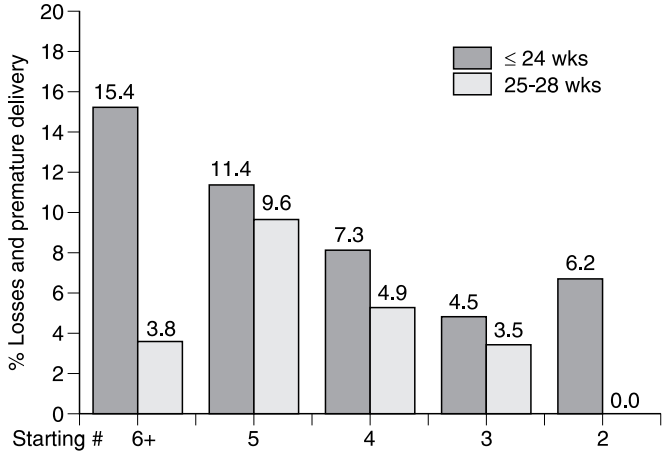

Figure 19.3 Multifetal pregnancy reduction: losses and very prematures by starting number. Adapted from Evans *et al*.[11] with permission.

much better in terms of loss and prematurity than do unreduced triplets. We believe that if a patient's primary goal is to maximize the chances of surviving children, then reduction of triplets to twins achieves the best live born results. More recent analyses suggest that while mortality is lowest with twins, morbidity is lowest with remaining singletons.

There has continued to be a debate in some circles over whether to reduce triplets or not. Yaron *et al.*[33] compared triplets to twins data to unreduced triplets with two large cohorts of twins. The data show substantial improvement of reduced twins as compared to triplets. The data from the most recent collaborative series suggest that pregnancy outcomes for cases starting at triplets or even quadruplets reduced to twins do fundamentally as well as starting as twins. These data therefore support some cautious aggressiveness in infertility treatments to achieve pregnancy in difficult clinical situations. However, when higher numbers occur, good outcomes clearly diminish. A paper published in 2001 suggested that reduced triplets did worse than continuing ones.[34] However, analysis of that series showed a loss rate following MFPR twice that seen in our collaborative series[11] and poorer outcomes in every other category for remaining triplets. Several other recent papers have likewise shown higher risks for 'unreduced' triplets than for reduced cases.[35–38] It is clear that one must use extreme caution in choosing comparison groups (Table 19.5). An ever-increasing situation involves the inclusion of a monozygotic pair of twins in a higher-order multiple.[39] Our experience suggests that provided the 'singleton' seems healthy, the best outcomes are achieved by reduction of the monozygotic twins. Obviously, if the singleton is not healthy, then keeping the twins is the next choice.

Pregnancy loss is only one of the deleterious outcomes. Very early preterm delivery correlates with the starting number. However, it has not been well appreciated that about 20% of babies born at less than 750 g develop cerebral palsy.[40] In Western Australia, Peterson *et al*. showed that the rate of cerebral palsy was 4.6 times higher for twins than singletons per live births, but 8.3 times higher when calculated per pregnancy.[41] Pharoah and Cooke calculated cerebral palsy rates per 1000 first-year survivors as 2.3 for singletons, 12.6 for twins, and 44.8 for triplets.[42]

In the 2001 collaborative report, the subset of patients who reduced from two to one (not for fetal anomalies) included 154 patients. These data suggested a loss rate comparable to three to two, but, in about one-third of the two to one cases, there was a medical indication for the procedure – e.g. maternal cardiac disease or prior twin pregnancy with severe prematurity, or uterine abnormality.[11] In recent years, however, the demographics are changing, and the vast majority of such cases are from women in their forties, or even fifties, some of whom are using donor eggs and who, more for social than medical reasons, only want a singleton pregnancy.[42,43] New data suggest that twins reduced to a singleton do better than remaining as twins.[13] Consistent with the above, more women are desiring to reduce to a singleton. In a recent series of triplets, we found the average age of outpatients reducing to twins to be 37 years and to a singleton 41 years.[44] While the reduction in pregnancy loss risk for three to one is not as much as for three to two, (15–7% and 15–5%, respectively), the gestational age at delivery for the resulting singleton is higher, and the incidence of births < 1500 g is 10 higher for twins than for singletons.[1] These data have made counseling of such patients far more complex than previously (Figures 19.4 and 19.5). Not surprisingly, there are often differences between members of the couple as to

Table 19.5 Comparison of reduced vs. unreduced triplets (from Evans *et al.* The optimal management of first trimester triplets: Reduce. *The Central Association of Obstetricians and Gynecologists Annual Meeting*, Las Vegas, NV, October 27–30, 2002)

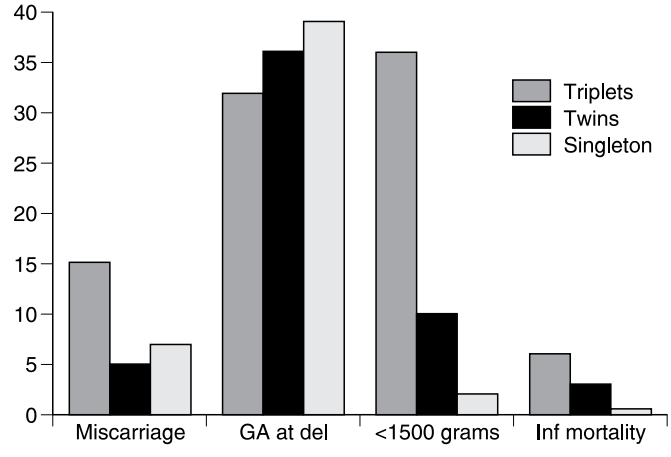

Figure 19.5 Risks starting with triplets. Reduction of triplets to twins has lower loss rates but higher incidence of prematurity, low birth weight, and infant mortality than reducing to a singleton.

Table 19.6 Frame comparison

	Medical frame	Conceptionalist frame	Lifestyle frame
Intensity of commitment to having children	High	High	High
Intensity of training in medicine, dentistry, hard sciences, and the law	High	Low	Modest
Intensity of commitment to belief that life begins at conception	Modest	High	Modest
Intensity of commitment to career	High	Low	High
Source of moral authority for resolution	Relative survivability of fetuses	Minimization of beliefs damage to moral though a 'barely sufficient' reduction	Having a 'normal' life in a culture that values both careers and family for women

the desirability of twins or singleton.[45] There are also profound public health and financial implications to these decisions, as 2000 United States Data show that of $10.2 billion spent per year on initial newborn care, 57% of the money is spent on the 9% of babies born at < 37 weeks.[46] This progress is much more likely to rise than fall.

Societal issues

There will never be a complete societal consensus on MFPR. Opinions have never followed the classic 'pro-choice/pro-life' dichotomy.[2,7,11,14] We believe that the real debate over the next 5–10 years will not be whether or not MFPR should be performed with triplets or more. A serious argument will be put forth over whether or not it will be appropriate to offer MFPR routinely for twins, even natural ones for whom the outcome has commonly been considered 'good enough'.[44] Our data suggest that reduction of twins to a singleton actually improves the outcome of the remaining fetus.[44] No consensus on the appropriateness of routine two to one reductions, however, is ever likely to emerge. We do, however, expect the proportion of patients reducing to a singleton to steadily increase over the next several years.

The ethical issues surrounding MFPR will also always be controversial. Over the years, much has been written on the subject. Opinions will always vary substantially from outraged condemnation to complete acceptance. No short paragraph could do justice to the subject other than to state that most proponents do not believe this is a frivolous procedure, but see it in terms of the principle of proportionality, i.e. therapy to achieve the most good for the least harm.[13,47–49]

How patients 'hear' and internalize data and make decisions with respect to reduction has been a subject of our investigation for several years. Much of the literature on medical decision making has emphasized a rational choice model in which emotions, feelings, and values are treated as complications that must be considered as the second stage of an analysis that puts hard data regarding relative risks into center stage.[50,51] Even in the literature that talks about genuine alternative models of decision making (systematic vs. heuristic, for example), a central assumption is that these are individual differences in style that can be identified through what people say.[52,53]

We have investigated this problem from a different direction, arguing that where controversial, high-anxiety decisions are concerned, patients treat these decisions as an ongoing part of the social reality that they are creating to live in and raise a family.[54] These realities, composed of supportive people and institutions together with complexes of supportive values, norms, and attitudes, are the source of frames that the patients use to view the data.[47–49] The decisions they make and how they justify those decisions may help resolve incompatible elements in the realities in which they find themselves enmeshed.

The one thing in common for all such patients is a very strong desire to have a family (Table 19.6). But there does not appear to be a single set of supportive institutions, people, and norms that is conducive to going through the pain, stress, and resource expenditure of IVF and then consider partial reduction as a pregnancy-management strategy. Rather, we think there are three viable alternative resolutions. The first of these, a rational *medical frame*, looks superficially like what one would expect from the rational analysis model. But the commitment to factual analysis comes from the patients having selected themselves into the hard sciences, medicine, dentistry, engineering, or law – disciplines in which 'facts' are crucial. Such women will want to see the numbers regarding the relative risk associated with different reduction choices and will want to engage in a rigorous discussion of the data and their implications. And they will be likely to choose a final number for reduction that maximizes the chances of a 'take-home' baby.

The lens of scientific objectivity is not the only frame through which women who have gone through IVF in order to have a child will examine these data. For those who have immersed themselves in a social reality that has a strong emphasis on norms against abortion and/or reduction – such that they themselves have such normative beliefs and are heavily involved in churches that reinforce similar beliefs – a detached examination of the 'facts' is simply not possible. These 'facts' hold no special moral authority. Their beliefs and those of the individuals and social institutions in which they have selected themselves have a moral authority as well. The balance that such women will likely seek is one that reduces their relative risk to acceptable limits. So, unless the consequences are dire, they will not reduce or choose to reduce only to three. We labeled such a resolution a *conceptionalist frame*.

Finally, there are those for whom the demands of career and/or existing children constitute powerful elements in their constructed realities. For such women – and this includes many of the older patients we encountered – the essential balance that they seek is a more secular one, a *lifestyle frame*, one that emphasizes creating a family situation in which having a family can be balanced with having a career. Such women will more than likely choose reduction to two or even one embryo, depending on the number of other children they have and the level of resources the family has.

Where women have selected themselves into and/or been trained to accept the legitimacy of rigorously determined statistics regarding relative risk (a *medical frame*), reduction choices *can* be straightforward – or at least, they can appear to be relatively straightforward. This is usually not the case, however, for women who must forge a resolution among potentially incompatible elements, as for women who are struggling to reconcile the potentially oppositional elements of religious beliefs and involvement with risks associated with higher-level pregnancies (*conceptionalist frame*) or those who are struggling to reconcile the potentially conflicting identities of home and career (*lifestyle frame*). We have been able to examine some of these issues in a few studies to date. In one we were able to trace the extreme fluctuations in anxiety and stress as women progress through IVF and then must confront the painful choice of reduction.[48] In a second, we were able to show that the meaning of detecting a fetal anomaly changes depending on the needs of the patient and her spouse for some confirmation regarding their choice.[47]

Summary

MFPR has become a well-established and integral part of infertility therapy and the attempts to deal with sequelae of aggressive infertility management. In the mid-1980s, the risks and benefits of the procedure could only be guessed.[10–14] Now we have very clear and precise data on the risks and benefits as well as an understanding that the risks increase substantially with the starting and finishing number of fetuses in multifetal pregnancies. The collaborative loss rate numbers, i.e. 4.5% for triplets, 8% for quadruplets, 11% for quintuplets, and 15% for sextuplets or more, seem reasonable ones to present to patients for the procedure performed by an experienced operator. Our own experience and anecdotal reports from other groups suggest that less-experienced operators have worse outcomes.

Pregnancy loss is not the only poor outcome. The other main issue of concern is very early preterm delivery and the profound consequences for such infants. Here again, there is an increasing rate of poor outcomes correlated with the starting number. The finishing numbers are also critical, with twins having the best viable pregnancy outcomes for cases starting with three or more. Triplets and singletons do not do as well. However, an emerging appreciation that singletons have prematurity rates less than twins is making the counseling far more complex. We continue to hope, however, that MFPR will become obsolete as better control of ovulation agents and ARTs make multifetal pregnancies uncommon.

20 Neonatal ethics

K. N. S. Subramanian

Background

Neonatal medicine has undergone significant changes over the last four decades. The increasing survival of smaller and younger infants is possible because of medical and technological innovations, such as antenatal steroid administration to a pregnant mother in preterm labor, the availability of surfactant to the premature infants, ventilators of different kinds (conventional, high frequency, etc.), inhaled nitric oxide (iNO), and extra corporeal membrane oxygenation (ECMO) to name a few. The mortality rate has improved over time in the USA[1,2] and the rest of the world,[3,4] and it has significantly declined in all weight categories. But there also is a need to have uniformity in the denominators we use for defining mortality and morbidity of these infants. Currently, the mortality rates are expressed as deaths per 1000 live born babies, deaths per all premature infants, by specific weight categories, by admissions to neonatal intensive care units (NICUs), or by deliveries in one hospital, geographic region, or country. The rates vary significantly depending on which terminology is used. Although rates of significant morbidities or serious handicaps have reduced or have remained steady across many gestational ages or weight groups over the years,[5] there is still a high rate of handicaps in lower birth weight or early gestational age groups.[6–8]

With increased survival and an increase in the total number of handicapped infants, society is confronted with the need for special assistance for these children. Decisions regarding resuscitation at the lower ends of gestational age (< 24 weeks) and birth weight (<400 g) become increasingly difficult. Decisions regarding the congenitally malformed or infants with chromosomal problems (like Trisomy 13 and 18), identified during pregnancy, pose an ethical and moral challenge for the various participants. The pregnant woman and the father of the fetus, along with the family and physicians and other health care providers, struggle with these decisions at times of extreme vulnerability and uncertainty. Numerous publications and guidelines by professional and legal organizations attempt to clarify the issues and guide the parents, health care providers, and hospitals. Management of these issues compels the clinicians to make decisions 'in the moment of clinical truth'.[9]

Significant medical and technological innovations have invaded the NICU. Thoughtful use of such advances might help to save more lives but attention should be paid to whether these advances decrease morbidity over time. Surfactant use from 1990 has significantly increased survival and reduced morbidity. Administration of antenatal steroids to pregnant mothers with preterm labor has increased both pulmonary maturity and survival. Short-term outcomes of these infants appear to be favorable but long-term outcomes are being evaluated. On the other hand, the introduction of ECMO and ventilators occurred without any controlled studies in NICUs. Later studies suggested limited benefit for some of these therapies. It is critical to evaluate any new medical or surgical therapies before implementing them on a widespread basis in NICUs.

In this chapter some of these issues, such as the lower limit of viability (periviable or how small is too small?), withdrawal and/or withholding life support including nutrition and fluids, economics, role of parents and health care providers, global perspectives, and a common framework for neonatal ethical issues, will be reviewed.

Threshold of viability or how small is too small?

The current published statistics about survival and morbidity rates of extremely low birth weight (ELBW) and very low birth weight (VLBW) babies will be presented to assist in addressing the issue of viability. Survivability of infants correlates with gestational age and birth weight. African-American infants comprise 36.8% of the ELBW (<1000 g) babies born in the USA but account for only 15.5% of all live births. Biomedical and biopsychosocial factors may be contributing to this disproportionate increase in ELBW in African-American births, and these dynamics need further investigation.

It is important to know the outcomes of these ELBW and VLBW infants, especially below 25 weeks of gestation, to assist in decision making regarding withholding or withdrawing support. Infants born and admitted to the NICU at or < 23 weeks have a less than 10% chance of survival. Less than 1% survival was reported in ELBW infants with birth weights < 400 g. In a large multicenter review in the USA, the survival rate from birth until discharge for infants born between 1996 and 2000 and with birth weights of 401–500 g was 17%.[10] Earlier reports by other investigators were more dismal in terms of survival of infants <500 g.[11,12]

In a prospective study from England and Ireland,[12] the survival rates expressed as a percentage of live births in 1995 for infants at 23, 24, and 25 weeks of gestation were 11%, 26%, and 44%, respectively. Expressed as a percentage of the admission to NICUs, the survival rates improved to 20%, 34%, and 52%, respectively. For the same cohort of infants, the survival rates expressed by birth weight for infants weighing < 500, 500–749, and 750–999 g were 6%, 32%, and 55%, respectively.

Birth-weight-specific statistics of admissions to NICUs in the USA have shown higher survival rates. The National Institute of Child Health and Human Development (NICHD) network[2] reported that survival rates for infants at 23, 24, and 25 weeks of gestation were < 20%, 47%, and 68%, respectively. In the same report, survival rates from birth until discharge for infants born between January 1993 and December 1994 with birth weights of 501–750, 751–1000, 1001–1250, and 1251–1500 g were 49%, 85%, 93%, and 96%, respectively. Among these survivors, chronic lung disease developed in 19%, intraventricular hemorrhage in 32% (with 11% having severe grades), and periventricular leukomalacia in 6%. The incidence of necrotizing enterocolitis ranged from 3% to 9% and that of late-onset sepsis varied from 9% to 34%, inversely related to birth weights. Infants in these weight groups stayed in the hospital for an average of 2–4 months. The report also notes that the mortality rate declined by 42% from 1988 to 1994 in all weight groups but with no significant drop in the morbidity rates of infants < 750 g (38% in 1988 and 37% in 1994).

In 1997, a report compared the survival and morbidity rates of infants weighing 501–800 g born in North Carolina, USA,[5] during three time periods from 1979 to 1984, 1984 to 1989, and 1989 to 1994. Survival rates increased from 20% to 36% to 59%, respectively. On the other hand, the major neurosensory impairments at 1 year of age remained relatively the same, at 25%, 28%, and 21%, during the same three periods. Hussain and Rosenkrantz[13] reported in a 2003 composite of many studies from developed nations a survival rate of < 3.5% at 22 weeks, 21% at 23 weeks, 46% at 24 weeks, and 66% at 25 weeks of gestation.

The cohort of infants born in 1995 in England and Ireland at < 25 completed weeks were prospectively followed for > 6 years. The report in 2005 suggested that the cognitive and neurological deficits were common at school age (21%).[14] A comparison with their classroom peers showed even more impairment (41%). The rates of mild, moderate, and severe disabilities were 34%, 24%, and 22%, respectively, in these survivors. Twelve percent had cerebral palsy. Even more sobering were the rates of survival with no disability among this group at 6 years of age: 1%, 3%, and 8% for those born at 23, 24, and 25 weeks of gestation, respectively.

While this information will keep changing in the future as mortality and morbidity rates change, one can attempt to address the issue of how small is too small. Biologically, at < 22 weeks of gestational age, the physiological and anatomical maturity of the lung will unlikely support extrauterine function and hence survival.[15–17] Over the last 10 years there seems to be a leveling of improvement in survival in these gestational age groups. This leveling suggests that we may have reached the threshold of viability with the current technology and support. Sharing this information and institutional, regional, national, and global mortality and morbidity reports with parents will be the first step in addressing the issue of viability.

Parents' role

In the USA, parents are generally considered appropriate surrogate decision makers for their children. They are also considered to have the required authority and best interests of the infant in their minds when making decisions about medical care for their children.

Attitudes of parents and health care providers regarding outcomes of ELBW infants, including quality of life, have been evaluated in many reports.[18–20] Saigal reported that when presented with hypothetical clinical vignettes, health care providers in NICU were significantly more negative than the parents of the teenaged ELBW children.[18] The parents rated the quality of life as good for their children even though they acknowledged that their children have a greater burden than other normal birth weight children. These studies suggest that parents are appropriate decision makers in most cases.

It is evident from the available data that the mortality and morbidity rates are high for infants born at < 24 weeks and/or weighing < 500 g. At 23 and 24 weeks, even though survival has improved, reported handicaps of survivors should give a pause to those in NICU in pursuing a course of aggressive action in the delivery room and subsequently in the unit. It is important to have the global, national, regional, and institutional data on not only survival but also outcomes of these ELBW infants so the information can be shared with the parents to assist in decision making. Because the statistics differ depending on which

denominators are used, one should be clear and consistent in the communication.

The issue of sanctity of life vs. quality of life is a running debate in neonatal and obstetric specialties, as well as with the prospective parents. Those who believe in sanctity of life may suggest that it is worth intervening with aggressive support for any live product of conception. Many have difficulty in accepting this notion as necessarily directing anyone to initiate or sustain treatments regardless of the mortality and morbidity. They suggest that it may be preferable to assess intervention after birth so that the decision can be made with more information at hand. On the other hand, the slippery slope argument about the quality of life judgment is well known. This issue remains a continuing debate in society and adds to the uncertainty in decision making.

Economics

As a result of advancing technology hospital bills have increased dramatically, and the total lifetime costs may go up even higher if the infant needs any type of rehabilitation or follow-up care. The cost of care in NICUs in the USA is now reported as exceeding four billion dollars. A 2003 California study[21] reported an average hospital cost of $224,000 for an infant with birth weight between 500 and 700 g compared to $4300 for infants between 2250 and 2500 g and $1000 for those with birth weights greater than 3000 g. In the same study, hospital costs averaged $202,400 for an infant born at 25 weeks compared to $2600 for an infant born at 36 weeks and $1100 for a 38-week infant. Similarly, another study[22] reported a median cost of $103,600 for infants born between 501 and 750 g, going down to $31,200 for those between 1251 and 1500 g. The hospital costs were highest for infants born at 25–26 weeks of gestation with a median of $101,600, dropping to $18,700 for infants born at > 32 weeks. Another 1987 California study[23] calculated that the average cost per first-year survivor in infants in NICUs with birth weights less than 750 g was $273,900; for those who weighed 750–999 g, the average cost was $138,800. In a May 16, 1988, article, *Newsweek* quoted the total cost for a surviving fetal infant as $366,480 with additional costs during rehabilitation. However, the aggregate cost of NICU is still far less than the cost of adult intensive care units providing care for those at the end of life.

This brief discussion of the economics of caring for critically ill infants in the NICU is necessary to understand the full impact on families, society, and the surviving infant with special needs. The infant's family undergoes severe emotional and financial stress with the birth of an extremely premature infant, and they are often confused, angry, and frustrated by the resulting issues. This concern needs to be understood by the medical team, and the public and society need to address it in an open forum.

Withholding/withdrawal of nutrition and fluids

The benefits and burdens of any medical intervention should be assessed so that a determination can be made regarding the withholding/withdrawal (WH/WD) of nutrition and fluids. Most will agree that if the burdens outweigh the benefits, the withholding or withdrawal of support to adults, children, or neonates is acceptable. Currently, most reports suggest that for adults with terminal conditions it is appropriate for the patient to request WH/WD of nutrition and fluids as well (*JAMA* 1990).[24,25] Most agree that appropriate family members, especially if authorized to make medical decisions, can request WH/WD of nutrition and fluids for a terminally ill adult patient. Increasingly, pediatric patients are also reported as appropriate candidates for requests for WH/WD in terminal conditions.[26–28] The premise behind such requests is that tube feeding or intravenous alimentation should be considered a medical intervention just like intubation or other treatments. Others would argue that withdrawal of nutrition and fluids, especially from neonates, should not be recommended.

In an excellent review by Carter and Leuthner,[29] the authors hold that WH/WD of nutrition and fluids in newborn infants is also appropriate. They state that the 'medical facts such as underlying diagnosis, response to previously given treatments, likely response to appropriate treatments or interventions not yet offered and ultimate prognosis for the infant's condition' should be considered and discussed in detail with the team, parents, and extended family. In addition, parents' expectations, culture, religion, traditions, and other social values should be brought to bear on this decision for their infant. The health care team should not usurp the authority of the parents without documentation (from independent experts) that they are not capable of making such decisions. The institution's policies and state legal statues should be reviewed and taken into account. Offering oral feeding in infants should be acceptable as well as pain medications as part of palliative care. Hospice care, if available, for such infants when the WH/WD of care including nutrition and fluids is indicated as a good alternative. More discussion by physicians, the health care community, parental groups, and society is necessary to guide the decision making about WH/WD of nutrition and fluids in the newborn in the future.

Global perspectives

It is clear that ethical decision making does not take place in the abstract. Societies, nations, cultures and traditions, and religions play an intricate part in such decision making. In developing nations, and now in developed nations as well, the economy also plays a

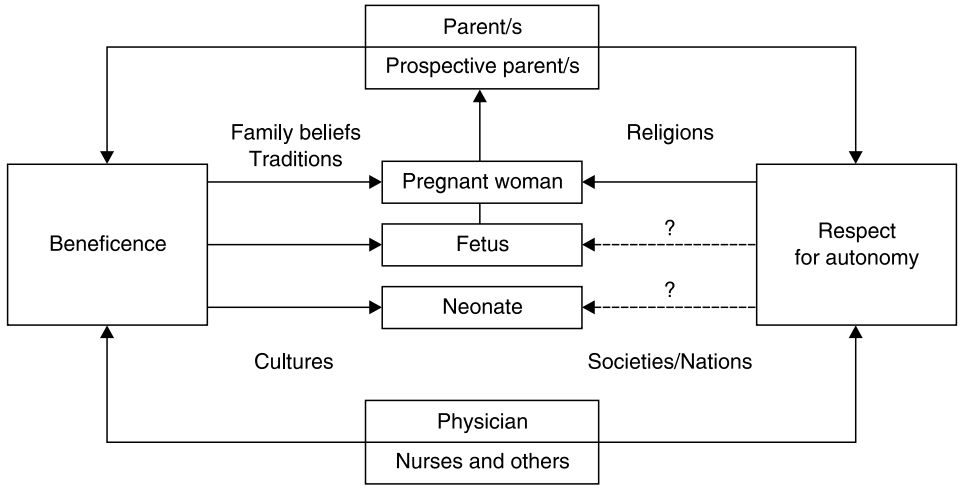

Figure 20.1 Common framework for perinatal/neonatal ethics. Modified from Subramanian and McCullough.[41]

role in such decisions at the macro level of national health care policy and at the micro level in the decision making of a patient (the principle of justice). In many countries, such as India, Nepal, and Sri Lanka[30] quality of life and economy clearly play a crucial role in parental and societal decisions regarding WH/WD of support. In Singapore[31] using an individualized prognostic strategy, 'a consensual decision that respects parental authority and promotes physician beneficence with the best interest of the infant placed in the center of analysis' is being reached. In Israel[32] the maternal birth place and level of religious observance were associated with aggressive intervention in hypothetical cases. In neonatal care, specific guidelines, such as those in The Netherlands and Japan,[33,34] led to infants at 22 or < 25 weeks of gestation being resuscitated, but resulted in significant mortality and morbidity. Similarly, a study in California, USA, requiring resuscitation of all infants > 22 weeks of gestation or > 450 g, resulted in significant mortality and morbidity, leading to a recommendation of providing other than comfort care as exceptional for infants < 23 weeks or < 500 g. A report from Scotland[35] outlined that eight European countries compared the 'legal, ethical and professional settings within which decision making for neonates took place'. Overly aggressive treatment was discouraged and comfort care recommended. Most of the countries prohibited 'active intentional ending of life', except Dutch pediatricians. Reports from the USA,[36,37] Australia,[38,39] and Austria[40] suggest that infants born at tertiary centers with neonatal and perinatal specialties had a better survival rate at these gestational ages. Those transferred *in utero* to tertiary centers at 23, 24, and 25 or 26 weeks of gestation showed lower morbidity and had a better prognosis. Globally, the viability limit seems to be slowly but steadily converging around 22–24 weeks based on biological and experiential data.

Common framework for perinatal and neonatal ethics

Attempting to create a common framework for neonatal and perinatal ethics is a daunting task. We proposed in 1987, a model[41] based on the ethical principles of beneficence and respect for autonomy, incorporating the families, religion, culture and traditions, societies, and nations as part of the fabric of decision making (Figure 20.1). With minor modifications it probably still holds as an anatomical framework for clinicians to work through difficult ethical dilemmas.

The principles of beneficence and respect for autonomy are clearly addressed in the model. The fetus and future neonate along with the pregnant woman are at the center of this schema generating both beneficence- and autonomy-related obligations. Even though there are ethical obligations generated toward the parent/s, the neonatologist's primary patient is the neonate. The future parent/s is included at the top of the model to reflect the relationship in the neonatal period. The physician is at the base of the model generating ethical obligations to prospective parents, the pregnant woman, and the fetus during the perinatal period and to the neonate and the parents in the postnatal period and beyond. It is recognized that these ethical dilemmas are affected by the context in which they occur and hence the schema recognize the need to add religious beliefs, traditions, family beliefs and values, cultures, societies, and nations as the very fabric on which this model is built. There are primarily beneficence-based ethical obligations to the fetus and neonate, but the model included autonomy-based obligations as secondary in the model because some may believe they exist. This structural guidance could be applied to ELBW infants, infants with congenital anomalies such

Table 20.1 Guidelines for care of extremely preterm infants [from Boyle RJ, c472. *NeoReviews* 2004;5(11): November]

Canadian Pediatric Society (1994)
- 22 weeks' gestation: treatment should be started only at the request of fully informed parents or if it appears that the gestational age was underestimated
- 23–24 weeks' gestation: there is a role for parental wishes, the option of resuscitation, and a need for flexibility in deciding to start or withhold resuscitation, depending on the infant's condition at birth
- 25 weeks' gestation: resuscitation should be attempted for all infants who do not have fatal anomalies

Colorado Collective for Medical Decisions (2000)
- 22 weeks' gestation: comfort care is the only appropriate choice
- 23 weeks' gestation: most participants would advise comfort care, but if parents understood the high risks, they would be willing to initiate a course of intensive care.
- 24 weeks' gestation: participants are able to support either decision, as long as a collaborative process with good sharing of information occurred
- 25 weeks' gestation: most participants were uncomfortable with withholding care, but some were willing to support a parental request for comfort care if there had been good education and an effort at collaboration

American Academy of Pediatrics/American Heart Association Neonatal Resuscitation Program (2000)
- Non-initiation of resuscitation in the delivery room is appropriate for newborns who had confirmed gestation of less than 23 weeks or birth weights of less than 400 g

Thames Regional Perinatal Group (2000)
- Less than or equal to 22 weeks' gestation: compassionate care only
- 23–24 weeks' gestation: resuscitation depends on infant's condition at birth
- 25–27 weeks' gestation: full resuscitation and supportive care

as Trisomy 13, Trisomy 18, anencephalic and other terminally ill infants.

This model extends Pellegrino's proposed framework[9] for clinical ethical dilemmas to the complex perinatal and neonatal areas. This model recommends a collaborative approach to decision making between the parent/s, physician, and other health care providers acting in the best interest of the baby. Parents should be able to make these decisions for their infant unless they are shown to be incompetent or incapable as assessed by independent specialists such as psychiatrists or, of course, the courts. Obtaining the opinion of ethics consultant or ethics committee will help the clinician and family in guiding the decision making. Many families have found the objective view of another expert or group of people helpful in facilitating the discussion and clarification of the facts of the ethical dilemma being faced and the options available.

The four 'C's of clinical ethical decision making include: (1) communication, (2) clarification, (3) consistency, and (4) caring. Maintaining a high level of communication between parents and health care providers is necessary in the NICU where issues are extremely complex and highly charged with emotions. Clarification of issues that arise among health care givers and between parents and medical and nursing staff is crucial for problem solving even before a dilemma arises. Providing consistent information available to date by all care givers (provided good communication exists between providers) will allow for a trusting environment in which decision making is encouraged. An attitude of caring from the very beginning provides the necessary environment in which parents feel comfortable in discussing any and all issues about their infants. All four of these facilitate decision making by the parents and health care providers during difficult times.

Guidelines

Currently, there exist guidelines from various organizations including the American Academy of Pediatrics (AAP), AAP Committee on Fetus and Newborn,[42,43] AAP Committee on Bioethics,[44] NICHD concensus conference,[45] American College of Obstetricians and Gynecologists (ACOG), ACOG Committee on Obstetric Practice,[46] Canadian Pediatric Society,[47] Thames Regional Perinatal Group,[48] Colorado Collective for Medical Decisions,[49] International Guidelines for Neonatal Resuscitation,[50] New York State Task Force on Life and Law,[51] and from other countries (Table 20.1). At 22 weeks or < 23 weeks or < 400 g, most guidelines recommend giving only comfort or compassionate care, which is consistent with available data on mortality, morbidity, and biological information. Most guidelines will also suggest comfort care at 23 weeks unless parents, after understanding the high risks, want to initiate aggressive attempts. At 24 weeks, resuscitation will

depend on the assessment of the baby's condition at birth and the parents' understanding of the mortality, morbidity, and prognosis; choosing to intervene to give a trial of life is an appropriate alternative. In some of the recommendations (Italy 2004, New York 1988), $\geq$24 weeks or $>$500 g are used as cutoff points for resuscitation. At 25 weeks and beyond, most guidelines recommend full resuscitation. However, some maintain that a parental request not to resuscitate should be followed even at 25 weeks. Most guidelines base the recommendations on gestational age. Because growth-restricted mature infants are included in the statistics presented by birth weight, a hard birth weight cutoff is more difficult to use in deciding viability.

All guidelines consistently recommend the need for clear communication among physicians, nurses, and parents both before delivery and afterward. Collaborative decision making between parents and physicians, along with other health care providers, is the best way to chart a course that is appropriate for the individual baby and parents, especially in infants expected to be $<$24 weeks of gestation or $<$500 g in birth weight. Any strict cutoff by gestational age or birth weight at this edge of viability should be avoided because the prognosis for the individual infant remains uncertain in terms of both mortality and morbidity. Parents who understand the high risks involved in aggressive interventions at the borderline gestational ages should be given the option of assessment at birth and resuscitation. Further action will depend on the infant's condition and the NICU course. Even prior to delivery, one should discuss with parents that, if assessment after birth indicates a significantly poor prognosis, withdrawal of support should be an option. There should always be room for individual decision making based on the specifics of the situation, such as a parent with infertility, advanced age, multiple pregnancy losses, etc. Even though ethically there is no difference between withholding and withdrawing care, emotionally the latter may be harder for parents or some health care providers. For some, withholding may be preferable to withdrawing, but clear communication before and throughout the hospital course will help in making the right decision.

Collaborative or consensus decision making between the parents, physician, and team with careful, clear communication and discussion is the best way to resolve any ethical dilemmas. In situations where disagreement exists between the health care team and parent(s), additional consultations with a colleague and other specialists and/or ethics consultants and committee meetings should help clarify the issues and resolve the differences. In those difficult situations where differences remain, one or the other party can seek legal action. Usually, courts are not in the best position to resolve these difficult moral and ethical issues except on narrow legal grounds. In many situations Law and Ethics may not see eye-to-eye in resolving the dilemma.

Summary

In summary, the tremendous advances made in the last four decades in neonatal medicine have also brought difficult ethical dilemmas for health care providers and parents. Over these years the lower limit of viability dropped from 28–32 weeks to 22–23 weeks of gestation. As we reach the physiological and anatomical limits of lung development and extrauterine survival we also reach a natural barrier of lower limit of viability. Of course, this can change if there are some additional advances in existing treatments such as liquid ventilation or providing nutrition in a novel way, or new interventions such as artificial placenta or uterus. But this 'medical miracles around the corner' argument or outliers in terms of survival of $<$23 weeks gestation infants cannot be used for decision making occurring now. Advances in technology and the ability to prolong life should be tempered with the benefits and burdens to the patient. Principles of beneficence and respect for autonomy obligations weigh heavily in neonatal ethical dilemmas in the milieu of principle of justice and cultures, traditions, religions, and nations. Weighing the benefits/burden to the patient should guide everyone in the decision making. Both obstetrician and neonatalogist have beneficence-generated obligations toward the fetus and neonate. The neonatologist has both beneficence- and autonomy-generated obligations toward the pregnant mother and father during antenatal consultations and subsequently to the parent/s when the neonate comes into the NICUs. Collaborative/consensus/shared decision making with parents, physicians, and others, applying the ethical principles outlined in the model, will result in the best practice in NICU for these infants. Judicial uses of the ethics consultant or committee and other experts may facilitate better communication and clarification in difficult circumstances. Providing communication in a clear, consistent, and caring way (four Cs) and sharing all the information about mortality, morbidity, and prognosis before and after delivery of a high-risk infant facilitates decision making.

Acknowledgments

My thanks to Ms Ninian Kring for preparing the tables and figures and Ramya Sivasubramanian, JD for reviewing the manuscript and providing valuable suggestions. I also thank all the infants that I had the privilege of taking care of over the years and their parents for the opportunity to serve and learn from and all the staff, residents, fellows, and colleagues at Georgetown University Hospital NICU.

21 Medicolegal aspects of perinatal medicine: European perspective

J. Walker

Introduction

A pregnant woman has similar rights to any other patient and these are protected by the normal human rights assigned to her by society. Therefore, her informed consent is required before intervention and her right to refuse treatment is accepted. However, there is a complication – she carries another potential individual; therefore, her rights and control over her pregnancy are influenced by the rights assigned to the fetus and how much of these rights are allocated to the mother to hold.

Irrespective of the rights the child has *in utero*, after birth, its rights are paramount, and although the parents may control these rights to a degree, this is not absolute and their control can be taken away in the best interests of the baby. Also, in some situations, the rights of the newborn baby can be considered to be present in retrospect; in other words, damage done prior to delivery that results in problems after birth can give rights of complaint to the baby that were not there at the time of the event. Therefore, potentially, the rights of this one individual, the child, and the rights of others over it, can change at the moment of birth and, in some instances, this change of rights can then be applied retrospectively.

This has caused increasing ethical dilemmas over the years because of the increasing knowledge of pregnancy physiology and, more importantly, the increasing ability to assess and visualize the fetus. This means that the fetus is increasingly seen as an individual that has access to medical care and is a factor in medical decision making. This has led to the concept of the 'fetus as a patient' and, by definition, medical rights.[1] Generally, what is good for the baby is good for the mother, so there is no conflict. It is when the mother disagrees with her carers about what is best for the baby that conflict appears.[2,3]

With advances in medical technology and the ability to salvage pregnancies that failed previously, society has begun to believe that medicine can achieve anything. This means that if damage occurs, there has to have been error and negligence. Since the fetus is usually the one that is damaged, it is the baby, or its guardian, who will have to proceed with litigation, even though the fetus may not have had rights at the time of the event. If a neonatal death occurs, this may increasingly lead to potential criminal proceedings,[4,5] but this can depend on the legal rights of the fetus and whether it is born alive or not. It is in these areas of litigation and fetal rights that there is so much difference between countries.

The rights of the fetus

There is no universal truth and this is never truer than for ethical and legal issues. Perinatal doctors in different countries work in different environments. What is acceptable in one country may not be acceptable in another, not because it is right or wrong, but because of differences in ethical, legal or social mores.[5] In medicine, we are taught to 'first do no harm', but in the case of perinatal medicine, we also need to consider 'to whom?'. The problem is that there can be conflict between the concept of the 'fetus as a patient' and the rights of the mother.

This situation is covered by the term beneficence.[1] Beneficence is the moral principle that one should aim to help and failure to do this when one is in the position to do so is morally wrong. However, one is obligated to act to benefit others when one can do so with minimal risk, inconvenience or expense. In perinatal medicine there is potentially two patients to consider. How much of a conflict this is depends on both legal and moral belief. In general, the life of the

mother takes precedence because the health of the mother is important for the health not only of that baby but also of any siblings. However, the main governor of the decision-making process is the legal rights of the fetus.

If the fetus has the same rights as a newborn baby, decisions can be made on behalf of the baby against the wishes of the mother, so-called court-ordered care. There is also the chance of the newborn suing for any damage sustained *in utero* from maternal or other's actions, so-called Wrongful Life decisions.[6]

However, where the fetus has no legal rights, the mother's wishes are paramount. It is only variations in law or ethical constraints that will restrict her and her carers' actions. However, this maternal control exists only up to the moment of birth, when full neonatal rights exist and the control transfers to the baby or its guardians. This change in legal status occurs in a matter of minutes and can be confusing to the mother, attendant staff and society as a whole.

Generally, in European law, the starting point is that a child *en ventre sa mere* is a part of its mother and therefore its rights are held by the mother.[7] However, in English common law an unborn child has rights to inherit property as follows:

> There is nothing in law to prevent a man from owning property before he is born. His ownership is contingent, for he may never be born at all; but it is nonetheless real and present ownership. A man may settle property on his wife and the children to be born of her. Or he may die intestate and his unborn child will inherit his estate.

This is traditionally called 'present ownership', that is, a right possessed by the unborn child at that time, but conditional on being born alive. If the child is stillborn, the inheritance (or rights) will revert to someone else. This is referred to as the 'born alive rule'.[7]

Therefore, any right the fetus has in English common law is dependant on being born alive. This means that actions leading to death of the baby before birth do not come under the normal crimes against the person, but if the baby is born alive and then dies then the baby's existence, and therefore rights, exists and action can be taken. Overall, the legal situation in Europe is somewhat confused and is constantly evolving, as will be described. Within the European Community, there is a further complication since the countries are governed by similar European laws on human rights, although there are still differences with the application due to the local law in each country.

The right to life

When the European Human Rights Act came into force in 2000, it was felt by many that the 'Right to Life' stated in Article 2 could be extended to the unborn fetus. This would protect it from termination of pregnancy and give it equal rights to those of the mother when considering medical decisions. However, a case based on this belief has recently been heard in the European Court of Human Rights, and it was decided that the rights of the fetus are not covered by Article 2. This is an important landmark decision not based on law but more on lack of consensus of what is right.

The case involved Mrs Vo, one of two women of the same name admitted to the same hospital at the same time, one for a medical examination when 6 months pregnant, the other to have a coil removed. The wrong Mrs Vo went for coil removal. In an attempt to remove the non-existent coil, Mrs Vo's amniotic sac was pierced and the pregnancy had to be terminated. The doctor was charged with unintentional homicide, the French equivalent of involuntary homicide. He was initially acquitted, but was then convicted on appeal and sentenced to 6 months in prison and fined 10,000 francs. He then appealed to the Court of Cassation – France's highest court – which overturned the ruling on the grounds that the fetus was not a human being and not entitled to the protection of criminal law.

Mrs Vo then took the case before the Grand Chamber of the European Court (application no. 53924/00). She alleged that France's failure to extend the law on unintentional homicide to the unborn violated the State's Article 2-based obligation to respect life. However, the court found 14 votes to 3 in favor of France.

The Court felt that the decision of when the right to life begins was a question to be decided at the national level. They noted that there was no European consensus on the scientific and legal definition of the beginning of life, particularly in France, where the issue had been the subject of public debate. At best, it could be said that the consensus was that the embryo/fetus belonged to the human race. Its potential and capacity to become a person required some protection in the name of human dignity, without making it a person with the right to life for the purposes of Article 2 or legal status in conflict with the mother. Therefore, the Court was convinced that it was neither desirable, nor even possible as matters stood, to answer the question whether the unborn child was a person for the purposes of Article 2 of the Convention. The main judgment of the Court was to accord each State a degree of autonomy, or a 'margin of appreciation' as it is called, to work out the right legal position for itself. So on this view, Article 2 did not apply. A minority of the judges felt that there was no issue since 'even if one accepts that life begins before birth, that does not automatically and unconditionally confer on this form of human life a right to life equivalent to the corresponding right of a child after its birth'.

Therefore, by a majority of 13 votes to 4, the court was in favor of the inapplicability of Article 2, implying a lack of rights for the unborn child and setting a precedent on the legal status of unborn babies that will be applied across European countries.

Wrongful Life and Wrongful Birth

After the baby is born, it has equal rights to the mother and the rest of society. To some extent these rights can be applied retrospectively and the events that occurred or did not occur prior to birth can, in theory, be litigated against if they adversely affect the baby after birth. There are two particular situations, Wrongful Life and Wrongful Birth, where the plaintiff claims that the baby would rather not have been born, i.e. be terminated. Since this usually involves failure of prenatal diagnosis and termination of pregnancy, it can produce conflict with the various legal and moral arguments.

Definitions

Wrongful Life is when the child takes the action against another party for allowing it to be born in a deformed or harmed way caused by actions or inaction prior to birth. In other words, it would rather have been terminated and litigates for damages to help it live as comfortably as possible.

Wrongful Birth is when the mother sues other people for being burdened with a disabled child, something she could have avoided.

In essence, these suits are genetic or prenatal diagnosis litigation cases where termination could have been offered. Again, much of the debate has occurred in France but affects all countries.

The Nicholas Perruche case

In 1982, when Josette Perruche was in her early pregnancy, her 4-year-old daughter developed rubella. She told her doctor that if she had been infected, she wanted a termination rather than risk giving birth to a handicapped child. She had two blood tests, 2 weeks apart, which gave contradictory results. Mrs Perruche was reassured that all was well. However, Nicholas was born with the rubella syndrome and, after investigation, it was discovered that the laboratory had made an error. A case was brought on behalf of Nicholas against the doctors alleging that failure by the doctors to diagnose the condition in the womb had prevented a termination of pregnancy and led to Nicholas being born with deformity. The French Court found in his favor, stating in its ruling: [8]

> … since mistakes committed by the doctors and the laboratory while carrying out their contract with Mrs Perruche prevented her from exercising her choice to end the pregnancy to avoid the birth of a handicapped child, the latter can ask for compensation for damages resulting from this handicap.

There was great discontent over the court ruling. Cathrine Fabre, of the Federation of French Families, said at the time, 'we cannot approve the idea of claiming for compensation for being alive'.

Further cases were brought where families argued that if doctors had detected the disabilities prior to birth, they would have had the pregnancies terminated.[9] This case went on appeal to the highest court in France, the Cour de Cassation. The court ruled that disabled children were entitled to compensation if their mothers were not given the chance of an abortion. The court stated that the Perruche precedent remained 'as long as a causal link can be established with an error committed by a doctor'.

Following this, doctors and campaigners for the disabled reacted furiously, describing the decision by the court as an incitement to eugenics. The case was widely described as establishing in French law a disabled child's 'right not to be born'. The Collective to Stop Discrimination against the Disabled (CCH), which was set up after the Perruche case, feared that parents would be attacked for giving birth to a handicapped child as a result of the decision. 'This is a real act of phobia. Now parents are going to be attacked and seen as irresponsible because they gave birth to a handicapped child', it said. 'The ruling means that the handicapped have no place in our society', said Yves Richard, a lawyer representing the medical profession. 'There is a real risk of this starting a process that ends with the search for the perfect child'.

Doctors expressed increasing concern that the verdict would push doctors to terminate pregnancies when they were unsure about the normality of the fetus. Some started to refuse to carry out routine antenatal scans as they were worried that they would be sued if a disabled baby was born that they had failed to diagnose. The doctors threatened strike action.

Ethicists and legal specialists also attacked the rulings. 'To allow a child to be born cannot be considered as a mistake – that must be written into law', said Laurent Aynes, a professor in civil law at Paris' Sorbonne University. Many called on the government to change the law on the subject. Initially, they held out against legislation, but were forced to act by public pressure and by the decision of some medical staff to stop carrying out prenatal scans. The bill was passed, and it states that nobody can claim to have been harmed simply by being born. By doing this, the government's ruling brought to an end a year's legal and moral debate.[8]

However, the new parliament bill prohibited Wrongful Life cases only, not Wrongful Birth suits. This means that the obstetrician or technician can still be sued, and the parents – not the affected child – will be able to seek damages, but only on the grounds of a 'blatant error' by doctors, the argument being that the birth of the disabled child is damaging the life of the mother.

The Dutch experience

After a court awarded damages to a severely disabled girl for the fact that she was born, Members of Parliament (MPs) called for The Netherlands to follow

France and ban damage claims for Wrongful Life. Doctors fear the judgment could lead to a sharp increase in defensive prenatal testing.

The case was of 9-year-old Kelly Molenaar whose parents had informed a midwife at the Leiden University Medical Centre that a relative of the father was disabled because of a chromosomal abnormality. The midwife reassured them and did not carry out further prenatal diagnostic tests or refer the case to a clinical geneticist. The abnormality was not detected early enough for intervention and Kelly was born with multiple mental and physical disabilities. She cannot walk, talk or properly recognize her parents; has deformed feet; is believed to be in constant pain and has had several heart operations. By the age of 21 months, she had been admitted to hospital nine times due to 'inconsolable crying'.[10]

The court accepted that damage to Kelly resulted from the midwife's error. The appropriate referral would have resulted in a termination and Kelly would not have been born. Damages against the hospital amounting to the cost of Kelly's care and upbringing until her 21st birthday were awarded to her parents. But the court went further, ruling that Kelly herself was liable to damages. The court judged that the damage experienced by Kelly was in a legal sense a predictable consequence of the midwife's mistake. Therefore, the court accepted the possibility of a claim for Wrongful Life. The amount of the damages is still to be decided.

The hospital's lawyers are considering an appeal to the Supreme Court to quash the judgment and MPs are urging the ministries of health and justice to respond to the decision. Boris Dittrich (MP) has called for Dutch law to be changed to prohibit Wrongful Life claims as has happened in France.

Joseph Hubben, Professor of Health Law at the Free University of Amsterdam, said:

> To recognize a disabled life as a source of financial damages gives the wrong signal to society. Disabled people should be fellow citizens not someone who should have been aborted.

He also argued that the decision would increase pressure for more prenatal diagnostic testing not just from parents but also from doctors.

The UK experience

In 2004, a UK mother was successful in suing her hospital after giving birth to a child with genetic abnormalities. She claimed damages, saying that if she had been informed of the child's disability, she would have had him killed before birth. The baby had had extensive scanning but no abnormality was detected. The baby boy was born in 1999 with a genetic abnormality that causes bladder, bowel and genitalia defects. The Hospital, Leeds Teaching Hospitals NHS Trust, had to pay an undisclosed amount of damages to assist the woman in the raising of the child. A spokesman for the Leeds Teaching Hospitals NHS Trust said, 'This was an extremely complex case and one which was defended by the trust because it raised important clinical questions'.

Summary of the European situation

As can be seen, the European situation is confusing, but it would seem that Wrongful Life cases are not being allowed, not only because of the litigation fears it brings, but also because of the moral aspects deciding that a disabled child is better off not being born. However, Wrongful Birth cases are increasing. These cases, unlike the usual litigation case, which relates to damage sustained, center around the doctor or technician's failure to diagnose a pre-existing abnormality and therefore prevent the mother from having the opportunity to terminate the pregnancy. This produces major problems and concern for obstetric units because any scan may sometimes 'miss' an abnormality. Also, which abnormalities 'merit' consideration for termination? This is accentuated by a case currently under consideration in the UK where a member of the public has asked for a judicial review of a case of a late termination of pregnancy for a cleft lip and palate.

The upper gestational limit of termination varies from country to country. In France, the law allows termination of pregnancy with no upper gestational age limit. In Italy, termination of pregnancy after the time of viability may be legally carried out only when continuation of pregnancy represents, either for physical or psychological reasons, a danger to the mother's life. In the UK, the most recent abortion act states that a termination of pregnancy can be carried out for a serious handicap right up to term as long as the baby is born dead.

What, however, is a serious handicap? A paper, in 2001, demonstrated that of the 270 children born with cleft lip and/or palate, 23 were positively diagnosed by ultrasound prior to birth.[11] Out of these 23 cases, two ended in termination of pregnancy, which is just less than 10%. The assumption from this and other studies is that if the diagnosis were available to more couples, then more terminations for cleft lip and palate would be requested. It also implies that there are many causes of fetal abnormality that parents may wish to terminate and that are not currently universally diagnosed or termination offered. In a European survey, only 2% of doctors would offer a termination for cleft lip/palate.[12] Do we need to extend the screening of babies to cover a wider range of abnormalities and offer all termination of pregnancy? If we do not offer them termination and/or the abnormalities are missed, will litigation follow to cover any surgical and other care costs? Who is to decide what a serious handicap is and whether a termination is justified?

Litigation – the European perspective

This problem relating to Wrong Birth cases is adding to the already increasing litigation culture in Europe. There are significant differences between Europe and the USA. In Europe:

(1) The litigation is usually brought by claimants paying for the legal costs. However, this is often supported by government grant (Legal Aid in the UK) although some *No Win, No Fee* cases are beginning to appear.
(2) The cases are heard in front of judges, not juries, which means that the cases are usually less emotive but lead to law of precedent.
(3) The awards are largely for cost of care required, not suffering. This means that the cost of an award for a child with cerebral palsy may be in the region of 4 million UK pounds but if the child dies, the award may only be £20,000.

The cost of litigation is mounting and, at present, the total *potential* payouts for litigation in the UK is more than the total cost of running three London teaching hospitals or providing all maternity care for England for a year. However, this is a misleading statistic, as the total amount *paid out* in *settling* claims each year is only about 1% of the total National Health Service (NHS) budget, not a huge sum.[13] In 1998, the rate of litigation was 0.81 closed claims per 1000 finished consultant episodes. The problem is that 65% of the cost, but not the numbers, are obstetric cases. Because of the rising litigation cost, medical malpractice insurance for obstetricians has escalated. This has led to the UK government bringing in 'Crown Indemnity', meaning that the NHS (the Crown) will cover the cost of litigation.[14] Therefore, it is the health authority that is sued and not the individual doctor. Also, all cases brought against hospitals are defended in England by lawyers working for the National Health Service Litigation Authority (NHSLA), a centralized body. Any costs up to £100,000 are paid by the individual hospitals but above that, the costs are met by the Clinical Negligence Scheme for Trusts (CNST), which was set up in 1995 to indemnify acute NHS Trusts against litigation. The CNST grades hospitals according to risk, and when a Trust undergoes this assessment it can earn a rebate of up to 30% of its indemnity payments if it can demonstrate significantly good performance in terms of certain risk management processes.[15] This can be a six-figure sum.

Therefore, litigation in Europe is becoming an increasing drain on health care resources and governments are stepping in to provide the financial cover in various ways. However, this does not come without strings; although individuals are no longer targeted for litigation, the government agencies are wielding increasing power to insist on risk management procedures and the appropriate training and supervision of staff. So although individuals are no longer responsible to reduce the litigation threat, the hospitals themselves have financial gains to be made if their staff follows the necessary guidelines and practices. This can be an important driver of improved care.[15]

Obstetric decision making

Decision making by doctors is a complex business influenced by training, culture and knowledge of outcome. A good example of this is the decision to deliver the premature fetus by cesarean section. Obstetricians in the different European countries were asked about what would be the earliest gestation at which they would intervene by cesarean section in the fetal interest in three different scenarios:

(1) when parents wanted everything possible done to save this baby,
(2) when parents were against aggressive management or
(3) when it was your child.

In the first situation, the median lowest gestational age at which obstetricians would be willing to perform an emergency cesarean section for fetal indication varied from 24 completed weeks in Sweden and Germany to 26 in The Netherlands, the UK, Italy and Spain. Knowledge that parents were against aggressive management would increase this figure by 1 week in Spain, France, The Netherlands, Luxembourg and Sweden. Interestingly, the most conservative approach, i.e. the latest gestation, was found in scenario 3, where it was your own child.[12] These results imply that if you want to achieve a live birth, then going early can be justified; but it is not if the best interests of the parents and the baby are taken into account. The recent Growth Restriction Intervention Trial (GRIT) study would tend to confirm the rightness of this view since delayed delivery reduced long-term disability.[16]

Neonatal decision making

As previously stated, at birth, the baby takes on individual rights, which may initially rest with the parents but ultimately can be practiced independently through an appointed guardian. This can cause confusion before birth, sometimes just minutes before; the maternal rights were paramount, now the baby's rights can be in conflict.

Here again, retrospective rights pertain. In English law, termination of pregnancy is allowed right up to term for significant fetal abnormality; however, the baby must be born dead. If the baby is born alive and then dies due to the result of prematurity or of the procedure itself, the doctor who carried out the procedure

that led to the baby's death can be charged with manslaughter. This means that late termination usually requires feticide. This adds to the stress and unpleasantness of the procedure for the parents and the staff carrying out the procedure, although others might feel that it is more humane.[17] The fact that the killing of a handicapped fetus is allowed but is not minutes later after birth adds to the confusion.

However, Dr Eduard Verhagen, of the Groningen Academic Hospital and Dr Louis Kollée of Radboud University Medical Centre in The Netherlands have asserted that euthanasia of infants is occurring worldwide. They called on the Dutch government to regularize the killing of handicapped newborn babies by providing guidelines that will protect physicians from murder charges. They felt that there should be a panel to consider guidelines for euthanasia for people with 'no free will', i.e. severely handicapped infants. The practice varies throughout Europe, most commonly in The Netherlands and France, but doctors are divided on whether it should be controlled by law.[18] Interestingly, nurses are more in favor than doctors.

An associated problem is when to initiate and/or withdraw care from an infant with a severe abnormality or gross prematurity. This problem was highlighted by the 'Baby Messenger' case in the US, where a severely ill preterm infant was resuscitated against his parents' wishes and was removed by his parents from ventilator support and allowed to die in their arms. The father was initially charged with manslaughter, although subsequently acquitted.[19]

The approach to the resuscitation of premature babies varies among countries with many producing clear guidelines of when small or abnormal babies should be treated or when treatment should be withdrawn.[20] The different approaches are based on various methodologies, including

- the 'statistical' approach, whereby treatment is withheld from infants defined as underweight and/or immature,
- the 'initiate and re-evaluate' approach, whereby aggressive treatment is begun and then re-evaluated relative to the infant's progress and parents' wishes and
- a 'treat until certainty' approach, whereby each infant is treated until death or discharge.

Each of these approaches has advantages and disadvantages. The Danish Council of Ethics produced a protocol that combines a minimum gestational age, maturity and parental wishes. Generally, infants younger than 24 or 25 weeks are not treated aggressively but this can be modified if the infant looks mature and can be resuscitated using 'low-technology modalities' and minimal handling.[19] Also, the approach can be modified by considerations of parental wishes. The long-term outcome for the baby is greatly influenced by the ability of his parents to provide the care it requires. Therefore, the threshold can be moved down by parents wishing to care for a child that fails to meet the criterion or can be moved up by parents requesting to withhold treatment from a newborn that meets the threshold requirement. Under these guidelines, Baby Messenger would not have been resuscitated. Even had the neonatologist decided that the gestational threshold had been met, the baby's immediate condition following birth did not meet the maturity criterion. This, together with the parent's refusal of ventilator support, should have meant that he should not have been resuscitated. The council's recommendations are based on two main factors, the infant's best interests and economic justice:

> The basis for the [modified threshold] recommendation is that the panel considers the 35% occurrence of severe handicaps in children born after a pregnancy term of 24–25 full weeks to be high in relation to the number of surviving infants; the panel also takes into account the comparison of the expenditure incurred with the possible alternative applications for that amount.[9]

Therefore, the infant's best interests and the cost to society are considered and not just survival. A 35% risk of severe impairment may be too high for a parent, physician or policy maker to accept. However, there is also a chance that the child may lead a relatively normal life. While this may seem a reasonable decision for parents to make, it does result in large numbers of healthy infants being allowed to die to avoid a smaller number of handicapped infants. One benefit of targeting care is to benefit those who would gain most.

> It seems reasonable to exercise reticence in the treatment of extremely preterm infants in order to benefit the slightly less premature, since the prospects of better results increase with age and fewer resources are consumed, allowing more to be helped.[10]

In a survey in different European countries, doctors were asked how they would care for a case of extreme prematurity (24 weeks' gestational age, birth weight of 560 g, Apgar score of 1 at 1 min). Most physicians in every country but The Netherlands would resuscitate this baby and start intensive care.[20] On subsequent deterioration of clinical conditions caused by a severe intraventricular hemorrhage, attitudes diverge: most neonatologists in Germany, Italy, Estonia and Hungary would favor continuation of intensive care, whereas in other countries some form of limitation of treatment would be the preferred choice. Parental wishes appear to play a role, especially in Great Britain and The Netherlands. Interestingly, again nurses are more likely than doctors to want to withhold resuscitation in the delivery room and to ask parental opinion regarding subsequent treatment choices. Among doctors who

would resuscitate, only in Great Britain and The Netherlands would a substantial percentage change the decision, knowing that parents were against resuscitation. In Estonia, Hungary, Italy, Germany and Spain, most doctors would withhold treatment in case of emergencies, such as cardiac arrest, whereas doctors in Great Britain, The Netherlands and Sweden would withdraw mechanical ventilation. Only in France and The Netherlands would definitive actions be taken to end life. Therefore, the range of care throughout Europe, in the same clinical situation, varied from active care until there was no hope to positively ending life.

Interestingly, the parents' responses to these decisions are varied, partly depending on the outcome, with 22% of the parents expressing reservations about the length of the dying process. Some reported that this had taken from 3 to 36 h. Deaths that medical teams had predicted would be quick had, according to the parents' recollections, taken from 1.5 to 31 h. When a baby died swiftly, it seemed to confirm the decision to stop, but when babies lingered, doubts were raised.[20]

Conclusions

So there is no pan-European perspective; each country has its own approach. The Danes have a varied statistical approach to what should and should not be done; the Dutch similarly have a definite cut-off point, with a pragmatic approach toward withdrawal of treatment and even active ending of life; the British wait and see, discuss the case with their colleagues and the parents and largely let nature take its course but will withdraw treatment when clear possibilities of a successful outcome have gone and the Germans will work to save the baby until it dies. This does not appear to be influenced by religious factors but by the social norms of the society in which the doctors work.

Similarly, the approach toward termination is extremely liberal and uninfluenced by religious prejudice. This is helped by the largely pan-European legal position that the fetus has no rights before birth, as this is the main pillar of the right to life battle. The recent findings in the European courts have ended this fight for the foreseeable future.

However, there is an increasing European problem of litigation with the number and cost of cases increasing. The UK leads the way in this situation and has tried to solve the insurance costs by the government footing the bill. This has just led to spiraling costs. The newer Wrongful Birth cases has opened up what appears to be an endless source of new cases, which can be of significant cost. Again, Governments have had to intervene to legislate in these situations, not because of the rights or wrongs but for the social good.

22 Malpractice issues in perinatal medicine: The United States perspective

B. S. Schifrin, M. R. Lebed and J. McCauley

Introduction

It was probably inevitable that the law and medicine would come into conflict irrespective of the fact that despite some obviously different approaches, these learned professions share more than they conflict. While medicine is fundamentally inductive and law deductive, both fields are centered in advocacy for the client. When it comes to medicine, the law tries to reconcile a body of science with the art of clinical practice. When it comes to the law, medicine tries to reconcile a body of laws with notions of fault and accountability. The relationship is abetted when the goals of better, more efficient care and prompt and effective methods of dealing with error and adverse outcome are agreed upon. On the other hand, when each profession deems the other side to hold some unscrupulous advantage, when the 'playing field is perceived to be not level', and when myth and misdirection are rampant and malpractice premiums have become excessive or insurance coverage unavailable, then the worst of the relationship comes to the fore and political and legislative resources are recruited to help control the dialog and the invective and define or create new rules of engagement. In the end, care is compromised as are notions of justice and access to the law.

Historic perspective of malpractice in the United States

Malpractice suits were unheard of until 1848. Prior to that there was no control over the practice of medicine or its numerous schools of practice. There was no need: patients generally were fatalists, believing that any adverse medical outcome was the will of God. It became an issue after 1848 only because allopathic physicians, to eliminate other 'schools of medicine', created objective standards of practice, created national medical societies and national standards, elected to support litigation under tort law rather than contract law, and established the 'deep pockets' of malpractice insurance – a profitable industry for attorneys.

But it was only with the beginning of the 1960s that more educated, informed, and assertive patients began to question their physicians in the same manner that they evaluated their other goods and services. In general, this was poorly accepted by physicians, who for the most part maintained a traditional authoritarian stance in the care of their patients. The legislative crises of the 1970s, and the subsequent 'crises' of the 1980s, 1990s, and today brought with them tort reform, health maintenance organizations (HMOs), increasing regulation, decreasing autonomy, strained relations between physicians, hospital administrations, and allied health care providers, and decreased physician and patient satisfaction. Although much has changed from the mid-1800 s there is one historic consistency: the major litogen (a promoter of lawsuits) is not outcome but physician behavior.

Malpractice law

Malpractice law is part of tort, or personal injury, law that affects large segments of society, including product liability, automobile accidents, airplane crashes, and other examples of unintended harm. As mentioned above, it was the physicians, themselves, who determined that due to their superior status, they were not subject to contract law with patients, who were not their equal, and set the higher civil law standard of Tort law. The objectives of malpractice litigation are straight forward: (1) to resolve disputes fairly with equal opportunity for 'justice' on both

sides, (2) to compensate persons injured through negligence, and (3) to prevent unsafe practices – i.e. raise the standard of care[1] – all without resorting to armaments or fisticuffs.

A plaintiff prevails in a lawsuit by proving the four Ds: that the defendant (1) owed a Duty of care to the plaintiff, (2) that there was a Deviation from an acceptable standard of care, and (3) that there was a non-trivial injury to the plaintiff (Damages) that was Directly caused by the deviation from the standard of care.[1] A failure to demonstrate any one of the four means that the requirements, under the law, are not met. To begin the process, a patient approaches a lawyer. The reasons patients sue are many.[2–5]

For patients and family members, the physical and emotional devastation of medical error cannot be easily overcome. As a rule, however, this circumstance has been made even more difficult because there was no satisfactory explanation to the patient of the reason for the adverse outcome, no admission of negligence, no opportunity for questions, and no consolation for loss.[6,7] In reality, the patients want a forthright explanation of what happened, and want to understand if they had played a role in it. And if, just if, a mistake had been made, they expect an apology and an offer to compensate for the expense and aggravation. They are real people and whether the injury was the result of negligence or not, they, not the physicians burdened with a lawsuit, are the real victims. When asked, 'What was wrong with the care you or your child received?' or 'What complaints do you have about physicians?', patients respond rather specifically (Table 22.1).[4] As underscored by these data, the attorney is often the last person who is contacted, not the first. Indeed, most often patients are directed to an attorney by a member of the medical community.

Indeed, many are amazed, when looking at medical malpractice cases, by the cold-blooded attitude so many defendants have taken toward patients who have been seriously, and sometimes grotesquely, harmed. Inhumanity and indifference to the suffering of others is in itself another form of injury. When patients file suit, they are often made to feel as though they had done something wrong, as if seeking legal redress and compensation was in some sense an affront to the system, a personal assault on the physician. Many plaintiffs feel pressured by all the parties involved to agree to a settlement. In some instances, such advice may come from the plaintiff attorney or even the sitting judge. Indeed, on occasion extraordinary amounts of offered settlement are turned down, not because of the size of the award, but because all the details of their case would then come out publicly – they would have their day in court.

Physicians believe themselves to be operating in an environment of zero tolerance for error. It is embedded in their oath and dedication to 'do no harm', in their professed desires to help others, and magnified by a historic paternalistic tendency to extend unrealistic expectations to their patients.[8] The physician who has erred is wounded, and suffers the consequences of guilt, fear of reprisal (from the patient, hospital, regulatory agencies), embarrassment (peer), and sorrow for having harmed someone (Levinson).[5,9] Because medicine, for centuries, has been loathe to identify negligent care (even in closed, protected settings), this system of justice has enfranchised the plaintiff's attorney, not especially trained for the purpose, to determine the medical and the legal merits of the case (they are not the same!) Under the contingency-fee relationship prevalent in the United States, the attorney takes a percentage of the award as a fee (often around 35%) to compensate for the costs, expenses, and time absorbed in pursuing the case irrespective of the outcome; they take nothing if the defendant prevails. These expenses are not trivial; bringing a 'damaged child' case to court, for example, may easily cost $100,000 of up front expenses. It is not undertaken lightly.[10]

But before the attorney can proceed, one of his first expenses will involve consultation with a medical expert (a physician) to determine whether the potential case satisfies the two most critical criteria of the four Ds: was there a Deviation from a reasonable standard of care and was there a Direct causal relationship between that failure and the adverse outcome? Damages and Duty, generally, are self-evident. Traditionally, the 'standard of care' is defined

Table 22.1 Why patients sue (Hickson *et al.*[4])

Cited deficiencies of care	
Recognizing fetal distress	53%
Managing fetal distress	57%
Timely cesarean section	35%
Physician unavailable	29%
Birth injury (forceps)	28%
Consultation or transfer	10%
What prompted the lawsuit?	
Person outside family	33%
Medical personnel	23/41 (56%)
Lawyer	8/41 (20%)
Money for long-term care	24%
Physician deception	24%
Child would have no future	20%
Find out what happened	20%
Prevent malpractice/revenge	19%
Complaints about physicians	
Not informed about injury potential	70%
Misled patient	48%
Would not talk or answer questions	32%
Would not listen	13%

as the quality of care (customs and behavior) that would be expected of a reasonable practitioner in similar circumstances. These standards are drawn from members of the profession itself as well as documents that reflect a consensus on appropriate standards (plural) of care.

It should be emphasized that there is no single standard of care. Satisfying the need to do something *reasonable under the circumstances*, indeed, may permit mutually exclusive choices to be within the standard of care. Because the law holds the arcane nature of medicine, 'a learned profession', to be beyond the grasp of common citizens, it requires the testimony of experts in the same field as the defendant.[11,12] Neither the courts nor the legislatures can reasonably establish detailed conduct for professional practice without 'practicing medicine'.[13]

Ideally, medical witnesses will be readily available and forthright and medical standards will be determinable from readily available medical records that are well documented, readable, and responsive to questions of whether or not the medical conduct met a reasonable standard of care. The medical consultant/potential expert witness will possess both current knowledge and experience with the issues at hand, but, at any time in the review process, is honor bound to use all available relevant information and to apply broadly understood, minimal, standards of care – not their own personal standards. An expert witness must elaborate the standard for medical care at the time of the plaintiff's injury and give an opinion on whether the defendant's conduct met this standard. The standard is not unique to the expert, but rather must reflect general principles applicable to all practitioners, but at the same time, specific to the individual patient's circumstances. Ideally, it should be supported by scholarly literature. While it need not prescribe a single course of action, it must either (for the plaintiff) proscribe the defendant's conduct or (for the defense) endorse the defendant's conduct as an acceptable alternative. Therein lies the conflict.

While the courts expect that medicine, as a learned, science-based discipline, will have articulated standards for practice in most circumstances, they also recognize that not all standards are formalized or even well defined, not all clinical circumstances can be circumscribed in some obvious standard of care, and there is 'art' to the practice of medicine. To overcome these hurdles the courts, using their own legal (not medical) standards of witness acceptability, allow appropriately qualified expert witnesses to express expert opinions. Indeed, the expert witness is the only party in the lawsuit who may express opinions; everyone else is only entitled to the 'facts' of the case. Ideally, the expert will not be an advocate, except perhaps of his own opinion, and will honestly present his or her understanding of the applicable standards without tailoring his responses to serve the single-minded ends of the lawyer engaging the expert.

Obtaining expert testimony has always been the most difficult part of medical malpractice litigation. Historically, experts were readily available to testify against competing medical disciplines, including homeopathic physicians and chiropractors, although they were expected to remain silent about the misconduct of members of their own profession (*omerta*). To abolish these vituperative, economic rivalries, the courts established the doctrines of 'school of practice' and 'locality rule' as the bases for qualifying expert witnesses.

The school of practice rule permits the differentiation of physicians into self-designated specialties depending on whether the case concerns procedures and expertise that are intrinsic to the specialty or general medical knowledge and techniques that are common to all physicians. Thus, obstetrical cases may involve family practitioners, midwives, obstetrician-gynecologists, as well as members in training; the potentially significant differences in their individual standards may indeed require expert witnesses from each of these specialties.

Before the standardization of medical training and certification that prevails today, there was a tremendous gulf between the skills and abilities of university-trained physicians and the graduates of 'less reputable' schools issuing diplomas. Thus, in many parts of the country, a physician's ability to serve as an expert would be determined by comparison with the other physicians in the community, or at least in similar neighboring communities. For obvious reasons, this rule essentially precluded injured patients from finding supportive expert testimony – effectively preventing most medical malpractice litigation. Reasonably, there is no longer a justification for any rule that impedes evaluation of what have become national standards of care on the sole basis that it is the norm for a given community. While most states have explicitly abolished the locality rule, it is being reinvigorated in some states as a tort reform measure (and *omerta*) to deal with the problems of access to care and facilities in rural areas.

A national standard of care implies that the rural and urban physicians will have the same training and exercise the same level of judgment and diligence. The rule does not require that the rural physician have the same medical facilities, consultants, or other resources available. If the community does not have facilities for an emergency cesarean section, for example, the physician cannot be found negligent for failing to do this surgery within the 15 min that might be the standard in a well-equipped urban hospital. The physician, however, to comply with the standard of care, must inform the patient of the limitations of the available facilities and recommend prompt transfer if indicated. He must also make reasonable efforts to deal with the inevitability of requiring an emergency section – even in a rural community. Proper informed consent allows patients to balance the convenience of local care against the risks of inadequate facilities.

At trial, judges and jurors (the triers of fact) have no alternative but to judge the testimony of witnesses whether expert or percipient (fact) on the personal credibility of the witness. For the experts and the defendants, positive factors such as academic degrees, specialty board certification, and publications enhance credibility. So do such factors as physical appearance, race, gender, command of English, and personality. Irrespective of these personal traits, the objective is to be believed. The defendant also has to be believed but his/her role is much more focused; he/she has but one chore: to convince *anyone* who will listen (judge, juror, attorney, stenographer, bailiff, passerby) that he/she is a thoughtful, caring, concerned human being who did what was professionally reasonable under the circumstances. The defendant has no other job. Performing research, providing expert opinion, or combating the opinions of the opposing expert are all, we believe, someone else's function. As mentioned above, the defendant's demeanor in deposition or trial (as well as with patients) has a great deal to do both with the likelihood of lawsuit and its resolution. For the expert witness, the foremost requirements are effective presentation and teaching ability. The expert must educate the judge and jury on the technical matters at hand.

Until 1993, federal courts had used the 'general acceptance' test, set forth in Frye v. United States, to assess the admissibility of expert scientific testimony.[14] In 1993, the United States Supreme Court modified the standard for determining the admissibility of expert scientific testimony in federal trials. In Daubert, the court stated that the Frye test did not comport with the Federal Rules of Evidence and that 'a rigid "general acceptance" requirement would be at odds with the "liberal thrust" of the Federal Rules and their "general approach to relaxing the traditional barriers to opinion testimony"'.[14] Accordingly, the court emphasized that a trial judge must screen the proposed scientific testimony to ensure that the testimony is relevant and reliable before allowing it to be presented at trial.[14–16]

If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education may testify thereto in the form of an opinion or otherwise. It is a judicial decision not a medical one.[16,17]

The court set forth four factors that may be used to assist the trial judge in determining 'whether the expert is proposing to testify to scientific knowledge that will assist the trier of fact to understand or determine a fact in issue'. The factors that may be considered when determining the validity of a scientific theory or technique are: (1) whether the theory or technique can be tested, (2) whether the theory has been subject to peer review and publication, (3) the rate of error, and (4) the acceptance of the theory or technique within the community. The court cautioned that '[t]he focus must be solely on principles and methodology, not on the conclusions that they generate'. The court emphasized that these factors are not exclusive.

Thus, under Daubert, a defendant doctor may be considered negligent for treatment and diagnosis even though he presents evidence from a number of medical experts genuinely of the opinion that the defendant's care followed customary medical practice. The court must determine for itself the appropriateness and the logic of the professional opinion and find reassurance that the body of opinion relied upon was not created for defensive purposes (see below). It is a curiosity that an expert's position may fail a Daubert challenge in one case but may continue to be offered in other cases! It seems counterintuitive that a lay judge is qualified to be asked to determine the qualifications and credibility of an expert. Some believe that the selection of medical experts be the purview of medically trained peers. Indeed, there is an argument to be made that the specialty societies develop a list of 'true' experts that are available to either side or the judge himself.

At least in Federal Court the expert's legal activities over the last 5 years must be listed with the court prior to his appearance. Federal rules also give a judge the authority to (1) limit cumulative evidence, i.e. more than one expert testifying to the same issues unrelated to qualifications, (2) retain experts to assist the court, or (3) with mutual consent appoint a single expert witness. Despite these available options, especially in 'damaged child' cases, there is an increasing tendency to line up a broad array of qualified experts on both sides, including an obstetrician, perinatologist, placental pathologist, neonatologist, neurologist, nurse, economist, neuroradiologist, etc. There is at least some evidence that this proliferation of experts (and costs), more likely driven by the defense, is counterproductive. Bors-Koefoed *et al.* found that the use of multiple defense expert witnesses decreased the chances of a successful defense.[18]

Many jurisdictions have attempted to insinuate the expert witness into the proceedings prior to the case being filed. In several states a report or affidavit of merit from the expert is required to launch the suit, in others only the testimony by the lawyer that he has contacted an expert is required. By and large there is no standard format for expert reports. While they are often quite minimal and non-specific there is an increasing trend to make them more substantive and even to limit in some states the allegations to those specifically identified in the report. There is also no requirement that the 'expert' who gave an affirmative opinion to the attorney, whether he signed the letter of merit or not, will subsequently be involved in the case, a deplorable circumstance as will be discussed below. Even if he/she were later involved, there are no mechanisms short of deposition or interrogatory to amplify on the experts' allegations. In some states, the

expert cannot be deposed before trial and indeed his identity is unknown to the opposing side until he is called to the stand – widely referred to as 'trial by ambush'.

While the expert's opinion is normally protected by the doctrine of witness immunity, this does not protect the witness from fraud or from professional malpractice liability[19] or from other forms of harassment. 'The goal to insuring that the path to truth is unobstructed and the judicial process is protected, by fostering an atmosphere where the expert witness will be forthright and candid in stating his or her opinion, is not advanced by immunizing the expert witness from … negligence in forming the opinion'.[19] In one instance, a consulting expert was sued for failing to testify on behalf of the plaintiff in trial. The expert believed that causation could not be satisfactorily proven.

It is perhaps instructive here to deal with the terms, 'meritorious' and 'frivolous' as applied to malpractice cases. In brief, whether the case is meritorious or not is a function not of the result, but of whether there is a substantive question about the standard of care and its relationship to the outcome. In a frivolous case, there is no substantive question, the four Ds cannot be shown or linked, or any question of negligence is readily answered in the negative simply with the most cursory examination of the evidence. Often, the complaints that prompt the visit to the attorney derive from actual or perceived slights by the physician related to a poor 'bedside manner', a disputed bill, a lack of timely response, etc. In this respect, it is important to understand how, given the unrequited emotional needs associated with adverse outcomes, malpractice litigation serves the purpose of emotional vindication.[20,21] Such complaints are usually dismissed out of hand by the attorney in the first interview with the patient or secondarily on the basis of the review by the consulting expert. It is not widely appreciated but the vast majority of patients who approach lawyers with complaints about their physicians are turned down (probably greater than 90%). Some patients are actually grateful to know that they did not receive substandard care, and equally important, that they themselves did not contribute to the adverse outcome. Despite any anger or frustration they may have with the conduct or deportment of the physician they often harbor notions of their own complicity in an adverse outcome, especially when there has been a brain-damaged baby. If they had only not skipped an appointment, not used the hot tub, not gained so much weight, etc Being turned down in a request to sue a physician may have positive benefits of closure. It may indeed help them to forgive themselves. While it is quite uncommon to pursue a lawsuit based solely on an emotional misdemeanor by the physician, it becomes a powerful incentive to bring a lawsuit if the care has also been negligent. As will be seen in the statistics below, many negligent physicians are exculpated or avoid lawsuits entirely not because of the facts of the case, but by a becoming demeanor to the patient or to the jury. Other physicians have been found negligent, not because of their care, but by their indifference toward the patient. It is this author's experience that the minute the jury perceives that the physician does not care vindication of his medical conduct is not possible.

Thus, to label as 'frivolous', as many physicians have, all cases that plaintiffs lose, or are settled 'for economic reasons' or are dismissed trivializes the tort system, the lawyers, the patients, the opposing expert witness and, in its way, impedes the solution of the malpractice problem and foments more error. This posture reveals an inadequate understanding of the dynamics of expert allegations, settlements, jury verdicts, and even the process of peer review.

Given the affirmative report by his expert, the attorney is legally *obligated* to pursue discovery – the accession of all the relevant clinical data from the medical records or other sources. To flesh out the records and to understand something of the personality of the defendants, depositions are taken of the relevant treating or factual witness – sometimes including the custodian of records, etc. and the various medical experts.

The defense against the allegation of failing to meet the standard of care of a malpractice case centers around issues of customary practice, clinical practice guidelines, informed consent, and differentiating error from complication. In judging the conduct of the physician in a court of law, the court is guided by a notion called 'reasonable conduct'. Indeed, it is sufficiently vague as to require the participation of an expert witness to state what is and what is not 'reasonable' conduct. At least theoretically, the creation of clinical practice guidelines would simplify and implement broadly understood practices subscribing to a quality of care that could be objectively measured. At the same time, the quality of care would be improved and iatrogenic injury diminished.

There has been a broad implementation of 'clinical practice guidelines' from various hospitals, professional organizations, and the government itself. A clinical practice guideline is any guide to the clinical management of a patient. These guidelines vary widely according to the purpose for which they are written and who has been selected to write them. They may be driven by medicolegal issues, by the cost of care, or by the quality of care. While great emphasis has now been placed on the process of writing guidelines, many providers have become concerned with the basic precepts of guidelines, including the possible emergence of 'cookbook' medicine, the effect of patient variability, and the need to keep guidelines flexible, current, and credible.[22,23]

Clearly, one impetus for the creation of clinical practice guidelines for specific medical conditions and their treatment was the notion that they would help avoid or defend malpractice claims. Indeed, someday they might replace the 'reasonable conduct'

standards and their dependence on expert testimony in medical cases and thereby discourage both defensive medical practices and spurious claims – after all, it is the medical profession and not the juries that establish the standard of care; the jury just attempts to find out what were the standards that the medical profession had set for itself in any given situation and then to determine whether those guidelines were appropriately and reasonably followed. There are several problems with the use of 'guidelines'. First, they may not be usable (admissible in evidence) at all. Because of the wide range of reasons for creating guidelines (care, costs, medicolegal protection) in many states, such guidelines constitute 'hearsay' in great measure because their author is not in court to be cross-examined. Finally, having followed the guidelines may not mean malpractice was not committed. Scrupulous adherence to the relevant guidelines for an amputation, for example, avails nothing if the wrong leg has been amputated. Thus, it is that the notion that compliance with guidelines renders the clinician immune from lawsuit has not been upheld. Consensus, after all, is not necessarily wisdom, or applicable in all cases!

When the opinions of the opposing experts conflict irreconcilably over this issue, the jury comes face to face with the logical conundrum. Is the disagreement related to lack of awareness of the standards or is one of the experts lying? The jury assesses the credentials and the credibility and various other sources of information, to help them decide which expert is more credible in relating the individual patient's care to the prevailing standards.

One of the most widely quoted and misunderstood guidelines requires that institutions be capable of instituting an emergency cesarean section within 30 min of decision.[24] Some institutions cannot meet these guidelines reliably while others maintain a standard that can result in an emergency cesarean section in 10 min or less. While several studies have attempted to determine the reasonableness of 'the 30-min rule', neither the studies nor the guidelines take into account certain realities or certain remedies.[24] The 30-min rule is shorthand designation for a more encompassing principle that, under certain conditions, performance of a cesarean section should be carried out as quickly as possible consistent with concern for the health and well-being of the mother and fetus, preferably within 30 min. But what is the standard if there is already one cesarean section in progress, or two? Under these circumstances, a delay becomes 'reasonable under the circumstances', notwithstanding the fact that the standard of care required an earlier cesarean section. However, if a physician is late in realizing the need for cesarean section or is ready to operate within 20 min but fritters away 10 min beforehand, his conduct cannot possibly comport with a reasonable standard of care, even if the patient is delivered within 30 min. Further, it stands to reason, that institutions normally unable to consistently meet the 30-min rule must modify their practices and exhibit a willingness to prepare for cesarean section early (even if it proves unnecessary) in anticipation of problems and make special arrangements for unique situations such as vaginal birth after cesarean (VBAC). Thus, the failure to meet the 30-min rule is rarely by itself a telling plaintiff's allegation. Much more frequently, the plaintiff's allegation is that the failure to properly interpret the fetal monitoring tracing or to properly estimate the feasibility of safe vaginal delivery hopelessly delayed the decision in the first place, irrespective of the 'decision to incision' interval.

There is frequent debate over whether 'official' pronouncements such as the 30-min rule are to be construed as monolithic 'standards of care'. More reasonably, it seems, that irrespective of whether these writings are entitled practice parameters, guidelines, standards, apocrypha, hints, clues, etc., the imprimatur of an official body, gives any statement about care the force of a 'standard'. Indeed, during litigation, both sides are apt to offer these professional publications as standards to support their case irrespective of the disclaimer that these recommendations are guidelines rather than standards of care. Thus, guidelines, whatever their provenance, are never 'medicolegally binding' and can be directly and reasonably contravened by a thoughtful, alternative choice of care – that is annotated!

Informed consent

Similarly, the patient has rights, no matter how appropriately they may be exercised, to influence decisions about her care. In dealing with matters of informed consent, most courts in the United States look to what a reasonable patient would want to know, not what a 'reasonable physician' would have said. The courts have on several occasions been asked to intervene in circumstances involving the refusal of treatment by a pregnant woman, refusal that nominally threatens the life and well-being of her fetus and herself. While the courts' responses have been varied, there is general consensus among the specialties that these ethical (not legal) issues should *not* be resolved in court and that considerable ethical weight should be given to the mother's decision as long as the consent has been proper and there has been no coercion. Lawsuits based entirely on informed consent are quite uncommon, but most such cases in obstetrics seem to involve VBAC, the use of operative delivery, and the decision to induce labor with a previous history of shoulder dystocia. If the consent document signed by the potential VBAC patient, for example, is to truly represent that her consent is truly 'informed', it must reveal the patient's understanding that she may either undergo an elective repeat cesarean section or, if she is a suitable candidate, attempt a VBAC. She must understand that not all patients are candidates for VBAC and that not all VBAC attempts will result in successful vaginal

delivery. She must be aware that some of the determinable clinical factors that affect the success of VBAC become apparent only in labor. The patient must also understand that all pregnancies carry a small risk to both mother and fetus, whether or not the mother has had a previous cesarean section. In patients with a previous cesarean section, the risk of uterine rupture during a VBAC is approximately 1% and this occasionally may result in serious, potentially life-threatening complications for the mother or the baby. If the patient initially agrees to attempt VBAC, she needs to understand that she is entitled to an updating of the likelihood of success and to change her mind at any reasonable time and to obtain a cesarean section even during labor. Finally, the patient should understand that no decision, however thoughtfully made, or however reasonably pursued, guarantees a normal outcome for the mother or the infant.

The reader may now compare this approach with the deliberations in an informed consent case that was decided by the Wisconsin Supreme Court and that stretched the limits to which some physicians would go to reduce their cesarean delivery rate. In this case a patient presented with a history of two previous cesarean sections, the first undertaken for arrest of labor after 17 h (the second was elective); she had agreed prior to labor to attempt VBAC.[25] During labor, in the face of slow progress and severe abdominal pain, she changed her mind and repeatedly requested a cesarean section. Just as often the obstetrician maintained that it was unnecessary. The obstetrician commented, '… if I performed cesarean section on every woman who wanted one then all deliveries would be by cesarean section'. Intimidated, the patient no longer requested cesarean section. Ultimately, the uterus ruptured and the child was hopelessly injured despite delivery within 30 min. The physician defended his conduct on the ground that the original informed consent should prevail throughout the labor and that the standard of care had been met by the 'timely' delivery within 30 min. He noted that the patient had reaffirmed upon admission her earlier willingness to undergo a trial of labor and he maintained that labor continued 'without objection'.

The court (inviting the implication that the patient had been coerced) rejected the defense position that the patient's resignation implied acceptance of a continued trial of labor.[25] The court did not comment on the change in the *medical situation* (dysfunctional labor, unexplained abdominal pain) that required medical reconsideration of the case and updating of the informed consent. The court did, however, conclude that the *legal situation* had changed:

> Where two or more medically acceptable options for treatment are present, the competent patient has the absolute right to select from among those treatment options after being informed of the relative risks and benefits of each approach. But consent, once given, is not categorically immutable and the patient was entitled to withdraw her consent to VBAC. That indisputable withdrawal, placed the patient and her physician in their original position – a blank slate on which the parties must again diagram their plan which in this case would have resulted in cesarean section.

It was foreseeable that as a backlash to the alarm generated by this verdict along with other reports and settlements, many hospitals no longer permit VBAC deliveries and an increasing number of malpractice insurers are limiting their indemnification of physicians performing VBAC deliveries![26]

Complication or error?

The 'recognized risk defense', asserts that the undesirable outcome or injury in question is nothing more than an unavoidable complication – an understandable and acceptable risk of a properly considered and provided treatment. Accordingly, so long as the patient is reasonably apprised of the more serious and the commonplace risks and participates in the decision, in theory there can be no issue of negligence. A typical example is subgaleal or intracranial hemorrhage in the newborn following vacuum-assisted delivery. Indeed, every obstetrical text devotes significant space to such complications but only rarely do they include a full discussion about preventability or even the distinction between complication and negligence. Is intracranial/subgaleal hemorrhage following vacuum extraction, for example, an *unavoidable* risk or, in some instances, the result of negligence and how would that be determined?[27] Similarly, is brachial plexus injury after shoulder dystocia a foreseeable event related to excessive lateral traction on the fetal neck, anticipated by multiple risk factors, or is it a totally unpredictable, unpreventable injury *always* unrelated to the care of the physician during delivery. In the courtroom, the plaintiff's attorney will use the statistics on complications as follows. A 'recognized complication' does *not* preclude that the complication was caused by negligence. Indeed, none, all, or only some of these complications may represent negligence. For example, if 2% of all drivers run red lights, running red lights is a known complication of driving, but it is also a case of negligence. The most likely situation is that some of the injury is potentially avoidable. Thus, that a given adverse outcome is a known complication of a procedure tells an attorney nothing. The attorney wants to know why the complication occurs and, more importantly, why it occurred in this particular case.

Pursuing the case

If the case is pursued, it may be settled by an agreement of the parties or may go to trial. While the physician believes himself disadvantaged in this system of finding fault, in reality the law gives health care providers considerable advantage. They are advantaged by the presumption of non-negligence.

They do not have to be right in their care, just reasonable. The law denies the jury the right to decide medical issues and even requires expert witnesses from the profession itself. After an agreement to settle the case or after an adjudication that finds the defendant negligent, his insurance company bears the costs of both economic losses (lost earnings and medical bills) and non-economic losses, so-called 'pain and suffering'. The system is maintained in balance by the provision of insurance for both hospitals and physicians based on a pooling of risk, historically through separate lines of insurance.[13,28] This minimizes the risk of bankruptcy by a single large payout and because resources are available to compensate patients. The cost of insurance coverage for hospitals is typically linked to the history of claims from year to year, an arrangement known as 'experience rating'. Physicians, on the other hand, unless their experience is extreme, are generally not risk rated, a potentially contrived actuarial practice.[29]

In practice, this theoretically balanced system falls short of its objectives, as illustrated in the 'ire and angst' of contemporary malpractice litigation.[13] This chapter, written at the end of 2004, will therefore attempt to review some of the competing, nay dueling, agendas that are being brought to bear in the medical, legal, and political arenas. The enterprise redounds with myth and divisive and often contradictory data – sometimes of dubious provenance. The dust of the latest in these, increasingly disagreeable, epochal skirmishes for the malpractice 'high road' has not yet settled and is unlikely to be settled to everyone's satisfaction in the near future. In the authors' view, this situation prevails because each side, for its particular reasons, is unwilling to make the tort system work as it was designed to. Indeed some of the issues raised are ethical in nature, beyond the purview of the courts and the legislature.

Malpractice mythology – the failure of medicolegal education

An enduring feature of the malpractice upheaval in the United States (and almost nowhere else) is the ignorance of malpractice doctrine in the medical community and beyond. Not only is there widespread fear of being sued, but there is also a great misperception about the requirements for proof of malpractice, the outcomes of lawsuits, and the reasons patients sue. There is little appetite to deal with the major litogen (a factor promoting lawsuit) – physician behavior.

Some current mythology: 'Malpractice relates to the incompetence of a few bad physicians'; 'Anyone can sue, everyone wins'; 'Every case resulting in CP will come to lawsuit'; 'The system is unfair and favors the plaintiff'; 'Patients who sue are greedy, ingrates'; 'Judges and juries cannot understand medicine'; 'Losing a lawsuit raises premiums and besmirches the physician's name in the community'; 'The plaintiff's attorney and the expert are the enemy, along with the judge, jury, insurance company'; 'Malpractice doesn't make care better'; 'The majority of suits in medicine are frivolous whether they are settled, dropped, go to jury trial, or lose'; 'We're living in a time when people have a higher expectation from physicians – that until proven otherwise, it's the doctor's fault'; 'The system is overrun with runaway juries and jackpot justice, with sinister lawyers and opportunistic plaintiffs preying on virtuous corporations, hospitals, and doctors in search of that big payout from the lawsuit lottery'.[30]

There is almost a universal belief that the injured child's appearance in the courtroom elicits sufficient sympathy from the jury for the plaintiff to win the case. Physicians, however, win about 80% of lawsuits that do go to court. It is naive to believe that these were the cases in which the plaintiff's attorney forgot to bring the affected child into the courtroom. More reasonably, it is the thoughtful, compassionate physician, who manifests his sympathy and compassion, who most easily obtains the jury's favor and a favorable verdict.

The defendant is often unaware of the statistics that about 40% of cases are dropped and about 50% settle, sometimes as befitting the merits of the case and sometimes as a calculated strategy that limits exposure of assets. The physician who is terrified by an *ad damnum* clause (demand for damages) that greatly exceeds his insurance policy limits is rarely in our experience reassured by his own attorney that the risk to his/her assets is essentially nil. The authors are unaware of any malpractice suit involving an obstetrician who was covered by a reasonable policy and who, despite a verdict that exceeded the policy limits, had to pay any money out of his own pocket. Despite counseling, the frightened obstetrician does 'not want to be the first one'. To some extent the defense attorney may be excused for failing to understand how impoverished the physician's medicolegal education is. As one American physician put it:

> I fought in the battle of the bulge in World War II. We were trained, we were fighting a good cause and we were armed. I felt safer then than I do in a malpractice suit.

Education is the antidote to disabling myth. Medical and legal organizations have long recognized the importance of legal medicine and have repeatedly recommended its study by physicians in training – with minimal success. In 1952, the American Medical Association (AMA) advised that 'No medical student should be permitted to receive his medical degree without instruction in legal duties'. Four decades later, less than 50% of medical schools had medicolegal courses, considering the subject too unimportant to teach. Even fewer schools have any formal instruction on communication and dispute management skills. Many medical schools feel that the intense curriculum leaves no room for such instruction, and that the ability to communicate and deal with conflict is part

of the student selection process, which is to be refined following their didactic medical school training, during their apprentice/mentor training of internship and residency.

Kollas, in 1997, studied the medicolegal knowledge base of senior residents in internal medicine. Only 28% felt they had been adequately trained in the subject. Only 26% could list the requirements for proof of malpractice, i.e. the four Ds.[31,32]

A national survey of physicians in 1999 revealed that 58% had faced malpractice charges and that more than 20% had been sued at least three times. Almost 70% expected to be sued during their career. Despite the fact that physicians win the vast majority of cases that go to court, more than 75% of physicians polled felt that lay juries were not capable of deciding malpractice cases! While ready to admit that everyone makes mistakes and that they had made mistakes in other cases, virtually all physicians believe that the cases filed against them had no merit.[33] Something (read tort reform) must be done, physicians cry, to stem the tide, to eliminate the reign of terror by the plaintiff's attorneys. Plaintiff's attorneys and some consumer groups also want to stem the tide as they see it – the tide of medical error, the tide of unsympathetic, unapologetic, and ill-informed physicians.[34]

When all of these myths are wiped away, the most devastating myth or fiction about malpractice, the one that resides deepest beneath the surface, is that the allegation of malpractice represents the allegation of incompetence, or misanthropy, or malice. In fact, it simply represents an allegation of fallibility – being human and being capable of error. Imagine the response of the physician who believes that he or she is being accused of malice – the intention to do harm. The allegation of malice is precluded by the precepts of tort law and is rendered improper by the Hippocratic Oath by which the physician swears to 'First, do no harm' and, by implication, to 'intend no harm', i.e. malice. Judges and jurors understand that the physician, like the speeding driver, did not intend harm. But the physician's good intentions are not the test of reasonable performance and the profession will be unlikely to regulate itself without fundamental understanding that the legal rules of evidence in negligence cases, including malpractice, exclude the accusation of the intent to harm. When misunderstanding about the law is combined with an appreciable incidence of medical error and a high resistance among physicians to report errors,[35] then it seems that the 'culture of secrecy' derives in part from a 'culture of fear'.[36] Thus, despite the attention to the subject of medical error and the formation of organizations devoted to patient safety, there has been little demonstrable evidence of a reduction in medical error. The solution will involve changes not only in the conduct of care but also in the educational, ethical, and emotional components associated with medical errors.[37]

We will attempt, in passing, to deal with these notions, but perhaps the following experiences will assist the reader to focus on the issue of patients' expectations of a perfect outcome. The senior author delivered his first baby as a medical student about 1963. After the delivery, the first words out of the mother's mouth were, 'Is my baby alright?' He would deliver his last baby about 40 years later and the first question this mother asked was exactly the same as the question asked by the mother 40 years earlier. In the intervening 40 years, the ultrasounds, computers, and monitors of every description have allowed us to visualize the fetus, characterize its genetic composition, and determine its behavior, its growth, and its tolerance to hypoxia. As a result, there has been a dramatic reduction in the risk of fetal anomaly or death, especially during labor. Labor rooms have become intensive care suites with remote surveillance capabilities. Indeed, it has never in history been safer to deliver a baby, or perversely, to be sued for negligent care. Everyone, patients and physicians included, understands that there are no guarantees with pregnancy and under the best of circumstances, considering the stakes, not all outcomes are perfect. As with all medical care, there is always an element of uncertainty – about care and about outcome. Are lawsuits generated by those patients who fail to understand this principle or by physicians who, confronted with a bad outcome, fail to educate their patients or respond compassionately?

With regard to the notion that the presentation of the handicapped child in the courtroom dooms the defense case because of sympathy for the child, the author has witnessed the following situation in the courtroom in the case of a neurologically handicapped infant. After their deliberations, the jury returned to the courtroom to announce their verdict before the judge and the various parties. When the judge asked for the decision of the jury, the foreman arose and asked the judge if he could first make a preliminary statement on behalf of each of the jury. With tears in his eyes, the foreman acknowledged that over the course of the trial the members of the jury felt that they had come to know and care for the parents and the afflicted child. He further stated that he wanted to extend from each member of the jury both their best wishes for the future and their considerable concern about the future support of the child. They did not find the physician negligent.

In medicine today there is considerable enthusiasm for 'evidence-based medicine', epidemiologically driven decisions, and structured reimbursement. There seems much less appetite for 'evidence-based law'. The initiatives derived from evidence-based medicine seem driven as much by motives of cost control as by the hope for better health care services. Similarly, the avoidance of error, such as the use of automated medication ordering and dispensing, and the efforts of risk management (safeguarding assets) while contributory may not directly enhance the quality of care. The extraordinary response to the Institute of Medicine study has led to a nationwide

movement to find ways to reduce error and increase patient safety. The foundation of these efforts is based on increasing the ease and confidentiality of error reporting, as well as the facilitation of root cause analysis systems, team approach techniques, and improved communication and dispute management techniques, all with the goal of improving patient care.

In this way, the avoidance of error and the efforts of risk management (safeguarding assets) have become as important as, if not more important than, ensuring the quality of care. The breadth of malpractice mythology and the detestation and fear of the malpractice system by the physicians and organized medicine have distracted our attention from the public's concern about the ineffectual efforts to improve outcome whether by the adoption of higher standards, improved educational processes, or the meaningful activities of peer review committees and professional societies.

Peer review

In 1973, the U.S. Congress enacted legislation requiring physicians to initiate Peer Review Organizations to monitor the utilization and the quality of hospital and physician services in the federally funded Medicare program. Now more than 30 years later we must acknowledge the lack of a gold standard, medical or legal, for reviewing allegations of negligence and dealing meaningfully with medical error. Peer reviews produce inconsistent agreement and operate without formal rules or guidelines for review.[38] They are left to the local hospital,[39] and although the American College of Obstetricians and Gynecologists (ACOG) has attempted to provide outside review to individual hospitals, there is no analysis of such efforts.[40] The majority of 'true' peer review exercises are driven by adverse outcomes and do not represent systemic reviews of the numerous latent processes promoting adverse outcome. These are left to the occasional review of a 'sentinel event'. With peer review the rules for reviewing records and for obtaining agreement about either the severity of any departure or the impact on the offending physician are inconstantly applied and haphazardly administered. Peer review requires the presence of the physician – an overt acknowledgment of the fact that medical records are often silent about important questions whose understanding is necessary to determine the standard of care. Despite the physician's presence, the deliberations of the peer review committee are not backed up by systemic reviews of the physician's conduct in similar cases. The system is not designed to promote either patient education or an apology.

Peer review in obstetrics is especially problematic. The medical records of the infant may not be present, and there may not be anyone (neonatologists/pediatrician) present to discuss the infant's course and the impact of the obstetrical care on that course. The patient, moreover, is rarely, if ever, questioned about her perceptions of the care! Invariably, there is no long-term follow-up, especially if the infant is transferred to another hospital. Imagine, therefore, a discussion at a Peer Review Meeting of the medical conduct in a case of shoulder dystocia and brachial plexus injury. The medical record is silent about the use of fundal pressure – as it should be: fundal pressure should not be used to relieve shoulder dystocia. As a result, the physician who had carefully documented a normal sequence of maneuvers was exonerated. During the malpractice case, however, incontrovertible evidence was produced that the 263-lb anesthesiologist was exerting sufficient force on top of the patient's abdomen to produce considerable pain and broad ecchymoses. The case was settled on behalf of the plaintiff!

Other complaints of lack of due process, poor reproducibility, and motivation by non-medical/non-scientific considerations plague discussions of the peer review process whether involving the practicing physician by a hospital department, the review of a manuscript submitted for publication, the funding of grants submitted for research, or the evaluation of expert testimony by professional societies (Judson, Cohen, Pegalis, American College of Physicians).[41,42]

Peer reviews are conducted by people from the same department of the hospital and in many states are safeguarded from legal scrutiny under the common law privilege of self-critical analysis, a privilege that protects and encourages quality assessment, but that secrecy, in the final analysis, may be counterproductive for the ultimate objective of improved patient care and better transparency of medicines self-governance.[34,43] At its most collegial, colleagues of the physician being reviewed are likely to minimize error on the notion that when their turn comes, similar cordiality and extenuation will prevail. After all, the objective of the process of review is not to find fault or apportion blame, but to improve outcomes for the future.[44] The greatest failure of error is the failure to learn from it.

Gawande in an article in *The New Yorker* describes a surgical peer review exercise and the limitations of this process. He admits that he had made a serious medical error, but he was not obligated to face the peer review committee directly and the committee did not deal directly with the error itself in any remedial way.[45] Under the heading of 'the banality of injury', Gawande acknowledges that medial error is ubiquitous and makes the point that medical error is *not* the province of a select few culprits as common wisdom suggests. He avers, 'There are no "incompetent, unethical, negligent few", no basket of "bad apples" that conspire to taint all of medicine'.

Sometimes, however, peer review meetings may not be cordial and the meeting may become the venue for limitation of privileges or dismissal. Here, the purpose is not educational or remedial but political or economic, described under such appellations as 'economic credentialing' or 'sham peer review'. At these times, generally, hostility may prevail, the

physician will have a lawyer present, and the battle will be joined. It is the law, not medicine, that must safeguard due process in these cases. If it can be shown that the peer review process was being used for purposes other than those related to medical care, the deliberations of the committee may no longer be protected. In either circumstance, it is an expensive, unsatisfying experience for which physicians have little appetite – whatever the outcome.

There is evidence that the knowledge of an adverse outcome (hindsight bias) may cause the peer review committee, like the expert in a malpractice case, to criticize retrospectively the decisions of the treating doctor.[46–48] While it might be better to withhold outcome information in both circumstances, it seems neither practical nor enforceable. While a 1988 study of anesthetic mishaps from a national database found strong agreement among anesthesiologist reviewers,[49] a later study about on agreement among anesthesiologists assessing 12 actual malpractice cases whose verdict was known has implications both for malpractice and peer review.[50] Here, the intraobserver agreement among observers was high (> 80%). Of the eight cases with complete or virtually complete agreement between respondent anesthesiologists, three (37.5%) disagreed with the verdict rendered by the actual juries. In addition, anesthesiologists showed significant disagreement (> 30%) among themselves in four of the case scenarios, indicating there may not be agreement regarding the standard of care in these clinical circumstances. Finally, anesthesiologists predicted jury verdicts poorly, with success rates of 50% or less in 7 of the 12 case scenarios. It should be pointed out that these reviews are usually parochial matters for only rarely does the peer review evaluation benefit from information obtained from the patient or in the hospital review, from bona fide experts in the field. These potential sources of enlightenment are available in the courtroom.

While there are correlations between the risk of lawsuit and such features of character as medical school prestige, physician intuition, gender, and even the apparently perverse inverse relationship between current medical knowledge and the likelihood of being sued, the fact is that most obstetricians are sued at least once in their professional life.[51] Repeat offenders may sometimes occur, but are not a common problem. As Gawande poignantly asks, 'How do we keep good physicians from harming patients?' He and others invite the inference that it is not the peer review process that can accomplish this, in part because of the dynamics mentioned above, but also because the contributing causes to adverse events are often not detected by current medical review processes.[38] We may also ask, what is the value of either peer review or even malpractice suits in improving care?[38,45]

A study (generally known as the Harvard study) commissioned by New York State in 1986, and released in 1990, showed that although actual malpractice is relatively rare, it is nevertheless underreported. If anything, the study group believed that there were too few lawsuits.[52–54] Further, they wrote, 'Physicians tended to equate a finding of negligence with a judgment of incompetence. Thus, although willing to admit that 'all doctors make mistakes', physicians were often unwilling to label substandard care as negligent and were opposed to compensation for iatrogenic injury. Given medicine's delayed response to the problem of medical error, including the limitations of peer review, the public's only alternative therefore was for individual patients to try to hold individual practitioners, one at a time, to whatever medical standards could be upheld by lawyers and expert witnesses.[55] It may be true that to 'address the problem of iatrogenic injuries seriously, we must reform the system of malpractice litigation'. What seems equally true is that the problems of iatrogenic injury and physician conduct cannot be contingent on changing the tort system alone.

The role of the physician

These complaints about the system also serve to camouflage the physician's role in the genesis of malpractice suits. 'It has been estimated that, the risk of lawsuit "seems not to be predicted by patient characteristics, illness complexity, or even physicians' technical skills". Instead, risk appears related to patients' dissatisfaction with their physicians' ability to establish *rapport*, develop trust, provide access, administer care and treatment consistent with reasonable *expectations*, deal effectively with conflict, and *communicate* effectively'.[4] In an article by Hickson *et al.*, patients who saw physicians with the highest number of lawsuits were more likely to complain that their physicians 'would not listen or return telephone calls', were 'rude', and 'did not show respect'.[2] Such complaints, furthermore, were similar to those documented in interviews with families who sued their physicians. Patients are less likely to sue (about 50% less) even for moderate and severe mistakes if the physician informs them of the mistake (basically, apologizes).

For the reasons mentioned above, physicians are untrained in the art of apology. It may seem counterintuitive for many physicians that one can accept responsibility for an outcome without admitting blameworthiness.[56,57]

In an analysis of 500 claims in obstetrics and gynecology, B-Lynch *et al.* show that 46% were misguided allegations and about half were due to incompetent care, an error of judgment, lack of expertise, poor supervision, or inadequate staffing. The other half were due to poor communication and 'misguided allegations', for which they recommend an alternative course of dispute resolution combined with improved communication.[58] Parenthetically, the more time the physician spends with a patient the greater is the satisfaction of *both* patient and physician.[59] In a survey reported by the ACOG,

Table 22.2 Malpractice-induced activities (from ACOG, 1990)

Modality	Percentage
Testing	76.2
Monitoring	73.3
Documenting	72.2
Informed consent	61.6
Consulting MDs	58.0
Patient information	51.2
Referrals	47.2
Staff presence	21.8

physicians reported wholesale changes in their practices (Table 22.2) and their fees as a result of malpractice suits – including greater consultation with the patient.[60]

In 1997, a highly publicized article recommended that when doctors make a mistake that harms a patient, they should tell the patient what happened, apologize, and do whatever it takes to repair the damage.[61] Basic professional ethics aver that patients have a right to know what happened to them. It seems like the right thing to do as part of the physician's responsibility to his patient and it may be therapeutic for the physician who may feel guilt and distress. Telling the truth may also strengthen the patient's faith in the doctor while a cover-up that fails, as many do, may anger the patient and make him/her more inclined to sue. Cover-ups also antagonize juries. Medicine is a human enterprise and error (i.e. fallibility) is part of being human. 'We are programmed for error'.

Understandably, the notion of admitting error has drawn skeptical review from the medical community, the insurance companies, and the defense bar.[62] They fear that admitting mistakes will 'open the floodgates' to lawsuits and hurt their reputations and careers. They fear also that without tort reform to decrease the number of malpractice suits and large settlements, and to reduce the punitive implications of existing reporting, few doctors could risk owning up to errors. The notion that telling the truth, apologizing, and reaching out to a family in grief can defuse some of the anger and polarization that characterize a typical lawsuit becomes hostage to the notion that every word you utter in consolation or contrition is an admission that can be used against you in a court of law. On top of that, defense lawyers then order doctors to say nothing until all the facts are in, and then to say nothing. It seems obvious to state that until legislative protections maintaining such admissions are enacted, it is very likely that lawyers will continue to order doctors to say nothing until all the facts have been ascertained through discovery, and then to say nothing. But is this a medicolegal problem, or is it an ethical problem?[61,63,64] Baldwin suggests that increased levels of moral reasoning may diminish the risk of malpractice suit,[65] making legislative protection unnecessary.

The Joint Commission on Hospital Accreditation (JACHO) standards require the disclosure of sentinel events and other unanticipated outcomes of care to patients and to their family members when appropriate. Hospital administrators, fearing medical liability suits, are reluctant to comply with this standard.[66] If disclosure is taken a step further to the offer of an apology, hospitals and physicians are even more likely to gravitate to traditional 'defend and deny' behaviors. Apology as it turns out is yet one more control that physicians exert over the risk of lawsuit. Thus, a prompt explanation of what is understood about what happened and its probable effects; assurance that an analysis will take place to understand what went wrong; follow-up based on the analysis to make it unlikely that such an event will happen again; and an apology will likely reduce the risk of lawsuit and heal, rather than harm, the physician-patient relationship.[67] In fact, a growing number of hospitals, doctors, and insurers have come to accept that genuine disclosure and apology may reduce error-related payouts and the frequency of litigation.[9,59,68,69] Further, a growing number of states are passing ('I'm sorry') laws that protect an apology from being used against a doctor in court.[68] Despite the ethical imperatives underlying such disclosure, it seems likely that more such fundamental protections will be needed before these practices become commonplace.

Common areas of litigation during labor

General problems relating to litigation in medicine include documentation, communication, institution of a chain of command, or internal systems conflicts, when there are unresolved disagreements between individuals, departments, and all levels of health care providers, such as between physicians and nurses or physicians and administrators. Of most concern are the attitudinal problems involving the interaction of nurses and physicians, which receive too little emphasis and are particularly difficult to change. Their potential serious impact on the ability of an obstetrical unit to provide 'high-reliability care' has been discussed at length by Simpson and Knox.[70] Of the many specific types of cases, only some will be briefly discussed here: (1) the failure to properly interpret fetal monitoring tracings, (2) the poor conduct of operative vaginal delivery, (3) the management of the large infant and shoulder dystocia resulting in either in brain damage with death or subsequent CP, or (4) the infant with brachial plexus injury (sometimes both).

Along with the measures taken by physicians in response to the threat of malpractice (Table 22.2), the profession, especially obstetrics, has embarked upon a series of defensive 'scientific' initiatives to *modify*

its vocabulary and its accountability. Defensive medicine is a practice designed not for the purpose of answering clinical questions or directing therapy, but for the purpose of preventing lawsuits or counteracting plaintiff testimony in court. The ACOG, for example, has recommended the elimination of such universally applied terms of art as 'fetal distress', 'perinatal asphyxia', and 'stat cesarean section' and have modified the definitions of 'low-' and 'mid-forceps'.[71–73] Further articles have created definitive, unyielding requirements for the diagnosis of birth-related injury and suggest that labor related injury is rare and perhaps irreducible.[74]

Irrespective of motivation, these publications have not been accompanied by any decrease in lawsuits, any improvement in outcome, or any less defensive posture on the part of the obstetrical community. These efforts to make our specialty 'fair of speech' and litigation-proof discount important mechanisms of injury, diminish notions of medical judgment, inhibit scientific inquiry into the timing and mechanism of fetal injury, and delay the testing of new paradigms for dealing with adverse outcome. These articles attempt to influence the defense in these cases in several ways. An inexperienced lawyer may turn down a meritorious case because, as the guideline states, 'It is not possible to ascertain retrospectively whether earlier obstetric intervention could have prevented injury or cerebral damage in any individual case where no detectable sentinel hypoxic event occurred', or because the umbilical artery pH was > 7.0 despite obvious injury during labor or delivery. In addition, by insisting that extreme derangements in pH values are required to begin to make the correlation between labor events and subsequent neonatal injury, these criteria modify the level of proof normally required in malpractice suits. The burden of proof in these suits requires that the level of confidence in the relationship between the events and the outcome be more probable than not. It is well to compare these pronouncements with a widely respected authority of neonatal brain injury.

> Brain injury in the intrapartum [period] does occur, [it] affects a large absolute number of infants worldwide … and represents a large source of potentially preventable neurological morbidity. Among the many adverse consequences of the explosion in obstetrical litigation has been a tendency in the medical profession to deny the importance or even existence of intrapartum brain injury. (Volpe, *Neurology of the Newborn*, 3rd ed., 1995)

These issues have also been discussed at some length for the brain-damaged infant[75,76] and for brachial plexus injury.[77]

Fetal cardiotocography (CTG)

In part, because of the pivotal role it plays in malpractice cases, there have been attacks on fetal monitoring that have come both from within the profession and from without. In an article in the Stanford University Law Review, Margaret Lent, a young defense lawyer, argues that the widespread use of electronic fetal monitoring (EFM) is both medically and legally unsound.[78] Ms Lent points to selected clinical trials to demonstrate that EFM does not reduce fetal mortality, morbidity, or CP rates. She argues that because EFM has a very high false-positive rate and its usage correlates strongly with a rise in cesarean section rates so that it offers no medical advantage over auscultation. Similarly, she argues, EFM provides no protection in the courtroom. Though obstetricians believe that they should use EFM because its status as the standard of care will protect them from liability, Ms Lent argues that given its failings it may in fact expose them to liability. She further argues that auscultation, at least as safe and effective as EFM, is also more likely to protect physicians from liability. Ms Lent concludes that obstetricians have an obligation to their patients and to themselves to adopt auscultation as the new standard of care. She finds 'no excuses left to defend the continued use of EFM'. The medical literature can be used to justify any position on monitoring, including those of Ms Lent. Thus, it may be shown that CTG increases the risk of CP and that 'substandard care' protects against subsequent CP.

While failure on the part of the health care provider to recognize clear fetal heart rate abnormalities is frequently alleged in malpractice cases, to isolate the CTG tracing under these circumstances frequently oversteps its permissive role in obstetrical care. A normal CTG pattern permits ongoing labor *only* as long as safe vaginal delivery is a reasonable option. If the pattern turns abnormal (rising baseline, decreasing variability along with variable/late decelerations), especially in the second stage, then the questions are several. Can the pattern be ameliorated (by reducing the oxytocin, moderating the pushing efforts)? If the pattern cannot be ameliorated what is the feasibility of safe vaginal delivery given the estimated fetal weight, previous obstetrical history, position, presentation of the fetal head, and progress in labor to this point? Experience suggests that the vast majority of cases hinge far more on the reasonableness of the conduct of obstetrical care (especially the second stage) than on the interpretation of the fetal monitor. Regardless, reviewers of malpractice cases consistently find that the CTG tracing has been frequently misinterpreted in allegations of negligence.[79]

The legal climate

Most changes in both the medical and the legal professions are evolutionary and it is often difficult to define any sea change. The last three decades, however, have witnessed a number of remarkable and

epochal changes in the medicolegal climate in the United States, with doubtless more to come. Many of the changes derive from periodic surges in malpractice premiums, reduced availability of insurance coverage, and the exodus of major insurers from the market first in the early 1970s, again in the mid-1980s, a lesser event in the 1990s, and more recently in the new millennium. In each epoch, affected providers clamored for policy changes to inhibit litigation.[80] In the 1970s, legislatures established joint underwriting associations to serve as insurers of last resort,[81] special state patient compensation funds were introduced to absolve commercial insurers of responsibility for specified dollar portions of malpractice payments, and public reinsurance mechanisms were established to fill gaps in the underwriting market. By the late 1970s, the malpractice crisis had abated – only to recur less than a decade later. In Washington State between 1984 and 1986, for example, malpractice premiums for obstetrics jumped approximately 100%. As a consequence, obstetricians marched on legislatures or joined many family physicians and midwives in an exodus from obstetric practice. Those remaining in practice became more reluctant to care for high-risk obstetric patients and less willing to accept indigent patients and reduced fees, irrespective of the fact that indigent patients, in fact, appear less likely to sue.[82] In many rural areas across the United States obstetric care became virtually unobtainable. Periodically, these circumstances galvanized legislative activity in virtually every state and led to further far-reaching reforms of existing tort and insurance law[83,84] with some stabilization of premiums – at least initially. After almost a decade of essentially flat premiums, premiums are rising exponentially, which is said to be due to the increasing size of awards and insurers leaving the medical malpractice business because of diminishing returns on investment. This has been aggravated by rising health care costs ($1.6 trillion in 2002 and increasing yearly), and efforts to control physician income. The average annual increase in health care costs from 2000 to 2004 was 12–16% with predictions that, whether or not the result of negligent care, they will rise by a further 8% in 2005, with likely little containment beyond that.[85]

It is important to emphasize that premium levels are responsive to a variety of factors besides litigation dynamics, including previous losses, past and expected investment returns, business strategies, and the degree of state regulation of rate changes.[86] A January 2004 study found that nationwide, average premiums for all physicians between 2000 and 2002 rose by 15% – a rate of rise almost twice as fast as per capita total health care spending. Certain specialties had even greater increases, including obstetricians/gynecologists (22%) and internists and general surgeons (33%).[87] Neurosurgeons, obstetricians, orthopedists, and emergency room physicians are particularly likely to have premium rate increases. The rates for obstetricians/gynecologists vary nationally, but according to ACOG, between 2002 and 2003 about half of obstetricians/gynecologists were experiencing increases of 10–49% in their insurance premiums.

Premiums may influence physicians' decisions to join and leave the labor force, their choice of a medical specialty, and their decision of where to locate, creating the potential for undeserved patient populations in certain specialties or geographic areas. Rising malpractice premiums may also encourage physicians to practice 'defensive medicine', performing more tests and procedures than necessary in order to reduce exposure to lawsuits. Parenthetically, however, defensive medicine (ordering a test not for the purpose of furthering patient care, but for the legal protection of the physician) is indefensible in court. Imagine the physician-defendant responding to a question about the indication for a certain test with the answer: 'I didn't want to get sued'. Both rising malpractice premiums and defensive medicine practices may contribute to the rising health care costs and thus to an increase in health insurance premiums.

The choices for the obstetricians – short of some windfall protection scheme – are leave practice, move to a 'more compliant' state, give up obstetrics, obtain employment where malpractice insurance is provided, raise fees, discontinue seeing patients with restrictive payment structures, or go bare, i.e. do not obtain any malpractice insurance. For many, there is no good option and their future will hinge on the least inimical choice. Beyond physicians, these rapidly rising medical malpractice premiums have again become an issue of increasing concern about the health care system for policy makers and the general public.

Underwriter data claims payments

The insurance industry also has its problems. In 2003, insurers were paying out in claims and expenses $1.38 for every medical malpractice premium dollar collected. (National Underwriter Data Services). Results have deteriorated steadily from 1998, when the rate of return was −7.6. Medical malpractice insurers' return on net worth was −7.4% in 2002, down from −4.7% in 2001.[88] Results in 2002 were the worst in the following states: Arkansas, Nevada, Montana, Mississippi, Illinois, and Missouri, with a return on net worth ranging from −33.7% in Arkansas −24.4% in Missouri. In reality, even in the good years, premiums rarely cover payouts. The system works in part because premiums are invested and with at least a modest return permit the insurance company to make a profit. This is abetted by the fact that malpractice suits, especially, take a long time to resolve – about 4 years on average.

The average claim payment rose almost 8% per annum from $95,000 in 1986 to $320,000 in 2002

despite the fact that the frequency of claims per 100 doctors has remained more or less constant. Only about 30% of claims result in insurance payouts, but expenses for cases, especially obstetrical (brain-injured baby cases), where there is no payout are considerable[18]. Concurrently, insurance companies, along with the population at large, faced reduced income from investments to help offset underwriting losses.

Another study in 2004 found that hospital professional liability and physician liability claims costs have increased at a steady 9.7% since 2000 and are likely to rise at the same rate in 2004. Frequency, or the number of claims, is growing at 3% a year; claim severity (the dollar amount) is increasing by 6.5% annually. Hospital liability claim costs for 2004 are expected to reach almost $150,000 per claim, compared with $79,000 per claim in 1996. The average claim against a physician is expected to reach $178,000, compared with $120,000 in 1996.[89]

Jury awards and settlements

In early 2005, a Towers Perrin study found that over the 28 years since 1975, when they were first identified separately, medical malpractice cost increases have outpaced those in other tort areas, rising at an average of 11.8% a year, compared with 9.2% for all other tort costs. In 2003, medical malpractice, at almost $27 billion, cost each American an average of $91 a year. This compares with $5 a year in 1975.[85] Recent data suggest that while jury awards are stabilizing and the frequency of claims may be decreasing, the severity of malpractice claims is increasing and the range of awards is moving upward.[89] Median medical malpractice jury awards have held steady at about $1 million over the 3 years 2000–2002.[90] Awards ranged from a low of $11,000, almost double the amount of the previous year, to a high of $95 million. The average award in 2002 hit $6.25 million, up from $3.91 million in 2001. However, only a small fraction of cases go to trial and very large awards are frequently reduced after the fact and after the publicity.

The costs of perinatal injury are quite high, relative not only to the costs of settlement and defense but also to personal and professional upheaval for all concerned. As Simpson and Knox have pointed out,[70] the perspective of human and system factors reveals themes, context, and conditions common to accidental injury in other high-risk domains. According to the Jury Verdict Research, in 2000 the median jury award for neonatal neurological injury had increased to $5 million compared to $725,000 in 1994, with 76% of the jury awards valued at greater than $1 million (compared to 40% in 1994).[90] Higher awards were more likely to occur when the hospital was the sole defendant than when both were defendants.

Conventional wisdom holds several contributing factors to account for the increased incidence of malpractice claims. (1) People are more litigious; it is part of our culture and extends everywhere from lawyers themselves to city governments. (2) Given the media coverage and watchdog groups, there has been an increasing understanding by the public of the fallibility of physicians. The Public Citizen Health Research Group, and the more recently formed groups emphasizing both medical error and the need to improve care as part of tort reform, have also helped fuel the public's demand for change.[34] (3) Another factor is the diminishing intimacy of the patient-doctor relationship fomented in part by larger changes in the way health care is distributed (HMOs), by increasing overhead and by deteriorating reimbursement schedules. (4) Then, there is the increasing availability of medical experts to testify in malpractice cases (the breakdown of *omerta)*. (5) Also, there is the increasing assertiveness of the courts and the increasing sophistication of the plaintiff's bar with more careful selection of meritorious suits. (6) Last, there is the need for assistance with financing medical bills. Indeed, there is a seeming increase in the frequency of lawsuits for the 'damaged child', in part due to the large verdicts sometimes realized but also due to the increasing incidence of CP related to the increasing survival of low birth weight infants and the costs thereof.

Several clinical practices and media attention would seem also to be impacting on the frequency and type of lawsuit. As an example, the United States Food and Drug Administration (FDA) issued a national advisory on the risks of vacuum extractors.[91] This was rapidly followed by a nationwide television program emphasizing some of the disastrous results with vacuums. In turn, there has been a dramatic increase both in the reporting of adverse events associated with vacuum deliveries to the FDA and in the number of lawsuits alleging negligent care in the use of vacuums. Similarly, the methods undertaken to lower the cesarean section rate in the United States have perhaps been accomplished at the expense of an increased risk of ruptured uterus, shoulder dystocia, and lawsuit.[92] While all authorities would agree that any woman with one previous cesarean section and no other adverse features may be eligible for an attempt at VBAC – if she chooses to do so after being carefully explained the options, some HMOs have refused to accede to the mother's choice and have required that *every* patient with a previous cesarean be given a trial of labor – a horrific, medically indefensible recommendation. One institution in California that adopted this policy was assessed almost $25 million as a result of 48 women who suffered adverse outcome as a result of this policy.

Prevalence of medical malpractice

When hospital medical records from New York State were examined as part of the Harvard study, the

incidence of adverse events or injuries resulting from medical 'interventions' or treatment was 3.7%. The percentage of adverse events due to what the physician team characterized as 'negligence' (not necessarily a legal definition) was 1%. However, only one in eight who suffered from an adverse event due to negligence filed a medical malpractice claim, and only 1 in 15 received compensation. Most adverse events resulted in only minimal and transient disability and most of the patients' medical care expenses were paid for by health insurance. This helps to explain why only a small percentage of patients who are injured as a result of negligence file medical malpractice claims. However, a significant proportion (22%) of patients who did not file medical malpractice claims suffered moderate or greater incapacity. In the second phase of the study, researchers confirmed that some of the tort claims filed provided little or no evidence of medical malpractice or even an adverse event, suggesting that the tort system is 'very error-prone', at least in its initial stages (related to the expert). This inefficiency in both the medical and the legal systems, notwithstanding, the study noted that 'if anything, there are too few lawsuits'. The inference here is that more patients with adverse outcomes related to negligence should be suing.[52,53,93,94]

There are several studies of closed claims in obstetrics and their relationship to negligence or their adherence to guidelines. Julian *et al.* reviewed the files of 220 obstetric closed-claim cases to identify common factors predisposing to claims and to suggest preventative measures.[95] Identification of common obstetric risks and correct management of these risks was poor in these cases. Only 54% of the risks were recognized; of these, only 32% were correctly managed. A high percentage of risks were thought to be directly related to the obstetric outcome leading to the claim (66%). The authors feel obstetric closed claims can be studied and suggestions made to aid obstetricians in providing care. They concluded that obstetric malpractice closed claims are amenable to study; physicians and their patients would benefit from better data collection systems to identify risks in individual pregnancies, along with available resources to aid their management of patients. They felt that suits can be avoided through modification of physician behavior.[95]

In 1989, Rosenblatt and Hurst reviewed all closed obstetric claims in the records of a major physician-sponsored malpractice insurer from 1982 to 1989.[96] Of the 54 files closed during the 6.5-year period covered by this study, 21 (39%) involved physician reports of bad outcomes that did not lead to a formal claim. Of the 33 formal claims, 14 (42%) were dismissed, either by the plaintiff's attorney or by the courts. Eighteen of the remaining 19 claims were settled before trial, with an average payment to the plaintiff of $185,000. The one suit that went to trial resulted in a defense verdict. A review of the case histories demonstrated that in the majority of cases when a payment was made, probable medical negligence had taken place. Non-meritorious claims were not compensated. For those cases in which a payment was made, the size of the settlement was commensurate with the seriousness of the injury, which almost always involved damage to the infant. Poor physician judgment was the most common source of error.[96]

The surviving, handicapped infant continues to represent the highest payout/case. There are numerous representative reviews of closed cases (Table 22.3). An analysis of 353 closed claims involving obstetrician-gynecologists revealed that the 40 highest-paid claims (11.3%) accounted for 88.7% of the total dollars spent. The majority of these 23 (57.5%) were obstetrical, including the five highest claims and 17 of the first 20 highest-paid awards. Obstetrical negligence represented over $5 million (76.5%) of the total expense. Of the 40 cases, 23 (60%) were resolved with a compromise settlement, 9 claims (22.5%) were resolved with indemnity payment on the basis of verdict or pretrial compromise; 7 (17.5%) had no indemnity payment because of a jury verdict or voluntary dismissal. These seven were in the highest-paid claims group only because of expenses.[91,96]

Of the 40 cases, none were considered frivolous, 28 (70%) were judged to be meritorious, and 12 (30%) were judged to be non-meritorious. Seven of the latter settled without indemnity costs, including four that went to trial with a defense verdict and three that were dismissed, leaving five others in this group with proper treatment and indemnity costs. Expenses to defend all 12 cases of proper treatment totaled over $500,000. Irrespective of the absence of strict negligence, each of these 'non-meritorious claims' illustrated substantial deficits with the medical record or system failures – inviting the allegation of negligence and lawsuit (making the case appear meritorious). These analyses clearly reveal that bad outcomes may not be the fault of the physician, but that physician behavior in the conduct of the case and the conduct of the medical record contribute heavily to successful allegations of malpractice.

Ogburn *et al.* reviewed 153 closed claims involving perinatal injury or death filed from 1980 through 1982 with the St. Paul Fire and Marine Insurance Company.[97] The claims included were those in which an indemnity was paid or $1,000 or more was expended on the legal defense. Cases were classified according to the presence or absence of medical negligence. Most of the complications leading to claims arose during labor and delivery. Many claims resulted from the failure to evaluate or treat in a manner consistent with accepted standards of care. Many lacked documentation of the physician's recognition of the risk factors involved. In the opinion of the reviewers, medical negligence occurred in 47% of the cases. Indemnity payment occurred with most (but not

Table 22.3 Operative delivery notes

Operative delivery note (A)

Op del note:

MF, OP≫OA, mid epis, no lac

Apgar 8, 9 P and M intact

EBL 400, M and B left DR in good cond.

Signature

Translation:

Operative delivery note:

Midforceps, occiput posterior (OP) to occiput anterior (OA), midline episiotomy, no lacerations

Apgar scores 8, 9 at 1, 5 min. Placenta and membranes expressed intact

Estimated blood loss 400 ml. Mother and infant left the delivery room in good condition

Operative delivery note (B)

Procedures: *Trial of forceps, midforceps rotation, episiotomy repaired*

Findings: *Gyneocoid pelvis, normal active phase, +3 station, minimal molding, direct OP, epidural anesthesia, second stage = 2.5 h, pushing inadequate, patient tired*

EFW = 3000. Prev. baby = 2800

Indications: *Persistent occiput posterior, prolonged second stage, secondary arrest of descent, tired patient*

Informed consent: *Discussed options with patient and husband, who agree and understand that if any difficulty is encountered, the forceps will be abandoned and cesarean section undertaken*

The operating room has been alerted

Methods: *Midline episiotomy Kielland forceps. Direct application to OP without difficulty*

Gentle rotation: ROT to OA. Kiellands removed, Simpson forceps applied. Gentle traction – delivered as OA

Fetal outcome: *3200-g male infant, APGAR 8, 9 (see individual features in chart)*

Resuscitation: *Oxygen only, no evidence of trauma to skull forceps, marks reveal appropriate placement*

Maternal outcome: *Perineum intact, episiotomy repaired, no lacerations. Placenta and membranes intact. Estimated blood loss: 300 cc*

Mother left delivery room in good condition

all!) of the claims judged to be associated with medical negligence. Payment to the claimant was also made in a number of cases in which the reviewer thought no malpractice had occurred. The authors concluded that these results suggest that improvements are needed in prenatal and perinatal health care as well as in the legal system used to address the problem of perinatal medical negligence.[97]

In a study published in 2003, Ransom et al, tried to estimate whether guideline compliance affected medicolegal risk in obstetrics and whether malpractice claims data can provide useful information about compliance.[98] From the claims experience of a large health system delivering approximately 12,000 infants annually, they retrospectively identified 290 delivery-related (diagnosis-related groups 370–374) malpractice claims and 262 control deliveries between 1988 and 1998. Clinical pathways for vaginal delivery and cesarean section, implemented in 1998, were used as a standard of care. They compared rates of non-compliance with the pathways in the claims and control groups. They found that non-compliance with the clinical pathways was significantly more common among claims than controls (43.2% vs. 11.7%, $P < 0.001$; odds ratio = 5.76, 95% CI 3.59, 9.2). In 81 (79.4%) of the claims involving non-compliance with the pathway, the main allegation in the claim related directly to the departure from the pathway. The excess malpractice risk attributable to noncompliance explained approximately one-third (104 of 290) of the claims filed (attributable risk = 82.6%). They concluded that malpractice data are a useful resource in understanding breakdowns in processes of care and that adherence to clinical pathways might (1) reduce clinical variation, (2) improve the quality of care, and (3) protect clinicians and institutions against malpractice litigation.

A study by Greenwood *et al.* from the National Perinatal Epidemiology Unit, Oxford, United Kingdom compared the prevalence of criteria suggesting acute intrapartum hypoxia in children with CP according to whether a lawsuit was brought alleging obstetrical negligence.[99] The subjects were singleton children with CP born between 1984 and 1993, excluding cases with a recognized postnatal cause for CP. Only one-fifth (27/138) of all singleton CP children were the subject of a lawsuit. The greater the number of criteria suggesting intrapartum insult the more likely was a legal claim ($P < 0.01$), but 36% (4/11) of those satisfying all required criteria did not make a claim. Of the 27 claims, 12 were discontinued, 8 were settled, and in 7 the legal process was still pending at the time of writing the article. Furthermore, the presence of the three essential criteria for acute intrapartum hypoxia did not increase the likelihood of a legal claim being settled.[99]

Other studies have focused on the costs and outcomes of litigation but not on culpability.[18] Closed claims provide valuable data, but because, on average, a medical liability case takes 3–5 years to come to closure,[86] opportunities for timely intervention in unsafe practices are lost. The research value is further compromised when the details of cases that reach settlement are suffocated by 'gag clauses' that mandate silence not only on the amount of award, but also on the allegations and the admission or even acknowledgment of wrong-doing, thereby removing

an obvious incentive to make care better. Hatlie and Sheridan have suggested that gag orders are counterproductive.[34]

Medical records

Unfortunately, the opinions that serve to launch medical or medicolegal proceedings are most often based on a review of medical records that are frequently silent on the intentions of the provider or their exercise of 'medical judgment'. They may be silent, as well, on fundamental details of the obstetrical care. As a result, medical records, which represent both a medical document and a legal document, often promote or perpetuate cases and confound their defense. A cost analysis of 3205 multispecialty claims showed an average cost per claim of $22,584.[100] Deficits in the medical record, e.g. inadequate instructions, delayed entries, inadequate notes, and consent-form issues, more than double the average cost. System failures nearly triple the average cost. Thus, while an erroneous decision may be defensible if the reasons leading to it are recorded in the chart, the changed record and the contradictory record are almost impossible to defend. Until medical records objectively communicate the findings, the attention paid, the comprehension that was achieved and offer a reasonable plan followed by appropriate and consistent action, their appearance in court will continue to be an uphill battle for the physician and he/she will get little credit for the thought process or use to his/her advantage the testimony of 'a witness whose memory never dies'.

As an aside, the reader is invited to compare the two enclosed notes regarding a midforceps procedure (Table 22.3). In the first example, the note invites lawsuit if there is an adverse outcome. The note provides no indication for, or details about, the procedure. It is more a personal memorandum than a responsible medical description relevant for decisions about care in future pregnancies, for example. The second note, on the other hand, would seem to protect against lawsuit in several ways. The note (1) clearly bespeaks thoughtfulness, (2) bespeaks understanding of the medical issues and alternatives, and (3) underscores the physician's efforts to provide a forthright explanation to the patient and her husband – all powerful disincentives to lawsuit. Naked may be the best disguise!

One can readily blame the plaintiff's attorney for bringing to suit an apparently frivolous case, but who is to blame (i.e. what has been learned?) for the negligent care and adverse outcome in situations where no suit is brought despite negligent care or where no award is made despite a suit, and the physician's care is vindicated? Should the plaintiff's attorney be blamed for pursuing a case that his expert has told him, based on a review of the medical records only, is negligent care? Each of the articles that evaluated closed cases found appreciable amounts of agreed upon negligent care. Each emphasizes (1) the need for better data, 2) the inculpating role of physician behavior, and 3) the importance of the review of malpractice claims to identify problem-prone clinical processes and suggest interventions that may improve outcome and reduce negligence.[101]

It must be readily apparent from even these limited studies that not all meritorious suits succeed and not all non-meritorious suits (not the same as frivolous) lose. These articles leave it open to speculation why patients victimized by obvious medical negligence do not sue or why they are not compensated by the system in the face of agreed upon negligence. Clearly, patients without demonstrable evidence of negligence bring suit and sometimes they are rewarded in the system. The system does not work perfectly, but these studies from various specialties and perspectives strongly suggest that it is not a lottery. Given the non-medical issues that incite or color a case, physicians squander much of the advantage they have in the system! Thus, it is with some justification that critics of malpractice litigation point out that it is unrealistic to expect that increased levels of litigation will make compensation for injuries more 'just' or health care better. A *reductio ad absurdum* argument suggests that immunity from lawsuit, perhaps the true goal behind physicians' notion of tort reform, will, by eliminating lawsuits, achieve these goals. Some conventional tort reforms appear to be effective in reducing litigation costs and stabilizing insurance markets; they are not, however, designed to remedy the fundamental failings of the malpractice system – making care better and making the physician–patient relationship better. Fulfillment of these objectives may not require more sweeping tort reform; perhaps more sweeping 'thought reform' may be required or, alternatively, trying to make the system work as it was supposed to. These reforms can only come from the medical community.

Legal vulnerability

The last several decades have also witnessed the development of new bases for lawsuit in reproductive matters, including wrongful birth and wrongful life. In the former, the parents with an injured child may bring suit alleging that negligent treatment or advice deprived them of the opportunity to avoid conception or terminate a pregnancy. The latter, brought on behalf of the child born with birth defects, alleges that the child would not have been born but for negligent advice to, or negligent treatment of, the parents. It should be emphasized that such allegations are actionable in some states but not in others. While not strictly related to malpractice, a mother who pleaded with her hopelessly premature infant's caretakers to discontinue resuscitation was not heeded, resulting in the survival of a severely handicapped child and a provisional $42 million verdict for the plaintiff.

Tort reform measures

Most liability reform acts have four major components: (1) reforms directly addressing the size of awards – under the heading of caps on damages; (2) reforms intended to modify liability rules, to control the number of claims and size of payouts by eliminating joint and several liability for cases in which a plaintiff found to be partially at fault becomes responsible for a disproportionate share of the damages; 3) reforms limiting access to the courts, through shortening statutes of limitation – a reduction in the length of time during which lawsuit can be brought; and 4) periodic payments – the latitude to pay future economic damages over time. Some initiatives have legislated review panels to pass on the merit of a case prior to the institution of suit, while others have attempted to remove the infant who is brain damaged during birth from the medicolegal arena by the institution of no-fault insurance. Still other initiatives have attempted to increase the percentage of any award that goes to the patient by limiting the attorney's fees.

The most popular of these, caps on premiums, have had the benefit of moderating the increases in insurance payments. A publication from the Rand Corporation has emphasized that in cases with modest claims there is indeed a reduction in indemnity payouts, but they cast doubt on the likely benefit of caps on the high-award cases where economic damages are large and 'pain and suffering' may be much smaller. It seems axiomatic that caps should not apply to frivolous suits where the cap should be zero.[102]

In the 1970's 22 states legislated some form of prelitigation processes, including screening panels and mandatory binding and non-binding arbitration: only two remain active and neither has been effective. The costs of constitutional battles over due process rights for binding processes and the failed reduction of litigated cases in non-binding processes, led to further soaring legal costs, rather than reductions. The only lasting 'tort reform', although, as discussed later, with questionable material impact on malpractice frequency and awards, has been caps on non-economic damages, with the gold standard being that of California's Medical Injury Compensation Reform Act of 1975 (MICRA).[102]

Tort reform, the mantra of both the ACOG and the Bush administration to deal with high medical malpractice costs, makes sense only from the political aspect.[30] Capping awards on malpractice suits may offend trial lawyers, but it helps or holds harmless special interests in the insurance, drug, and health care industries. It provides no assistance to patients who suffer grievous harm as a result of negligent care nor does it improve the delivery of medical care. To many, a $250,000 cap (the cap placed on non-economic damages in California) is poor acknowledgment indeed for the physical and emotional damage done to people who have suffered total paralysis, permanent blindness, or severe brain injury because of medical errors. Indeed, many states burdened with high premiums have already set their own caps, but generally at more reasonable levels. It would seem more useful to consider making it harder for insurance companies to gain rate increases.

Guidelines for judges and juries might be enacted to help determine what compensation is reasonable in a given circumstance. Similar guidelines could help ensure that punitive damages, sometimes masquerading as non-economic damages, are high enough to deter bad conduct; $250,000 would hardly amount to a slap on the wrist.

The problem with frivolous lawsuits is best addressed by raising the hurdles for filing a malpractice suit, for example, requiring an expert judgment on the merits of a case before it can proceed through the courts. As mentioned above, there seems to be no place for the expert witness to certify a case as meritorious if that same expert will not appear on the record for (public) report, deposition, and trial if necessary.

The notion that the crisis of escalating malpractice insurance premiums is forcing doctors out of business remains murky. Insurance companies have substantially raised premiums for malpractice coverage for doctors in high-risk specialties like obstetrics and neurosurgery in some states, leading at least some doctors to curtail their services, retire, or move. But when the Government Accountability Office visited five of the hardest hit states in 2003, it found only scattered problems and was unable to document wide-scale lack of access to medical care.[86]

None of the tort reform proposals deal with the underlying need to diminish malpractice and to identify harmed patients and provide them with fair, prompt compensation, or provide tools for health care providers to properly prepare patients and deal effectively with unanticipated outcomes. Although, they do resolve the desire of the health care industry and the insurance companies for fewer big court awards, they do not materially impact the frequency of suit. But they do act as a rollback of the legal rights of patients who are injured.

The Center for Justice and Democracy, a consumer advocacy group, recently commented:

> It may be hard to understand why 'tort reform' is even on the national agenda at a time when insurance industry profits are booming, tort filings are declining, only 2% of injured people sue for compensation, punitive damages are rarely awarded, liability insurance costs for businesses are minuscule, medical malpractice insurance and claims are both less than 1% of all health care costs in America, and premium-gouging underwriting practices of the insurance industry have been widely exposed.

Despite claims by the insurance industry, there is no evidence that soaring malpractice premiums are the result of sharp increases in the amounts of money paid out for malpractice claims. And, tellingly,

industry executives have carefully acknowledged that tort reforms will not result in substantial premium reductions – only an improvement in care can do that.[30,103]

Caps do not limit lawsuits. More reasonably, caps are intended to increase the hurdles to a lawsuit by diminishing the economic value of a suit. In cases where there is little economic loss (irrespective of negligence), victims may not be able to find lawyers to take their cases (www.saynotocaps.org/newsarticles/WSJEffectof Caps.html) because malpractice cases can cost plaintiff's lawyers hundreds of thousands of dollars out of pocket to prosecute, with no guarantee of recouping those expenses. As pointed out by the Rand Corporation study, caps have little impact on lawsuits where there are substantial economic losses, e.g. brain-damaged infant, maternal death. A one-size-fits-all cap cannot encompass the unique facts in any case and, in fact, more reasonably creates a system of 'one-size-fits-none'.[102] It unfairly discriminates against victims with no economic losses, such as children, stay-at-home moms, the elderly, the poor, and the mentally handicapped. The media unflinchingly promulgates numerous cases of tragic, ineffable medical error where such arbitrary limits (originally set in 1979) seem inadequate and, if not inadequate, arbitrary.

Caps will not lower doctors' malpractice insurance premiums.(www.saynotocaps.org/reports/Premium Deceit.pdf: The Failure of Tort 'Reform' to Cut Insurance Rates) Average premiums are actually 16% higher in states with caps. In states that have recently adopted caps, most notably Texas and Florida, insurance rates are continuing to increase. Indeed the only thing keeping rates down in California – a state often cited as a model for caps – is insurance industry regulation provided by Proposition 103.

The amount of money awarded on pain and suffering is not known. In the majority of awards, those reached by settlement out of court, there is no distinction between economic and non-economic damages. In jury trials economic and non-economic damages are awarded separately, but there appears to be no calculation of either the amount or the propriety. Nor has there been any compilation of those extreme awards that are reduced, sometimes drastically, by judicial review. In three cases where the jury awarded over $220 million, the total cumulative amount received was $14 million (6 cents on the dollar!). There was no publication of the reduction! (Public Citizen.pdf.)[104] When adjusted for the sky-rocketing rate of health care inflation, total payouts in malpractice cases remained flat until 2001. In the 3 years since, total payouts have declined each year (newsarticle/LowerPayouts.htm).

Many states have enacted legal reforms that have effectively eliminated any lawsuits that could be construed as 'frivolous' by requiring a 'certificate of merit' from a physician certified in the same medical specialty as the doctor being sued. There have also been laws enacted to prevent 'venue shopping' for a more favorable jury. Indeed, a Republican state senator from Pennsylvania declared that 'There is no such thing as a frivolous lawsuit any more' in Pennsylvania. In addition, again in Pennsylvania, one of the 'red alert states', there has been a significant increase in the number of physicians over the past several years, prompting one state legislator to call such claims of a doctor exodus as 'scare tactics'.

It is far from clear that malpractice costs are driving up the costs of health care. Malpractice costs account for less than 2% of the U.S. health care budget. The Congressional Budget Office, in a report released in January 2004, found that legislation to cap damages in medical malpractice lawsuits would 'do little to hold down health care spending' or eliminate the practice of 'defensive medicine'. There is little evidence that the threat of malpractice lawsuits contributes to the practice of defensive medicine. Rather, it has been suggested that doctors order additional tests because it is good medical practice; doctors make money from additional testing; and managed care discourages unnecessary testing, or 'bad' defensive medicine.[86]

Faulty underwriting and misfeasance by malpractice underwriters are additional factors contributing to the rise in premiums. In Pennsylvania in the late 1990s, six major malpractice insurers became insolvent because of risky premium underpricing, poor investment strategies, and Enron-style malfeasance, leaving doctors to pay for their mismanagement (InsolvencySummary.pdf.).

There is no basis for the notion that insurance companies routinely settle lawsuits just to make them go away. This seems more like a strategy for self-destruction and is contradicted by the closed-claims data presented above (factsandfigures/fibsysfacts.html).

There can be little doubt that there is an immediate question of affordability that must be dealt with acutely. Indeed, several states have contributed significant amounts of public money to subsidize insurance premiums. Physicians remain the highest-paid professionals in the state, according to U.S. Census data. Indeed, the incomes of obstetricians – the physicians most affected by higher premiums – are rising. For many, on average, doctors spend 1–5% of their gross revenues on medical malpractice insurance. It seems obvious also that many doctors supplement their incomes with fees from attorneys for providing 'independent medical evaluations' in malpractice cases.

Alternative system reforms

Experts have suggested a number of approaches, including special health courts with judges trained to deal with malpractice issues, required mediation,

mandatory reporting of errors by doctors, and prompt offers of compensation. Some of these will be reviewed briefly here. Not strictly a part of tort reform, alternative dispute resolution has much to recommend it.[58]

The *strict liability (no-fault) administrative system* supports creation of a just patient safety culture and encourages reporting (and prevention) of adverse events. It has the advantages of dispensing with trial and supports open disclosure to the patient (not the public) as the deliberations are administrative. In this system the provider is accountable for all avoidable medically related losses and the matter can be resolved promptly. It eliminates the requirement of proving negligence, but the patient must establish that their injury was actually caused by the treatment. As a generalization, eligibility is based on avoidability rather than providers being strictly responsible for medically related losses. There is, unfortunately, the common perception that 'no-fault' means 'no accountability'. Examples include the Neurological Injury Compensation Association (NICA) in Florida and Virginia.[104–108]

Although, the system of No-Fault is modeled after that of Workers Compensation and Automobile No-Fault claims, the complexity of determining causal and avoidable injury medical injury claims is very different. And although it removes negligence as a basis for the claim, it does not replace the regulatory system of reporting and the resultant physician fear, nor does it address the inbred philosophy of 'do no harm', 'zero tolerance'. Since premiums in any no-fault system are based on injury rates, this creates an incentive to conceal injuries and reduce the admission of high-risk specialists to medical staffs. It may also discriminate against patients at high risk for injury. It is uncertain how the establishment of a no-fault system will impact cost. Some test programs have demonstrated that costs of a general no-fault system would exceed those of the present tort system. Finally, the introduction and administration of a no-fault medical injury system, whether public or private, will be complicated and likely politically encumbered.

Preventable events (ACEs) represents consensus on what constitutes an avoidable event.[106] These are predetermined events that should not occur in quality health care delivery. They encourage prevention of avoidable events that can trigger eligibility for an early compensation offer. ACEs make 'avoidability', and therefore eligibility for compensation, transparent to providers and patients alike. They standardize eligibility for compensation and provide quicker identification of eligible cases. There is, however, no comprehensive ACE list currently available, and there is concern as to who is to develop the categories of avoidable events. Brain-damaged infants, for example, would not be covered. Development of the list will, of course, require an array of expert consensus (selected by whom?). The use of ACEs provides a basis to determine eligibility for alternative and conventional compensation systems. It can also be paired with a standardized compensation fee schedule.

Mediation

Mediation represents a highly efficient option for non-adversarial resolution of health care conflicts. It is a process in which the parties to the conflict themselves, not lawyers, craft their own unique resolution to a conflict. Mediation is essentially facilitated communication and negotiation using a neutral third party. The process itself is non-binding and does not prevent the patient from moving forward to litigation. However, if a resolution is reached, it becomes binding under contract law and may even be brought as an order of the court. Mediation is highly cost-efficient and time sparing, in that it makes response to adverse events and their resolution more timely, and boasts a greater than 90% resolution rate. It is widely accepted and highly successful in many 'industries' such as real estate and education, but has met with much resistance in the health care industry, especially in medical malpractice. It intensifies the pressure on patients to settle, thus reducing or avoiding litigation. Because confidentiality has been stripped from the mediation process in medical malpractice disputes by medical regulatory boards and reporting agencies, the successful application of the mediation process in physician–patient conflicts has therefore been crippled. Although confidentiality in error reporting is the foundation of most of the proposed legislation, it has not been extended to the resolution of conflicts arising from alleged medical errors. The statutory obligation physicians have to report settlements of disputes involving quality of care issues creates a perverse incentive for physicians to move forward in litigation, especially when one considers the high attrition rate of malpractice claims and the likelihood of a physician prevailing in those cases that persist. It is likely that even in the face of tort reform mediation will remain an infrequently used medium for the resolution of physician–patient disputes.

Arbitration

As with mediation, arbitration provides economical and prompt adjudication of adverse events. Like mediation, it provides prompt, private settlement and compensation, yet is also subject to reporting requirements and regulatory oversight. The processes differ, however, in a few major factors. With arbitration the decision maker is a third party, the arbitrator(s), and the process is highly formalistic and adversarial. There are two forms of arbitration, binding and

non-binding. The latter is similar to mediation in that if either party disagrees with the arbitrator's decision, they may move on to litigation. The former, however, is a binding decision that cannot be appealed. Binding arbitration for malpractice claims has met with considerable legal opposition and non-binding arbitration has met with low utilization and increased litigation costs. Such systems intensify the pressure on patients to settle, thus reducing or avoiding litigation. They may be used with the current tort system – as well as with no-fault and ACEs. Kaiser Permanente, for example, requires enrollees to sign a 'willingness to arbitrate' agreement. With this approach, the health plan undertakes to resolve disputes through arbitration rather than go through the courts. This of course is not the same as a waiver of liability.

Specialized medical malpractice courts

There are three types of specialized courts under consideration: the Health Court, the Medical Board Administrative Adjudication System, and the Tripartite Panel.

Health Court: This involves the creation of an alternative court system within the federal court system. This proposal will, as touted by the consumer advocate group Common Good, presumably make judgments more reliable and provide clearer lessons for deterrence of adverse outcome. In theory, it can provide more timely access, faster resolution of claims, along with more reliable and standardized compensation. It requires appointment of special expert courts to hear medical cases or administer compensation based on avoidable events. Health courts also make the system more transparent by providing public access to settlement and adjudication findings. It will require judges who have special knowledge or training in medicine. Although proponents believe that this form of adjudication will offer more consistent and informed decisions than the traditional trier of fact, a lay jury, many studies find that in comparison with expert's reviews, the present jury system is quite consistent.

Health courts may be paired with ACEs and a standardized compensation schedule – and may even add a trial option to an administrative system. There are precedents for these types of courts in certain tax and patent infringement and workers' compensation laws.

Medical Board Administrative Adjudication System: In 1988, the AMA, 31 medical specialty associations, the Physician Insurer's Association of America (PIAA), and the Counsel of Medical Specialty Societies created the Medical Liability Project to develop an equitable and efficient method to handle malpractice claims.[109,110] They proposed a claims adjudication process based on fault and suggested that the states' medical boards act as the trier of fact in addition to their regulatory and disciplinary roles. This system would initially screen cases, offer free legal counsel for cases passing review, and offer limited judicial review. In a parallel development, the AMA considers that the provision of expert testimony constitutes 'the practice of medicine' and that it should be subject to peer review by state medical boards. The AMA encourages the state medical associations to work with the licensing boards to develop effective disciplinary measures for fraudulent testimony.

Tripartite Panel: Also in 1988, the PIAA proposed an administrative system similar to that used for workers' compensation in the hope that patients would elect this more speedy system through the offer of incentives. The panel would consist of a judge, a physician, and a lay person and function much like the few state screening panels that remain active. In cases where malpractice was found, all medical expenses would be paid under a specific method of computation, all non-economic awards would be based on a fixed schedule of benefits, and there would be a limit on attorney's fees.

Pretrial screening panels

This is a system that is modeled after state programs that are presently functioning, with those of Maine and Vermont the most recognized. To enlist the Panel, the patient provides written notice to the physician and with the superior court to be acted upon within 90 days. The superior court selects a Panel Chair from a pool of retired judges and/or mediators with judicial or legal experience. The Chair selects from a court issued list one attorney and one physician panelist, of the same or relevant specialty. The parties may challenge the selection for cause. There is a Prehearing Discovery, then a Pretrial Screening Hearing that follows the format of an arbitration. Depositions are admissible, but expert testimony is unusual. The panel has prior access to written briefs, complete medical records, deposition transcripts. The panel then acts as the trier of both fact and law, under the standard used by lay juries, 'preponderance of the evidence'. It evaluates the case on the basis of the four Ds of negligence. Unanimous decisions by the panel on negligence and causation are admissible in court, in favor of either the patient or the provider. The decision of the panel, like in non-binding arbitration, does not bind either party from pursuing litigation and trial. Some systems allow recovery of costs by the losing party, but as stated previously, if it is the plaintiff, actual recovery is unlikely.

Enterprise liability

Enterprise liability provides an incentive for prioritization of enterprise-wide safety. It shifts liability from

the individual provider to a provider organization such as an integrated medical staff, IPO, large group practice, or hospital capable of influencing care across the systems. Enterprise liability essentially makes these organizations 'strictly liable' in both a legal and an economic sense by their responsibility for liability premiums for all staff involved in the organization, which could potentially impact the present punitive reporting system and allow for a freer flow of error reporting. Such a system would promote institutional safety, and potentially stabilize liability insurance fees. Legal provisions (Stark laws) may prohibit liability insurance coverage of non-employee physicians. It works equally well with alternatives as well as the current tort system. The Department of Health and Human Services Office of Inspector General (OIG) historically has been concerned that a hospital's subsidy of malpractice insurance premiums for potential referral sources, including hospital medical staff, may implicate the antikickback statute, because the payments may be used to influence referrals. 'There is a particular concern where subsidies are offered in a conditional or selective manner that reflects current or anticipated referrals from the subsidized practitioners'. Hospitals may be able to subsidize the malpractice insurance of local obstetricians without triggering antikickback sanctions, according to an advisory opinion issued by the OIG. In this opinion, OIG outlines a specific case in which it would not impose antikickback sanctions against a medical center that provides subsidies to four community-based obstetricians who hold staff privileges at the medical center but are not employees of the facility.[111]

Tort reform in many of its guises, however, has historically not been universally 'friendly' to the physician. In 1988, the U.S. Congress established a National Practitioner Data Bank authorizing the collection of data about physicians and dentists from malpractice settlements, awards, and disciplinary actions; these data were to be supplied by insurers, hospitals, and HMOs.[112] Queries of the Data Bank might be made by hospitals and physicians, but there is to be no access by the public or actual or prospective litigants including patients and attorneys although expanded access to this information is the subject of much debate. This tracking by the Data Bank has probably decreased the willingness of physicians to settle cases, but has probably not decreased the frequency of malpractice. The non-departmental public body (NPDB) reporting system is primarily based on the reporting of any formal written claim of malpractice that results in even one penny changing hands, regardless of admission of blame or severity of injury. Such reports carry great weight in considerations for staff privileges, provider contracts, and malpractice premium rates. Hatlie and Sheridan have argued that the NPDB should be abandoned.[34]

Even more recently, there has been increasing attention on the amount of medical error that has heretofore gone unnoticed and undocumented. The AMA has created a Patient Safety Initiative and the Federal Government is considering legislation that will likely reorient the approach to error. Indeed, since the publication of the prestigious IOM's 'To Err is Human', which claims that between 44,000 and 98,000 hospitalized patients die per year as a result of medical error, and subsequent studies such as that of Chaudhry and coworkers, patient safety has become the mantra of the Joint Commission on Accreditation, which has now embellished the requirements for disclosure of error.[36,66,113] Programs for the evaluation of root cause analyses of reported errors and the resulting error reducing actions have become, as they should, a national priority.

Also potentially threatening to the physician are those tort reforms that are linked (politically) to the establishment of enhanced physician review panels, the creation of 'three strikes and you are out' rules, etc. In Texas, for example, along with a stringent tort reform bill passed in 2003, the Texas legislature gave the Texas State Board of Medical Examiners new authority to regulate medical practice through the passage of S.B. 104. This bill gave the board increased funding for expert consultants and staff. These resources were used to assess the approximately 6000 complaints the board receives each year. As a result, Board enforcements have increased dramatically. Before the augmentation, cases were filed against physicians immediately, which immediately affected their records. The new system provides more due process, but is more far wide-ranging. Opponents of this feature of Texas Health litigation argue that standard of care issues should be left to local community medical societies or hospital peer review and credentialing societies. But when the boot is on the other foot and these organizations engage in sham peer review or economic credentialing, physicians complain about their unfair practices (see below). Physician groups complaining about S.B. 104 want the presumption of innocence, the right to access details of the complaints against them, the right of discovery, the right to present witnesses and cross-examine witnesses, and the right to appeal. How seductive is the illusion of a new idea – all of these features are present in current malpractice law, the beneficiary of 200 years of accumulated jurisprudence. Public Citizens's Health Research Group ranked Texas 23 out of the 50 states.

Reviews of the impact of tort reform on premiums suggest that while premiums do respond to increases in payments, they do not increase dollar for dollar (http://www.nber.org/papers/w10709). This suggests that other factors may also be important in explaining the recent jump in malpractice premiums, such as a less competitive insurance industry or a decline in insurers' investment income. There is little evidence that changes in malpractice premiums are linked to changes in either the total number of physicians or

the number of physicians working in obstetrics/gynecology, surgery, or internal medicine. There is weak evidence to suggest that the entry decisions of young physicians and the exit decisions of older physicians may be affected by malpractice premiums. There is stronger evidence to suggest that rural physicians are more sensitive to a change in premiums – a 10% increase in premiums results in a 1% decrease in rural physicians per capita and a 2% decrease in older rural MDs (http://www.nber.org/papers/w10709).

Although there is no change in the frequency of most treatments, some data suggest that physicians may increase the use of screening procedures in response to higher premiums. Such practices however have had little effect on total Medicare expenditures, suggesting that the costs associated with defensive medicine practices may be small, at least for this age group. Thus, it is far from clear that state tort reforms will avert local physician shortages or lead to greater efficiencies in care. The stabilization of premiums, the initial response to most rounds of tort reform, may not indeed be the result of the tort reform legislation. Normally, it takes years before legislative tort reform has a direct impact on malpractice premiums and several, but not all, state courts have invalidated the cap on damages, the component of the law with the greatest potential to reduce premiums.[114,115] Malpractice premiums are affected by a constellation of additional factors, including the general investment climate, interest rate cycles, and insurance regulations.

Whether driven by legislation or not, it seems reasonable that stable malpractice insurance premiums offered by experienced, reputable companies are important reasons for maintaining physician availability and equilibrium.

There is no evidence that tort reform has resulted in better care or more realistic confrontation of error. Tort reform simply 'tinkers with certain aspects of the system in a piecemeal fashion without having to grapple with fundamental reform of either the health care delivery system, the reimbursement system or physician behavior'.

Tort reform and finances – litigation and risk management

There is universal agreement that the medical needs of those with adverse outcome require more attention, whether they are related to negligence or not. There is also universal agreement that the present functioning of the medicolegal system is an anachronism – neither is it efficient or error-free in reaching a settlement nor is the distribution of money equitable. In the United States, only about 28 cents of every premium dollar goes to injured patients after an average delay of 4.9 years to dispose of a case.

Is no-fault insurance better? To determine whether Florida's implementation of a no-fault system for birth-related neurological injuries reduced lawsuits and the total spending associated with such injuries, and whether no-fault was more efficient than customary tort procedures in distributing compensation, Sloan *et al.* compared claims and payments before and after implementation of a no-fault system in 1989.[6] They found that the number of tort claims for permanent labor-delivery injury and death indeed fell by about 16–32%. However, when no-fault claims were added to tort claims, the total frequency of claims rose by 11–38%. Further, of the estimated 479 children who suffered birth-related injuries annually, only 13 were compensated under no-fault. The total combined payments to patients and all lawyers did not decrease, but under no-fault, a much larger portion of the total went to patients. Thus, less than 3% of the total payments went to lawyers under no-fault versus 39% under tort – a new equilibrium. Some claimants with birth-related injuries were winners, taking home a larger percentage of their awards than their tort counterparts. Lawyers clearly lost under no-fault, but so did many children with birth-related neurologic injuries who did not qualify for coverage because of the narrow statutory definition.

Solving the malpractice problem

While the focus of clinical risk management intuitively rests on the analysis of adverse events, it seems clear that this is the most inefficient way of reducing or eliminating harm to the patient. In the current climate, risk management tends to deal more with avoidance of blame and litigation than with the avoidance of harm to patients.

One of health care's principal patient safety success stories is anesthesiology. In the 1980s, in the midst of a separate medical liability crisis, the rate of anesthesia-related deaths was one in 10,000; 6000 people per year who had undergone anesthesia died or suffered brain damage, and anesthesiologists' liability insurance premiums had sharply escalated.[68] Following a national news magazine broadcast that pilloried the field for these outcomes, the American Society of Anesthesiologists (ASA) decided to seize the opportunity presented by the crisis to improve anesthesiology safety.

It started with the hiring of a systems engineer. Through close scientific examination of 359 anesthesia errors, every aspect of anesthesia care – equipment, practices, and caregivers – was analyzed. Eventually, with the commitment of leadership and resources toward the task, the many system failures revealed by the study were re-engineered, and anesthesia-related death rates fell dramatically.

The ASA uses case analysis to identify liability risk areas, monitor trends in patient injury, and design strategies for prevention. Today, the ASA Closed Claims Project – created in 1985 – contains 6448

closed insurance claims. Analyses of these claims have, for example, revealed patterns in patient injury in the use of regional anesthesia, in the placement of central venous catheters, and in chronic pain management. Results of these analyses are published in the professional literature to aid practitioner learning and promote changes in practices that improve safety and reduce liability exposure.

Closed claims data analysis is the one way in which the current medical liability system helps to inform improvements in care delivery. However, reliance on closed claims for information related to error and injury is cumbersome at best. It may take years for an insurance or malpractice claim to close. These are years in which potentially vital information on substandard practices remains unknown. Providing patient safety researchers with access to open claims, now protected from external examination, could vastly improve efforts aimed at identifying worrisome patterns in care and designing appropriate safety interventions.

In addition to anesthesiology's early work in identifying the human factors and system failures that cause error, anesthesiology has also promoted reliance on standards and guidelines to support optimal anesthesiology care. Anesthesiology has also been at the forefront in the use of patient simulation for research, training, and performance assessment. With simulation, no patients are at risk of exposure to novice caregivers or unproven technologies.[116] Anesthesiology is still far from perfect. But, its 'institutionalization of safety' continues to serve the field well as it tackles the continuing threats to patient safety that are endemic to modern medicine.

Medicine is different from industry in that the medical system has not adjusted to the realities of human fallibility. The circumstances of the contemporary malpractice situation continue to compromise both the provision and the safety of health care as well as our notions of justice, of access to the law and to health care. This state of affairs benefits neither the patient nor, in the long run, the physician. While in some instances the fear of lawsuit has increased the amount of surveillance and may have even had a salutary effect on outcome, there is little argument that the present format for dealing with allegations of negligence provides any incentive to the profession to practice better medicine, provide better peer review, or, in the occasional instance, restrict the future practice of the physician whatever his conduct. True reform will require a systemic approach to error in medicine as elsewhere and some refinement of our ethics and an appreciation of the paradoxes of contemporary malpractice. To lower the risk of malpractice we must continue to attempt to raise the standards of care. We need this more than we need the identification of the 'bad apples' of our specialty. We must increase communication with the patient and remain their advocate. We must address the formal teaching of communication skills, conflict management, and team development techniques throughout medical school and residency. We must construct effective error reporting and systems analysis programs that promote error reduction, while protecting physicians from being punished by arbitrary and ineffective reporting systems. We must not squander our greatest asset – the medical record – and we must stop playing the role of victim. Often the ultimate failure is often not the individual provider but the latent, systemic errors, errors for which our systems are programmed, but which are functionally immune from lawsuit. A lawsuit cannot make 'the system' a defendant. Finally, we must be willing to participate in the process of uncovering error and make the patients our allies in these efforts.

23 Epidemiology in perinatal medicine

L. S. Bakketeig

Definitions

For a long time, it has been recognized that events during pregnancy and childbirth influence the health and development of the newborn. This recognition has led to the establishment of perinatology as a medical specialty that bridges the gap between the obstetrician's concern for the pregnant woman and the pediatrician's care of the newborn.

Population-based studies of these phenomena are labeled 'perinatal epidemiology', which has evolved into a major subspecialty of epidemiology, representing an important contribution to perinatal medicine. Traditionally, perinatal epidemiologists have focused on exposures and outcomes occurring in the perinatal period, which most commonly covers the time from conception through to birth and the first part of life (1 week, 1 month or the first year of life). In recent years, though, it has been realized that events or exposures that take place *in utero*, or shortly after birth, can also affect development and health even into adult life. We also have come to realize that even events occurring long before pregnancy, sometimes intergenerationally, can affect our reproduction.

An Austrian pediatrician suggested nearly 75 years ago that stillbirths and deaths during the first week of life should be treated as one statistical entity in the analysis of causes of death.[1] The term 'perinatal mortality' was increasingly used from the 1940s onward.[2–4] The increasing attention being paid to perinatal mortality was caused by the observation that the fall in infant mortality (death during the first year of life) in the first half of the 20th century derived mainly from the reduction in mortality of infants surviving beyond the first week of life.[5] It appeared that the progress made was mostly a result of the success in combating deaths due to infectious diseases in early infancy. Mortality among infants shortly after birth, as well as fetal mortality, had decreased far less.[5]

Perinatal mortality is the most commonly used death rate as an indicator of perinatal health. The other death rates used in perinatal epidemiology are stillbirth, neonatal, postneonatal and infant death rates, as illustrated in Figure 23.1. The death rates are defined as the number of deaths per 1000 births, or per 1000 live births for the last three rates.

Perinatal surveillance

Perinatal surveillance can be based on the perinatal and infant death rates, but also on other health indicators such as the frequency of different congenital anomalies or the frequency of preterm births or low-birth-weight (LBW) births. Some countries, for example, the Scandinavian countries, have established medical birth registries where all births in the country are monitored. Thus, the occurrence of different adverse outcomes can be monitored and changes in frequencies can be detected and further investigated. The thalidomide disaster in the early 1960s was the main reason why such a medical registration system was established in Norway in 1967. This was the first national population-based registration of births ever established.[6] Later, similar registration systems were established in Denmark, Sweden and Finland.

The medical registration of births contains information on the parents (a few items on civic and medical information), the course of pregnancy and delivery and, finally, some information about the newborn baby. Therefore, the medical birth registration information can be used for perinatal audit purposes beyond the surveillance of congenital anomalies. Perinatal audit represents a current assessment of the quality of perinatal care, based on the structure of care, the process of care and the outcome of care. The information collected through the medical birth registration represents a valuable basis for assessing at least the process and the outcome of care, while data on the structure of care will have to be collected separately.

The medical birth registration forms the basis of the Medical Birth Registries in the Nordic countries. The child and its parents are identified by unique identification numbers. This facilitates the linkage of the information with other data sources, like the death registry, the census data and the education registry. Also,

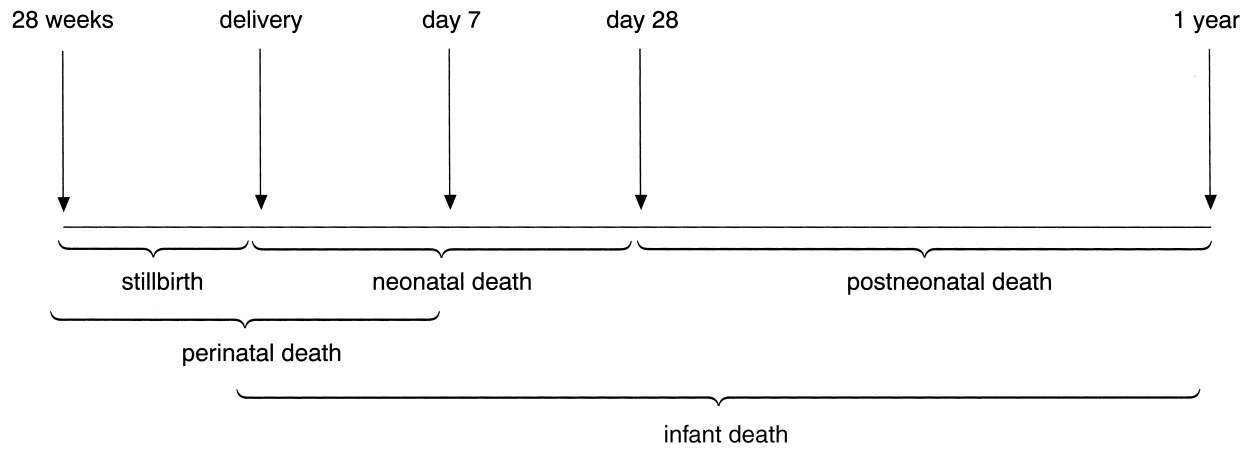

Figure 23.1 Time of death surrounding birth and during the first year of life.

the identification number makes it possible to link the medical birth registries with other morbidity registries, such as the cancer registries, which represent high-quality data sources in the Nordic countries.

Risk factors

Perinatal epidemiology focuses on different risk factors associated with pregnancy and childbirth. Births with an adverse outcome are compared with controls and whether one group has more often been exposed to the risk factor under study than the controls (case–control study). An outstanding example of such a study is the discovery of the strong association between the use of diethylstilbestrol in pregnancy to prevent miscarriages and the risk of cancer vaginalis in the female offspring of these women when they reach their early reproductive years.[7]

The other approach in studying associations between exposures and adverse outcomes is the use of cohort studies, where two groups of women are selected, one exposed and the other not exposed to the suspected risk factor, and then comparing the outcomes in the groups. In Table 23.1, an example is shown of such a cohort study, which focuses on the risk of small-for-gestational-age (SGA) births in groups of women with established risk factors at the start of their pregnancies, and evaluates the additional risk associated with cigarette smoking. The data shown in the table are based on a longitudinal study of fetal growth.[8] For women with no known risk factors at the beginning of the pregnancy, 6.5% will have an SGA birth. If the women smoke cigarettes, the risk increases to 11.8% [relative risk (RR) = 1.8]. If the women have had a previous LBW birth (birth weight below 2500 g), then the risk of an SGA birth is more than doubled (RR = 2.4), and if they smoke cigarettes, there is a further doubling of the risk (RR = 5.4).

Case–control and cohort studies are both observational studies. Furthermore, within perinatal epidemiology as well as other areas of epidemiology, observational studies are the dominant tools in addition to more descriptive and even hypotheses-generating studies. The more powerful experimental approaches are obviously less suitable. However, in evaluating perinatal care, one can use randomized controlled trials, applying either individual or cluster randomization. This approach can also be applied in the evaluation of preventive programs. Here, the cluster randomization approach ought to be used more often. For example, in evaluating a new program for antenatal care, instead of randomizing individuals, one could randomize areas, counties, municipalities or clinics to alternative programs and then compare the results.[9]

Recurrence risks

The feasibility of linking parents and child in the medical birth registries makes it possible to study the recurrence of pregnancy and childbirth events within sibships. This has been done extensively, based on the Norwegian Medical Birth Registry data over the last 25 years, starting with a paper in 1977, which demonstrated the strong tendency to repeat preterm, LBW and SGA births in successive pregnancies in the same woman.[10]

As it turned out, as shown in Table 23.2, LBW was the best predictor of subsequent LBW birth, preterm birth was the best predictor of later preterm birth and SGA birth was the best predictor of subsequent SGA births. These and later analyses have indicated that women are 'programmed' to have births of a similar size in subsequent pregnancies.

The first babies included in the Norwegian Medical Birth Registry from 1967 onward have now long since started to reproduce themselves, which facilitates the study of intergenerational effects. As it turns out, birth weight correlates across generations, but gestational

Table 23.1 The frequency of SGA births in cohorts of women with different risk factors, including cigarette smoking, at start of pregnancy (derived from Bakketeig et al.[8])

Risk factor	SGA births				
	Women (*n*)	*N*	Percentage	Relative risk	95% Confidence interval
None*					
Non-smoker	3190	208	6.5	1.0	
Smoker	1515	179	11.8	1.8	(1.5, 2.2)
Previous LBW birth					
Non-smoker	286	44	15.4	2.4	(1.7, 3.3)
Smoker	238	84	35.3	5.4	(4.2, 7.0)
Low prepregnancy weight (< 50 kg)					
Non-smoker	164	20	12.2	1.9	(1.2, 3.0)
Smoker	175	45	25.7	3.9	(2.9, 5.4)

*Defined as the absence of the following risk factors: previous LBW birth, low prepregnancy weight, previous perinatal death or chronic maternal diseases (essential hypertension, heart disease or renal disease)

Table 23.2 Prediction of LBW, preterm and SGA second births based on birth weight and gestational age of first birth (76,398 mothers with first two births in 1967–73) (from Bakketeig[10])

First birth	Risk of second birth					
	LBW		Preterm		SGA	
	%	Relative risk	%	Relative risk	%	Relative risk
LBW	15.2	5.6	15.4	3.7	20.5	4.1
Preterm	11.8	4.1	16.4	4.0	11.5	1.5
SGA	7.7	2.8	6.6	1.4	22.1	3.9

Table 23.3 Recurrence risks across generations

	Relative risk
Preterm birth (< 37 weeks)	1.18
LBW birth (< 2500 g)	2.25
SGA birth (sex and parity specific)	2.57

age correlates to a lesser extent.[11] A recent analysis is based on 105,104 mother/child pairs recruited from females in the Norwegian Medical Birth Registry born since 1967 and reproducing through 1995. Based on 101,579 single mother/child units, the recurrence risks across generations are shown in Table 23.3. The recurrence risk or LBW is of the same magnitude as the recurrence within sibships.[10] However, for gestational age, the recurrence risk across generations is much weaker compared to the recurrence within sibships. This could indicate that genetic factors affect fetal growth more than the duration of pregnancy and that gestational age might be more affected by environmental factors. Further studies of paternal effects and the association among paternal and maternal half-siblings might help to clarify these relationships.

Future perspectives of perinatal epidemiology

The idea that health in adult life may reflect circumstances in childhood, or even earlier in life, dates back many years.[12] The notion that at least some adult diseases may originate *in utero* has recently captured attention across a wide range of biomedical sciences. Editorial comments have ranged from being enthusiastic, claiming a 'paradigm shift',[13] to being more critical and skeptical.[14]

Barker has introduced a series of hypotheses of relationships between perinatal events and later health.[15] For example, Barker *et al.* have examined the association between blood pressure and measures of size and shape at birth, indicating that the ratio of birth weight to placental weight is an important predictor of subsequent blood pressure, where men who were light at birth, but with a relatively heavy placenta, had the highest blood pressure.[16]

Most of these associations will require more sophisticated studies before the issues can be resolved. In the Nordic countries we have some advantages in approaching some of these challenges, particularly since we have relatively homogenous populations where the

individuals can be traced over time due to our identification number system, which thus facilitates longitudinal studies with follow-up over a long time.[17]

Epidemiology certainly has an extremely important role to play in perinatal medicine, and genetic epidemiology and molecular epidemiology are likely to introduce new and more effective analytical methods, which will provide the basis for improved prevention of adverse outcomes of perinatal events, regardless of when these outcomes occur.

24 Structure of perinatal care systems

G. A. Little

Pregnancy outcomes are clearly dependent on the availability and effective delivery of reproductive care. Advances in knowledge and technology have resulted in improvement in national perinatal statistics such as survival of low-birth-weight infants, but the degree of improvement is dependent on the care environment. Structure, the systematic organization of perinatal care, is a primary determinant of the degree of success in meeting the needs of a population.

Constant improvement of pregnancy outcomes is a logical objective. The optimal state of health involves functioning at full individual potential, without disease or abnormality. The ultimate positive expression of reproductive health would be pregnancies without adverse medical outcomes occurring as intended events within a healthy emotional and social environment. A zero adverse outcome rate may not seem attainable at this time, but there is no reason to believe that there is an irreducible minimum of poor outcome that cannot eventually be overcome.

This chapter discusses the organization of perinatal care in the effort to improve outcomes of pregnancy. While each geopolitical entity – population, region or country – must be analyzed and subjected to individualized planning and intervention, there are common concepts that apply.

The problem

Throughout the world, disease associated with reproduction represents a dominant part of medical need and is a major contributor to mortality and long-term morbidity. Even if that part of reproductive system pathology not necessarily associated with pregnancy, such as infertility and sexually transmitted diseases, is removed, the human and economic costs of pregnancy-related disease remain very high in both developed and less fortunate countries.

The disparity between developed and developing regions is especially dramatic in the area of reproductive health. Thirty-nine of the 50 million yearly deaths worldwide (approximately four-fifths) occur in the developing countries, where maternal, perinatal, and communicable causes are said to be responsible for 40% of deaths as compared to 5% in developed countries. Pregnancy-related conditions are estimated to be responsible for 18% of the burden of disease in women between 15 and 44 years of age, and in children under 5 years of age about 19% of loss of healthy life is said to be due to perinatal complications.[1] Of five essential groups of clinical interventions for developing countries identified in a world development report – prenatal and delivery care, family planning services, management of the sick child, treatment of tuberculosis, and case management of sexually transmitted diseases – three involve perinatal and reproductive health.[2,3]

Within developed countries there have been remarkable advances in outcomes in recent decades, but there are persistent differences between countries. Furthermore, expenditure of greater resources per capita and availability of proportionately more providers does not necessarily result in better outcomes. The United States, despite greater application of resources to neonatal intensive care, does not appear to have better birthweight-specific mortality than some other countries.[4]

Indicators

Perinatal systems of care have traditionally used vital statistics indicators to quantify relative magnitude of outcomes. The following are illustrative of indicators that are based on events that are relatively easy to define and record, such as death, birth weight, and gestational age.

Maternal mortality, usually defined as death of a woman during or within 42 days of pregnancy of any cause other than accidental or incidental, remains a problem in the industrialized world, where deaths approximate 10–20 per 100,000 live births. This indicator is said to document the widest disparity of human reproductive outcomes yet reported, with some sections of the world, notably sub-Saharan Africa and South Asia, apparently experiencing an incidence as much as 200 times higher than the safest areas.[5]

Fetal mortality, neonatal mortality, and infant mortality serve as valuable indicators by themselves or when included in various rates and ratios. Perinatal mortality, including all newborns, live and stillborn, of 1000-g weight and greater and up to 168 h or 7 days of age (early neonatal), is used frequently. Neonatal mortality (deaths up to 28 days) is part of infant mortality (deaths in the first year), and the two, independently or when analyzed together, give valuable insights into the health of a population and availability of care. For example, it has become evident that improvement in infant mortality in some countries such as Egypt has exceeded the rate of improvement in neonatal mortality, suggesting that advances in perinatal care of the fetus and neonate may lag behind advances in care of conditions of infancy, as programs such as oral rehydration for diarrheal diseases make an impact.[6]

Low-birth-weight rate and *birth-weight-specific mortality* provide information about the general health of a population and the relative success of intervention, especially for the population of prematurely born babies (< 37 weeks' gestation). Within the United States, for example, the low-birth-weight rate varies by a factor of 3 or 4 for various subpopulations and has not responded favorably to interventions, while birth-weight-specific mortality has improved considerably, probably due to neonatal intensive care and regional programs. The result is a situation where individual low-birth-weight babies do relatively well and birth-weight-specific mortality is perhaps the best in the world, but the number of low-birth-weight babies per thousand births remains higher than in many other countries.

Figure 24.1 serves to illustrate the breadth of possible perinatal outcome indicators. Identified values can be used to derive indicators. Traditional outcomes based on vital statistics address a small portion of the value and outcome spectrum. The clinical value compass model can be applied to all aspects of a care delivery process including the parent perspective of the neonatal intensive care experience.[7] Perinatal care systems in all stages of development will rely on vital statistics based indicators. Those in complex environments that are market driven with a strong interest in consumer- or family-centered care may also employ a variety of indicators.

Risk assessment, need identification, and resource allocation

Risk assessment is a key concept in perinatal care systems. The process of evaluating the possibility that a patient has or will have a specific problem is an integral part of all medical practice including perinatal medicine. *Needs* are identified and quantified for both individual patients and populations. *Resources* can then be allocated to meet identified or anticipated needs.

Risk assessment has furthered care and improved outcomes through identification of populations and

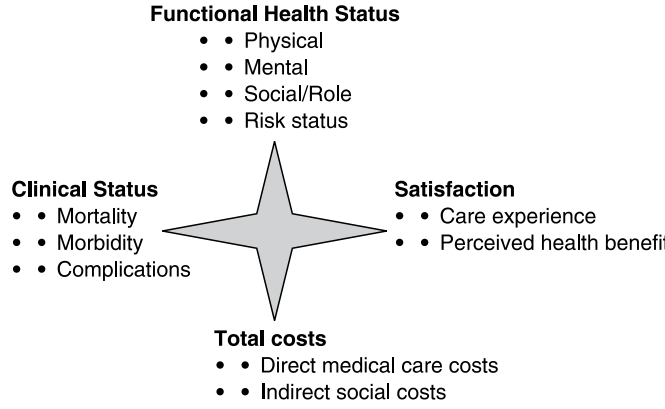

Figure 24.1 The clinical value compass model has been used to derive the four parental neonatal intensive care outcome groupings. A wide range of outcome indicators can be developed for each of these groupings. Derived from Conner and Nelson[7].

individuals at increased risk for specific conditions. It also can result in false positives and negatives. Furthermore, there is legitimate concern that the concept of risk has meant to some that pregnancy is never normal except retrospectively. These shortcomings must be managed.

A method entitled the *risk approach* has been developed to improve availability and use of existing healthcare resources and systems, especially in resource-poor areas. Health problems, including their associated risk factors and populations, are identified, the status of function of the existing health-delivery system is assessed, interventions to deal with risk and performance are put in place, and these are followed by monitoring and evaluation.[8] This process has been applied to construct programmatic approaches to population-based maternal and child health care. Shortcomings have been discussed, including the inability in some situations to recognize or evaluate all forms of risk, inadequate preparation or training of personnel, lack of complete understanding of the determinants of risk including cultural factors, and inability to achieve a balance between preventive and curative services.[9,10]

Patient care and the need for structure

The individual perinatal patient has benefited greatly from advances in care. For example, if access to preventive and acute care is available and timely, all of the five main causes of maternal mortality – hemorrhage, unsafe abortions, hypertensive disorders, sepsis, and obstructed labor – can be managed successfully. Most of the common causes of fetal and neonatal mortality and morbidity, such as peripartum asphyxia, prematurity, and infections, respond to assessment of fetal well-being, obstetric intervention, neonatal resuscitation, and intensive care. Although there are many diagnostic and therapeutic challenges that remain, such as prevention of permaturity, the simple fact is that most of the world's perinatal pathology can be detected and

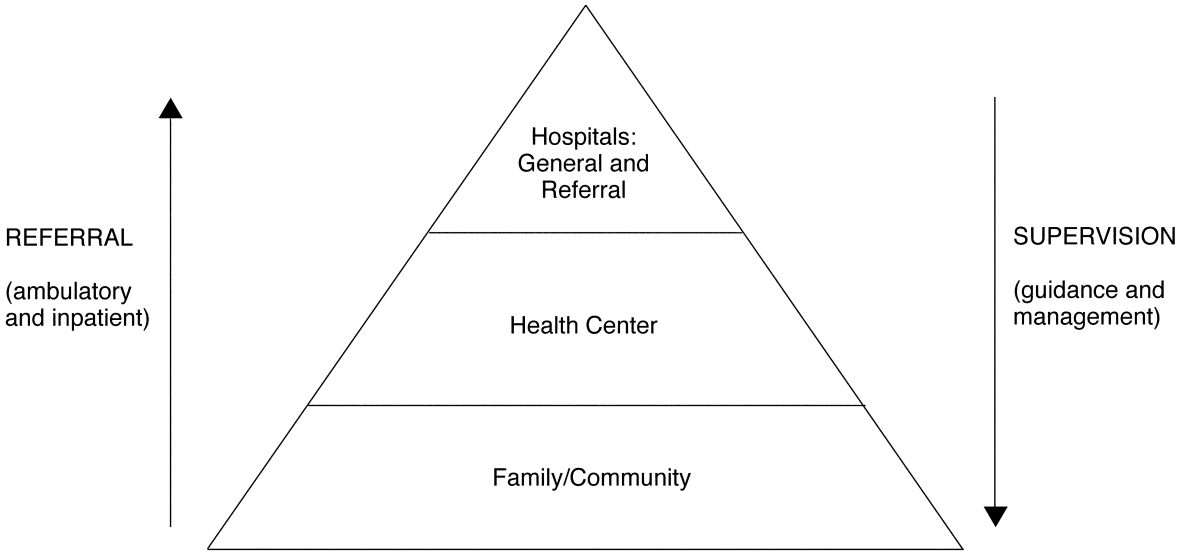

Figure 24.2 The World Health Organization health-care pyramid. Modified from World Health Organization[3].

treated successfully with available knowledge and structured care.

Because it is not possible to meet all needs in all places, a structured system that allows for efficient use of resources and maximizes outcomes is a logical objective.

The health-care pyramid

The World Health Organization (WHO) has presented an ideal health-care pyramid with three levels: family/community, health center, and district hospital.[3] With slight modification (see Figure 24.2), this model can serve as a conceptual framework for the structure of perinatal health care in countries and societies at all stages of development. The basic importance of the family/community sector is emphasized; it is here that the need for clinical intervention arises and moves to health center and hospital when necessary (see referral arrow, Figure 24.2). The arrow on the right pointing down suggests a family/community objective for supervision in the WHO model; the guidance and management terms were added to this illustration to suggest proactive clinical and educational interventions that originate in health-care institutions.

A problem associated with improving pregnancy outcomes is the need for both comprehensive preventive and acute care for an entire population. One without the other will not be successful. As the health-care pyramid suggests, an effective and efficient framework or structure of component activities is necessary.

Perinatal systems

Systems consist of components functioning together for common goals and objectives. Understanding of the complexity and breadth of activities associated with perinatal care is essential if systems are to be effective.

Perinatal system activities

Table 24.1 provides an overview of the basic activities associated with systematic efforts to improve pregnancy outcomes of a population. Patient care is essential and must be facilitated by administration and management. If standards of care and outcomes are to be maintained and improved, ongoing data collection, evaluation, and research must take place to provide the substrate for quality improvement. Training and education of personnel must be available either from within the system itself or from a cooperating resource.

System development

Much of the effort of system development in technically-advanced nations has focused on hospital inpatient services. The hospital is usually the community institution where knowledge and technology are concentrated, with individual members of the community coming to that location. In developing and less fortunate environments, a single regional institution such as a district hospital receives designated governmental support, while in more affluent areas there may be multiple hospital alternatives that, in fact, may compete.

Perinatal systems and their patients originate from communities and families. The focus on hospitals as an identified community resource and site of many if not most births leads to a challenge for systems to adaquately address needs in the ambulatory and education sectors. Preconception and prenatal care tends to be less well addressed in many systems as inpatient services.

Table 24.1 Perinatal system activities

Patient care	Date acquisition, evaluation, and research	Administration	Education
Primary (basic)	Vital statistics	Clinical services	Public
Pregnancy planning	Pregnancy outcomes	System development and maintenance	Patient
Preconception	Maternal	Institutions	Prevention
Prenatal	Neonatal/infant	Clinics	Preparation
Peripartum	Technology assessment	Hospitals	Training
Postpartum	Professional/provider	Quality assessment and improvement	Continuing
Maternal	Medical and social science	Fiscal	System (outreach)
Infant			
Specialty (consultative, referral)			
Genetics			
High-risk obstetrics (Maternal–fetal)			
Neonatal (medical and surgical)			
Psychological and social			
Ancillary services			
Radiology/imaging			
Anesthesia			
Laboratory			
Transportation			
(Interhospital care)			
Maternal–fetal			
Neonatal			

In an ideal situation, need assessment followed by resource allocation to guide initial development of a basic perinatal system for a defined population is a relatively uncomplicated exercise. As previously discussed, vital statistics and perinatal indicators can help to quantify the magnitude of the need and support solutions that direct resources toward systems and comprehensive program activities. The reality of perinatal systems development is complex, with each situation involving different medical, economic, social, and political determinants.

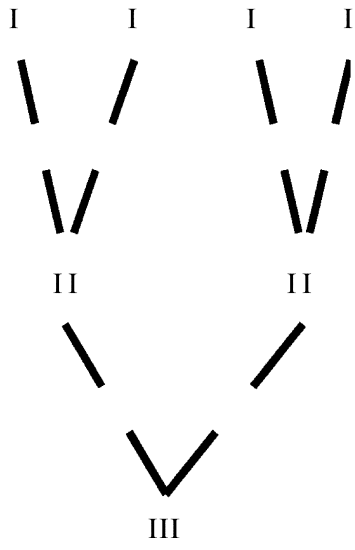
Perinatal regionalization in the United States: evolution of a systems approach

During the 1960s and early 1970s, significant advances in perinatal care, especially in hospital-based services, were occurring in the United States, Canada, and many countries in Europe and elsewhere. Neonatal intensive care in particular was emerging, as was the concept of interhospital transfer, including care instituted prior to and during movement to established centers. Perinatal providers and their organizations, including the American Academy of Pediatrics (AAP) and the American College of Obstetricians and Gynecologists (ACOG), became convinced that a systems or programmatic approach to perinatal care could improve outcomes. With the assistance of a private foundation, The National Foundation – March of Dimes, the AAP, and the ACOG, joined by the American Medical Association and the American Academy of Family Physicians, formed an *ad hoc* Committee on Perinatal Health.

Toward Improving the Outcome of Pregnancy: Recommendations for the Regional Development of Maternal and Perinatal Health Services was formally released in 1976.[11] The first sentence states that to make optimal care available for each person, 'a systems approach is essential'.

The publication, now known as TIOP I, while directed broadly at maternal and perinatal services, focused heavily on the third trimester and neonatal period and on the hospital or inpatient sectors primarily. Central to the recommendations and subsequent influence of TIOP I was a three-level categorization of perinatal services. The level framework was promoted to introduce cooperative interaction and organization into a system having as its only objective the improvement of pregnancy outcome (see Figure 24.3).[11,12]

By the mid-1980s, perinatal regionalization, including the level concept of organization, had been



ACTIVITY	LOCATION
Usual level of patient entry Risk assessment Uncomplicated care Stabilization of unexpected problems Data collection Sponsor of local education	Community or district clinics and hospitals
Level I activities plus: diagnosis and treatment of selected high-risk pregnancies and neonatal problems education for part of network	Large community hospitals with many support services
Level I and II activities plus: diagnosis and treatment of most perinatal problems regional transport research and outcome surveillance regional education regional administration	Large medical centers with comprehensive, often academic, programs

Figure 24.3 Levels of hospital perinatal services originally recommended in the United States in 1976. Derived from Frigoletto and Little[12].

implemented throughout the United States, with most authorities agreeing that it had been responsible for improvement in outcomes.[13] The degree of governmental involvement in the form of leadership and regulation varied widely across the 50 states. The three-level categorization was broadly accepted, although some argued for a four-level system with a few perinatal centers, usually academic, to provide the most technologically demanding care as another level. Others argued for a two-level system involving primary, routine, or specialty care and a referral level for subspecialty care. Some felt that the level system inappropriately centralized care, although the TIOP documents clearly state that that is not intended.

Recently, the AAP released, after considerable collection of practice data and debate, a new categorization of levels of newborn care that maintained a basic three-level framework with subcategorization based on functional capabilities.[14] The rationale utilized, while applied to neonatal care, is seemingly also applicable to obstetric units. As perinatal services in hospitals and within systems are interrelated, assigning the level of perinatal service is an important aspect of structure.

By the late 1980s, a great deal of concern was being expressed by US professionals and health planners that so-called 'deregionalization' was occurring and that outcomes might be worsening or at best the rate of improvement was inadequate. Some argued that the levels categorization had outlived its usefulness. It is important to place this concern into a context of a nationwide deliberation about the entire system of care and health-care reform. A movement to review and revise TIOP I emerged.

TIOP II, *Toward Improving the Outcome of Pregnancy, The 90s and Beyond* was released in 1993 by a reconstituted and expanded Committee on Perinatal Health.[15] In it are included a review of past development of US prenatal services, consideration of indicators of outcome, and recommendations for improvement that are broad and strongly state that successful interventions such as intensive obstetrical and neonatal hospital-based interventions must be maintained, while a newly energized focus on ambulatory care, especially in the preconception, prenatal, and postpartum intervals, should be instituted. The levels categorization is supported but with a recommendation that review and revision on a local or state basis should be undertaken as part of an emphasis on the need for regional systems to be community focused. Also stressed are health awareness and promotion, universal access to care, and a recognition that social and fiscal, as well as medical, factors must be addressed. TIOP II is also not a *laissez-faire* document; it recommends that community resources as well as professionals should play a role in a system that includes a forum, usually government led, for addressing accountability, access, and progress.[16]

Thus, in the United States, the need for structure in the delivery of perinatal care, which includes risk identification, patient referral and possible transport to a site of available service, and categorization of levels of care has been debated and largely accepted. Agreement on the specifics of system implementation and management is not as universal. In some states, structure has evolved informally, while in others, considerable structure has been mandated. The care-related activities presented in Table 24.1 are largely in place, while some, such as continuous quality improvement involving an entire geopolitical unit such as a state, are not. The current movement toward managed care and

competition on the one hand supports the development of systems of care that are internally structured and largely self-contained, while on the other hand urging the freedom to compete and limited external structure and review. In many areas, there are regionalized perinatal networks that function in parallel, with limited interaction including assessment.

In this millineum the US perinatal system continues to evolve while there is ongoing questioning of resource allocation. The dominence of hospital-based services including obstetric high-risk and neonatal intensive care is being debated from the perspective of whether it improves outcomes.[17] Availability of neonatal intensive care capacity is thought to be responsible for a significant portion of improvement in outcomes such as low-birth-weight survival, with obstetric care contributing a smaller but definite portion.[18] There is research that supports a concern that neonatal intensive care capacity may be excessive and not able to contribute further to improved pregancy outcomes.[19]

A cross-national study of reproductive care involving the United States, Australia, Canada, and the United Kingdom determined that the United States has more neonatal intensive care capacity with 6.1 neonatologists per 10,000 live births compared with 3.7, 3.3, and 2.7 for the other countries, respectively. Neonatal bed capacity was also greater in the United States. Birth-weight-specific mortality outcomes were not the best in the United States where proportionately less resources are allocated to such efforts as preconception, prenatal, and other maternal and child health services.[4] This study questions the effectiveness of the current distribution of reproductive care resources, as did TIOP II,[15] and should serve as a resource for other perinatal systems in development and evolution.

Present and future challenges

Access to clinical care

The implementation and improvement of perinatal systems remains challenging across the spectrum of economic development and political structure. In the less developed situations, certain key system components, such as the first referral level for emergency obstetric care and the ability to perform operative interventions like cesarean sections, are yet to be made universally available. In others, access may be less than optimal due to organizational or economic factors. System structure may have to be modified or individualized to meet prioritized acute care needs. In situations where care is readily available and perhaps even oversubscribed, such as neonatal care, there are challenges related to the relative priority of technologies and services. Dissemination of evidence-based innovations has been pointed out as a challenge in all industries including health care.[20]

Data acquisition and analysis

The ability to use existing computer technology to provide data about events and outcomes in a practical and real-time fashion is now available to perinatal system management. Individual providers, centers or hospitals, and systems can record data economically, and through analysis derive information to effect improvement and change. Efforts such as the Oxford Database for Perinatal Trials, the emergence of measures of acuity,[21,22] and the growing worldwide presence of collaborative networks, such as the Vermont–Oxford Neonatal Network[23] with its international cumulative database of 400- to 1500-g-birth-weight babies from over 400 units, provide opportunity for evidence-based collaborative research.[24] These tools need to be supported, developed further, and used by perinatal systems.

Quality improvement

The concept of continuous quality improvement employed with success in business and in health care is not foreign to perinatal care. In fact, an emphasis on measurement and improvement of outcomes has always been a fundamental part of perinatal care, as evidenced by the Apgar score and neonatal follow-up efforts. Perinatal systems can benefit from advances in quality management being championed in other sectors, including competitive business. Data acquisition and analysis are essential in this effort and the productive linkage of data with quality improvement is a systems function.[25]

Expectations and accountability

Perinatal systems, their institutions, and their personnel are formally and informally considered to be accountable for their actions and outcomes. Accountability is well defined in some areas such as procedures on patients in hospitals and less evident in other concerns such as who is responsible for patients who receive inadaquate prenatal care. Problems such as maternal mortality in developing countries and infant mortality in subpopulations of some advanced countries may become part of a political process that asks for identification of the responsible party and improvement. In such situations the media may become involved by publicizing issues and demanding accountability and change.

Families and communities in this era of patient or consumer involvement in health care have expectations. They can profoundly influence care. For example, perinatal parents have successfully advocated for change leading to the presence of fathers at operative delivery and increased involvement in decision making in the neonatal intensive care unit.[26]

A basic principle of public health is to involve the entire population in analysis and efforts for improvement. Many perinatal systems across the economic and

political spectrum of countries study parts of the total population. Accountability or responsibility for less than the total cohort is inadequate. If more than one perinatal network, program, or system exists within a population, then responsibility must rest somewhere, often with the government, for total cohort accountability.

25 Perinatal quality indicators and perinatal audit

G. Lindmark and J. Langhoff-Roos

Health-care services should be evaluated not only in quantitative terms, which is still often the case, but also with respect to the quality. The qualitative dimensions of health care are fundamental for its impact on health. Clients, not least in maternal health care, increasingly demand to be considered as individuals and not only as objectives of the health-care activities. Resources are restricted even in the most affluent parts of the world and do not allow unlimited use of health-care interventions. Critical scrutiny and assessment of the quality of health care are therefore mandatory.[1]

In maternal and perinatal health care, the survival of mother and baby without short- or long-term morbidity is the first and fundamental need. However, in childbearing there are other needs related to social, cultural and existential dimensions, which also have to be considered in the care of mothers and infants. One obvious reason to acknowledge these dimensions is their importance for acceptance of and compliance with care.

To maintain and improve quality in health care, it is necessary to clearly define the goals and objectives related to patient's needs, and assess the resources available.[2] For such a process to be possible, good communication and collaboration must be present. It is also essential that health workers at all levels feel themselves as subjects and a part of the process and not as objects of scrutiny or criticism.

To define quality as the extent to which the care is meeting the expectations and needs of the patient is attractive, and implies that also other outcomes than the strict medical ones must be considered. However, the expectations of health care do not come only from the patient but also from society and from the agencies that cover the cost of the care. Therefore, not only individual but also public health outcomes must be considered, and the effective use of available resources will therefore be a quality aspect of great interest. When comparisons of the quality of perinatal care are performed, it is common to relate only to indicators of outcome or process and not mention indicators of structural input. Also, single-process or -outcome indicators – like rates of cesarean section and perinatal mortality – have been used to measure quality without considering the relation with other important aspects of care.

It will be increasingly important to define quality also as cost-effectiveness, in any case if the aim is to offer universal high-quality care to all mothers and newborns.

Indicators of quality

A weighted sum of all essential indicators, including fetal and maternal, short-term and long-term outcomes as well as maternal satisfaction and the impact on future pregnancies and deliveries, would be the ideal measure of quality. This will imply that an unrealistically high amount of resources are spent to collect quantitative as well as qualitative data – at least in the same population. The most important source for quality improvement activities is the routinely collected indicators at the local and regional levels. However, we still need to supplement this with results from other and larger regions. Published descriptive–analytical clinical research will also in the future constitute one of the backbones of regional quality assessment activities.

Decisions on the best indicators must consider not only their relevance for assessment of the objectives of care, but also their feasibility. For an indicator to be useful it must be constructed from data that are possible to collect within the available resources, and both these variables and the indicator itself must be clearly defined. The usefulness of quality indicators for comparisons over time or between regions depends on agreement on these definitions and continuous data collection by all the participating health facilities.

Quality assessment of the *structure* of care includes organization, resources, qualifications of staff and availability of structured and adequate programs of care. The *process* or utilization of resources in the provision of health care can be assessed so that each activity for screening, prevention, diagnosis or therapy is correctly applied and used for the intended or appropriate

purpose. Assessment of process quality should ascertain that the care is carried out according to evidence-based guidelines or recommendations.

In perinatal care the *result* of the health-care process in terms of mortality and morbidity traditionally has been discussed most often. Nowadays, patient satisfaction and provision of relevant and reliable information are products of care generally appreciated as important not just in cases with perinatal complications but also in the majority of cases in which everything is normal from a strictly medical perspective.

These quality indicators are useful for constructive discussions about the content and quality of perinatal health care. The variations in outcome are not related to physical resources in a simplified way, but must be discussed in the wider context of attitudes, practices and training of health staff at all levels. Assessment of results of care should not be limited to intermediate variables such as the results of tests or examinations, but should focus on essential patient-related indicators. In perinatal care, it is common that a screening procedure or an intervention during pregnancy is validated by parameters that are indirectly related to the actual health outcome of mother or infant or even to the result of another test or examination. Variables that are indirectly related to health outcome, such as low birth weight and preterm birth and to some extent low Apgar score, may be useful, however, if there is a direct relationship with short- and long-term morbidity.

Data collection

Since quality assessment includes both the general level of care in all cases as well as serious adverse events, variables and indicators must include both information about all mothers and newborns and special information in selected cases of special interest. The data collection system must therefore include both routine registration of basic information and more detailed information on complicated events – usually to be retrieved from the medical record.

Existing routinely collected data, for example, from medical birth registers, should be used whenever possible, in order to limit the resources needed.[3] Studies show that the quality of routine data in maternity services can be adequate for quality control.[4]

In some countries, routine data may be retrieved from clinical information systems in hospitals or primary care, or civil registers of births and deaths. In the Scandinavian countries, national medical birth registers provide important information. In some countries, routine surveys of reproductive health outcomes are performed at regular intervals and data from routine child health care may be used for quality assessment purposes. However, register data and standard data collected without a specific purpose or unrelated to specific quality improvement activities may be of questionable validity. Registers may also be unreliable regarding causes of death, diagnoses of complications or autopsy data. Terms such as hypoxia, placental dysfunction or pre-eclampsia are frequently used without clear and uniform definitions of the variables.

For comparisons – not only of trends over time in one specific region, but also between regions or using the data compiled for international comparisons – it is essential that all variables are defined according to international standards.

Definitions of basic concepts such as perinatal mortality, gestational age and diagnoses describing maternal and infant condition must be uniform. It is particularly important that all extremely preterm deliveries and infants with the lowest birth weight are included, because of their high risk of mortality and morbidity.

The patient record is an important quality instrument if it is standardized and contains specified and well-defined data. It is nowadays often in a computer format and can be used directly to produce data for special purposes. However, there must be specified definitions for registration to make a variable useful for quality assessment. All data that are the result of a subjective interpretation are also less reliable than absolute values of test results.

Specific surveys and interviews, as well as observations of the process of care, are valuable instruments for assessment of quality, but cannot usually be routinely used since they are more resource demanding and also require training and skills of the data collectors. Thus, these methods will be limited to specific, short-period projects.

Validity of data

The most common problem in the initial discussions about choice of indicators is that people underestimate the difficulties of performing continuous data collection in routine care over long periods of time. The validity of the data registration must therefore be given attention before the data registration begins, as well as regularly over time. Also it is important that definitions and indications are not changed too often. A change should not be considered unless a significant improvement is foreseen to follow, considering both the initial rather poor validity of data during the first phase and the loss of longitudinal aspects of data collection.

In order to secure valid registration of indicators it is important that health personnel are provided with regular and immediate feedback based on registered data and that regular proper validation based on internal registry analyses and external studies based on case notes are performed.

Validation of reported indicators depends on whether the data are aggregated, anonymous case based or case based linked to a personal ID. At an aggregated level, validation may be achieved by logic checks for outliers, at a case-based anonymous level by logic checks for relations between indicators (such

Table 25.1 Obstetric clinical indicators developed by the American College of Obstetricians and Gynecologists

Maternal indicators
Maternal mortality
Unplanned readmission within 14 days
Cardiopulmonary arrest
In-hospital initiation of antibiotics 24 h or more after term vaginal delivery
Unplanned removal, injury or repair of organ during operative procedure
In-hospital maternal red blood cell transfusion or hematocrit < 22 vol% or hemoglobin of < 7.0 g or decrease in hematocrit of 11 vol% or hemoglobin of 3.5 g or more
Maternal length-of-stay more than 5 days after vaginal delivery or more than 7 days after cesarean delivery
Eclampsia
Delivery unattended by the 'responsible' physician*
Postpartum return to delivery room or operating room for management
Induction of labor for an indication other than diabetes, premature rupture of membranes, pregnancy-induced hypertension, postterm gestation, IUGR, cardiac disease, isoimmunization, fetal demise or chorioamnionitis
Cesarean delivery required
Primary cesarean delivery for fetal distress.
Primary cesarean delivery for failure to progress
Delivery of an infant with a birth weight < 2500 g or respiratory distress syndrome following induction of labor

Neonatal indicators
Perinatal mortality of a fetus or infant surviving less than 28 days and weighing 500 g or more at delivery
Intrapartum death, in hospital, of a fetus or infant weighing 500 g or more
Neonatal mortality of an inborn infant with a birth weight of 750–999 g in an institution with a neonatal intensive care unit**
Delivery of an infant weighing < 1800 g in an institution without a neonatal intensive care unit**
Transfer of a neonate to a neonatal intensive care unit in another institution
Term infant admitted to a neonatal intensive care unit
Apgar score of 4 or less at 5 min
Birth trauma (#767 in ICD-9 directory), such as shoulder dystocia, cephalohematoma, Erb palsy and clavicular fracture but not caput
Diagnosis of fetal 'massive aspiration syndrome' (#770.1 in ICD-9-CM)
Inborn term infant with clinically apparent seizures recorded before discharge

*To be defined by each institution; **an inborn infant is one born in this hospital rather than transferred from another institution

as compatibility – cesarean section vs. sphincter rupture), whereas at a case-based level where case notes are traceable a proper external validation may be carried out.

Sets of indicators for quality assessment

Many quality assurance projects have used process indicators in health care, often recorded as proportions of cases subject to various interventions. Several national and international agencies and scientific societies have developed lists of essential quality indicators for maternal and perinatal care.[5] An example of a set of clinical quality indicators for monitoring results is the one developed by the American College of Obstetrics and Gynecology (Table 25.1).[2] Other sets reflect a more public-health-oriented perspective. Usually, they are a mix of imput from clinicians (obstetricians or midwives) and public health professionals. Clinicians usually focus more on indicators of specific areas to be improved by clinical interventions (process–outcome indicators), indicators such as cesarean section, sphincter rupture and asphyxia at delivery. Public health professionals focus more on areas that are public health issues (structure–outcome indicators), such as maternal age, marital status, congenital malformations, length of hospital stay for childbirth, etc.

By comparison these sets of indicators are quite heterogenous and show a considerable amount of diversity, reflecting differences in interest, but also characterized by a number of common indicators that were found to be essential, such as maternal, perinatal and infant death.

A recent European collaborative effort, PERISTAT – a part of the European Commission's Health Monitoring Programme – has developed indicators of perinatal health for health professionals, policy makers, researchers and health service users who wish to monitor and evaluate perinatal health. The aim of this project, which included 13 countries, was to facilitate monitoring and comparison by harmonizing indicator definitions and encouraging the collection of comparable data based on the following priorities:

- Assess maternal and infant mortality and morbidity associated with events in the perinatal period.
- Describe the evolution of risk factors for perinatal health outcomes in the population of childbearing women, including demographic, socioeconomic and behavioral characteristics.

Table 25.2 PERISTAT[6] working list of indicators

Category	Core	Recommended	Future development
Neonatal health	Fetal mortality rate Neonatal mortality rate Infant mortality rate Distribution of birth weight Distribution of gestational age	Prevalence of congenital anomalies Distribution of Apgar score at 5 min	Causes of perinatal death Prevalence of cerebral palsy Prevalence of hypoxic-ischemic encephalopathy
Maternal health	Maternal mortality ratio	Maternal mortality by cause of death Severe maternal morbidity Prevalence of trauma to the perineum	Prevalence of fecal incontinence
Population characteristics or risk factors	Multiple birth rate by number of fetuses Distribution of maternal age Distribution of parity	Percentage of women who smoke during pregnancy Distribution of mothers' education	Distribution of mother's country of origin
Heath-care services	Distribution of births by mode of delivery	Percentage of all pregnancies following fertility treatment Distribution of timing of the first prenatal visit Distribution of births by mode of onset of labor Distribution of place of birth Percentage of infants breast-feeding at birth Percentage of very preterm births delivered in units without a neonatal intensive care unit	Indicator of support to women Indicator of maternal satisfaction

- Monitor the use and consequences of medical technology in the care of women and infants during pregnancy, delivery and the postpartum period.

In 2003 a list of recommended indicators (Table 25.2) was published on the Internet together with the figures for the year 2000 from most of the participating countries.[6]

Analysis of indicators

Differences in quality indicators are usually interpreted as mainly related to the care itself, but it is important to consider also differences in the population. Even when comparing area-based populations, differences in maternal characteristics such as parity, multiple pregnancy, preterm birth rate, etc. influence the rates of interventions and outcome. Differences in social and economic conditions may be important for outcomes, but are difficult to assess in a reliable way.

Analyses also depend on the level at which data are reported. Aggregated data merely provide a basis for frequencies and predefined tables, whereas case-based data allow *ad hoc* analyses involving all the variables or indicators recorded. When cases have an ID-number with a link to the newborn's personal ID, longitudinal follow-up of maternal and infant morbidity and mortality and even intergenerational studies are possible.

When data are reported at a case-based level, regional differences may be adjusted by multivariate analyses. This is often used in epidemiological analyses for a scientific purpose. Multivariate analyses have the advantage that adjustment may be made in a model that considers several variables/risk factors and ends up in a single odds ratio with confidence intervals. The disadvantages are that the analysis considers only very simple mathematical relations, that the procedure is not easy to explain and that the analysis often is perceived as something happening in a black box.

Standard populations or risk stratification

Another way to adjust for differences in maternal characteristics is to apply 'standard populations'. One of the first standard populations used in perinatal quality assessment is the 'standard primipara'.[7] The standard primipara is a 20- to 35-year-old parturient without pregnancy complications, admitted in spontaneous labor at term with vertex presentation. This standard primipara is only one of several possible standard populations that adjust for clinically relevant preconditions, and – not least – reflect a risk of interventions and complications that occur in a specific group of mothers. Thus, the results from these analyses are relevant for that specific group of women when informed to choose mode of delivery.

It is possible to construct a structure of mutually exclusive standard populations that constitute the whole population.[8] In this way the variables primi/multiparity, preterm/term, vertex/breech–transverse, singleton/multiple pregnancy and elective delivery (induction of labor/cesarean section) have been used to define standard populations.

National birth statistics stratified by place of birth and standard population may be useful for clients choosing place of birth and midwives and obstetricians as a basis for discussions on quality improvement issues.[9]

To compare regional differences in cesarean section rates in a population with an average rate of 23%, a specific low-risk standard population was defined and used.[10] The low-risk standard population, which constituted 49% of the population, consisted of women of all parities without previous cesarean section, spontaneous labor at term, vertex presentation and without specific pregnancy complications or fetal malformations. The average rate in this standard population was 5.8%. Places of birth were categorized by a higher, lower or average rate of cesarean section in the low-risk group. With this method it could be demonstrated that neonatal morbidity was increased in centers where the cesarean section rates were either higher or lower than average.

Audit of perinatal deaths

Perinatal audit can be performed at different levels: local, regional and national. The levels are of importance when discussing the methodology and outcome of an audit.

Audit at the *local level* is often performed on materials that cannot be compared in a quantitative way because of the small sample sizes. However, it is very useful for improvement in structure and process. Depending on whether the audit is performed by a selected group (leaders) or by all involved in the care (all midwives, all obstetricians, a keen pathologist, all neonatologists), the audit process will be perceived as a superior control or as constructive discussion on how to improve within the team. It is very important that audit meetings of the latter type are supervised in a permissive way to underline the fact that by discussing our mishaps openly we share with each other experience that probably will reduce the risk of repetition. This can also reduce the guilt that many carry subsequent to a more or less preventable adverse outcome.

For practical reasons audit at a *regional level* will not take place very close to the obstetrical or neonatal department where the event took place. Regional audits, however, can work as a forum for discussion of guidelines and attitudes. Also, since the distance between the auditors and the local department where implementation should take place is not very far, often at least one participant in the activity will represent the local department or hospital. Quantitative analyses of common events will sometimes be possible at a regional level, and comparisons between regions are often valuable for initiating quality improvement activities. The results of qualitative activities, such as auditing in different regions, however, may be difficult to compare unless audit procedures are identical and the auditors are well matched. In addition, historical comparisons in the same region imply that criteria are explicit and identical and that auditors do not change their sense of judgment over time.

At the *national level* epidemiological analyses of clinical indicators and well-defined categories can be used for surveillance and provision of subgroups for audit, in order to identify health-care structures or processes that should be changed to improve perinatal health care on a national level.

The premise for a valuable international audit is that indicators and categories are similarly defined. The major advantage of the higher level is the larger sample sizes, which in many cases reach a magnitude suitable for statistical analyses with confidence intervals that allow differences to be detected and addressed.

Classification of perinatal deaths

One of the main objects of perinatal care is to avoid serious adverse outcomes. Most perinatal audit activities have focused on perinatal deaths, which is the most important fetal adverse outcome to be avoided. However, perinatal deaths are heterogenous, and chains of events and causes of death differ widely. Clearly, some deaths are potentially more avoidable than others. A perinatal death classification, which stratifies the perinatal deaths in appropriate groups aiming for quality improvement, including qualitative analyses by audit, and comparison between regions may be helpful as a basic tool. It should rely on simple, routinely recorded variables for allocation into mutually exclusive groups, which should be associated with specific areas for health-care interventions.

In an investigation that analyzed the differences in perinatal mortality rate between Denmark and Sweden, a new perinatal death classification was proposed in order to categorize the perinatal deaths in relevant groups for further qualitative audit. This classification was discussed and evaluated at a Nordic Baltic collaborative workshop with obstetricians, pediatricians and perinatal epidemiologists. The final classification system was named the Nordic–Baltic Perinatal Death Classification[11] (Table 25.3). Perinatal deaths with fetal malformations were placed in a separate category, and subsequently the rest were categorized by time of death (before, during or after delivery), gestational age, Apgar score, plurality and birth weight [considering intrauterine growth retardation (IUGR)] into mutually exclusive groups.

This classification can be applied both to medical records data and, because of the simple structure, to register data.

Table 25.3 The Nordic–Baltic Perinatal Death Classification[11]

I	Fetal malformation
II	Antenatal death. Single growth-restricted fetus ≥28 weeks of gestation
III	Antenatal death. Single fetus ≥28 weeks of gestation
IV	Antenatal death. Before 28 weeks of gestation
V	Antenatal death. Multiple pregnancy
VI	Intrapartum death. After admission. ≥28 weeks of gestation
VII	Intrapartum death. After admission. Before 28 weeks of gestation
VIII	Neonatal death. 28–33 weeks of gestation. Apgar score > 6 after 5 min
IX	Neonatal death. 28–33 weeks of gestation. Apgar score < 7 after 5 min
X	Neonatal death. > 33 weeks of gestation. Apgar score > 6 after 5 min
XI	Neonatal death. > 33 weeks of gestation. Apgar score < 7 after 5 min
XII	Neonatal death. Before 28 weeks of gestation
XIII	Unclassified

Thirteen mutually exclusive groups

Qualitative audit

It is possible to continue the analysis of cases in subgroups in a qualitative way. Applying the Nordic–Baltic perinatal death classification, a panel from Denmark and Sweden found that there were significantly more intrapartum deaths of non-malformed infants in Denmark than in Sweden. By subsequent qualitative audit on case notes blinded by nationality, a panel of Nordic obstetricians concluded that there was more insufficient care and a higher rate of potentially avoidable deaths among the Danish cases. It was proposed that a cardiotocographic recording should be done on admission, and that swifter intervention during delivery should be implemented in Denmark.[12]

Register-based subanalysis

When comparing Lithuania with the Nordic countries, the higher perinatal mortality in Lithuania was mainly explained by a doubled rate of malformed infants, a three-fold increase in intrapartum and two- to five-fold increase in neonatal deaths of non-malformed infants.[13] Since qualitative audit by case notes was not feasible, a register-based subanalysis of the type of malformation was performed. The higher rate of malformed perinatal deaths was explained by a four times higher mortality from neural tube defects.

Perinatal deaths in Europe

In the Euronatal Study, a research project contracted by the European Union for the period 1996–2000, factors related to differences in populations and health care were studied to explain the differences in perinatal death rates. To determine whether suboptimal factors were present in the cases of perinatal deaths, a regional case-based audit was performed in 10 European regions.[14] Using the Nordic–Baltic perinatal death classification, the groups in which care and treatment were most likely to have a significant impact on the outcome were audited: singleton fetal deaths and intrapartum deaths of 28 weeks of gestation or more, and neonatal deaths in children born after 34 weeks of gestation or more.

Suboptimal factors were mostly identified in the antenatal care period, often related to professional care delivery, with failure to detect severe IUGR as the most prominent factor. Maternal smoking was also a significant suboptimal factor among potentially avoidable deaths.

Perinatal quality assessment and audit in low-income countries

In low-income countries, regions are not always clearly defined and referral systems are often not working even if there is a structure proposed. The most common situation is that the regional center with its better resources is overloaded with fairly normal deliveries whereas the complicated cases may not even reach the first level of care. The denominator for any area-based assessment of outcome is therefore very uncertain and also the process-related indicators will reflect only what happens to a minor part of the obstetric population. Still, there is an agreement that especially in settings with limited resources and large health problems, quality assessment of care is even more important than in affluent regions. It is essential that quality assessment activities in low-income countries are focused and their results implemented to improve quality of care.

The baseline registration of data in low-income countries is usually limited to a delivery book in which all mothers who are coming for delivery are noted. This registration is done on admission, and the information about complications and interventions that occur later is usually not complete. Usually, the outcome of the baby is not registered beyond a notation of stillbirth. In uncomplicated cases the neonatal observation time is very short and can be a few hours. If the newborn baby needs special care, it is separated from the mother and the information is not available in her file.

Therefore, routine registration needs to be improved at several levels before it is valid for regional quality assessment activities. Until then local and focused quality improvement activities are needed to motivate staff for relevant routine registrations.

Perinatal audit is such an activity, which is suitable for all levels irrespective of the standard of care and has been found to increase motivation in staff and quality of care. This process, however, needs good leadership and careful introduction to overcome initial suspicion and cultural barriers.

26 Audit in perinatal medicine

J. M. Thomas and S. Paranjothy

Definition

Research is concerned with discovering the right thing to do, audit is concerned with ensuring that the right thing is done.[1] Clinical audit aims to improve patient care and outcome by reviewing the care provided to patients against explicit quality criteria and implementing change to improve the quality of care as a result. The structure, processes and outcomes of care can be selected and systematically evaluated against explicit criteria. Where indicated, changes are implemented at an individual, team or service level and further monitoring is used to confirm improvement in health-care delivery.[2]

Is audit effective at improving the quality of care?

A review of the evidence by the National Institute for Clinical Excellence (NICE) concluded that audit is an effective method for improving the quality of care. The same review also described the audit methods associated with successful audit projects.[2] These findings are drawn upon in this document to give practical advice for undertaking audit.

What can be audited?

Audit may evaluate the structure (organization or provision) of services, the process of care or the outcome of care against an agreed standard.

Measure of structure or service provision

Audit can provide an overview of service provision. For example, research evidence shows that the outcome for patients with ovarian cancer is better if they are operated on by an appropriately trained gynecologist and managed within the framework of a multidisciplinary team.[3–9] An audit of the referral and management of patients with ovarian cancer can provide an overview of service provision in this area. Good-quality health-care services need to be patient centered and acceptable to those who use them. Measuring the views of those who use services enables health care providers to assess the service delivered from the patient's perspective.

Process measure

Process measures are clinical practices that have been evaluated in research and shown to have an influence on outcome. For example, research evidence shows that the use of antenatal steroids has improved perinatal outcome. Evaluation of this process of care would entail measuring the proportion of appropriate women who received antenatal steroids. Process measures may be used to assess the quality of care and have some advantages over outcome measures:

- They provide a more direct measure of the quality of care provided.
- They occur more frequently, so smaller samples are needed.
- The findings are easier to interpret.
- As smaller audits are needed, they cost less to achieve.

Outcome measure

Outcome measure is the physical or behavioral response to an intervention, for example, the health status (dead or alive), cure following surgery for stress incontinence, level of knowledge or satisfaction (e.g. users' views on the care they have received). Outcomes can be desirable, for example, improvement in the patient's condition or quality of life, or undesirable, e.g. adverse effects of a treatment. The assessment of outcomes such as cancer survival rates is fundamental to measuring quality of care but the use of outcomes alone in assessing quality of care has the following limitations. Outcomes are not a direct measure of the care provided; ascribing causal factors to variation in care may be problematic, e.g. social and health inequalities may contribute to variation in mortality rates. Not all patients who experience substandard care will have a poor outcome. Many factors contribute to the eventual outcome (e.g. disease severity, health status and social and health inequalities);

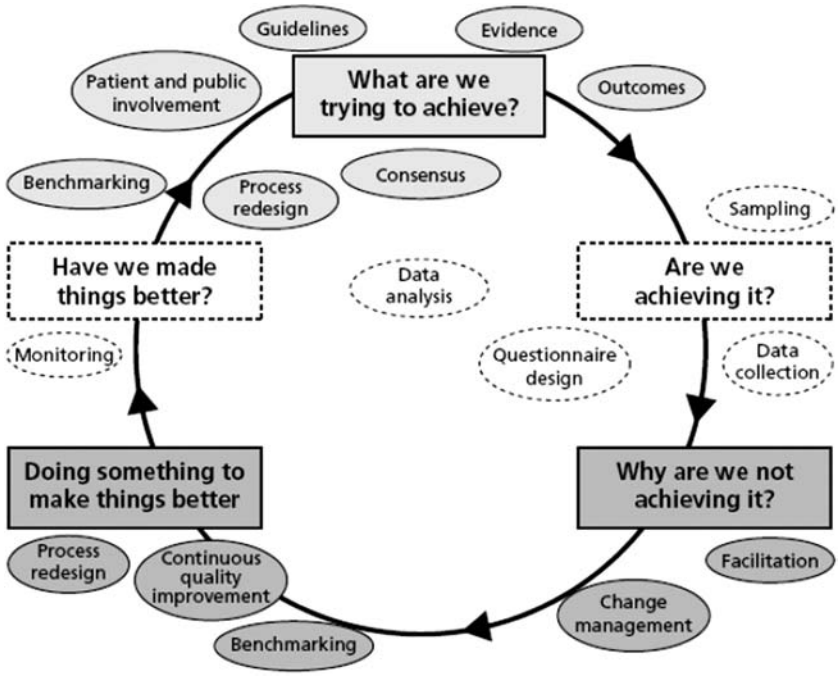

Figure 26.1 The clinical audit cycle.

therefore, mechanisms to account for these differences are required (e.g. case-mix adjustment for comorbidity). Outcomes may be delayed. Research evidence about the impact of some care processes on outcome is limited. Adverse outcomes occur less frequently, so larger samples will be needed.

Despite all the difficulties associated with the interpretation of outcome measures, mortality and morbidity measures are important and this is a major justification for regular monitoring. 'Critical incident' or 'adverse event' reporting involves the identification of patients where an adverse event has occurred, such as the Confidential Enquiries into Maternal Deaths (CEMD), the Confidential Enquiry into Stillbirths and Deaths in Infancy (CESDI) and the National Confidential Enquiry into Perioperative Deaths (NCEPOD). These are examples[6] of outcome reporting. However, only adverse events are reported and usually only adverse events are considered.

The audit cycle

Audit can be considered to have five principal steps, commonly referred to as the audit cycle (Figure 26.1):

1. selection of a topic
2. identification of an appropriate standard
3. data collection to assess performance against the prespecified standard
4. implementation of changes to improve care if necessary
5. data collection for a second, or subsequent, time to determine whether care has improved.

Audit projects require a multidisciplinary approach with the involvement of stakeholders (including consumers or users of the service provided) and the local audit department at the planning stage. Good planning and resources are also necessary to ensure their success.

Selecting a topic for audit

It is essential to establish clear aims and objectives at this stage so that the audit is focused and addresses specific issues within the selected topic. A key consideration is how will the results of this audit be used to change or improve practice.

In selecting a topic for audit, priority should be given to common health concerns, areas associated with high rates of mortality, morbidity or disability and those where good research evidence is available to inform practice or aspects of care that use considerable resources. If successful change is to occur it is important to involve those who will be implementing change at this stage of the audit process.

Identifiying an appropriate audit standard

Review criteria

These are defined as 'systematically developed statements that can be used to assess specific health-care decisions, services and outcomes'. In audit, review criteria are generally used for assessing care; this approach is sometimes referred to as criterion-based audit (Table 26.1). The criterion is the reference point against which current practice is measured.

Table 26.1 Examples of audit and review criteria

Audit topic	Review criteria
Induced abortion	Screening for lower genital tract organisms and treatment of positive cases among women undergoing induced abortion should be carried out to reduce postabortion infective morbidity
Cesarean section	A thromboprophylaxis strategy should be part of the management of women delivered by cesarean section
Hysterectomy	Transcervical resection of the endometrium or endometrial ablation should be available and offered to women with dysfunctional uterine bleeding as an alternative to hysterectomy

High-quality evidence-based guidelines can be used as the starting point for developing criteria. Where this is not possible, criteria should be agreed by a multidisciplinary group including those involved in providing care and those who use the service. Where criteria are based on the views of professionals or other groups, formal consensus methods are preferable. Review criteria should be explicit rather than implicit and need to[2]

- lead to valid judgments about the quality of care, and therefore should be based on research evidence about the importance of those aspects of care;
- relate to aspects of care that are important either to patients or in terms of clinical outcome and
- be measurable.

Standard and target level of performance

This is defined as 'the percentage of events that should comply with the criterion' (e.g. the proportion of women undergoing induced abortion who were screened for lower genital tract organisms, the proportion of women delivered by cesarean section who received thromboprophylaxis, the proportion of women with dysfunctional uterine bleeding who were offered transcervical resection of the endometrium or endometrial ablation). Information about the levels of performance that can be achieved may be helpful when making plans for improvement. Target levels of performance should be examined periodically. The most common approach for setting target levels of performance is informal agreement among the group leading the audit or among health professionals. In some settings, external standards can be useful. However, in many audits no explicit targets are set and the aim is to improve upon current performance.

Target levels of performance have been used most in screening programs. For example, in screening for cervical cancer there are quality criteria to be met, such as the proportion of cervical smears that have endocervical cells.

The term 'standard' has been used to refer to different concepts, sometimes as an alternative word for 'clinical guidelines' and 'review criteria', either with or without a stated target level of performance and, somewhat confusingly, also to refer to the observed or desired level of performance. However, it has been defined as 'the percentage of events that should comply with the criterion' in the interests of clarity.

Benchmarking

This is the 'process of defining a level of care set as a goal to be attained'. There is insufficient evidence to determine whether it is necessary to set target levels of performance in audit. However, in some audits, benchmarking techniques could help participants in audit to avoid setting unnecessarily low or unrealistically high target levels of performance. Reference to the levels achieved in audits undertaken by other professionals is useful. National audits may provide data for benchmarking. For example, the National Sentinel Caesarean Section Audit Report[7] gives regional and national data for comparison on topics such as the use of regional anesthesia in women having cesarean section.

Data collection to assess performance against the prespecified standard

Data collection in criterion-based audit is generally undertaken to determine the proportion of cases where care is in accordance with the criteria. In practice, the following points need to be considered.

What data items to collect

Consideration needs to be given to which data items are needed in order to answer the audit question. For example, if undertaking an audit on cesarean section rates, collecting information on the number of cesarean sections alone will not give sufficient information to measure the cesarean section rate. Data on the number of other births that took place are also required. In general, for audit projects with clear aims, objectives and well-defined review criteria, it is easier to identify those data items that require collection. Definitions need to be clear so that there is no confusion about what is being collected. The definitions will depend on the review criterion that is being assessed. For example, if collecting data on rupture of membranes, it may need to be specified whether this is spontaneous or artificial. Data collectors should always be aware of their legal responsibilities regarding confidentiality and having electronic patient data such as those under the Data Protection Act in the UK and the Caldicott Principles.[8] Under the Data Protection Act 1998, it is an offence to collect personal details of

patients such as name, address or other items that are potentially identifiable for the individual without consent. It is rarely necessary or acceptable to use patient identifiers, such as names and addresses, but some form of pseudoanonymized identifiers may be used. Clinical audit may be considered part of direct patient care and therefore consent to the use of data for audit can be implied through consent to treatment, provided that information is given to patients that their data may be used in this way. Audit project protocols should be submitted to the local research and development committee and ethics committees to seek approval if necessary. Guidance on how to do this can be obtained from the respective bodies.

Data collection

Sources of data include:

- Routinely collected data if available (e.g. birth registers); this enables repeated data collections with a minimum of extra effort.
- Clinical records.
- Data collection through direct observation or from questionnaire surveys of staff or patients.

Routinely collected data can be used if all the data items required are available. It will be necessary to check the definitions for data items that are used within the routine database to ensure their usefulness for the aims of the audit. Also, the completeness and coverage of the routine source needs to be known.

Where the data source is clinical records, training of data abstractors and use of a standard *pro forma* can improve the accuracy and reliability of data collection. The use of multiple sources of data may also be helpful. However, this can be problematic, as it will require linking of data from different sources with common unique identifiers.

Questionnaire surveys of staff or patients are often used for data collection. There are several validated questionnaires on a wide range of topics that may be adapted to a specific audit project. There is also literature on developing these (see Appendix).

Developing a questionnaire

There is a large amount of literature on how to develop questionnaires.[10,11] Some of the general principles involved are presented here. Questionnaires are often used as a tool for data collection. Questions may be open or closed. Generally, questionnaire design using open questions, e.g. 'What was the indication for cesarean section?', followed by space for free-text response, is easier. However, analysis of these data is difficult, as there will be a range of responses and interpretation can be problematic. Open questions may be more difficult and time-consuming to answer and can lead to non-response, which results in loss of data.

Questionnaires can be composed entirely of closed questions (i.e. with all possible answers predetermined). More time is needed to develop this type of questionnaire but the analysis is generally easier. An example of this type of questionnaire is given below:

Which of the following statements most accurately describes the urgency of this cesarean section?

A. Immediate threat to the life of the fetus and the mother.
B. Maternal or fetal compromise that is not immediately life threatening.
C. No maternal or fetal compromise but needs early delivery.
D. Delivery timed to suit the woman and staff.

Closed questions assume that all possible answers to the question are known but not the distribution of responses. Time and consideration needs to be given to the options available for response as, if a desired response is not available, the question may just be missed out and it may put people off completing the rest of the questionnaire. For some questions, the 'other' category can be used with the option 'please specify', which gives an opportunity for the respondent to write in a response. However, if this is used, thought must be given *a priori* as to how these free-text responses will be coded and analyzed. In some situations, not having a category of 'other' may lead to the question not being answered at all, which means that data will be lost.

If questionnaires are developed for a specific project, they need to be piloted and refined to ensure their validity and reliability before use as a tool for data collection. While those who developed the questionnaire understand the questions being asked, the aim of piloting is to check that those who have to fill in the questionnaire are able to understand and respond with ease. Questionnaires that are not user friendly are associated with lower response rates, the quality of data collected will be poor and hence results will be of little value.

Data management

Thought needs to be given to who will collect the data, as well as the time and resources that will be involved. In small audit projects it may be feasible for the principal investigators to go through clinical notes for data abstraction. However, for larger projects, e.g. a prospective audit on induction of labor practices within a maternity unit, it may be more appropriate for those involved in the care of the woman giving birth (e.g. midwives or obstetricians) to fill in standard data collection sheets. Where available, audit support staff should be involved.

Data that are collected on paper forms are usually entered onto electronic databases or spreadsheets such as Microsoft Access®, Epi Info® or Microsoft

Excel® for cleaning and analysis. Data entry may be done by optical character recognition (OCR) software, optical mark readers (OMR) or manually. OCR is the most accurate for questionnaire data using tick boxes but less accurate for free-text responses. The method of data entry needs to be taken into account when designing the questionnaire or data collection sheet. For manual data entry, accuracy is improved if double data entry is used. However, this can be a time-consuming exercise. If the facilities and resources are available, electronic collection of data can be considered. In this case, data are entered immediately, at source, into a computer. While this is quick and requires minimal storage space, it can be difficult to handle unexpected responses and as information is entered directly into a computer it cannot be verified or double entered.[9]

Consideration also needs to be given to the coding of responses on the database. For ease of analysis of closed questions it is generally better to have numeric codes for responses. For example, yes/no responses can be coded to take the value 0 for no and 1 for yes. Missing data will also need to be coded, for example, with the number 9. Missing data should be distinguished from those where the response is 'not known' (if this was an option on the questionnaire).

It is advisable to incorporate consistency checks as data are being entered, in order to minimize errors. For example, if there are two questions:

(1) How many previous pregnancies of at least 24 weeks of gestation has this woman had?
(2) How many previous cesarean sections has she had?

A consistency check will highlight entries with responses other than 0 to question (2) if the response to question (1) is 0.

Data analysis

Simple statistics are often all that is required. Statistical methods are used to summarize data for presentation in the form of summary statistics (means, medians or percentages) and graphs.[12]

Statistical tests are used to find out the likelihood that the data obtained have arisen by chance and how likely it is that a real difference exists between two groups. Before data collection has started it is essential to know what data items will be collected, whether comparisons will be made and the statistical methods that will be used to make these comparisons.

Data items that have categorical responses (e.g. yes/no or A/B/C/D) can be expressed as percentages. Some data items are collected as continuous variables, for example, the mother's age, height and weight. These can either be categorized into relevant categories and then expressed as percentages or, if they are normally distributed, the mean and standard deviations can be reported. These summary statistics (percentages and means) are useful for describing the process, outcome or service provision that was measured.

Comparisons of percentages between different groups can be made using a chi-square test; *t* tests can be used to compare means between two groups, assuming that these are normally distributed. Non-parametric statistical methods can be used for data that are not normally distributed. These comparisons are useful in order to determine whether there are any real differences in the observed findings, for example, when comparing audit results obtained at different time points or in different settings. In some situations a sample-size calculation may be necessary to ensure that the audit is large enough to detect a clinically significant difference between groups, if one exists. In this situation, it is important to consult a statistician during the planning stages of the audit project.

These simple statistics can be easily done using Microsoft Excel spreadsheets and Microsoft Access databases. Other useful statistical software packages include Epi Info, SAS, SPSS, STATA and Minitab.

Implementation of changes to improve care if necessary

Data analysis and interpretation will lead to the identification of clinical areas that should be addressed. There are many methods by which this can be done. The feedback of audit findings is most commonly used; for example, presentation at regular audit meetings will stimulate discussions and solutions may be agreed. The NICE review[2] identified several audits in which change in care had occurred. Simple methods were occasionally effective, for example:

- feedback of data collected
- provision of clear data, perhaps using modern information systems, supported by active teamwork
- support from the organization for teamwork
- use of several methods together within the context of an implementation plan.

Change does not always occur in audit and consideration of the reasons for failure may take place after the second data collection. Resistance to change among local professionals or in the organizational environment or team should be considered. Patients themselves may have preferences for care that make change difficult.

The significance of teamwork, culture and resistance to change has led several authors to propose frameworks for planning implementation. These usually include analysis of the barriers to change and use of theories of individual, team or organizational behavior to select strategies to address the barriers. For some topics, such as adverse incidents, systems for continuous data collection may be justified.

Organization of audit

The NICE review[2] found that some methods of organizing audit programs were better than others. The following features are associated with successful audit:

- structured programs with realistic aims and objectives
- leadership and attitude of senior management
- a non-directive, hands-on approach
- support of staff, strategy groups and regular discussions
- emphasis on teamwork and support
- an environment conducive to conducting audit.

Common reasons why audits fail

- *Failure to participate and attitudes to audit*: Involving all stakeholders (including service users) in the project can encourage participation. It is important to recognize the attitudes of those whose behavior is being audited, and to modify the audit process to accommodate these views.
- *Failure to continue and complete the audit cycle*: This makes it impossible to determine whether the audit has led to any improvements in care.
- *Failure to provide a supportive environment for audit*: Perceived lack of support at all stages, together with a range of structural and organizational problems, is associated with poor progress in conducting audit. Research has pointed to a theory–practice gap for clinicians carrying out audit, one solution being to change the organizational culture to one in which clinical audit is supported and actively encouraged.
- *Lack of resources, especially time*: This includes lack of protected time to investigate the audit topic, collect and analyze data, and the time to complete an audit cycle. It follows that audit should be recognized as an important part of clinical practice and those directly involved in audit need to be allocated protected time.
- *Lack of training in audit methodology and evidence-based skills*: Health professionals and audit support staff require adequate knowledge and skills for undertaking audit, and they should be keen to learn. Barriers identified in the literature include a lack of training in evidence-based audit skills and the failure to apply what has already been established.
- *Cost*: It must be recognized that audit requires appropriate funding and that improvements in care resulting from clinical audit can increase costs.

27 Systematic reviews in perinatal medicine

Z. Alfirevic

The principles of evidence-based medicine are not disputed. What constitutes the evidence, however, is hotly debated. Traditionally, medical textbooks and review articles written by experts and opinion leaders have been the main sources of evidence. Recommendation on diagnostic and therapeutic interventions in such material was predominantly based on personal clinical experience and easily accessible literature. Although there has always been some concern about the possible biases inherent in this traditional approach to teaching and information sharing, a more formal criticism gathered momentum in the early 1990s. For example, Antman *et al.* published in *JAMA* a comparison between treatment recommendations for myocardial infarction extracted from review articles and textbook chapters on the one hand and randomized clinical trials on the other.[1] The evidence that thrombolytic therapy saves lives had been available in the early 1970s, when a combined reduction in deaths from 10 clinical trails with around 2500 enrolled patients reached statistical significance. Unfortunately, there were no attempts to analyze the results from the different studies together and further clinical trials continued well into the 1990s with tens of thousands of patients exposed unnecessarily to placebo and many given no treatment at all. Even more worryingly, it took more than 15 years for this evidence to start appearing in medical textbooks and authoritative review articles. In perinatal medicine, the evidence that antenatal corticosteroids can reduce not only neonatal respiratory distress syndrome, but also the risk of neonatal intracranial hemorrhage and perinatal death was available from the early 1970s. Even if early studies could have been seen as hypothesis generating, the reluctance to consider the totality of evidence on this topic in the late 1980s was inexcusable.

Systematic reviews have emerged as one of the most effective ways of bridging the gap between already available evidence and clinical recommendations. The main differences between traditional and systematic reviews are summarized in Table 27.1. The numbers of published systematic reviews have risen quite considerably in the last decade (Figure 27.1) and such reviews are now considered not only an integral part of clinical guidelines, but also a prerequisite for any planned research on diagnostic and therapeutic interventions. The term meta-analysis is often used as a synonym for a systematic review in this context because of the misconception that systematic review must always include a quantitative synthesis of the data to yield a summary statistics (meta-analysis). This is clearly not the case, as systematic reviews may fail to identify studies suitable for statistical pooling.

Table 27.1 The main differences between traditional and systematic reviews

	Narrative reviews	Systematic reviews
Defined clinical questions	Rarely	Common
Reproducible, clearly defined literature search	No	Mandatory
Defined exclusion criteria for potentially eligible studies	Rarely	Common
Prespecified comparisons and outcomes of interest	No	Common
Statistical pooling of the results (meta-analysis)	No	Common
Peer review before publication	Rarely	Common

Cochrane Reviews

Major advances in the scientific rigor and availability of systematic reviews in perinatal medicine have come from the Cochrane Collaboration – an international, not-for-profit organization established in 1993.[2] The aim of the Cochrane Collaboration is to facilitate the preparation, maintenance and dissemination of up-to-date systematic reviews of the effects of health-care interventions. The Cochrane Collaboration Pregnancy and Childbirth Group (CCPC) was the first registered review group within the Cochrane Collaboration and

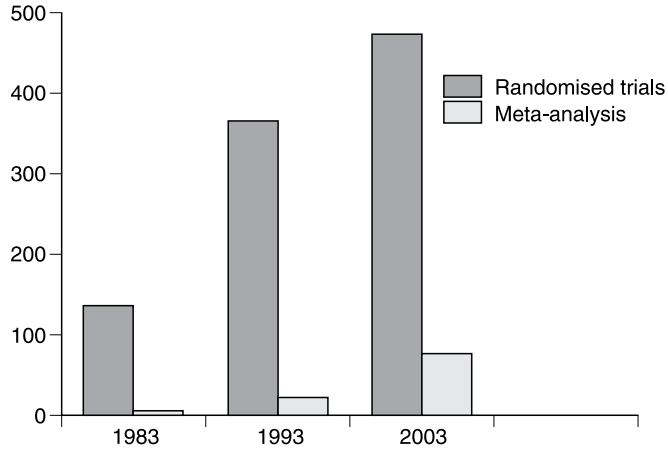

Figure 27.1 Progressive increase in the number of randomized trials and meta-analyses related to pregnancy included in the PubMed *(number of hits for three separate 12-month periods using keywords: pregnan* or labor or labour)*.

was subsequently joined by around 50 other topic-based groups, each of them working under the guidance of an international editorial team. The CCPC remains the largest and most productive Cochrane review group with more than 400 registered reviewers from 27 countries.

The distinguishing features of the Cochrane Reviews published quarterly in the electronic publication *The Cochrane Library* are transparent peer-reviewed protocols published in anticipation of each new review, significant input from consumers and consumer advocates throughout the reviewing process[3] and a commitment to keep Cochrane Reviews regularly updated. The main criticism of Cochrane Reviews is a limitation of any evidence based solely on randomized trials.

The criticism that systematic reviews of randomized trials ignore the wealth of knowledge generated by observational studies and basic science is valid. However, the restriction of Cochrane Reviews to randomized trials is primarily pragmatic. The methodology for systematic searches of observational studies is nowhere near as sophisticated as searches restricted to randomized trials. The current register of randomized trials compiled by the Cochrane Pregnancy and Childbirth Group contains more than 10,000 trial reports the majority of which are yet to be included in the Cochrane Reviews. It is anticipated that any similar register of all literature relevant to the evaluation of health interventions related to pregnancy could contain more than a million records.

Other types of systematic reviews

Two other types of systematic reviews have gathered momentum recently as a welcome addition to the already established analyses of aggregate data from randomized trials – systematic reviews of diagnostic and screening tests and individual patient data analysis.

Systematic reviews of diagnostic tests differ from standard reviews in the assessment of study quality and the statistical methods used to combine results (pooled sensitivities, specificities, likelihood ratios and summary receiver operating curves).[4] Most published systematic reviews of diagnostic tests are hindered by the poor quality of the included studies. It is also important to note that the evaluation of diagnostic accuracy of a test is only one aspect of clinical usefulness; the most accurate test can still be clinically useless or, even worse, harmful.

Methods of undertaking a meta-analysis of several studies may involve collecting either aggregate data or data on each patient individually. The advantages of the latter approach, described as the 'yardstick',[5] include a more complete analysis of 'time of event' outcomes and a more powerful analysis of whether treatment is more or less effective in particular subgroups. The drawbacks can include the increased use of time, staff and financial resources and the lack of availability of the original data for some trials.

Summary

Systematic reviews have made an important contribution to perinatal medicine by reinforcing the evidence on effective therapies like antenatal corticosteroids in threatened preterm labor and highlighting ineffective interventions like thyreotropin-releasing hormone in the same clinical scenario. Equally important has been the role of systematic reviews in identifying gaps in our knowledge. The challenge for the future is to provide regularly updated unbiased summaries of observational, randomized and qualitative data in a format that is understandable to both patients and health professionals. We have nothing to fear. The time currently spent on information gathering and the haphazard critical appraisal of incomplete evidence will be much better spent communicating with our patients and helping them to achieve perinatal care and outcomes that truly suit their needs.

28 Cost benefit in perinatal medicine

Z. Stembera

Greatly increased advances in medicine lead on the one hand to a high quality of care expected and demanded by both health-care professionals and patients, but on the other hand the resources available for responding to the expectations and demands are becoming increasingly stretched. Even in high-income countries, the available resources are scarce in relation to these demands.

Because of this, more and more studies have been reported in the expert medical literature of these countries in the last two decades trying to solve the disproportion between the increasing investments in health care and the principal factors that have led to basic improvements in health by means of methods of economic evaluation.

The key question on how best to choose between the different and competing ways of using the resources that are available has considerable importance in perinatal medicine, whose share in the costs of health care is quite high. There are three reasons for this. First, the number of users – pregnant and childbearing women and their infants – is quite high. Second, the number of preventive screening examinations and preventive hospitalizations during the course of pregnancy has increased. Third, the number of special, sometimes very expensive, examinations using technological advances in medicine has increased.

The approach to preparation of these studies and to their exploitation shows considerable variations. It is different in the professionals within the perinatal field, who wish to make optimal use of the budgets and resources that are available to them, than in the planners, who must decide on the appropriate level of funding for maternity care. There are also differences between the views of the patient, of the hospital, as well as of the government or the community at large.

Methods of economic evaluation

When discussing the already classical studies of Drummond *et al.*[1] and Mugford and Drummond,[2] it is necessary first to state some basic considerations related to the role of economics in the evaluation of care:

(1) The first consideration must be that the care for which the resources are used is likely to do more good than harm. Only afterward comes the consideration of both the most cost-effective or efficient use of the resources available for perinatal care and the extent to which society's resources should be allocated to perinatal care.
(2) Economic evaluation requires a contrast between alternative courses of action, in term of both costs and consequences.
(3) There are three main stages of economic evaluation. First, the likely costs and benefits must be enumerated; second, they must be measured; third, they must be expressed in comparable units.
(4) Among the most important methods of economic evaluation of perinatal care programs are cost-minimization, marginal, cost-effectiveness, cost–utility and cost–benefit analyses.

The nature and scale of any economic evaluation will vary according to the question that is being asked. While all approaches involve to some extent deriving a balance sheet of the costs and benefits of the different strategies compared, some approaches are more complex than others.

Cost-minimization analysis

This, probably the simplest, analysis comes from the presumption that benefits of treatments that are compared are equal, which makes it possible to compare the resource costs without any need to measure benefits. A different length of hospitalization of a woman subsequent to a spontaneous delivery and physiological pregnancy, who delivered a healthy, term newborn, whose adaptation to extrauterine life was normal in the first hours of life, could serve as an example. This is the problem that is being solved at present in the

Czech Republic. Before the transformation of health care to the conditions of market mechanism, that is, before 1990, hospitalization after delivery in the given case lasted for 5–6 days, whereas in the majority of high-income countries with advanced perinatal care, such hospitalization lasts for half that time on average without adversely affecting the health condition of the woman or her child.

From the given example concerning the calculation of decreased costs with the same benefit, it explicitly emerges that it is possible to save the costs of hospitalization for 2–3 days. On the other hand, however, new costs arise for the home visits for the mother and infant when women are discharged earlier from hospital after delivery. This has to last at least until the time of separation of the umbilical stump in the child, and healing of the perineal wound in the woman. Even if, in comparison with the more expensive hospital care, the cheaper home care clearly decreases the costs of postnatal care, this change opens new concerns:

(1) A decrease in satisfaction of Czech women (predominantly primiparae) in consequence of the shorter spell of rest after delivery and the early care of the newborn at home.[3]
(2) A choice of the optimal method for cord care associated with a reduction of the number of home visits by midwives.[4] However, these types of studies fall within other methods of economic evaluation.

Marginal analysis

This analysis would be particularly useful in the case of routine and repeated testing, which is so common in the care of women during pregnancy and childbirth. But the key question is: How many of them should we use? There may be a general agreement that certain screening tests should be applied to high-risk pregnancies. But should they be applied routinely to all pregnant women and possibly also repeatedly? When analyzing the majority of screening tests performed in the course of pregnancy, it should be first taken into account that there exist complex factors affecting the mother's health. It is consequently extremely difficult to evaluate the effectiveness of the analyzed test, because many other variables that influence maternal and fetal health are interacting at the same time and confound the findings. These variables are considerably different in developing and industrial countries, where the most important ones influencing the outcome of pregnancy include socioeconomic factors, level of education, desire for pregnancy and maternal age. Taking into account the above background information and limitations, we shall try to ascertain the effectiveness of these screening tests and subsequent measures from the following two aspects:

(1) *Biological*: Each intervention is considered in terms of what it intended to achieve.
(2) *Programmatic*: Do the maternal health programs successfully deliver the biologically effective intervention to the intended target population?

The widely used practice of ultrasound imaging of the fetus during pregnancy can be employed as a typical example. From the biological point of view this method is routinely performed up to the 20th week of pregnancy since it

(1) defines more precisely the expected date of confinement, hence reducing the induction rate in pregnancies mistakenly diagnosed as post-term;
(2) allows an earlier diagnosis of twin pregnancies, leading to reduced premature labor connected with an increased mortality and morbidity of these newborns and
(3) improves the detection of malformed fetuses, which is followed by termination of pregnancy if the pregnant woman agrees, thereby reducing the number of impaired babies.

Repeated routine ultrasound examinations at the beginning of the third trimester improve a timely diagnosis of fetal growth retardation and placenta previa, leading to reduced mortality and morbidity in newborns.

In a series of studies, the routine and repeated performance of ultrasound examinations during the course of pregnancy was compared with only selective examinations for predicting the expected date of delivery and for assessing subsequent measures upon the occurrence of adverse outcomes. From the programmatic point of view, the health resource implications of such screening programs between the two strategies of care can be considered on the basis of costs, which include equipment, trained staff and clinic accommodation. These then vary with the number of cases treated and differ between the two types of care offered. Of the studies mentioned concerning the effectivness of ultrasound screening programs, only a few refer explicitly to health resource implications.[5] However, since several of the above-mentioned pregnancy complications are studied at the same time in the course of one ultrasound examination, it is very difficult, if not impossible, to earmark out of the total cost of this examination, the partial cost of diagnosing only one of these conditions. For instance, in the Czech Republic, it was possible to successively eliminate anencephaly out of the population of newborns by means of routine ultrasound screening, which is performed in 94% of all pregnant women before the 20th week of pregnancy.[6]

In an effort to limit some relatively expensive and, in the majority of cases, invasive tests connected with a certain, albeit very small, physical risk, while enabling a reliable and timely diagnosis of a serious pathological condition, the procedure was divided from the programmatic point of view into two levels. The timely

diagnosis of some chromosomal or genetic disorders in the fetus can be taken as an example. By means of a routine screening program using relatively cheap and non-invasive tests, a high-risk group is selected from the total population of women on the first level. Only in the small group of women selected in this way are reliable diagnostic methods allowing a timely identification of the disease used, for example, chorionic villus sampling or examination of fetal cells after obtaining a sample of amniotic fluid by amniocentesis. Over the past few years in the Czech Republic, such a programmed procedure has decreased the incidence of neural tube defects and Down's syndrome by 50%, as in the majority of high-income countries.[7]

Cost-effectiveness analysis

Cost-effectiveness analysis of any intervention requires calculation of the change in costs divided by the change in outcome of the intervention; the outcomes are measured in units of health (for example, survival rates, or life-years saved).

Change in cost

The best economic analysis will consider all costs, regardless of who has to pay: the health insurance company, the hospital, the patient, the family or the community at large. A distinction has to be made between charges and costs. Only in some cases will the charge for a service equal the cost, and only under such circumstances can charge be substituted for costs.

Change in survival rates

A differentiated approach to the change in survival rate can be demonstrated with the example of care for newborns of very low birth weight. When evaluating the effectivness of the care for these newborns in the sense of their survival, the following considerations are taken into account:

(1) Birth weight of the newborn: The lower the birth weight, the longer the period of hospitalization in the neonatal intensive care unit (NICU) and the higher the costs of the treatment, because the two factors are combined.
(2) Whether the evaluation concerns a country-wide or regional program, all live births or only neonatal intensive care in the hospital.
(3) Whether the newborn was delivered in a perinatologic center where there is an NICU, or whether the newborn was transported to the NICU only after delivery, because out-born newborns have a different prognosis.
(4) Whether all liveborns are evaluated, or whether certain newborns are excluded, for example, those with lethal malformations, whose death is not influenced by the quality of intensive perinatal care.

The results of this deliberation determine which newborns must be accounted for in the denominator of any calculation of survival rate.

An internationally recommended objective criterion for the intensive care of newborns of a very low birth weight differentiated in this way is the birth-weight-specific neonatal death rate (potentially after exclusion of lethal malformations), which can be further differentiated into death during the first 7 days after delivery (early neonatal death) or during the subsequent 3 weeks (late neonatal death).[8,9]

Cost–utility analysis

In cost–utility analysis, the social value of the outcome is determined. The analysis requires calculation of the change of costs, which is the same as for cost-effectiveness analysis, divided by the change in outcome adjusted for the quality-adjusted life saved, or quality-adjusted life-years saved. From the point of view of utility, the outcome is also the satisfaction gained from consumption of a service.

Change in quality-adjusted life-years or survival rate

The major difficulty is the inability to define what constitutes a normal quality of life, and what is the possibility of measuring the health status and health-related quality of life. The broad definition of health as formulated by the World Health Organization (WHO) is 'a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity'. WHO has also developed a classification of impairment, disability and handicap.[10] Conventionally, an outcome with normal health and quality of life is allotted a utility of 1, and death is allotted a utility of 0.[11] Any outcome of less than normal health or quality of life has a value of less than 1. But many handicapped children lead productive lives, and their health-related quality of life might be fairly good. In this respect, measurement of health-related quality of life adds a different, additional and important dimension to the standard description of cognitive and motor functioning in outcome studies. It is therefore clear that the available adult measures cannot be applied directly to children, whose life experiences and daily activities differ substantially from those of adults. Therefore, the six-component multi-attributable system known as the Health Utilities Index was worked out to describe the quality of life of children, and this includes sensory and communication ability, happiness, self-ability, freedom from moderate to severe pain, learning and school difficulty and physical ability.[12] In spite of this, there still remain a series of factors that may influence the measurement of the health-related quality of life of these children, for example:

(1) Children of different ages have varying capabilities, and with increasing age they develop new and more advanced skills and challenges. Therefore, the dimensions of any measure of health-related quality of life have to take these changes into consideration.[13]
(2) Health status measured by health professionals, self-assessment and parental score might not be consistent.[14]
(3) Children with the same disability might view their quality of life very differently.

A particular problem represents the justification of estimating the health status at the time of a striking decline in neonatal monitoring of very immature newborns, although improvements in morbidity of these children have not been significant. Offering intensive care to all newborns of borderline viability without having the possibility of predicting reliably the quality of life gained in every individual case is being questioned by both parents and health-care providers. It is well recognized that parents, health professionals and members of society may have different views on both the dimensions of importance and the values placed on different health states.[15] The fundamental question, however, is whose values are important for consideration of allocation of health-care resources and for decision making.

Another criterion for analogous decision making, for example, between neonatal intensive care and other programs, is the probability of the length of life gained by means of intensive care. Most surviving adults admitted to intensive care will be dead within a shorter time than the neonates admitted to the NICU, of whom the surviving ones may well live for 70 years or more.

However, cost–utility is also used from the point of view of utility to women. For example, pregnant women may be anxious about their genetic history, or because of their age that they may be carrying a fetus with one or more abnormalities. It is precisely the above-mentioned two-level screening performed in these women that will affect an unnecessary prolongation of their anxiety up to the time of assessment of the correct diagnosis on the second level, since there exists a certain percentage of false-positive results on the first level. The anxiety of the women will be also prolonged if the correct final diagnosis is made by amniocentesis, which can only be performed in the second trimester. On the other hand, the examination by means of chorionic villus sampling can be performed earlier, in the first trimester.

However, routine ultrasound screening also has a psychosocial benefit in some cases. A mother's attitude to her pregnancy can be positively affected by the observation of the first fetal movements on the screen of the ultrasound apparatus, even more than by their perception.[16] It is, in this way, possible to create a relationship with the child before it is born.

Another example of utility to women represents the lower satisfaction of women in connection with the shortened time of hospitalization after delivery that is mentioned in the section Cost-Minimization Analysis.

Cost–benefit analysis

This method of economic analysis in perinatal care, the last one to be mentioned, similarly allows the outcome to be converted into monetary terms. The cost–benefit analysis of perinatal intensive care requires the subtraction of additional costs per live birth from additional earnings per live birth; the results can be expressed in units of currency and would be termed the net economic benefit, or net economic loss if negative.

The data used for the change in cost are the same ones as mentioned in the section Cost-Effectiveness Analysis. The major difficulty is to estimate the lifetime earnings of a survivor, when such imponderables as life expectancy, career choice (including the possibility of unemployment) and inflation have to be predicted so far into the future. Affected children may have different skills and capacities than unaffected children, different health care, education and other needs throughout their lives.

Another important point of view when taking into account the timing of costs and benefits is a generational view, when, for example, the favorable result of treatment of a pregnant woman 40 years ago may have an adverse effect on the fertility of her offspring, as happened in the case of diethylstilbestrol.[17]

The already classical randomized trial of MacDonald *et al.*[18] concerning the economic evaluation of electronic fetal heart monitoring vs. intermittent auscultation achieved the same outcome of care. Since, however, the whole course of labor in every individual woman was always followed by one midwife, and if, rather than her salary bill, the time necessary for such a follow-up should be measured, we would find that hardly any workplace would have a sufficient number of staff for such a procedure.

Costs and benefits arise from changes in the uses not only of a community's, but also of a family's, resources. Returning back to the example of early postnatal discharge from hospital, it is likely that more family resources will be needed for informal home care and support for a mother who comes back home very soon after delivery.

International comparative studies

The cost-effective analysis for better health outcome is also solved in the form of international comparative studies. In some of the above-mentioned problems, for example, because the costs have to be standardized if different areas are compared, further sources of confusion arise when comparing different countries due

Table 28.1 Increase of costs for hospitalization of pregnant women. The data are based on a comparison of two groups of pregnant women: Czech Republic (n=106,680) and Hessen (58,430) in 1994. The costs are calculated in accordance with the rate table of the Czech Health Insurance Company in Czech crowns

Length of hospitalization (days)	Hospitalization of pregnant women in population (%)		Cost increase, difference (%)	(Czech crowns, millions)
	Czech Republic	Hessen		
1–7	10.9	10.1	0.7	0.8
8–21	9.8	7.6	2.2	10.4
> 21	6.6	3.1	3.5	47.8
Total	27.3	20.8	6.4	59.0

Table 28.2 Decrease of costs for the care of low-birth-weight newborns in consequence of their decreased incidence in the population. The data are based on a comparison of two groups of newborns: Czech Republic (n=107,721) and Hessen (n=59,198) in 1994. The costs are calculated in accordance with the rate table of the Czech Health Insurance Company in Czech crowns

Birth weight (g)	Incidence of low-birth-weight newborns in population (%)		Cost decrease, difference (%)	(Czech crowns, millions)
	Czech Republic	Hessen		
<1000	0.30	0.37	0.07	69.9
1000–1499	0.55	0.62	0.07	34.1
1500–1999	1.07	1.23	0.16	18.6
2000–2499	3.55	3.82	0.27	7.3
Total	5.47	6.04	0.57	129.9

to the fluctuations in the respective currency rates over time.

Of these studies, the World Bank data[19] on infant mortality and life expectancy in 21 high-income and 27 low-income countries are meaningful. For each country, the differences between actual and predicted values were calculated for health expenditure per capita on the basis of per capita gross national product and health. From the results of this comparison, it emerged that for high-income countries, the marginal return of health expenditure per capita as measured by mortality is negligible. This means that improvement in health and reduction in mortality can be expected to arise not from further increases in costs, but from greater efficiency in the use of resources, more reliance on preventive measures, advances in lifestyle, behavior and medical technology.[20]

It was the preventive measures to which a comparative epidemiological study was devoted, concerning the effect of bed rest during pregnancy upon two internationally accepted indicators of maternal morbidity: rate of eclampsia and neonatal rate of low birth weight.[21] The incidence of these indicators in the Czech Republic was compared with the incidence in Hessen (one of the federal states of the Federal Republic of Germany), where there is a lower rate of prenatal hospital admissions, while the system of perinatal care and the perinatal mortality rate are similar. From the economic point of view, it was calculated under the conditions of the Czech Republic that:

(1) The increase of expenses for hospitalization of women is higher by 7% in the Czech Republic (predominantly because of hospitalization for different lengths of time for preventive reasons) (Table 28.1).
(2) There is a decrease of expenses for specialized care in the NICU due to a 0.5% lower incidence of low-birth-weight infants in the population (further differentiated into four groups according to birth weight) (Table 28.2).

The two-fold lower sum spared from the NICU costs against the sum paid for the higher percentage of preventively hospitalized women does not include the benefit attained in the second analyzed indicator, that is, the decreased incidence of eclampsia (one case per 2556 deliveries per year in the Czech Republic compared with a greater than two-fold incidence in

Hessen, that is, one case per 1328 deliveries per year). However, it is not possible to express this benefit in monetary terms.

Conclusions

In the economy at large, the costs and benefits of activities are made visible through the market system. However, the market mechanism in general either does not apply, or works imperfectly in the health-care field. This is also true of the use of the terms 'cost' and 'benefit' during economic evaluation of perinatal care. Economists thus have to use other approaches in estimating the benefits of health-care programs. The most promising approach appears to be the evaluation of health improvements not in monetary terms. Also, the monetary cost is often an inadequate measure of the true economic cost. From this point of view, the main methods that economists consider in the evaluation of health-care alternatives and in the comparison of health-care programs were described. These methods of economic evaluation should also ensure wise spending during allocation of resources.

The application of the methods of economic evaluation in perinatal care cannot overcome the moral dilemmas that arise in the choice of different screening or therapeutic methods or allocation of resources. It does, however, provide a framework within which such factors become less easily avoided and more readily discussed from the point of view of both the care givers and the care receivers.

29 3D–4D ultrasound evaluation of the embryo and the early fetus

F. Bonilla-Musoles, L. E. Machado, F. Raga, F. Bonilla Jr and F. Machado

Introduction

Following the USA Food and Drug Administration (FDA) approval of 3D in November 1997, interest in the technique has soared to the extent that reports on 3D in obstetrics and gynecology are now in the thousands. Moreover, any international or national ultrasound congress or meeting of our specialty has main lectures, courses or workshops dedicated to this issue.

Today, 3D is an integrated part of ultrasound (US), not only in obstetrics and gynecology but also in other medical streams.

Most important, the FDA with its strict guidelines has highlighted the importance of this technology for the future of medicine.

Because of the most recent advances in informatics, several important innovations have appeared recently.

The first 3D instruments that appeared in 1991 took 25 s to store an image and minutes to hours to reconstruct the 3D rendering. Then, the defocused instruments[1,2] formed 3D images in real-time. Current software has improved to the extent that images are stored in tenths of a second, and spatial images can be reconstructed immediately, in 1 s. In this way, images are obtained in quasi-real-time showing embryonic or fetal movements, the so-called 4D.

The newest instruments limit the field of vision (a disadvantage similar to 2D) and eliminate distorted echoes. They also store transparency systems allowing immediate visualization and avoiding loss of time. The smaller and easier-to-handle transducers and the better proportionate image quality are also definitive improvements.

But not only has 3D changed and improved in only 2 years, in our opinion two amazing improvements have been introduced:

- The combination in quasi-real-time at the same time and in the same frame of the 2D and 3D images. This advantage allows a rapid and better orientation and, for those with scarce experience, easier identification of structures and planes.
- The integration of successive images in only 1 s, allowing the visualization of embryonic or fetal movements.

But these are not the final effects of the new computer technology. Recently, we used new Japanese prototypes of 3D machines, which were able to produce six images per second, with a store capacity of minutes (the existing machines store only 10 s) and an incredible image quality.

Today, more than 11 commercial establishments make use of 3D, but not all are good. Many use ill-equipped 'work stations' that necessitate spending time (and money) after the exam. These are not real 3D machines, and one should not forget that what the patient, and the sonographer, wants is to visualize the baby in the frame.

In our opinion, and until very recently, none of the workstations are good enough. Recently, a new one with important advantages has been approved by the FDA (although it is not yet approved in the European Community):

- The software program is cheap (€15,000).
- Adaptable to all US machines (also the small ones) and transducer images.
- Excellent image quality.
- Immediate free-hand 3D rendering image of excellent quality.
- No limitation of storing space, as with all existing 3D transducers.
- Very rapid 3D rendering, allowing the study of the heart motion.
- Adaptable to old stored clinical cases, and not only in US machines but in videos, PCs, DVDs, etc.

Some problems remain to be solved:

- There is a shortage of learning centers where interested professionals can learn about new techniques, learn how to use the new instruments and become acquainted with the variety of equipment that is constantly appearing on the market.
- Health-care professionals must not only be aware that all commercial instruments have the latest technological advantages, they must also know that every month new machines are being offered with new and better technology.
- The three first and most important statistics on fetal malformations (reported by Merz, Pretorius, and Bonilla-Musoles) need to be reproduced by other investigators. All the articles that have recently appeared show isolated cases, superficial malformations, or use with few cases.

In summary, we would recommend starting to work with 3D, *it is the future.*

History of 3D

3D reports started 10 years ago. The first descriptions were devoted to emphasis on the diagnostic possibilities in obstetrics or gynecology.[2–67]

Sporadic reports of normal[2,4–8,10,11,13,15,16,26,68–84] and malformed fetuses[2,18–20,38,49,54,70–72,80–82,85–110] followed.

Soon after, descriptive images of specific organs and areas were available:

- craneum and fontanelles[111,112]
- central nervous system[113–118]
- head[21,119,120]
- face[12,22,39,91,105,119,121–124]
- lips[108,125]
- forehead[126]
- eyes[127]
- thorax and vertebral column[14,27,34,37,111,122,128–132]
- heart[60,110,126,133–143]
- fingers[28,75,80,131,144–147]
- genitalia, normal or ambiguous.[148–153]

Comparative 2D/3D biometric studies of fetal weight[154–162] and organ volumes[12,156,157,163–165] showed that 3D provides more accurate results.

Specific organ studies allowed for nomograms regarding:

- anatomic structures (e.g. long bones)
- volumetry of organs (e.g. the gestational sac and lung)[83,156,157,166–169]
- functions (e.g. the heart)[60,86,126,133–138,170]
- vascularization[160,171–179]
- estimation of the fetal weight or fat content through calculation of the muscle circumference.[180]

Extensive casuistics have shown that 3D improves the diagnostic accuracy of 2D in more than 70% of malformations.[18–20,70,71,73,96–105,181,182] Also, the more recent specific reports on selected malformations, such as facial,[91,55] lips,[125] head, neck and spine,[70,111] abdominal wall[59,183] and limbs[90,147] have confirmed these findings.

With regard to the first-trimester fetus, many abdominal or transvaginal (TV) descriptions have been published.[6,7,10,52,69–73,107,112,184–200] The most outstanding are those related to studies of the cerebral cavities.[5,8,69–73,115,116,118,184,185,201–203] Also, uterine-introduced 10-MHz transducers have been used[191] without success.

Gestational sac and secundines have been volumetrically studied.[32,35,204,205]

A new field of publications concerning the early diagnosis of malformations has appeared. These publications show the ability to study important markers of chromosomal anomalies, such as the nucal translucency,[70,73,195] ectopia cordis,[196] trisomy 18-affected fetuses[199] or conjoined twins.[71,88,186,197]

Outside the prenatal diagnosis some important articles have been published related to assisted reproduction,[56,199,206–215] the cervix in pregnancy,[216] urogynecology,[138,217,218] gynecological and breast cancer.[120,219–225]

This chapter deals with the appearance chronology of embryonic and fetal structures up to week 16 based on our own previous published investigations.[5–8,69–73,185]

Abdominal US

As when using 2D, the TV approach is superior to the transabdominal for 3D in the first trimester. Abdominal 3D should not be recommended.

Nevertheless, in this chapter we show the 3D schedule images of the abdominal US, because all machines are equipped with abdominal transducers, but not all make use of TV transducers, which are optional additions.

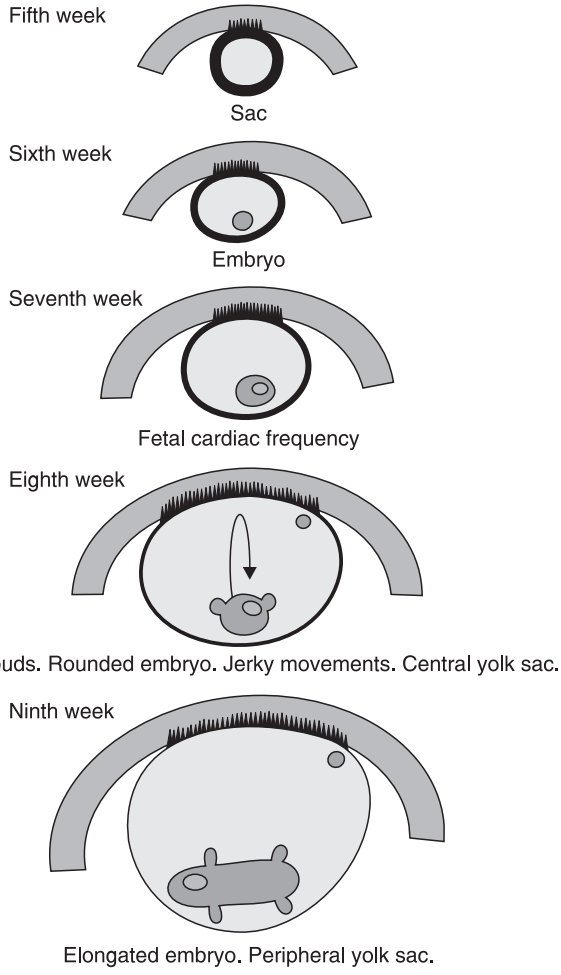
In our book *Atlas de ecografia obstetrica* of 1988, the schedule of appearance of embryonic and fetal structures according to the gestational week was established.

This embryologic–echographic schedule is still completely adaptable today to the first-trimester abdominal 3D (Graphics 29.1 and 29.2).

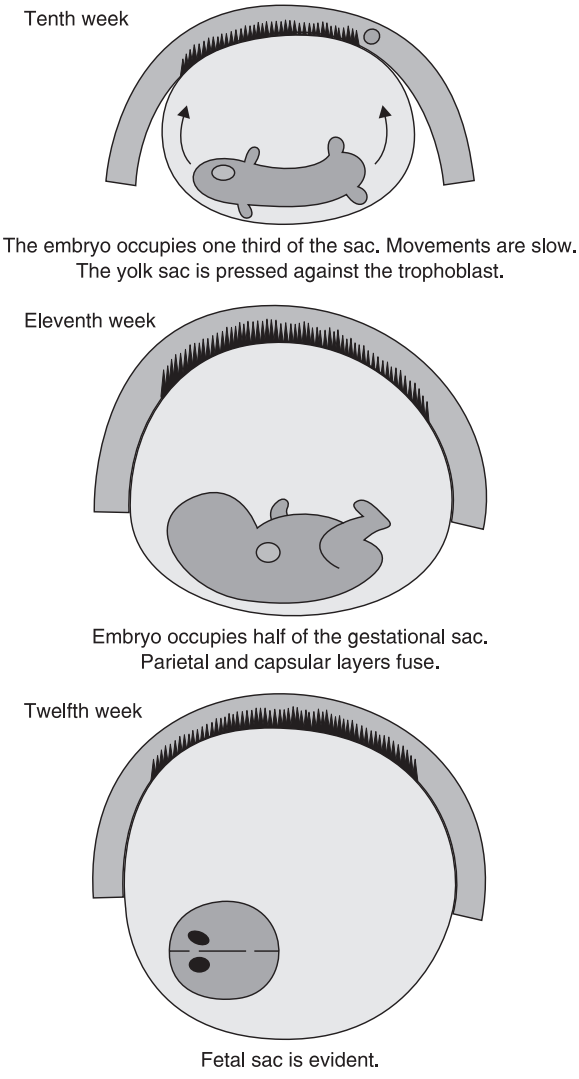
Because of the lack of interest and the difficulty in obtaining good 3D first-trimester abdominal images, there is a scarcity of publications. However, with care, 3D images of exceptional quality can be obtained.

Fifth week

The gestational sac can be observed with the following characteristics:



Graphic 29.1



Graphic 29.2

- oval or round with limpid boundaries
- homogenous trophoblastic rim greater than 5 mm
- no internal contour irregularities
- progressive growth (1 mm/day)

Viewing the abdominal 3D gestational sac at this age is not easy, and there is no improvement when compared with 2D. At present, only the TV route is useful.

The sac's shape is round between the fifth and sixth weeks and becomes oval later on. Irregular forms, such as enlarged, comma shaped, should not be considered abnormal if not accompanied by other anomaly/ies, such as:

- irregular growth: no growth, too slow, too rapid
- decidual refringency changes
- contour irregularities
- embryo not visible (vanishing), etc.

Abnormal sac forms in normal evolution pregnancies are common in cases of myomas, ovarian cysts, distended bladder or sigmoid, etc.

The gestational sac wall thickness decreases as the gestation progresses due to the progressive atrophy of the deciduas capsularis and parietalis.

Following the visualization of the embryo, the crown–rump length should be measured. This measurement should be made from the cephalic pole to the rump taking care to measure the embryonic curvature. The crown–rump length should be measured across the dorsal curvature.

Sixth week

The most important finding is the embryonic visualization. It appears as an echorefringent round structure located in the inferior pole because of its specific gravity, which is greater than that of the amniotic fluid. Its length is of approximately 10 mm.

The gestational sac grows approximately 1.15 mm/day, so that at the end of the sixth week it measures 20 mm, up from 10 mm at the beginning of this week.

The embryonic growth is 1 mm/day, reaching 15–17 mm at the end of the sixth week.

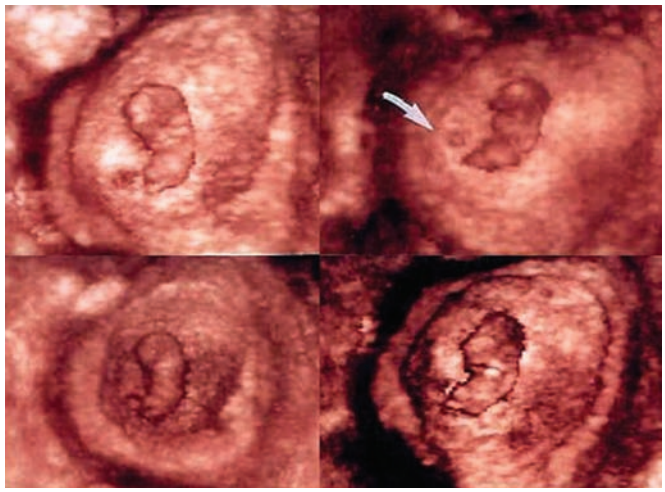


Figure 29.1 Abdominal 3D US in 9+6 weeks. Observe the profile of the embryo lying over the placenta, showing well-defined cranial and caudal poles. The yolk sac can be seen in the upper pictures (arrow). The remaining pictures show the lower limbs.

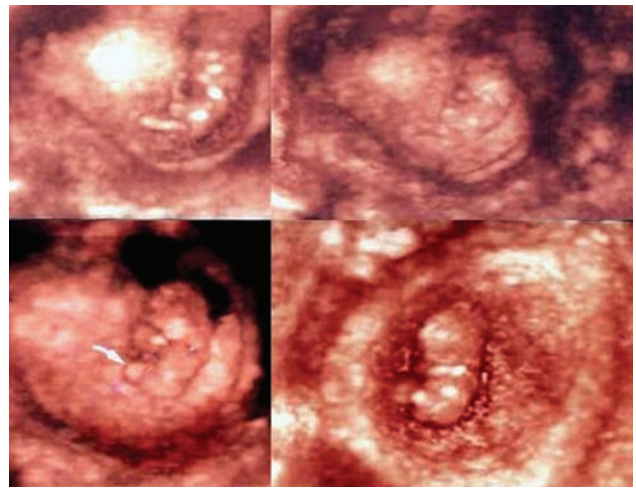

Figure 29.2 Abdominal 3D US first trimester, 10+1 weeks. The fetal head, abdomen and extremities are clearly defined. The ossification nuclei of the jaw and the face profile along with the four limbs are visible. The physiological herniation is depicted in the two lower pictures.

Seventh week

Along with the increasing size of the embryo and sac, the most important feature is the visualization of the cardiac activity. The embryo remains round.

Eighth week

The limb buds appear in an embryo, which is still round. So-called jerky embryonic movements are detectable. We say 'so-called' because the embryo in fact moves up and down repeatedly within the sac.

The yolk sac can be observed in a location near the gestational sac.

Ninth week

For the first time, the embryo appears elongated with definite cranial and caudal poles. The limbs are fully developed, although the fingers are not yet visible. The yolk sac is in a more peripheral location.

From this week on, 3D visualization is superior to 2D due to the amount of amniotic fluid (Figure 29.1).

Tenth week

So-called slow and lazy movements appear. They are characterized by fetal rotations around its longitudinal axis, balancing and movement of the extremities.

The fetus occupies more than a third of the space in the gestational sac; it can be viewed well with 3D along with the yolk sac (Figures 29.2–29.4).

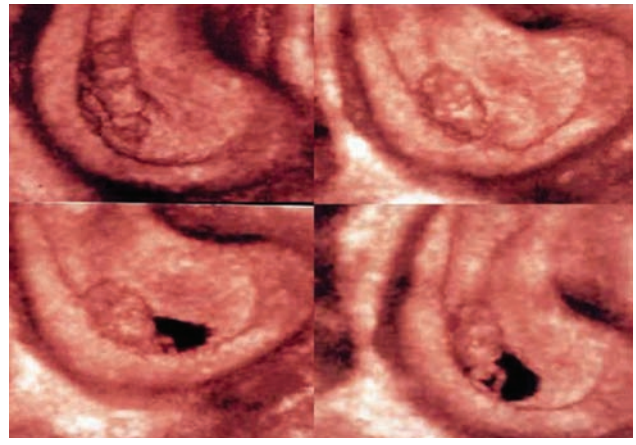

Figure 29.3 3D abdominal US. 10+3 weeks. Frontal view of the fetus showing semiextended legs. The fetus is resting on the placenta (left upper and lower pictures), seen in a frontal view where the face can be observed (bottom right) and the feet already formed (bottom pictures).

Eleventh week

There is fusion of the parietal and capsular decidual layers, eliminating in this way what is considered a gestational sac.

The fetus now occupies one-half of the amniotic cavity. Structures in the head, abdomen and limbs are clearly visible.

Twelfth to sixteenth week

In week 12, the skull is fully formed (Figures 29.5 and 29.6). Facial and abdominal structures can be

Figure 29.4 Abdominal 3D US. 10+4 weeks. The extremities are complete. The fetus lies over the placenta. Fully developed fetus with well-formed arms and legs lying over the placenta.

Figure 29.5 Abdominal 3D US in first trimester. 13 weeks. In this fully developed fetus the physiological herniation has disappeared. The orbits, nose, mouth and limbs with hands and feet can be seen.

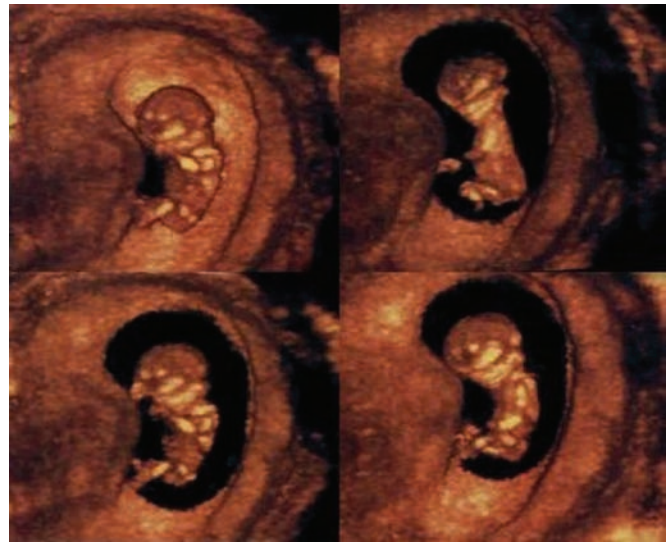

Figure 29.6 Thirteen weeks days. This image shows hands and feet with fingers and toes.

observed. Hands and feet are fully developed. Fingers and toes are identified.

From week 13 on the normal fetal development can be followed (Figures 29.7–29.12).

Twin pregnancy

Twin pregnancy can be diagnosed after week 6, when two gestational sacs are clearly visible, each with its own embryo.

It is not acceptable to miss a diagnosis of twins by transabdominal US examination after the eighth week of pregnancy (Figure 29.11).

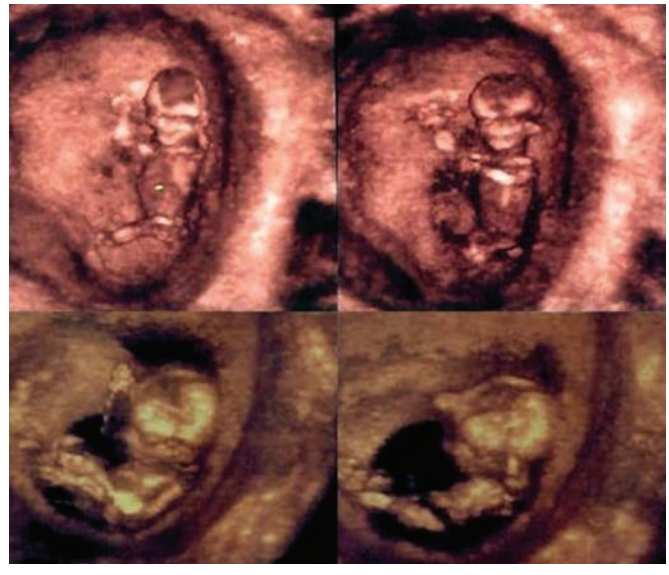

Figure 29.7 Top: Fourteen weeks and 1 day of gestation. Observe the frontal view of the fetus with uplifted arms, the superciliary arches, the nose, ears and hands. Bottom: Fourteen weeks and 4 days of gestation. Fetal profile, superfiliary arches, eyes, sutures and fontanelles.

Figure 29.8 Fourteen weeks and 5 days of pregnancy. This lying fetus reveals arms and hands with clearly defined fingers. The mouth can be seen on the profile view of the face (left).

Figure 29.9 Fifteen weeks plus 1 day of pregnancy. Frontal view of a fetus. Skull bones along with sutures, fontanelles, orbital sockets, mouth and lower limb bones. The right figure shows the profile, forehead, eyes, nose and mouth.

Figure 29.10 Gestations of 14 weeks plus four and five days. Left: The fetus shows open eyes. Right: The eyes are closed.

Transvaginal 3D US

Fourth week (from 4 + 0 to 4 + 6 days)

The first structures observed with 3D as with TV 2D are obtainable between weeks 4 and 5.

The first image that indicates the possibility of pregnancy is the persistence proximal to the menstrual days of a decidual transformed endometrium accompanied by a vascular active corpus luteum (Figure 29.13).

What is first observed is the gestational sac (day 31 ± 1), and the visualization threshold is now established when the β-human chorionic gonadotropin (β-hCG) values have surpassed 1000 mUI.

Being able to observe in the three orthogonal planes and with 3D rendering allows observation of the exact site of implantation in the endometrium (Figures 29.14–29.21).

The gestational sac appears round or oval, perfectly delimited by an echogenic zone greater than 3 mm: the trophoblastis rim. At this time, the size of the gestational sac is 2–3 mm (Graphic 29.3).

One day later, the yolk sac appears. It is round, central, well delimited and measures 3–4 mm in diameter (day 32 ± 1 day). It is linked through the omphalomesenteric duct to the embryo.

On day 33 (±1 day) the embryo can be seen laminar, small, wide, refringent and 2 mm in length. The yolk sac is always visible facing the ventral surface of the embryo.

In cases of multiple pregnancies, monochorial or bichorial, sacs and embryos can be observed (Figures 29.22–29.26): two sacs and two embryos in bichorionic or two embryos in one sac in cases of monoamnionic twin gestation.

Fifth week

By the end of week 5, all these structures are evident, the embryo enlarges and is connected to the yolk sac by a long and slender duct (Figures 29.27–29.29).

From the fifth week on, different organs and structures appear and will be visible according to the schedule showed in Graphics 29.4 and 29.5.

Figure 29.11 Monochorionic twin gestation at 13 weeks and 3 days. Discordant fetuses are already evident. The fetus on the left is already evident. The fetus on the left is already smaller.

Figure 29.12 Dichorionic diamnionic twin pregnancy at 14 weeks and 5 days. Both fetuses are aligned longitudinally, one in cephalic and the other in breech position. The face, sutures and fontanelles of one of them can be observed.

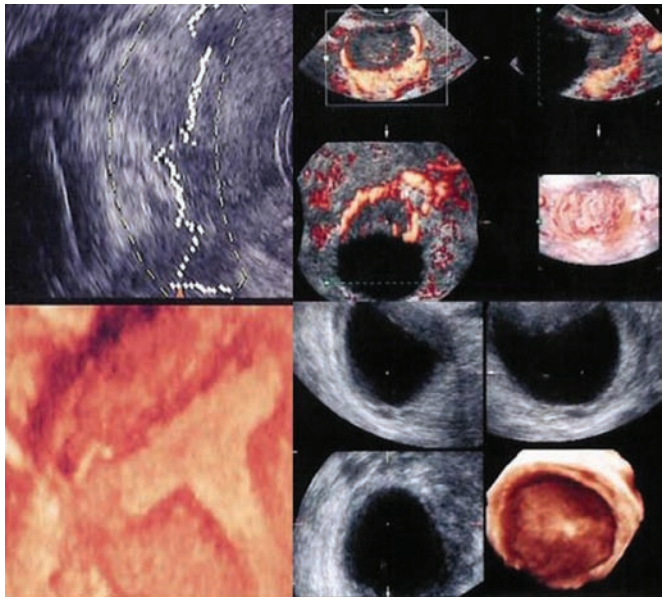

Figure 29.13 Left: 2D and 3D images of the decidua. Right: The corpus luteum with its vascularization. The gestation is not yet defined.

Graphic 3

Structure	Day	Growing velocity
Gestational sac	31±1	1.15 mm/day
Yolk sac	32±1	1.0 mm/week
2 mm embryo	33±1	1.0 mm/day
Heart Activity	35	
Intervillous flow

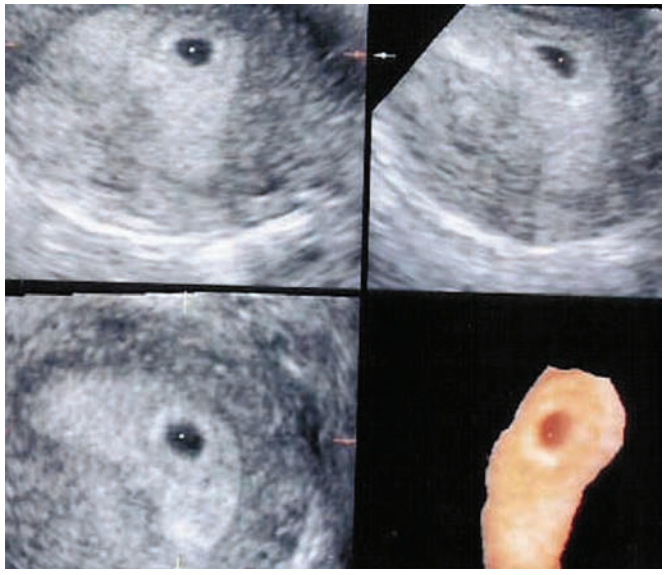

Figure 29.15 Four weeks and 3 days of pregnancy. The decidua and the gestational sac are showed. Observe the rim.

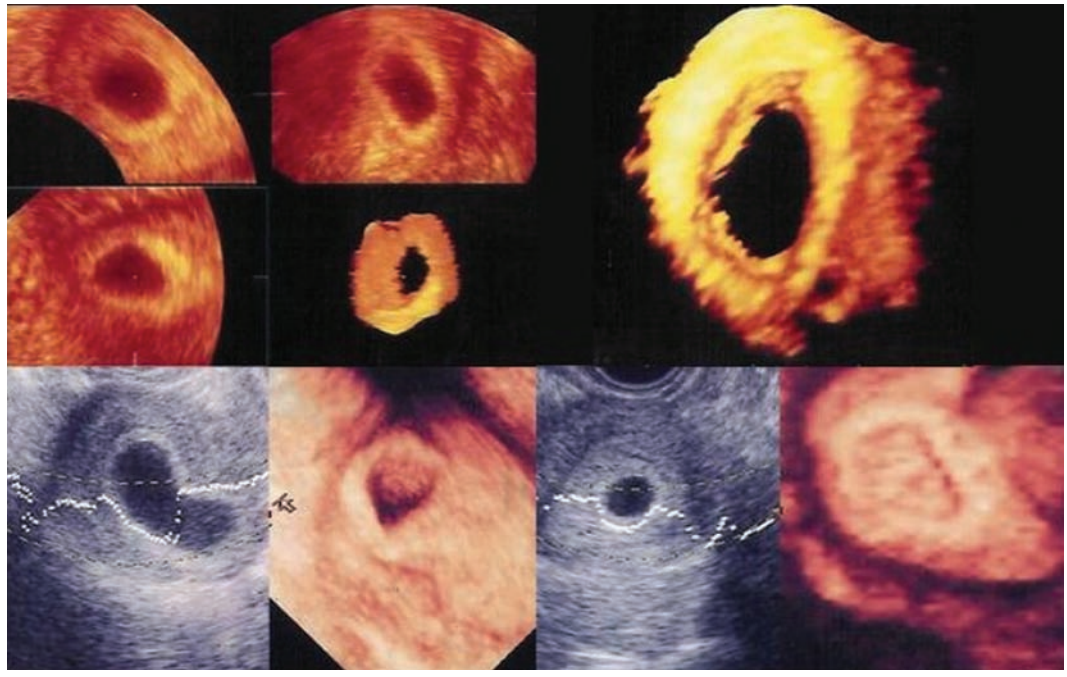

Figure 29.16 3D normal gestational sacs. The trophoblastic rim is clearly depicted and can be measured. Its thickness has to be bigger than 5 mm.

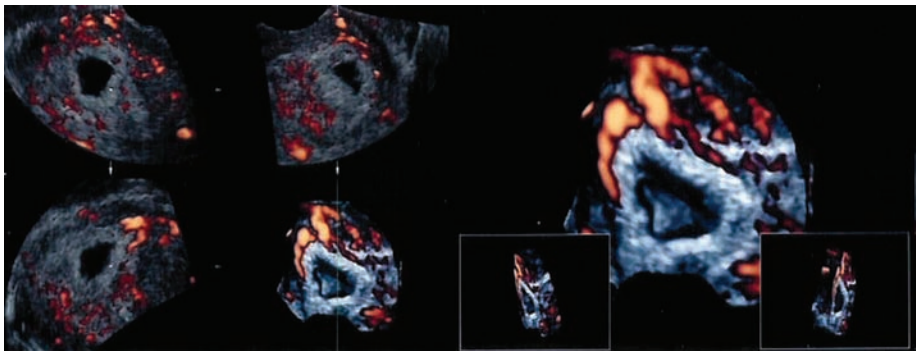

Figure 29.17 4D color Doppler of a normal gestational sac vascularization. Observe the trophoblastic rim.

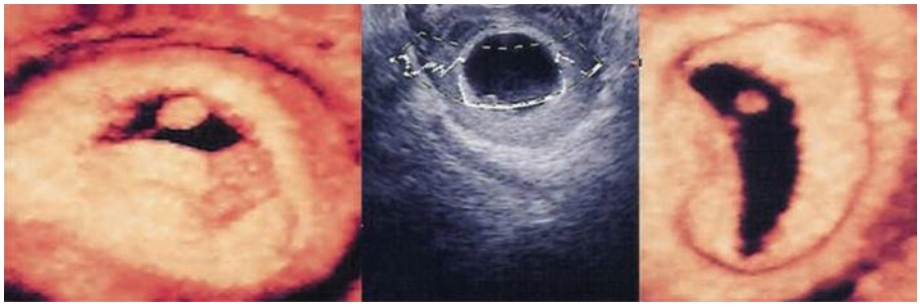

Figure 29.18 Day 32. The yolk sac appears. A small segment of the omphalomesenteric duct can be observed in the left image.

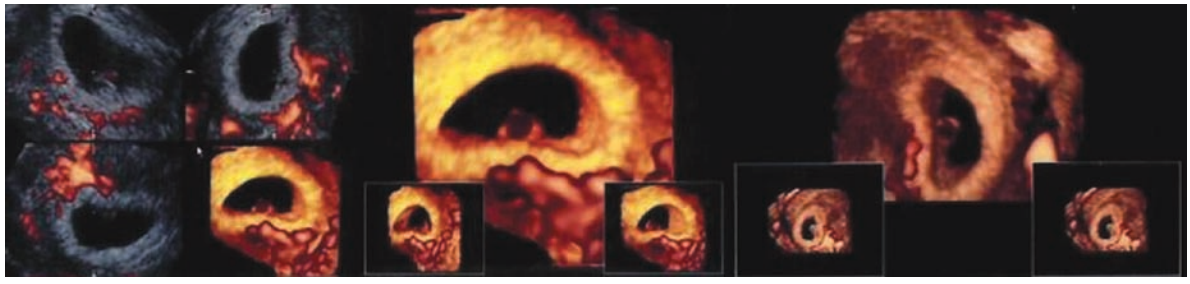

Figure 29.19 4D pictures of normal yolk sacs, gestational sacs trophoblast and vascularization.

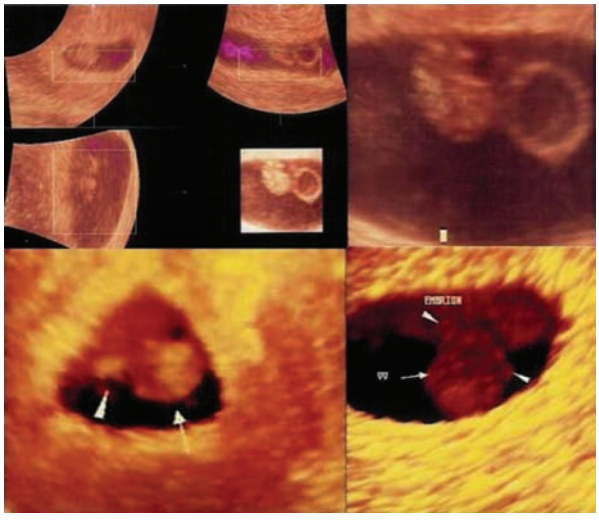

Figure 29.20 Day 33 the embryo is visible measuring 2–3 mm. The yolk sac faces the abdominal embryonic wall. The embryo's growth is very rapid, and only days after it is bigger than the yolk sac.

Sixth week

In only 1 week, the embryo enlarges, allowing the observation of two well-differentiated poles: the cranial and the caudal. Also, the limb buds can be visualized, especially the superior, which appear earlier. This finding occurs earlier than what we have seen in TV 2D US.

Another interesting finding is that at this age, in the distal portion of the caudal pole the cauda is visible. This structure is not observable with other US techniques.

In this week, it is especially remarkable to study the secundines.

The amnios appears as a very thin membrane on the surface of the dorsum of the embryo, just on the opposite side from where the yolk sac is visible. The amnion will soon surround the entire embryo, leaving out the extraembryonic mesenchyme and the yolk sac (Figures 29.30–29.33).

The yolk sac remains visible until weeks 13 to 14. It is always round and grows very slowly, 1 mm a week.

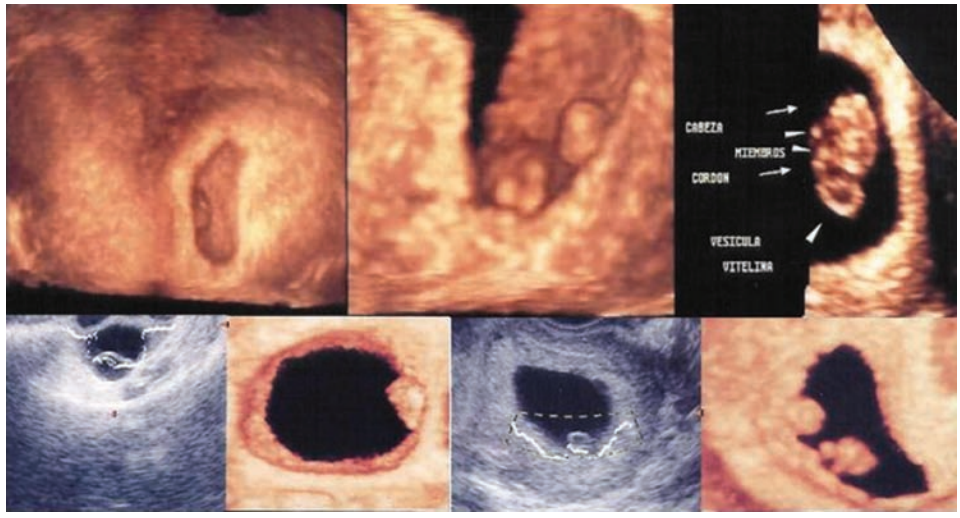

Figure 29.21 Visualization of the embryo. Days 33–35. The embryo takes a laminar form. Two poles are depicted.

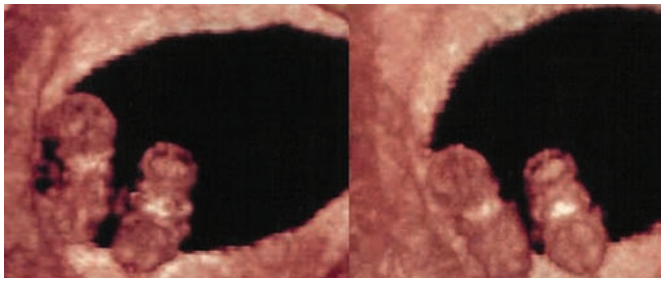

Figure 29.22 Seventh week monochorionic monoamniotic twin pregnancy.

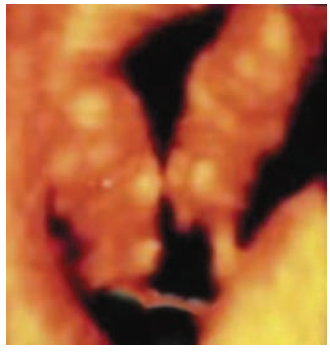

Figure 29.23 Eight-week monochorionic twin.

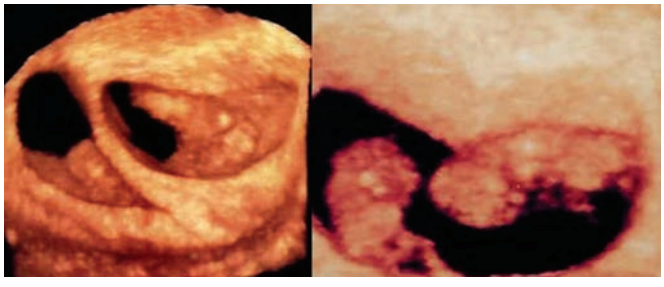

Figure 29.24 Comparison between bichorial biamniotic with lambda sign twin (left) with a monochorial monoamniotic one (right).

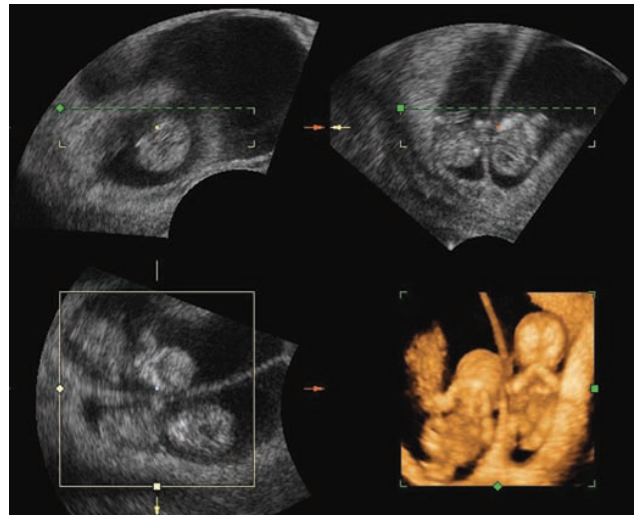

Figure 29.25 Orthogonal planes and 3D rendering of a 12th-week twin pregnancy.

As the cord forms, its anchoring site narrows and thins out.

Seventh week

The embryo clearly shows the limb buds. This detail is used to establish the gestational age (Figures 29.34 and 29.35).

The cephalic pole is flexed. It is very interesting that in the back of the embryo two parallel layers are observable, which represent the first vision of what will be the fetal spine. This finding is only visible with 2D TV US in the eighth week.

Eighth week

The configuration of the embryo is completed. The cranial pole is large and voluminous. The profile, face, orbits, mouth, jaw and maxilla can be identified.

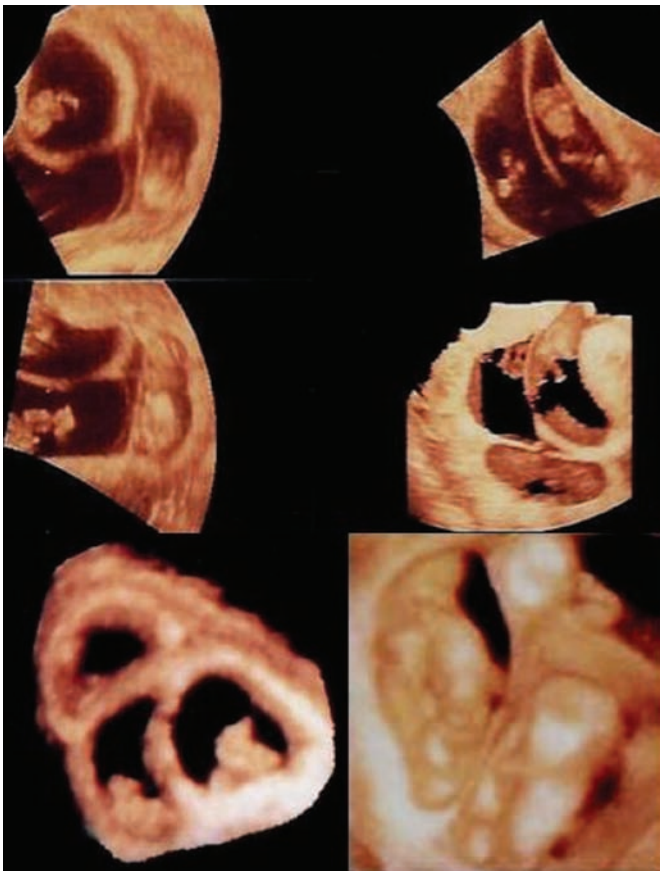

Figure 29.26 Different cases of triplets. Top: Week 10. Bottom: Weeks 6 (left) and 13 (right).

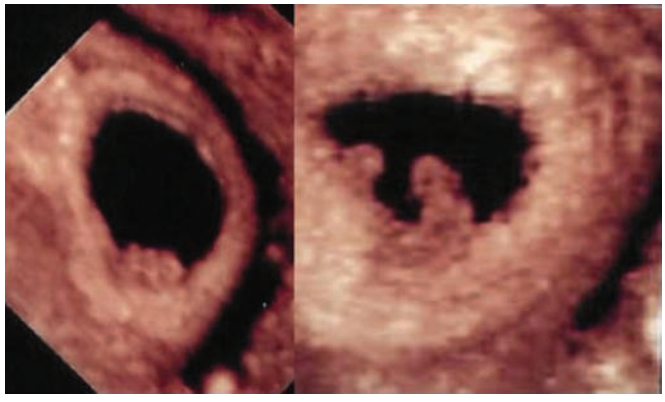

Figure 29.27 Five weeks' pregnancy. Elongated embryo with two poles. The yolk sac is visible on the left of the right image.

The caudal pole shows large limb buds with stubby ends that resemble hands and feet. Joints and articulations are visible.

The spine is completely formed, and appears as a white line in the dorsum. The superior portion (axis and atlas) still remains separate.

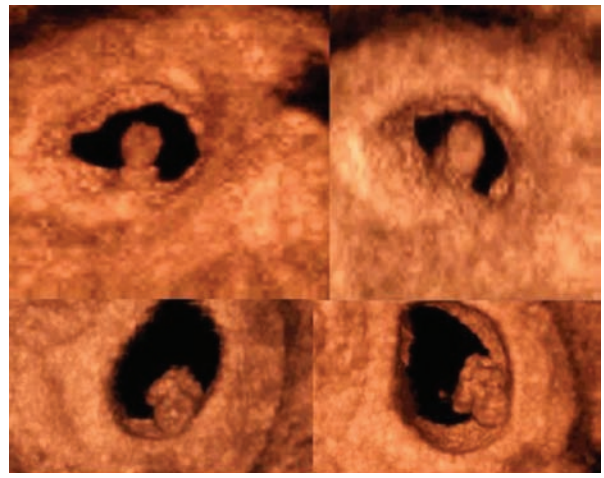

Figure 29.28 Five weeks' pregnancy. These four images show the embryo, still smaller and elongated, and the yolk sac round and facing the embryo.

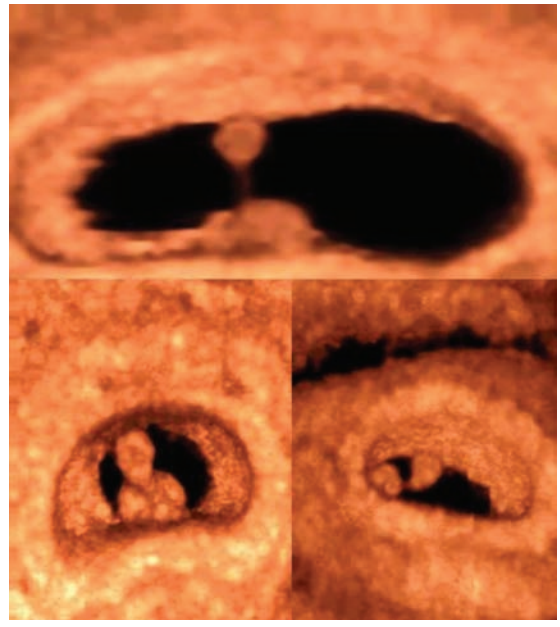

Figure 29.29 The same case as Figure 29.10. Five weeks' pregnancy showing the embryo with a thin omphalomesenteric duct linking the yolk sac.

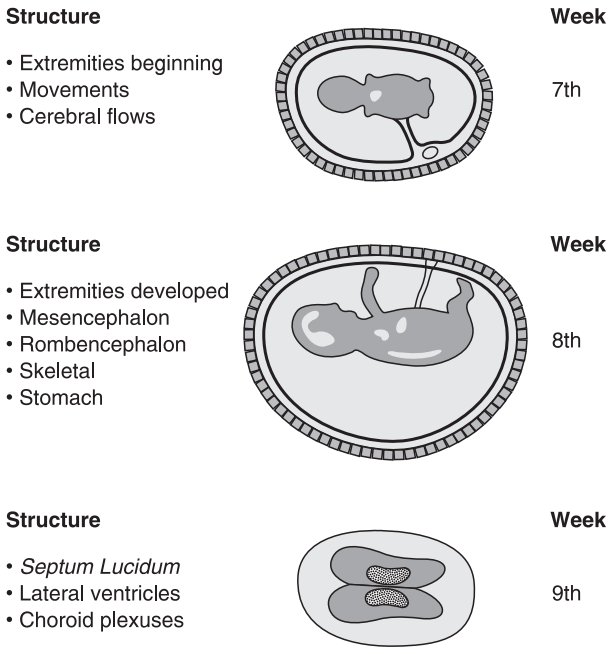
Graphic 29.4



Graphic 29.5

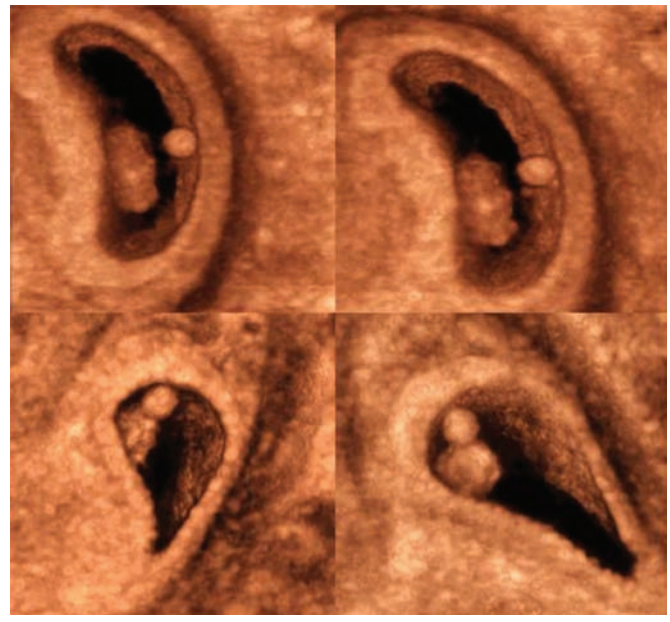


Figure 29.30 Beginning of week 6. The embryo is much bigger than in week 5, shows clearly two poles, the craneal and the caudal, and the upper and lower buds of the extremities are depicted. The cauda appears between the lower buds of the extremities.

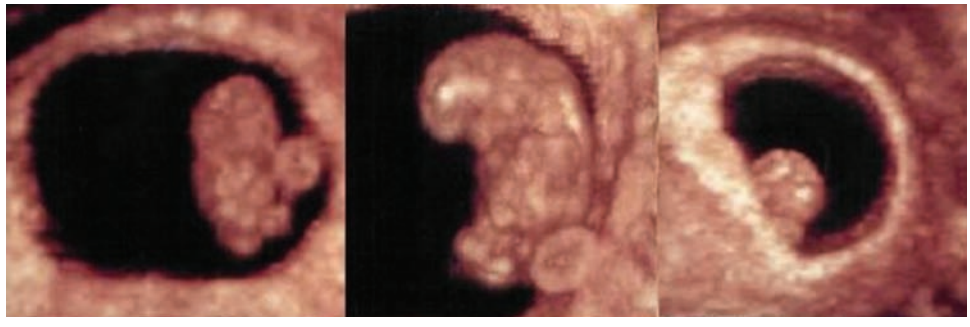

Figure 29.31 End of week 6. The embryo shows a bigger size, the cephalic pole is slightly angulated and the extremities buds are longer.

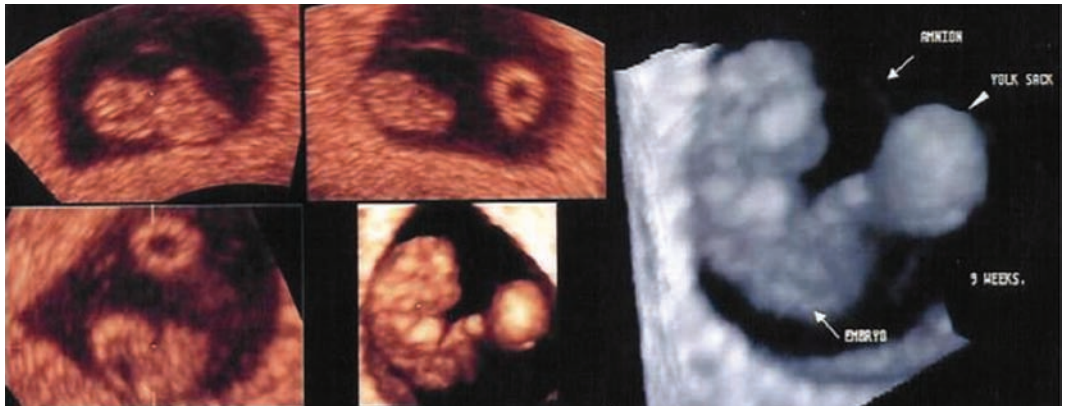

Figure 29.32 These two figures show the 3D image of the whole omphalomesenteric duct and the yolk sac in week 6.

Figure 29.33 End of week 6. The embryo shows in detail the curved cephalic pole and an elongated, sometimes thick, sometimes thin but very long omphalomensenteric duct.

Figure 29.34 Seventh week of pregnancy. Observe the cephalic pole, the extremity buds and a long coiled umbilical cord. The yolk sac lies away from the embryo.

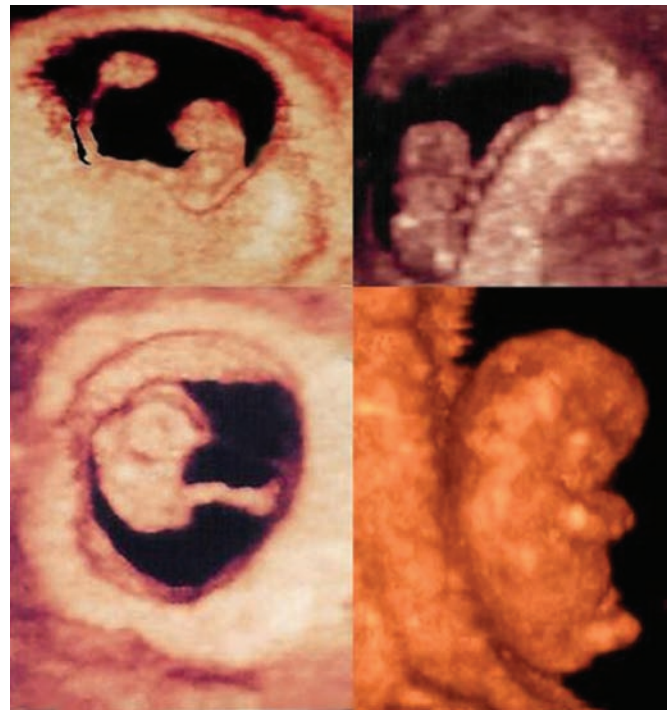

Figure 29.35 Seventh week of pregancy, fetuses showing the cauda, the buds and a very long omphalomesenteric duct.

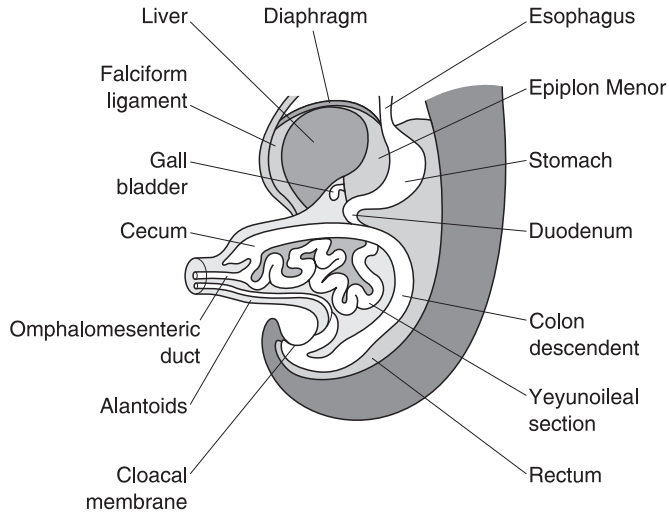

Graphic 29.6

It is important to note that during this week the physiologic herniation can be seen. It is a round and well-defined structure, refringent and linked to the abdominal wall at the site of the umbilical cord insertion (Graphic 29.6).

Its refringency is that of the abdominal wall, its size is small, less than 7 mm, and it always disappears between the 11th and the 12th weeks.

Although at this week the profile, forehead, nose and mouth are visible, they will be clearly defined by the 10th week (Figures 29.36–29.39).

Ninth week

During this week the head appears always flexed anteriorly and the finger and toe buds appear (Figures 29.40–29.42).

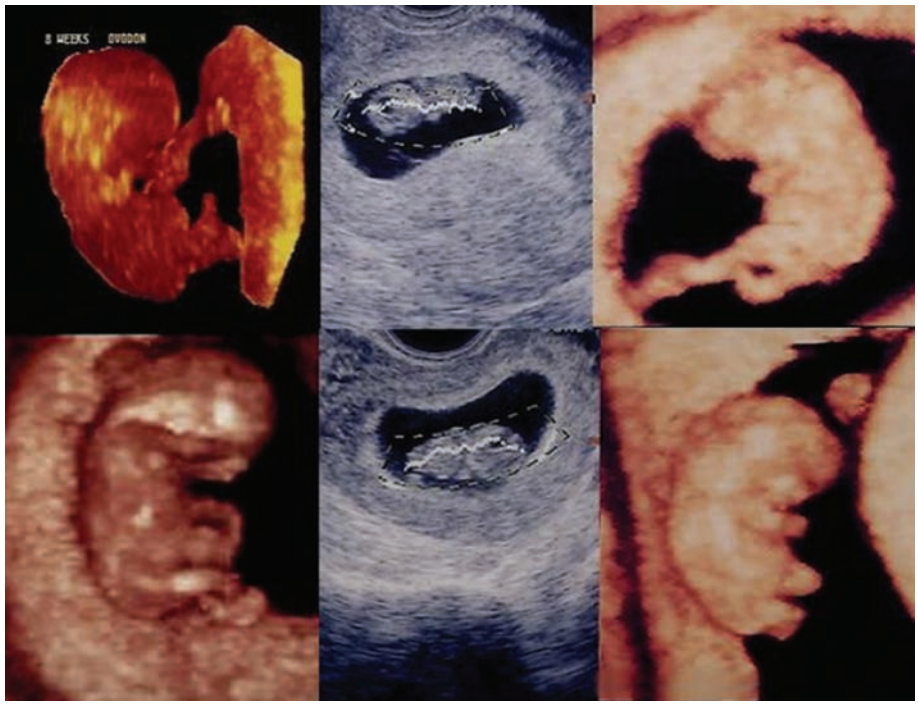

Figure 29.36 Eight weeks' pregnancy. The embryo shows full extremities. The profile can be identified. The umbilical cord is fully formed.

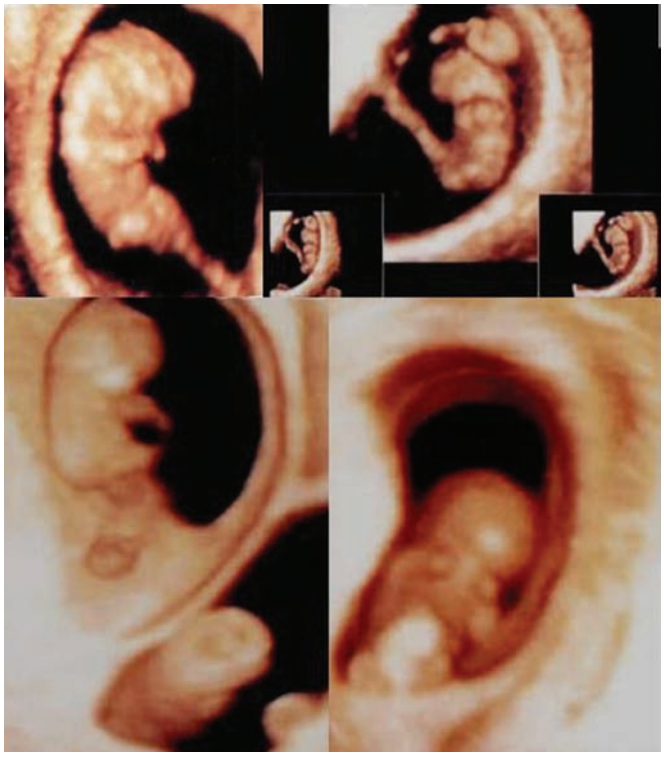

Figure 29.37 Frontal and sagittal 4D view of an eighth week embryo.

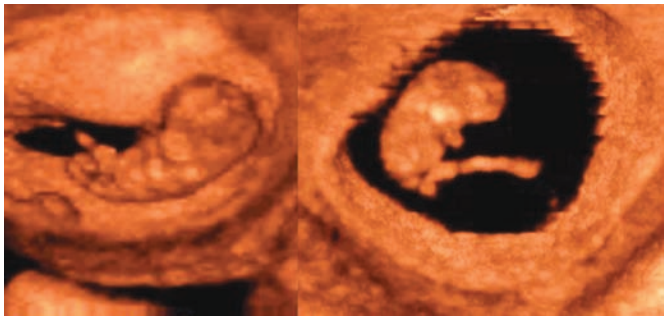

Figure 29.38 This picture shows the ossification nuclei of jaw and maxilla. The mouth is visible as well as the complete extremities.

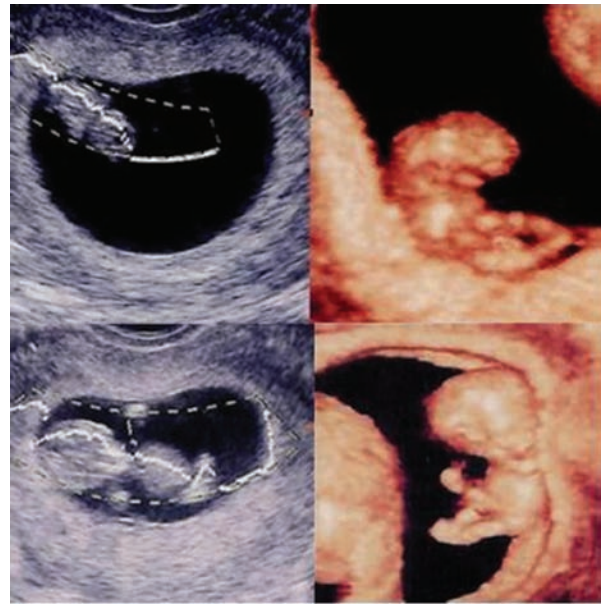

Figure 29.47 Ten weeks' pregnancy. The fetus shows the profile and the eyes and it is surrounded by the amnion (arrows). Extremities, hands and feet are clearly depicted.

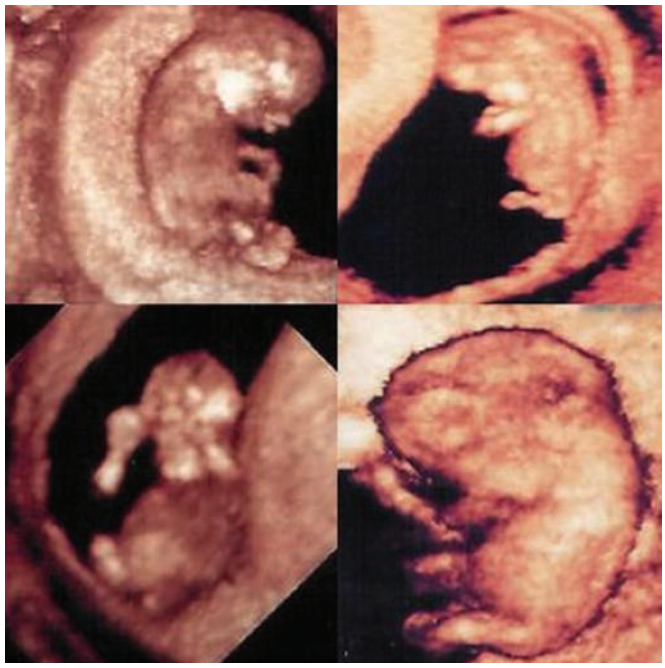

Figure 29.48 Eleventh-week fetuses. The herniation is getting smaller.

Figure 29.50 Visualization of fetuses of 13 weeks, showing intense arm and leg movements.

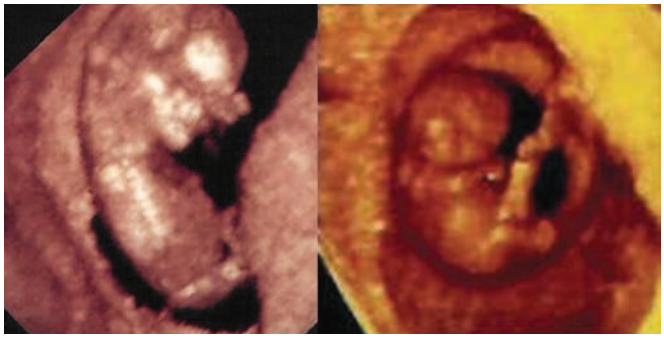

Figure 29.49 Twelve weeks. Visualization of the whole fetus, umbilical cord and placenta.

Figure 29.51 Frontal view of 13th-week fetuses showing the development of the face. Special details can be observed from the development of the nose, eyes and mouth.

Tenth week

The fetus is completely formed. Generally, the head is flexed over the thorax, but even so, we are able to see the face with big orbits, lips, mouth, etc. We can visualize prominent fontanelles and sutures on the forehead.

On the remainder of the fetal body the arms are well developed with elbow and knee flexions as well as hands and feet visible (Figures 29.43–29.46).

The umbilical cord is very long and thick, proportionally larger and thicker than at the end of the pregnancy. By using the transparency system, we can observe for the first time, and identify, the femur, tibia, fibula, humors, radius and ulna. At the beginning of the 11th week the superciliar arch, the orbits, eyes, forehead, nose, ears and jaw can be observed (Figures 29.44, 29.45 and 29.47).

Other organs and structures

The fingers and toes are clearly observed in the 11th and 12th weeks, and are better defined than what is seen with 2D TV US (Figures 29.48 and 29.49).

It is of interest to note how these structures move independently. It is possible to notice that the thumb

Figure 29.52 4D 13th-week fetus showing completely developed arms and legs.

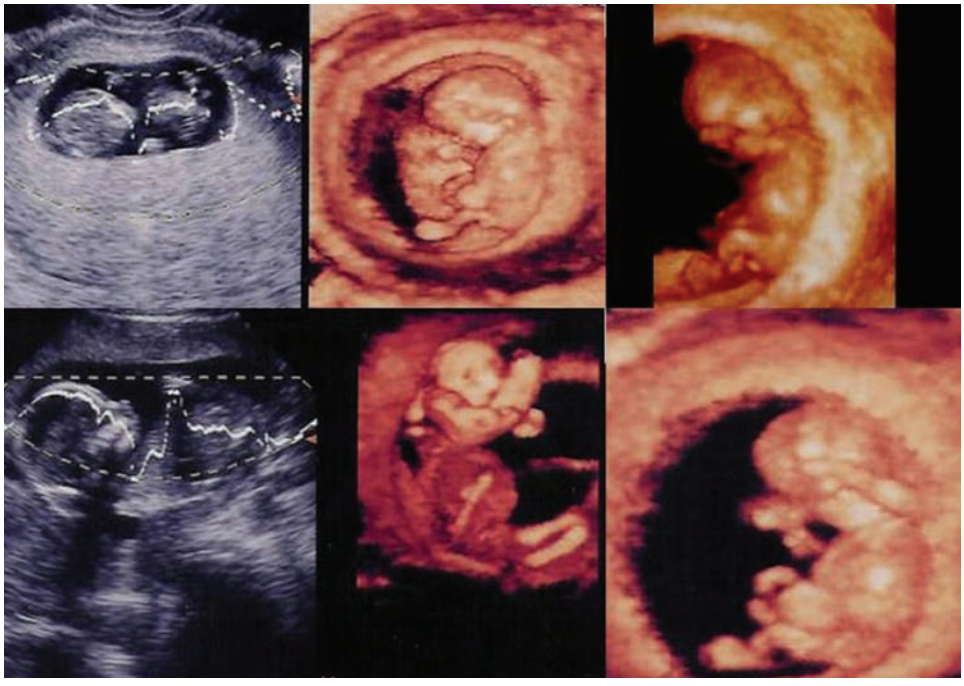

Figure 29.53 3D and 4D visualization of 13th-week fetuses. The herniation has disappeared. The femur, tibia and ulna are visible.

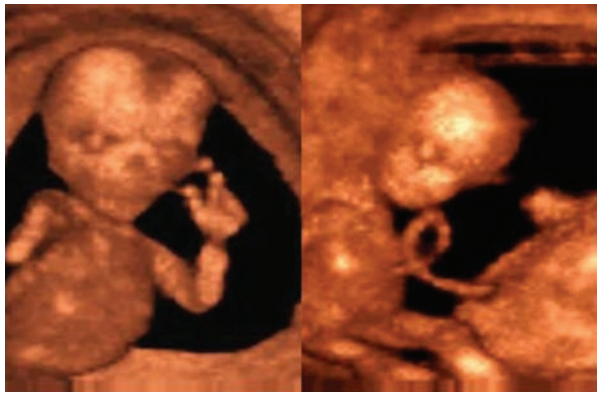

Figure 29.54 Fourteenth-week fetuses showing the face, the fingers and the palm, as well as the arm bones.

apposes the other fingers. The phalanges can be observed in the fingers and toes (Figure 29.54).

Although we have observed movement since the seventh week, by the eighth week we can observe the fetus flexing its arms and legs across the abdomen. These movements, as well as others like opening and closing the mouth, etc., are better observed by using the 4D system available today (Figure 29.50).

We consider the use of the transparency and x-ray systems essential for the study of the spine and pelvic bones after week 12. In this way, the medullary canal, the vertebrae and the ossification nuclei in the ribs can be visualized. It is important to remember that the high portion of the spine is not completely closed until the end of week 12 (axis and atlas). This is of great importance for cases of hygroma colli (see the corresponding chapter), and we think that this will also serve in the future for early diagnosis of neural tube defects (Figure 29.56).

At the same time, the ribs can be seen, the principal pelvic bones (ischium and ilium) and their ossification. All of this will be useful to measure the intervertebral spaces.

Normally, fetuses are flexed, and cover their faces with their hands. But after the 10th week, they can deflex, showing in this manner their faces. The orbits and eyes are more visible and the lids are evident (Figures 29.51–29.58).

Figure 29.55 Fourteenth-week fetuses showing the whole face.

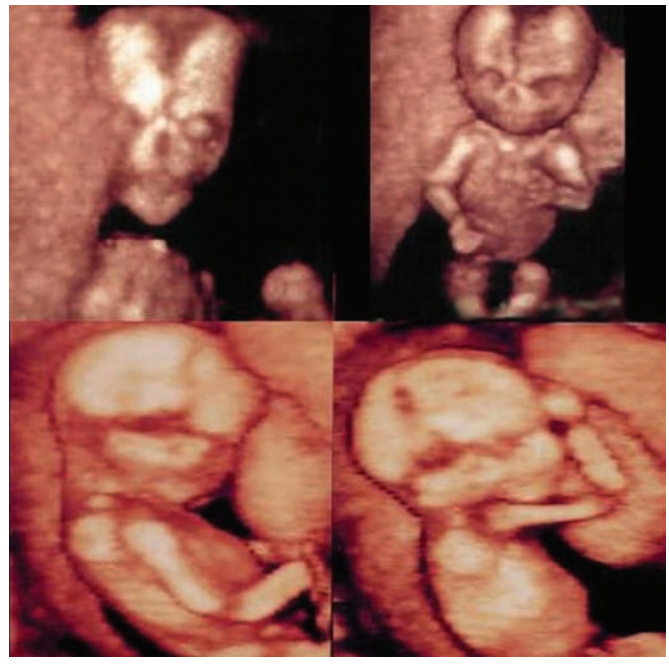

Figure 29.57 Frontal and sagittal view of fetuses between weeks 14 and 16 showing the development of the whole skull. See the clear view of all bones and sutures.

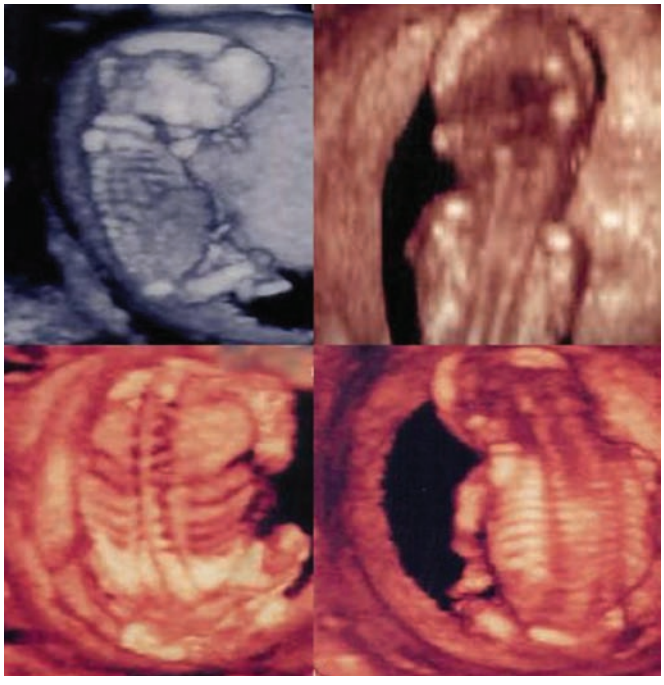

Figure 29.56 Either the use of the transparence system or introducing the ROI into the thorax allows study of the thoracic cage, ribs, vertebrae and medullary channel.

Figure 29.58 Eighteen weeks' pregnancy. The upper images show a fetus with the mouth open. The bottom images show the skull bones, fontanelles and sutures.

The nose is more protuberant and is completely formed between weeks 10 and 13. The mouth, lips and jaw are perfectly defined. The sutures and fontanelles will approximate progressively (Figures 29.51, 29.53 and 29.57).

Finally, in some cases we have observed the fetal sex clearly as early as the 13th week only in male fetuses. The labia of female fetuses can occasionally be distinguished clearly during the 16th week.

30 Malformations of the gastrointestinal system

V. D'Addario and L. Di Cagno

A correct ultrasonic examination of the fetal gastrointestinal tract includes the visualization of the following structures:

- the stomach (Figure 30.1)
- the small and large bowels (Figure 30.2)
- the liver with its main vessels and the gallbladder (Figure 30.1)
- the abdominal wall and the insertion of the umbilical cord (Figure 30.3)
- the diaphragm (Figure 30.4).

The systematic evaluation of the above-mentioned structures allows the recognition of several congenital anomalies of the gastrointestinal system. The reported sensitivity of ultrasound in diagnosing gastrointestinal malformations varies from 24% to 86%, according to different authors' results. This wide variation is due to the different study designs (mainly the number of scans performed during pregnancy), inclusion criteria and levels of examination. Since many gastrointestinal malformations appear late in pregnancy, the best results are obtained when the screening design includes a scan also in the third trimester.

The malformations of gastrointestinal tract and abdominal wall can be divided into four groups:

(1) anterior abdominal wall defects
(2) diaphragmatic defects
(3) bowel disorders
(4) non-bowel cystic masses.

Anterior abdominal wall defects

The congenital abdominal wall defects include gastroschisis, omphalocele and body stalk anomaly.[1] The ultrasonic prenatal diagnosis of these defects is relatively simple and possible in the first half of pregnancy. However, it must be remembered that there is a physiological herniation of the small intestine outside the abdominal cavity between the 5th and the 11th weeks of gestation (Figure 30.5) and therefore a prenatal diagnosis of abdominal wall defect cannot be made in the earliest stage of pregnancy.[2]

Gastroschisis

This malformation consists of a paraumbilical full-thickness defect of the anterior abdominal wall, which is usually located to the right side of the umbilical cord insertion, associated with evisceration of abdominal organs.

The incidence ranges from 1:10,000 to 1:15,000 live births.

Gastroschisis is considered a sporadic event with a multifactorial etiology, but cases of familial occurrence have been reported. Young maternal age, maternal cigarette use and vasoactive drugs consumption during the first trimester are considered as possible etiological factors.

The malformation results from vascular compromise of either the umbilical vein or the omphalomesenteric artery. The abdominal wall defect is generally small but the amount of bowel protruding from the defect and floating freely in the amniotic fluid may be disproportionately large. The herniated organs include mainly bowel loops that are not protected by a membrane but are usually covered by an inflammatory exudate, possibly resulting from chemical irritation by exposure to amniotic fluid.

The ultrasonographic diagnosis of gastroschisis is suggested by the finding of a partly solid, partly cystic mass adjacent to the anterior abdominal wall and freely mobile in the amniotic fluid (Figure 30.6), which has a cauliflower-like appearance. The differential diagnosis from omphalocele is based on the presence of a normal insertion of the umbilical cord, the lateral location of the mass and the absence of a membrane covering the herniated mass.

In contrast to omphalocele, gastroschisis is rarely associated with other malformations and chromosomal anomalies, but additional gastrointestinal abnormalities (malrotation, atresia, volvulus and infarction) may occur in 20–40% of the cases.[3,4] A high percentage of fetuses with gastroschisis (77%) present intrauterine growth retardation and preterm labor occurs in one-third of cases. The extent of bowel damage is variable and strictly affects the prognosis. Most of the bowel damage is caused by constriction at the site of the abdominal wall defect: the sonographic

Figure 30.2 The echogenic bowel is seen below the liver.

Figure 30.4 Longitudinal scan of the fetal chest and abdomen showing the diaphragm between the lung and the liver.

evidence of small bowel dilatation and mural thickening correlates with severe intestinal damage and poor clinical outcome.

The mode of delivery of fetuses affected by gastroschisis is still controversial although there is no striking evidence for cesarean section over vaginal delivery. Maternal transfer before delivery to a tertiary care center is recommended. The mortality rate ranges from about 8 to 28%.

Omphalocele

Omphalocele is a ventral wall defect characterized by an incomplete development of abdominal muscles, fascia and skin and the herniation of intra-abdominal organs (bowel loops, stomach and liver) into the base of the umbilical cord, with a covering by amnioperitoneal membrane. The defect is thought to be caused by an abnormality in the process of body infolding. The classic omphalocele is a midabdominal defect, although there is also a high or epigastric omphalocele (typical of the pentalogy of Cantrell) and a low or hypogastric omphalocele (as seen in bladder or cloacal extrophy), due to cephalic and caudal folding defects, respectively. The incidence of omphalocele ranges from 1:4000 to 1:7000 live births. It is more frequent in older women; most cases are sporadic, although a familial occurrence with a sex-linked or autosomal pattern of inheritance has been reported.

The ultrasonographic appearance of omphalocele varies according to the type of defect, the presence of ascites and the organs herniated. The principal diagnostic features are the umbilical cord insertion into the membrane covering the abdominal wall defect,

Figure 30.5 Physiological herniation of the midgut at 10 weeks of gestation.

Figure 30.7 Omphalocele: a round solid mass, covered by a thin membrane, protrudes from the anterior abdominal wall.

Figure 30.6 Gastroschisis: a cauliflower-like mass protrudes from the abdominal cavity into the amniotic fluid.

the presence of the intrahepatic portion of the umbilical vein coursing through the central portion of the defect and the presence of a limiting membrane that can occasionally rupture (Figure 30.7).

There are different syndromes that include omphalocele, such as pentalogy of Cantrell (midline supraumbilical abdominal defect, lower sternum defect, deficiency of diaphragmatic pericardium, anterior diaphragm defect and cardiac abnormality) and Beckwith–Wiedemann syndrome (macroglossia, visceromegaly and omphalocele). Although most cases of omphalocele are sporadic, a familial occurrence of this anomaly with a sex-linked or autosomal pattern of inheritance has been reported.

The most important prognostic variable is the presence of associated malformations (50–70% of cases) or chromosomal abnormalities (30% of cases).[5] Some authors have demonstrated that small defects involving only the bowel are associated with an increased risk of chromosomal abnormalities, as opposed to large defects that have an exposed liver. The main associated malformations are cardiac anomalies (up to 47% of cases), genitourinary abnormalities (40% of cases) and neural tube defects (39% of cases). Fetal mortality is highly dependent on associated malformations but respiratory complications also account for a significant percentage of morbidity and mortality.

The mode of delivery of fetuses with omphalocele has been debated in the literature. The goal of management is to deliver the fetus as close to term as possible in tertiary care centers. Cesarean section may be necessary to avoid dystocia or sac rupture in large omphaloceles. In the case of small defects vaginal delivery is recommended.

Body stalk anomaly

The body stalk anomaly is a severe abdominal wall defect caused by the failure of formation of the body stalk; it is characterized by the absence of umbilical cord and umbilicus and the fusion of the placenta to the herniated viscera. The incidence is 1:14,000 births. This malformation is caused by a developmental failure of the cephalic, caudal and lateral embryonic folds.

The ultrasonographic diagnosis is suggested by the finding of a large anterior wall defect attaching the fetus to the placenta or uterine wall, the absence of umbilical cord and the visualization of abdominal organs in a sac outside the abdominal cavity (Figure 30.8).[6,7] The position of the fetus may lead to scoliosis and kyphosis. Multiple malformations such as neural tube defects, and gastrointestinal and genitourinary anomalies may be associated. The body stalk anomaly is a uniformly fatal condition.

Diaphragmatic defects

The classification of these malformations is based on the location of the diaphragmatic defect:

(1) diaphragmatic hernia (Bochdaleck and Morgagni types)
(2) septum transversum defects (defect of the central tendon)
(3) hiatal hernia (congenital large esophageal orifice)
(4) eventration of the diaphragm
(5) agenesis of the diaphragm.

A diaphragmatic hernia is a defect in the diaphragm, due to failure of the pleuroperitoneal canal to close between 9 and 10 weeks of gestation, thus determining the protrusion of the abdominal organs into the thoracic cavity.

The incidence of congenital diaphragmatic hernia is 1:3000–1:5000 live births. This entity can be either sporadic or a familiar disorder but its etiology is quite unknown. The most common type of diaphragmatic hernia is the Bochdalek type, which is a posterolateral defect mostly located on the left side (80% of cases), less frequently on the right side (15%) or bilateral (5%). Stomach, spleen and colon are the most frequently herniated organs. When the hernia is on the right side, the main organs involved are the liver and the gallbladder.

The Morgagni type is usually a very small hernia that occurs in 1–2% of cases. It is a parasternal defect located in the anterior portion of the diaphragm; it involves the liver, which may limit the degree of herniation. In the case of eventration of the diaphragm, this structure appears to be weak so that the abdominal contents are displaced in the thoracic cavity.

Eventration of the diaphragm consists of an upward displacement of abdominal organs into the thoracic cavity secondary to a congenitally weak diaphragm, which has the aspect of an aponeurotic sheet. It occurs in 5% of diaphragmatic defects and is more common on the right side.

Diaphragmatic hernia can be either a sporadic or a familiar disorder and although the etiology is unknown, this abnormality has been described in association with maternal ingestion of drugs such as thalidomide, quinine and anticonvulsants. There are two hypotheses to explain the mechanism responsible for the origin of a diaphragmatic defect: (1) delayed fusion of the diaphragm and (2) a primary diaphragmatic defect. In addition to this classification, another one has been proposed concerning a late onset of this anomaly:

(1) Herniation occurring early during bronchial branching causing a severe bilateral pulmonary hypoplasia and lately death.
(2) Herniation at the stage of distal bronchial branching leading to unilateral hypoplasia, with survival depending on the balance between pulmonary vascular and ductal resistances.
(3) Late herniation in pregnancy, which causes a compression of otherwise normal lung and a good prognosis.
(4) Postnatal herniation without pulmonary pathology and with good chances of viability.

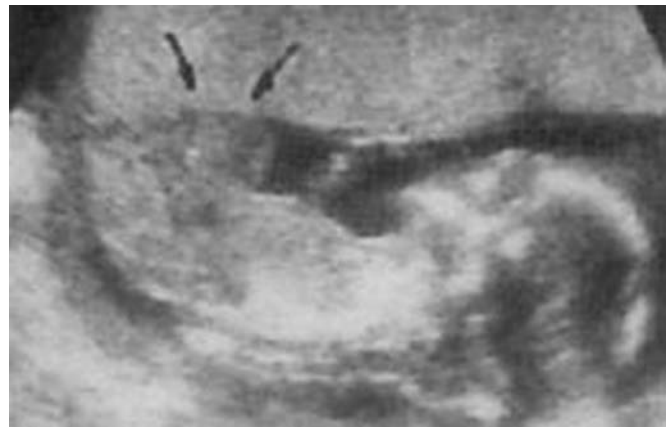

Figure 30.8 Body stalk anomaly: a large anterior abdominal wall defect attaches the fetus directly to the placenta.

The prenatal sonographic diagnosis of diaphragmatic hernia is mainly based on the visualization of abdominal organs at the same level of the four-chamber view of the heart in the transverse section of the fetal chest. The heart is usually shifted on the right side of the chest (Figure 30.9).

The visualization of the fluid-filled bowel or the stomach bubble in the thoracic cavity is highly diagnostic. The presence of peristalsis of bowel loops may help make the differential diagnosis with other conditions such as cystic adenomatoid malformation of the lung, bronchogenic cysts and mediastinal cysts. Polyhydramnios is common and is secondary to the bowel obstruction.

The rate of associated anomalies is 25–75%, increasing to 95% in stillborns. Such anomalies include central nervous system, cardiac and chromosomal abnormalities, omphalocele and oral cleft.

The prognosis for this malformation is still very poor and becomes poorer if other malformations are associated. The poor prognosis mainly depends on the severity of pulmonary hypoplasia induced by the prolonged compression of the lungs by the herniated viscera. For this reason experimental prenatal surgery has been suggested to prevent the lung damage. The different outcome is related to variation in the timing of entry of abdominal organs into the chest (the earlier is the entrance, the worse is the prognosis). Due to the complexity of this malformation and the different diagnosis and treatment, the ultrasound examination is very essential. Management relies on protecting the controlateral lung hoping that it is normally formed, which depends on the gestational age at diagnosis. If the fetus is less than 24 weeks' gestation, parents may choose to terminate the pregnancy, to continue the pregnancy with postnatal care or even to consider repair of the defect *in utero*. Between 24 and 32 weeks, parents may choose between conventional postnatal therapy and fetal surgery. Anytime a diaphragmatic defect is diagnosed, prenatal karyotyping and detailed ultrasound examination to detect associated anomalies

Figure 30.9 Transverse section of the fetal chest in a case of diaphragmatic hernia: the heart is displaced to the right side by the presence of the stomach and bowel loops in the thoracic cavity.

are recommended. There are no indications for preterm delivery or for cesarean section. The delivery should be planned in a tertiary care center.

Bowel disorders

Prenatal ultrasound examination allows the detection of the majority of gastrointestinal malformations because they are often associated with a dilated bowel, cystic masses or intra-abdominal calcifications, although the prenatal diagnosis generally does not influence the mode or the timing of delivery (except in the cases with polyhydramnios, which can cause premature labor or delivery). Moreover, it allows maternal referral to a center with appropriate perinatal, neonatal and surgical expertise, which, in some cases, may improve the outcome.

Esophageal atresia

This anomaly consists of the absence of a segment of the esophagus and is often associated with a tracheo-esophageal fistula (86–90% of cases). Five types of esophageal atresia may be distinguished:

(1) Isolated (type I)
(2) Associated with a fistula connecting only the proximal part of the esophagus and the trachea (type II)
(3) Associated with a fistula connecting the lower part of the esophagus and the trachea (type III)
(4) Associated with proximal and distal fistulas (type IV)
(5) Tracheo-esophageal fistula without esophageal atresia (type V).

Among different types the most common is the esophageal atresia associated with a fistula connecting the proximal part of the esophagus and the trachea (80% of the cases). The incidence varies between 1:800 and 1:5000 live births and the etiology is unknown.

The prenatal diagnosis is possible in only 10% of the cases and should be suspected in the presence of polyhydramnios with absent stomach bubble in several and repeated ultrasound examinations or visualizing a dilated proximal tract of the esophagus with absent stomach (Figure 30.10); however, this malformation can occur even in the presence of a normal or small stomach, due to the frequently associated tracheo-esophageal fistula.[8]

Associated anomalies are present in 50–70% of the cases, including cardiac, genitourinary, chromosomal (trisomy 21), additional gastrointestinal and musculoskeletal anomalies. A characteristic association is the 'VACTERL' (Vertebral, Anorectal anomalies, Cardiac anomalies, Tracheo-esophageal fistula, Esophageal atresia, Renal anomalies and Limb anomalies). Fetal karyotyping is suggested. The prognosis depends on the associated malformations and on the severity of polyhydramnios, which can facilitate preterm delivery.

Duodenal atresia or stenosis

The incidence of this malformation is 1:10,000 live births and its genesis goes back to the 11th week of gestation due to the failure of canalization of the primitive bowel. In most cases the etiology is unknown. Atresia is more common than stenosis (70% of cases) and could be associated with chromosomal abnormalities (trisomy 21), skeletal defects and other anomalies.[9]

The most typical sonographic finding is the characteristic 'double bubble' sign caused by the simultaneous dilatation of the stomach and the proximal duodenum (Figure 30.11). The diagnosis is usually made in the late second trimester.[10] Up to half the duodenal atresia cases are complicated by polyhydramnios and this can contribute to preterm labor, but the main cause of death are the associated anomalies. This malformation can present late complications (motility disorders, megaduodenum, gastro-esophageal and duodenal-gastric reflux, gastritis and blind loop syndrome) and late death even months or years after management.

Bowel obstruction

The incidence of bowel stenosis and atresia is 2–3:10,000 births and the most common locations are distal ileum (36%) and proximal jejunum (31%). There are four types of intestinal atresias:

(1) Type I: presence of a transverse diaphragm of mucosa or submucosa (20%).
(2) Type II: presence of blind ends of bowel loops connected by a fibrous band (32%).

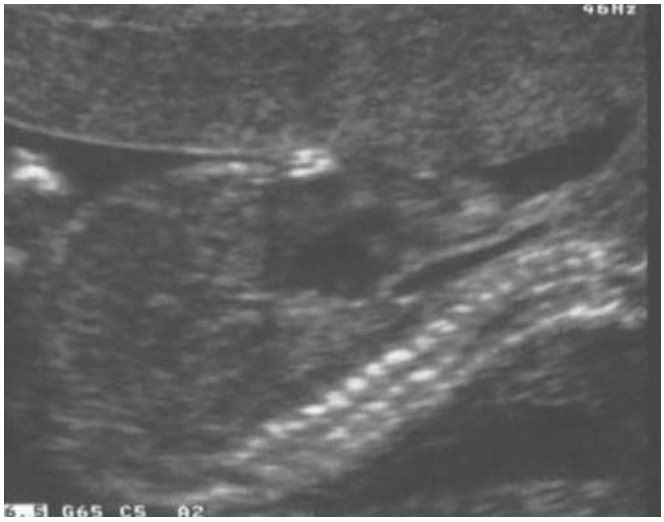

Figure 30.10 Esophageal atresia: the diagnosis is suspected by the association of absent stomach and dilatation of the proximal tract of the esophagus.

Figure 30.11 Duodenal atresia: the dilated stomach and proximal duodenum are clearly recognized.

(3) Type III: complete separation of blind ends with a corresponding mesenteric defect (48%).
(4) Type IV: absence of a large tract of small bowel with the typical 'apple peel' deformity, resulting from loss of the superior mesenteric artery.

These defects are usually sporadic, although familial cases have been described.

According to the site of the obstruction the defects are divided into (1) jejuno-ileal atresia and stenosis, (2) colonic atresia and (3) imperforate anus.

The sonographic prenatal appearance varies according to the level of the defect. In the case of jejuno-ileal atresia multiple dilated bowel loops in the fetal abdomen may be seen in association with polyhydramnios (Figure 30.12).[11,12] In colon atresia (which usually occurs proximal to the splenic flexure with a significant segment of absent colon with distal microcolon) the sonographic finding is similar to distal ileal occlusion and the differential diagnosis may not be possible. In the imperforate anus dilated intestinal loops with increased peristalsis may be seen as well as intraluminal hyperechogenic small areas referring to meconium (Figure 30.13).[13]

The diagnosis of bowel obstruction is usually made in the third trimester: the lower the obstruction the later is the appearance of the sonographic signs.

The prognosis of these malformations mainly depends on the level of obstruction (the lower the obstruction, the better the outcome), the length of remaining intestine and birth weight. Other important prognostic factors are the presence of associated malformations (especially gastrointestinal anomalies including bowel malrotation, esophageal atresia, microcolon and intestinal duplication), meconium peronitis and intrauterine growth restriction.

Meconium peritonitis

This condition is the consequence of *in utero* perforation of the bowel with spread of meconium into the peritoneal cavity leading to a local sterile chemical peritonitis. The peritonitis may be localized, with the development of a dense calcified mass or fibrous tissue, or diffuse, with a fibrous reaction leading to bowel adhesions and pseudocyst formation. Inflammatory reaction leads to an exudative process and ascites. Its incidence is 1:35,000 live births. Bowel perforation involves the proximal tract, with some form of obstruction such as intestinal atresia (65% of cases), meconium ileus, volvulus, gastroschisis or Meckel's diverticulum.

The prenatal sonographic appearance of meconium peritonitis varies according to the underlying anatomical finding: the main signs are intrabdominal calcifications (85% of cases), polyhydramnios, fetal ascites caused by exudate and bowel dilatation.

Postnatal management depends on the etiology of meconium peritonitis; up to one-third of all cases have cystic fibrosis.

Echogenic bowel

Sonographically, 'echogenic bowel' is defined as echogenicity of the bowel loops equal to or greater than the density of the iliac wing (Figure 30.14). A total of 1:200 midtrimester fetuses present this feature, which might depend on a slow or delayed transit of the meconium along the bowel. This finding has been considered as a 'soft marker' of chromosomal abnormalities but actually the increased risk of chromosomopathy in the presence of such an isolated marker is extremely low.[14] The risk increases when further sonographic markers are present. The echogenic bowel may also be the first sign of cystic fibrosis or can be

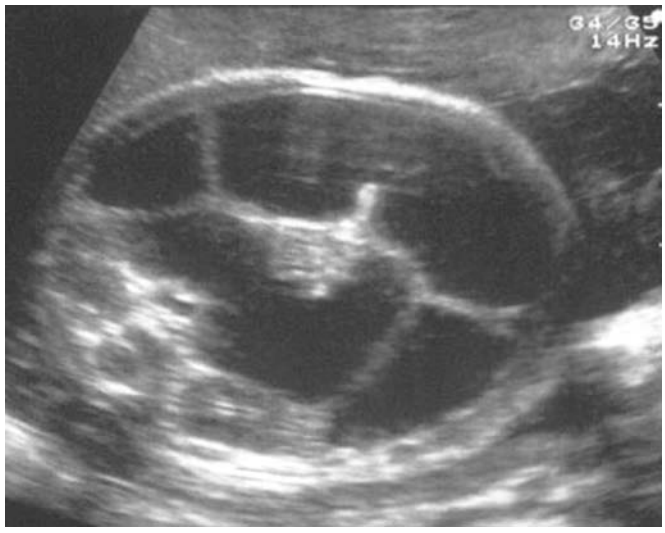

Figure 30.12 Jejunal atresia: multiple dilated bowel loops are present in the fetal abdomen.

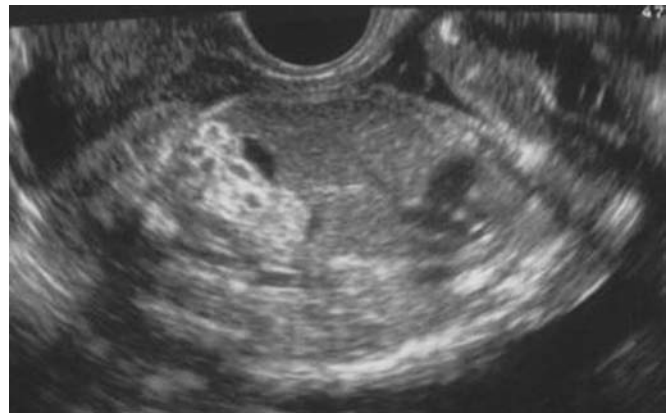

Figure 30.14 Echogenic bowel.

Figure 30.13 Imperforate anus in a third-trimester fetus: a dilated distal colon is seen containing multiple small echogenic foci due to meconium.

Figure 30.15 Hepatic hamartoma appearing as an isolated intraepathic area.

seen in cases of intraamniotic bleeding.[15] However, it is important to stress that the recognition of hyperechogenic meconium does not always represent a pathological condition but might be a normal variant and an isolated finding.[16]

Non-bowel cystic masses

Choledocal cysts

Choledocal cyst is a rare congenital cystic dilatation of the common bile duct. The incidence is about 1:2000. The cysts can be single or, in rare cases, multiple involving the intrahepatic or extrahepatic portion of the biliary tree. Choledocal cysts are classified into four types: (1) fusiform dilatation of the common bile duct, (2) diverticular dilatation of the common bile duct, (3) intramural dilatation of the common bile duct and (4) intrahepatic biliary duct dilatation. Its sonographic appearance is that of a cystic structure located in the upper right abdomen with dilated proximal ducts. Differential diagnosis includes duodenal atresia, hepatic cyst, dilated gallbladder, ovarian cyst and biliary atresia. The cystic size and the association with biliary obstruction affect the prognosis.[17]

Mesenteric and omental cyst

This benign malformation consists of cystic structures located in the small or large bowel mesentery or in the omentum filled with serous or chilous fluid. Its sonographic appearance is that of a thin-walled, unilocular or multilocular cystic mass. It is difficult to

make a differential diagnosis with other intraabdominal cystic conditions such as choledocal, ovarian and hepatic cysts.

Hepatic masses

Hepatic masses might originate from an obstruction of the hepatic biliary system or might have a tumoral origin (hemangioma, hamartoma, etc.).

Their sonographic appearance changes depending on the origin: mesenchymal hamartomas usually appear as irregular hyperechoic areas (Figure 30.15), while hemangioma appears hypoechoic, hyperechoic or mixed depending on the degree of fibrosis and the stage of involution.[18] Hepatoblastomas and adenomas have a solid appearance. Polyhydramnios may be associated; many cases of reduction in volume or even disappearance *in utero* have been described.

The management is expectant in terms of monitoring the size and evolution of the tumor; for large tumors cesarean section is indicated.[19]

31 Ultrasound diagnosis of urinary tract anomalies

P. Prats, N. Maiz, A. Rodriguez, C. Pedrero, M. Torrents, F. Astudillo and J. M. Carrera

Embryology and anatomy of the nephrourologic system

The nephrourologic system has the functions of production and conduction of the urine toward the exterior by means of two independent nephrourologic tracts, but with the same functions that converge toward a reservoir that is the bladder, where the urine produced by the kidneys is stored, and it is excreted to the exterior through the urethra.

Embryology

The nephrourologic system has its embryonic origin in the intermediate mesoderm, located on both sides of the dorsal wall of the body. As the embryonic development advances it suffers transformations and specifications that will be translated into different anatomical parts of the urinary tract.

It would be possible to say that the embryonic development of the nephrourologic system occurs in two areas but in a synchronous way.

The superior nephrourologic system consists of kidneys (nephrons), collecting tubules, papillary ducts, calyces, renal pelvis and ureters.

Toward the fifth week of gestation, the paraspinal mesoderm differentiates into pronephros and mesonephros, which present some structural changes to become the metanephric blastema (that would be undifferentiated mesenchyma from the nephrogenic crest, which will give place to the future kidneys).

At the sacral level, there are also some paraspinal structures of mesodermic origin named ureteral gemmae from where some canals arise in caudocephalad direction address denominated mesonephric ducts or wolffia ducts that in their ascent penetrate inside the metanephric blastemas and ramify in their interior until a total of 15 generations.

In the seventh week of gestation, the functional units of the kidney, the nephrones, begin to differ due to the inductive influence of the ureteral gemma.

In the 20th week of gestation, the collecting system has already been formed: collecting tubules, papillary ducts, calyces, renal pelvis and ureters and 30% of the total population of nephrones.

Starting from this week and until the 36th week of gestation, an exponential increment in the total number of nephrones will take place.

The lower nephrourologic system consists of bladder and urethra. Both structures are unique and they take charge of transporting the urine produced in the superior nephrourologic system toward the exterior.

They arise from the mesoderm and the paramesonephric ducts (that also participate in the formation of the genital system) that will give place at the pelvic level to an embryonic structure called cloaca.

The cloaca, among the fourth and sixth weeks of gestation, presents a tabication by means of the urorectal septum that divides the cloaca into two parts: a posterior one that will be the rectum and another anterior one that will be the primitive urogenital sinus whose superior portion together with the allantois will give place to the bladder that will receive posterolaterally the ureters from the ureteral gemmae.

The inferior portion of the primitive urogenital sinus will give place to the membranous urethra and vaginal introitus in females and to the membranous and prostatic urethra in males.

Normal anatomy and variants

With the transvaginal ultrasonography, the kidneys and the bladder can be detected in the fetus from the ninth week of gestation. From the 12th week, the kidneys look like bilateral echogenic structures in the paraspinal region (Figure 31.1). The renal pelvis can be identified central to the medial hipoecogénicas. The bladder is in the pelvis and looks like a round anechoic structure that is well defined. Its position can be confirmed with the Doppler technique to identify the two umbilical arteries that surround it.

From 18–20 weeks of gestation, the kidneys can be defined clearly as oval masses lateral to the psoas

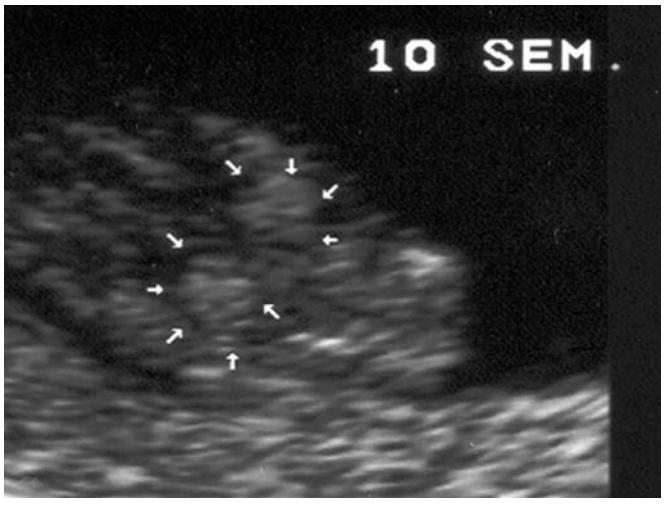

Figure 31.1 Kidneys at 10 weeks of gestation. Bilateral echogenic structures in the paraspinal region.

Figure 31.2 Sagittal scan of the kidney.

muscles and below the suprarenal glands using coronal or sagittal sections. These look like hypoechoic triangular that delimit the superior pole of the kidneys. In the traverse plane, the kidneys look like round paravertebral structures and the renal pelvis looks like anechoic areas medial to the kidneys (Figures 31.2 and 31.3). The renal pelvis is measured better in the anteroposterior projection, whether the fetus' column is up or down. The normal limit is 4 mm until 33 weeks of gestation and 7 mm from this date until the term. The normal values of the renal dimensions have been published, including the renal longitude, the anteroposterior diameter and the renal circumference.

With high-resolution devices, the renal pyramids can be seen as hypoechoic areas in the renal cortex, which should not be confused with renal cysts.

Figure 31.3 Coronal scan of the kidney.

The ureters are not usually seen, and if they are identified they are suspected for a renal obstruction or vesicoureteral reflux.

In the first trimester, the bladder looks like a round anechoic structure with the rectum behind. It is often possible to differentiate it from the intestine that surrounds it. However, it is better to measure the wall thickness at the umbilical artery level when this surrounds the bladder. The normal limit for the bladder wall thickness is 2 mm.

Ultrasonographic study

The ultrasonographic study of the fetal urinary system involves the evaluation of the kidneys, the bladder and the volume of amniotic fluid. It is also necessary to eliminate the associated anomalies.

Fetal kidneys

First, it is imperative to confirm if two kidneys are present. If a kidney is not present, it is necessary to look for it in ectopic positions like the pelvis. If it is not found, it is necessary to consider the possibility of unilateral renal agenesis. The bilateral renal agenesis usually associates to a severe oligoamnios, mainly starting from 17 weeks of gestation. When a renal anomaly is detected, it is fundamental to explore the contralateral kidney to confirm or to exclude a bilateral renal illness.

The size and echogenicity of both the kidneys should be valued. The hyperechoic kidneys can be normal, but it is also necessary to think about the possibility of a cystic renal disease, particularly when they are big.

The presence of macroscopic cysts usually indicates a multicystic kidney, but it is necessary to make sure that the cysts do not spread, because there are cases of multicystic kidneys with a great central cyst and smaller outlying cysts that can be mistaken for

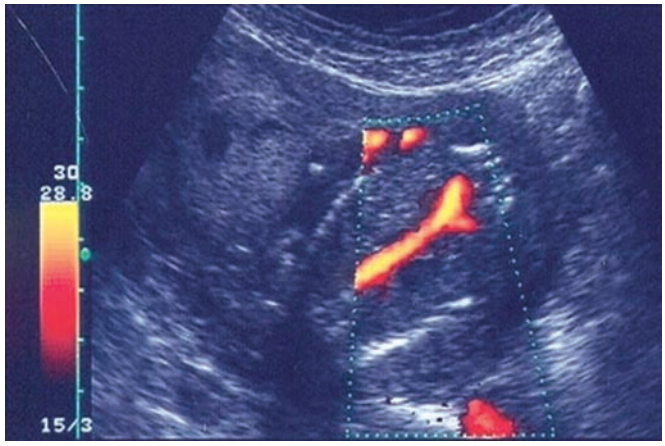

Figure 31.4 Bilateral renal agenesis. Absence of the renal arteries.

Figure 31.5 Bilateral renal agenesis. Note the enlarged adrenal gland.

hydronephrosis. If there is only one cyst, it can be considered a simple cyst.

The collector system of both kidneys should be evaluated not only with respect to the size but also the number. If two collector systems are seen it is necessary to discard a double kidney and to explore the bladder to rule out an ureterocele.

The dilatation of the collector system forces us to consider the possibility of a renal obstruction. The grade of dilatation of renal pelvis, ureter and bladder usually suggests the level of obstruction. When there is a dilatation of the collector system it is necessary to value the renal cortex echogenicity and the presence or absence of renal cysts to rule out secondary renal dysplasia.

Bladder

Bladder exploration includes size evaluation and – when it is large – the visualization of the posterior urethra, because if this is dilated it is necessary to think of an obstruction of the vesical exit. The thickness of the vesical wall can be measured at the level of the umbilical artery. It is necessary to rule out the existence of the ureterocele, particularly when there is a renal duplicity. In a period of 30–40 min, it is usually possible to demonstrate vesical filling and drainage.

Volume of amniotic fluid

This volume can be evaluated in different ways. Most echographers carry out a subjective evaluation first and then they adopt more objective approaches if they find that there is too much or too little. It seems that the best technique is the calculation of the index of amniotic fluid from the measures in the four uterine quadrants and its half-value. Severe oligoamnios of the second trimester usually has a bad prognosis and if it excludes premature rupture of membranes and a severe intrauterine growth restriction (IUGR), it usually indicates the presence of a severe bilateral renal illness.

Urinary tract malformations

Renal agenesis

Renal agenesis is the absence of one or two of the kidneys. The incidence of unilateral renal agenesis is 1 per 1000 births, and bilateral is 1 per 4000 births.[5] The etiology is ignored. Some cases of unilateral agenesis could be secondary to an intrauterine regression of a dysplastic multicystic kidney.[6] The embryological origin of the renal agenesis is the lack of union or penetration of the ureteral sprouting in the metanephric blastema, so that the primitive collecting tubules do not induce nephrone formation starting from metanephric mesoderm.[7]

Diagnosis

Bilateral agenesis: Echographic diagnosis is carried out for:

- The absence of kidneys in renal fossae that is difficult to evaluate because of the oligohydramnios in many cases
- Severe oligoamnios
- No bladder visualization[8]
- The absence of renal arteries by means of the color Doppler study[9,10] (Figure 31.4)
- The 'lying down adrenal sign' where the renal fossae is not occupied by the suprarenal glands[11] (Figure 31.5)
- Fetuses in podalic presentation where transvaginal ultrasound will help to improve the image[12,13]
- The infusion of intraamniotic and intraperitoneal physiologic salt solution to improve the image quality[14,15]

Unilateral agenesis: For diagnosis a meticulous evaluation of both renal fossae must be carried out. Ultrasound findings will be:

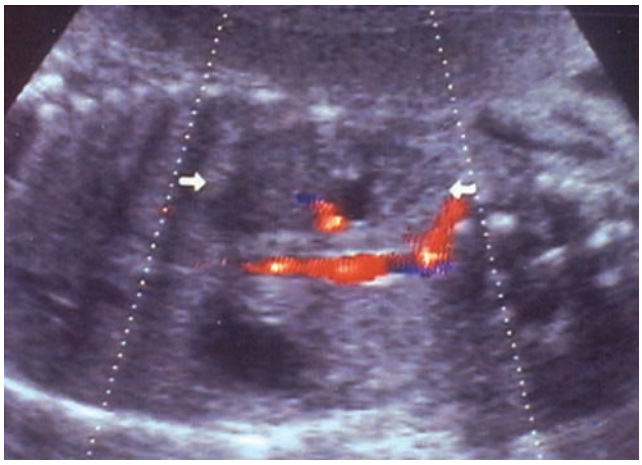

Figure 31.6 Unilateral renal agenesis. Renal artery in Doppler color. Notice the absence of the renal artery.

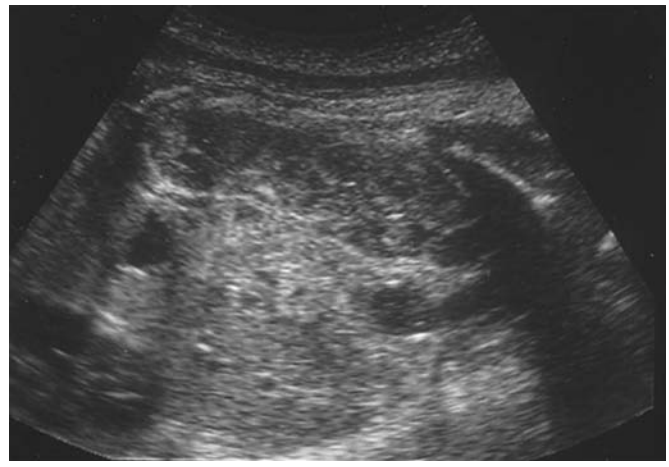

Figure 31.7 Unilateral renal agenesis. Note the large kidney.

- Absence of kidney in the renal fossa
- Absence of ipsilateral renal artery by means of color Doppler (Figure 31.6)
- Absence of pelvic kidney or renal ectopy, for this the renal pelvis and contralateral kidney needs to be evaluated.

The contralateral kidney can be increased in size because of compensatory hypertrophy[16] (Figure 31.7).

Differential diagnosis

Differential diagnosis will be mainly carried out for other causes of severe oligoamnios:

- Renal pathology
- Bilateral multicystic kidneys. The kidneys are usually evident for their cysts
- Infantile polycystic kidney disease. The kidneys are usually big and echogenic
- Uretral obstruction. The bladder is usually much evident
- IUGR. The kidneys and the bladder are present. It is usually accompanied by an alteration in the flow wave speed (FWS) of the umbilical artery
- Premature rupture of membranes (PRM). It usually has an antecedent of loss of vaginal liquid. The kidneys and the bladder are present.

Associated anomalies

Bilateral agenesis

- The Potter sequence (wide and plane nose, ears of low implantation, hypertelorism, receding chin, deformities of extremities) appears as a consequence of the severe oligoamnios
- Fifty percent present other associated anomalies
  - Cardiovascular
  - VATER (vertebral defects, anal atresia, tracheoesophageal, radial and renal anomalies)
  - Gastrointestinal (anal and duodenal atresia, omphalocele)
  - Phrenic hernia
  - Musculoskeletal: sirenomelus, digital anomalies
  - Central nervous system (CNS): neural tube defects
- Associated syndromes
  - Fraser syndrome
  - Brain-occulo-facial skeletal syndrome
  - Acrorenal–mandibular syndrome
  - Branchiootorenal syndrome.

Unilateral agenesis

- Anomalies of the contralateral kidney in 48% of the cases
  - Vesicoureteral reflux
  - Obstruction of vesicoureteral junction
  - Obstruction of pelviureteral junction.

Prognosis

- Bilateral agenesis: The prognosis is very poor. All newborns die in the first few hours or days similar to the consequence of lung hypoplasia
- Unilateral agenesis: In general, the prognosis of these newborns is very good, although it will much depend on any anomalies associated with the contralateral kidney.

Management

- Bilateral agenesis: A pregnancy interruption may be offered due to the lethal prognosis. If the mother decides to continue with the pregnancy it will be opted by a conservative behavior, a vaginal delivery will always be attempted, and reanimation maneuvers will not be made in the neonate
- Unilateral agenesis: During the pregnancy normal controls are followed. As much as during the pregnancy as in the newborn the appearance of anomalies will be watched over in the contralateral kidney.

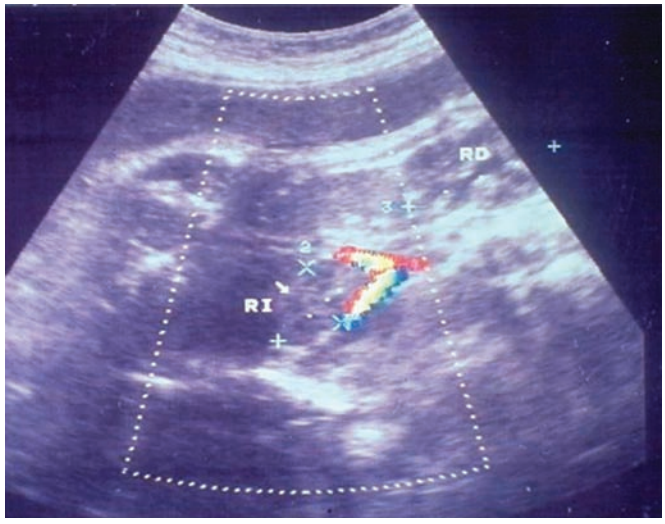

Figure 31.8 Ectopic pelvic kidney. Between iliac arteries.

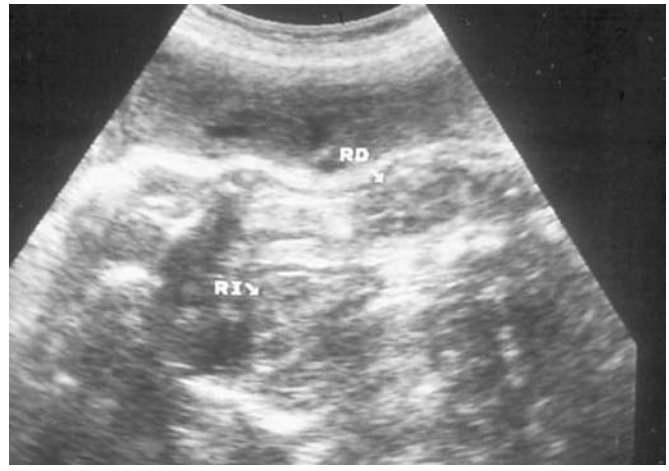

Figure 31.9 Ectopic pelvic kidney. Between iliac arteries.

The recurrence risk of the bilateral renal agenesis is approximately 4%.[17] About 9% of first grade relatives of the fetuses or newborns with renal impotence will have asymptomatic renal malformations. If the renal agenesis is part of a syndrome, the recurrence risk will depend on the inheritance type.

Renal ectopy

Ectopic kidney is that which is located outside the renal fossa. The most frequent locations are the pelvis (pelvic kidney) and the crusader of the other side (ectopia renal crusade); other less frequent ones are lumbar or thoracic. The incidence is approximately 1/1200 and 1/1900, respectively.[18,19]

Pelvic kidney

The lack of ascent of the kidneys originates the pelvic kidneys and other ectopic forms.

Diagnosis The echographic signs that will be found are:

- *Absence of the kidney in the renal fossa.* In these cases it is very important to make an exploration of the fetal pelvis and the contralateral side in search of a possible ectopic kidney
- *Localization of the kidney adjacent to the bladder or the wing of the ileum.*[18] In some cases, it may be difficult for its echogenicity to be similar to the adjacent intestine (Figures 31.8 and 31.9).

Differential diagnosis

- Unilateral renal agenesis.

Associated anomalies. Other anomalies have been described as:

- Gynecological anomalies
- Gastrointestinal, cardiovascular anomalies and skeletal defects [18]
- Unique umbilical artery
- Contralateral kidney anomalies, as vesicoureteral reflux.

Prognosis The prognosis is very good, although it will depend on the associated anomalies of the contralateral kidney.

Crossed ectopic kidney

During the renal ascent, a kidney crosses to the other side, resulting in crossed renal ectopy.

Diagnosis

- Absence of kidney in the renal fossa
- Big contralateral kidney and bilobate.[20]

Differential diagnosis

- Unilateral renal agenesis with compensatory hypertrophy. In these cases, the kidney is not bilobed and it does not present a second collector system
- Renal tumor. The contraleteral kidney is present. A collector system is not identified in the tumor.

Associated anomalies

- Vertebral anomalies (myelomeningocele, sacral agenesis)
- Anal atresia
- Urinary anomalies like ureterovesical reflux, hydronephrosis, urinary infections etc.

Prognosis If it is presented in an isolated way the prognosis is good.

Horseshoe kidney

Horseshoe kidney is the union of the lower, or occasionally, the upper extremities of the two kidneys by a band of tissue extending across the vertebral column. The incidence is 1 per 400–600 births.[21,22] Because of their proximity, the kidneys fuse before completing

their ascent, so that the root of the inferior mesenteric artery will avoid completing their ascent.

Diagnosis

Because of subtle findings, it is underdiagnosed. The echographic diagnosis is based on the demonstration of the presence of a renal tissue bridge that connects both the kidneys. Generally, in the inferior poles, it can be identified both in the transverse and coronal sections.

Associated anomalies

- *Urogenital anomalies*: Hydronephrosis, vesicoureteral reflux, hypospadias, and cryptorchidism
- *Extraurological anomalies*: Anomalies of CNS (neural tube defects[23]), cardiovascular, gastrointestinal anomalies, and musculoskeletal defects[24]
- *Chromosomal anomalies*: Turner's syndrome,[25] Trisomy 18[26,27]
- *Renal tumors*. In children it has been associated to the Wilms' tumor,[28] and in adults it has been associated to a higher incidence of adenocarcinoma[29] and transitional cells tumor.[30]

Prognosis

The prognosis is excellent. A higher incidence of vesicoureteral reflux, renal stone, infection and hydronephrosis must be kept in mind.

Obstructive uropathies

The fetal kidney responds in different ways to an obstruction depending on the gestational age in which it occurs. Very precocious obstructions, in the first trimester or beginning of the second, will give place to polycystic dysplastic kidneys. Later obstructions (after the 22nd week) can produce hydronephrosis.

A particular difficulty in the diagnosis of renal obstruction is the high proportion of false-positive estimates in 36–81%. This is due to the mild hydronephrosis that is solved at the end of the pregnancy or in the neonatal stage. In order to avoid these false positives, limiting values of the anteroposterior diameter of the renal pelvis have been defined, for which the obstruction should be suspected. Unfortunately, these cut-off points vary: from 4 to 10 mm in the second trimester and from 7 to 10 mm in the third trimester.

For some authors, the best echographic approach to predict postnatal uropathies is an anteroposterior diameter of the renal pelvis greater than or equal to 7 mm in the third trimester with a 69% positive predictive value.[31,32] Other authors have calculated echographic false negatives below 10%[33] and negative predictive values of 98%.[34]

Diameters of the renal pelvis above 15 mm have a high predictive value of renal pathology that needs postnatal surgery.[35]

The group that has more problems is those that have pelvic diameters from 4 to 10 mm from the 20th week because 10–30% of children will present a vesicoureteral reflux that could damage the renal function without follow-up.[31]

These cases should be re-evaluated toward the 28th week of gestation and in the neonatal period to rule out a possible progression of the pyelectasis.

A sign of serious concern of the hydronephrosis is the presence of caliectasis, because it bends the necessity of surgery with regard to when the hydronephrosis is only present.[36]

Another aspect is the association between the dilatation of the urinary tract and chromosomal anomalies. In most of the cases, they are part of a multisystemic alteration secondary to a genetic alteration.[37] In the case of isolated mild hydronephrosis, the association with chromosomopathies is less clear; according to Nicolaides it would be a 3% in isolated hydronephrosis.[38]

Obstruction at the pyeloureteral junction level

Obstruction at the pyeloureteral junction level is the most common cause of obstruction at renal level, with an unknown real incidence; some authors have calculated it in 1/2000 born alive.[39] It is more common in males, and in 30% it is bilateral; when it is unilateral it is more frequently on the left side.

It is produced by a stenosis at the pyeloutereral junction level.

The obstruction is in most of the cases functional, so it would result in a urine propulsion failure.

Histologically, the ureter frequently shows signs of chronic inflammation with disruption and disorganization of the collagen and muscular fibers in its wall. In 69% of the cases a muscular anomaly exists so that there is an absence of the longitudinal fibers.[40]

With less frequency there are anatomical causes of obstruction like fibrous adhesions, bands, anomalous ureteral insertion and obstruction for double kidneys.

Diagnosis In the sonographic scan a dilated renal pelvis will be seen with or without dilation of the renal calyces and without ureteral or vesical dilation (Figures 31.10–31.13).

In cases of severe obstructions dilation of the renal chalices takes place with weight loss of the renal cortex (Figure 31.14). In rare cases, an abdominal cyst will be present or it will rupture with consequent perirenal urinoma (Figure 31.15).

The volume of the amniotic fluid is usually normal; however, it can cause polyhydramnios for increase of urine production. The appearance of oligoamnios is not normal.

Differential diagnosis It is necessary to consider other causes of lower renal obstruction where the ureters appear usually dilated like those of the vesicoureteral junction, vesical exit and the bilateral vesicoureteral reflux. It will also be necessary to consider polycystic kidneys, simple renal cysts or urinomas.

Associated anomalies In the cases of pyeloureteral obstruction we should study both kidneys in detail in search of possible associated anomalies (25–27%) as agenesis, multicystic dysplasia, vesicoureteral reflux, as well as possible extrarenal anomalies (12–19%) like cardiovascular anomalies, neural tube or digestive anomalies and chromosomal anomalies.[41]

Prognosis The postnatal prognosis is usually good and the hydronephrosis grade is usually correlated with the renal function.[35]

Prenatal management is usually conservative with the echographic follow-up in the third trimester. In the newborn, antibiotic profilaxis is prescribed and a complete evaluation is carried out with echography, isotopic renogram and cystourethrography. The examinations are delayed for about 10 days except in the cases that present severe bilateral affectation.[42]

In most cases postnatal management is conservative except when an increment of the hydronephrosis or decrease of the differential renal function exists, where pyeloplasty is the surgery of choice.[43]

Though most of the cases are sporadic family forms of dominant inheritance have been described.[44]

Figure 31.10 Mild dilatation of the renal pelvis.

Obstruction of the ureterovesical junction

This is the second cause of hydronephrosis, affecting 1/6500 newborns.[39] It is more common in males (ratio 2:1). It can be bilateral in 25% of the cases.

The obstruction is generally due to a regional malfunction or an estenosis at the ureteral end, without evidence of vesicoureteral reflux or obstruction of the vesical exit. This is also called primary megaureter or megaureter without reflux.

Diagnosis The affected kidney is shown with pyelectasis and a tortuous ureteral course (Figures 31.16 and 31.17).

The intravesical urine volume and amniotic fluid volume are usually normal, although they can be diminished in some cases of severe bilateral obstructions.

Differential diagnosis The dilated ureter can be easily differentiated from intestine because the urine is anechoic while the intestinal content transmits low echogenicity.

A differential diagnosis with the vesicouereteral reflux should be carried out, which can have the same prenatal echographic appearance and not to be able to exclude until the realization of a cystouretography in the neonatal period. It will also be necessary to carry out the differential diagnosis with strange cases of obstructions in the exit of the bladder that produce a massive uretral reflux and in the cases of double kidneys where the ureteral dilatation is produced by an ureterocele, in this situation it is usual that the superior pole is hydronephrotic and that the ureterocele is visualized inside the bladder.

Associated anomalies The contralateral kidney will present anomalies in 16% of the cases, including

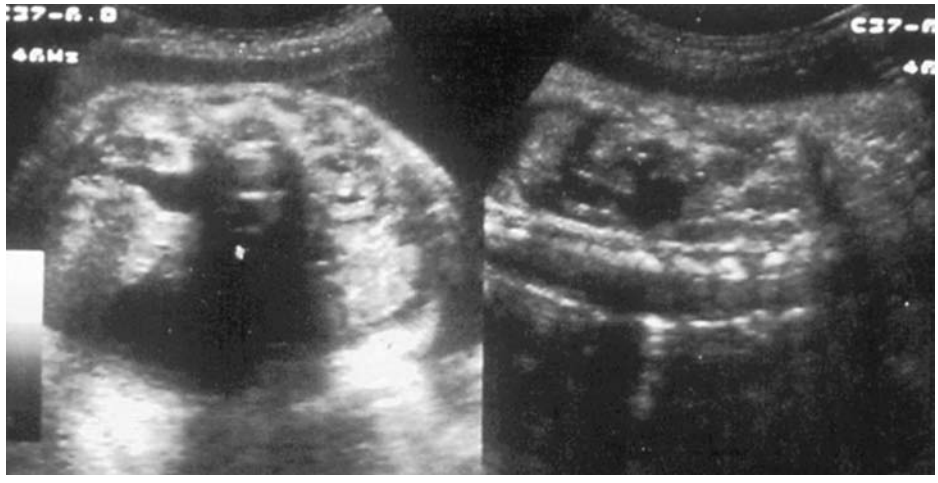

Figure 31.11 Mild dilatation of the renal pelvis.

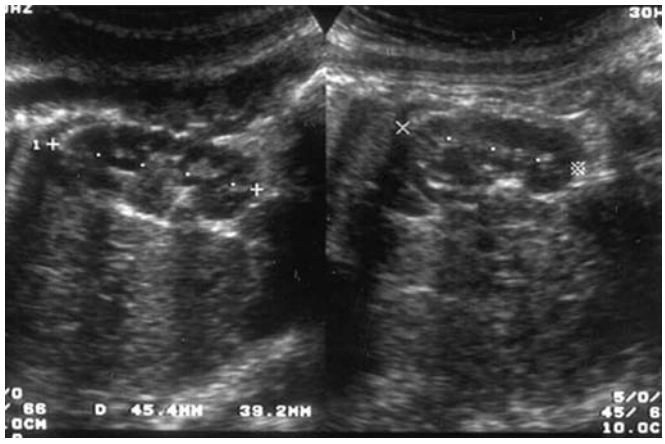

Figure 31.18 Duplex kidney. A sagittal scan through a duplex kidney shows two collecting systems.

Figure 31.19 Duplex kidney. A sagittal scan through a duplex kidney shows two collecting systems.

pyeloureteral obstruction, multicystic renal dysplasia, pelvic kidney, renal agenesis and vesicoureteral reflux.[45]

Prognosis It is generally good so that up to 40% resolves postnatally in a spontaneous way. Ureters with diameters of less than 6 mm are associated with low surgery incidence, while those that have a diameter above 10 mm have a higher incidence of surgical corrections.[46,47]

A neonatal follow-up should be carried out with cystourethrography and a renogram to evaluate the renal function. Those that present a poor renal function will be candidates for surgery with ureteral reimplantation.

It is sporadic with a low recurrence risk.

Secondary obstruction to ureterocele and ectopic ureter

The ureterocele is a cystic dilation of the distal ureter in its intravesical portion.

An ectopic ureter is that which is not inserted near the posterolateral angle of the trigone.

An ectopic ureter can end in the urethra, in the neck of the urinary bladder or in the trigone, in an inferomedial localization regarding the normality. In girls, it can also be inserted in the vestibule of the vagina, vagina or uterus and in males in the seminal vesicle, ductus deferens or ejaculatory ducts.

The incidence is difficult to determine. There are studies that estimate it in 1/9000 newborns.[39]

The ureteroceles frequently associates in girls (up to 80%) with double renal systems being located in these cases the ureterocele in the superior system.[48]

However, in 40% of children the ureteroceles drain to a unique collector system. The ureteroceles and the ectopic ureteres are bilateral in 10–15% of the cases.

The double systems occur for the development of two ureteral gemmae starting from the mesonephric duct. In the double systems, the place where it drains is reversed, so the ureter of the superior pole drains into a more inferior and more medial place and the inferior pole drains into a superior and lateral place. The presence of ureterocele will produce hydronephrosis in the superior pole, which can produce dysplasia and deterioration of the renal function. In the inferior pole, it can also have hydronephrosis but it is usually due to vesicoureteral reflux.

Diagnosis In the absence of hydronephrosis, it may be difficult to diagnose prenatally a double system. In these cases, a meticulous echographic study would demonstrate a kidney of increased size with two collector systems. The prenatal diagnosis of the double system is usually carried out during the second half of the pregnancy with the presence of two or more of the following signs: limited hydronephrosis to a kidney pole, double renal pelvis not communicated, ipsilateral megaureter and ureterocele[49] (Figures 31.18 and 31.19).

When hydronephrosis exists, the superior pole is usually affected and the ureterocele can be demonstrated if the bladder is full. The ureterocele cannot be seen for different reasons: dysplasia of the superior pole that makes little urine excretion, empty bladder, large ureterocele that confuses with the own bladder. An ectopic ureter will be suspected when hydronephrosis exists in the superior system of a double system, and this dilated ureter seems to end below the base of the bladder without ureterocele. The utility of the magnetic resonance has been described in doubtful cases[50] (Figures 31.20 and 31.21).

The ureteroceles can be large enough to produce obstruction of the exit of the urine from the bladder. They can be bilateral in 15% of the cases[51] (Figures 31.22–31.24).

The amniotic fluid is usually normal in unilateral cases.

Differential diagnosis With the reflux and the vesicoureteral obstruction. Also with posterior urethral

Figure 31.20 Duplex kidney. A sagittal scan through a duplex kidney shows two collecting systems.

Figure 31.21 Duplex kidney. A sagittal scan through a duplex kidney shows two collecting systems.

Figure 31.22 Ectopic ureterocele in the bladder.

Figure 31.23 Ectopic ureterocele in the bladder.

valves in cases of ureteroceles that occlude the urethra, the posterior urethral valves occur only in males.

Associated anomalies The vesicoureteral reflux is presented in the inferior pole in 50% of the fetuses with ureterocele in the superior pole.[52] Higher association with other anomalies does not exist.

Prognosis It is better when a prenatal diagnosis is carried out. The necessity to carry out second surgery is reduced when it has been diagnosed prenatally.[53] The renal function will depend on the grade of dysplasia of the superior pole that is usually higher in ectopic ureters than in ureteroceles. In cases of severe reflux in the inferior pole, dysplasia and worsening of the renal function can also exist.

Figure 31.24 Ectopic ureterocele in the bladder.

Figure 31.25 Dilated bladder and a 'keyhole' deformity of the posterior urethra.

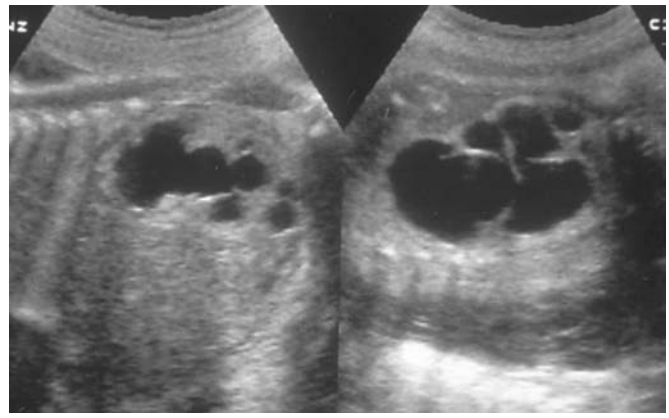

Figure 31.26 Kidney showing moderate dilatation.

Prenatal follow-up ultrasound will be carried out to evaluate the progression of the hydronephrosis.

In the postnatal period, it will be re-evaluated with echography, renogram and cystourethrography. In cases with good renal function the ureterocele can be punctured through the urethra by cystoscopy, which although has a risk of increasing the reflux in 30% does not seem to increase the necessity of second surgeries.[54] The non-functional superior poles are usually resected.[55–57]

It is sporadic with a low risk of recurrence.

Posterior urethral valves

This is the most frequent cause of severe obstructive uropathy in children, constituting 9% of the cases of fetal urinary obstruction.[55] The approximate incidence is 1 in each 5000–8000 children. It only affects males.

It is produced by folds of membranous tissue with a fibrous estruma that go from the prostatic urethra to the external urinary sphincter producing a more or less severe difficulty of the urine exit from the bladder.[59] The etiology is unknown; one of the theories is an anomalous insert of the mesonephric conduit into the cloaca.[60]

Diagnosis It is usually diagnosed in the second and third trimester. The characteristic echographic findings will be bladder dilatation with wall thickening (due to a detrusor thickening) and dilatation of the posterior urethra. It can exist in renal dysplasia recognized echographically for echogenic kidneys whether or not accompanied by cortical cysts[61] (Figure 31.25).

It is usually associated with a variable grade of bilateral ureterohydronephrosis[60] (Figure 31.26). The vesical distension can give place to its rupture causing urinary ascites, this ascites is considered a sign of good prognosis, since it liberates the kidneys of the pressure due to obstruction and therefore diminishes the risk of dysplasia.[55–62,63]

They can also break the renal chalices giving place to perirenal urinomas, which is a sign of bad prognosis since it is associated with renal dysplasia.[64]

It can exist as an asymmetric hydronephrosis by a massive reflux to a kidney that is practically destroyed; this can be a protection mechanism for the contralateral kidney.[65]

The amniotic fluid can be diminished, which is a sign of poor prognosis.

Differential diagnosis It is mainly with severe bilateral vesicoureteral reflux. Sometimes diagnosis is not easy. It may be useful to observe that in the reflux the bladder wall is usually thin, the dilatation of the posterior urethra also will not be seen.

We will also carry out the differential diagnosis with the ureteral atresia in which a marked vesical distension usually exists, of precocious detection in the first trimester or second initial trimester usually accompanied by oligoamnios.

We will also consider other rare causes of obstruction of the exit of the bladder like the congenital megalourethra, where a distal obstruction in the penile urethra exists and cystic images among the fetal legs can be observed in the ultrasound,[66] the cloacal persistence and hydrometrocolpos associated with a urogenital sinus that only takes place in girls,[67] and the microcolon-megalocysts syndrome where bilateral hydronephrosis and vesical dilatation can exist but it can be polyhydramnios and stomach distention. It affects the females more and it is of recessive autosomal inheritance.[68,69]

Associated anomalies They will be associated with a sequence of anomalies in variable grade secondary to the obstruction: megalocysts, megaloureter, hydronephrosis, paraurethral diverticula and dilatation of the proximal urethra. Other associated urinary anomalies are: megalourethra,[70] cryptorchidism, hypospadias and urethral duplications. Anomalies in other organs are also very frequently found (up to 43% of the fetuses)[71] like: tracheal hypoplasia, persistent ductus arteriosus,

skeletal anomalies, imperforate anus, VACTERL syndrome[72] and frequent association of chromosomal anomalies.

When a precocious oligoamnios exists, lung hypoplasia will occur and the typical findings of the Potter's syndrome (low ear implantation, micrognathia, hypertelorism, limbs contracture) will be observed.

It can be the cause of the prune belly syndrome (thickening of the abdominal wall muscles, urinary tract alterations and undescended testes) due to the abdominal distension secondary to the vesical distension.

Prognosis The prognosis is variable depending on the graveness of the obstruction that in turn will be translated in the ultrasound findings, so that the most serious cases, diagnosed before the 24th week, will have a perinatal mortality or chronicle renal failure in 53%, while those diagnosed later will have a bad evolution risk of 7%.

The precocious oligoamnios, signs of renal dysplasia as the echogenic kidneys, cortical cysts, the perirenal urinoma and the association with other anomalies are the signs of a poor prognosis.

A determination of urine electrolytes is used to evaluate the renal function, with serial determinations to avoid the stagnated urine (Table 31.1). According to the result it will also be able to classify as good or bad prognosis.

It will also be convenient to carry out a fetal karyotype.

In the fetuses diagnosed before 32 weeks without signs of renal dysplasia but with oligoamnios the decompression of the urinary tract should be evaluated by means of the realization of a vesico-amniotic bypass.[74] After the 32nd week, it will be necessary to evaluate the finalization of the gestation for the decompression of the urinary tract in the proximate neonatal period. Nowadays, an option of intrauterine fetal therapy exists, which can be carried out by means of valvular resection with endoscopy. The criteria for this intrauterine surgery will be the absence of echographic dysplasia findings, normal karyotype and some appropriate values of electrolytes in the vesicocentesis.[75,76]

It is sporadic with a low recurrence risk.

Atresia urethral

The real incidence is ignored. It affects males more.

Etiology is ignored. It is characterized by the complete obstruction from the urethra secondary to the obliteration of the membranous urethra.

Diagnosis It can be seen as a very dilated bladder with oligoamnios in the ecograph. Detection can be carried out very early, on occasion starting from the 10th week. Frequently, an anhydramnios exists with such a loosened bladder that it is difficult to explore the fetal anatomy (Figures 31.27–31.29).

In some occasions, a vesicocutaneous fistula is developed being able to be the amniotic liquid normal.[77]

Table 31.1 Poor prognostic values in fetal urine

Sodium	100 mEq/l
Chlorine	90 mEq/l
Osmolarity	280 mOsm/l
Calcium	2 mmol/l
Phosphate	2 mmol/l
B_2 microglobulin	2 mmol/l

Figure 31.27 Axial plane through the fetal abdomen demonstrating fetal megacystis.

Figure 31.28 Axial plane through the fetal abdomen demonstrating fetal megacystis.

Differential diagnosis With other causes of vesical exit obstruction: posterior urethral valves, megalourethra, megacystis-microcolon syndrome, persistent cloaca and severe vesicoureteral reflux.

Associated anomalies They are very frequent (more than 50%) but difficult to diagnose because of the oligoamnios. Among them are: heart anomalies, diaphragmatic hernia, polydactily, VACTERL syndrome and chromosomal anomalies.

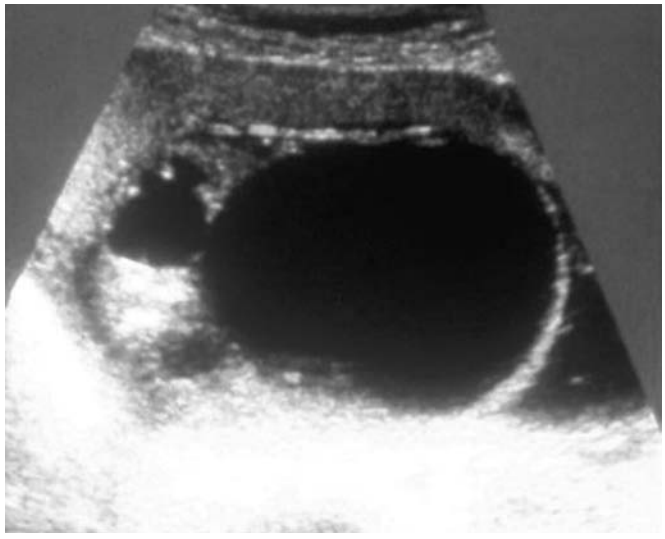

Figure 31.29 Kidney showing moderate dilatation.

It is one of the causes of the prune belly syndrome.[79]

Prognosis It is always poor and almost always lethal. Due to the oligoamnios or anhydramnios they develop a lung hypoplasia. The development of a vesicocutaneous fistula can improve the neonatal survival; however, they usually develop a renal failure that makes them need a renal transplantation with a bigger surgical reconstruction or hemodialysis.[77]

Due to the possibility of an early diagnosis an appropriate option is the interruption of the pregnancy. If the gestation is continued the possibility of the realization of a vesicoamniotic shunt will be evaluated.[80]

It is sporadic with a low recurrence risk.

Vesicoureteral reflux

This is the backward flow of urine from bladder into ureter and the pyeloureteral system.

This reflux occurs in around 1% of all the children. Fetal vesicoureteral reflux presents a masculine prevalence, of up to 80% and a high frequency (20%) of high grade reflux (III–IV).[81,82] Around 60% is bilateral. It represents 11% of the prenatal hydronephrosis cases.[83]

The etiology seems to be multifactorial. The neonatal reflux seems to have its origin in a distortion of the vesicoureteral junction *in utero*, secondary to the high casting pressures that some fetuses present.[81]

Pathology

- Urinary tract infection, which is more frequent in this group, is typically associated to parenchymatous affectation
- Up to 50% of the infants with sterile vesicoureteral reflux can present parenchymatous renal anomalies, which suggests a congenital etiopathology of renal lesion independent of the urinary infection.[84,85]

Figure 31.30 Moderate pyelectasis with vesicoureteral reflux.

Figure 31.31 Moderate pyelectasis with vesicoureteral reflux.

Diagnosis

- *Hydronephrosis*. It is the main echographic finding. It can be unilateral or bilateral (Figures 31.30 and 31.31)
- *Hydroureter* and a dilated bladder with a thinner wall. These are findings that we could find in the most severe cases. It may be confused with some posterior ureteral valves
- The amniotic fluid volume is normal
- The moderate *pyelectasis* (4–10 mm) can also be associated to vesicoureteral reflux.

Differential diagnosis

Other hydronephrosis causes should be considered

- Unilateral: obstruction of pyeloureteral or vesicoureteral junction
- Bilateral: posterior urethral valves.

Associated anomalies

These are mainly anomalies of the contralateral kidney

- Obstruction of the pyeloureteral junction
- Multicystic kidney

- Renal agenesis
- Renal or ureteral duplicity.

Prognosis

- Many resolve completely spontaneously. A total of 60% grade III, 50% grade IV and 28% grade V were resolved in 14 months[83]
- 30% of these fetuses present renal scars, and two-thirds of them present widespread renal lesions
- The reflux is the cause of 25% of the renal failure in children and 15% in adults.

Management

- If there is a hydronephrosis:
  - *Prenatal control*: *In utero*, we must make an echographic follow-up of the hydronephrosis and of the volume of amniotic fluid.
  - *Postnatal control*:
    - Echography starting from 48 h of life
    - Antibiotic prophylaxis
    - Serial cystourethrography
- If there is a moderate pyelectasis
    - Postnatal echography
    - Echography up to 3 months
    - Urologic follow-up.

Treatment will be surgical in those cases that present new renal scars, a high reflux grade, a progressive reflux, or persistent urinary infections.

The recurrence risk in brothers of the affected cases is 34%[86] and in children of the affected cases is 66%.[87]

Renal cystic diseases

Renal cystic disease compromises a mixed group of heritable, developmental and acquired disorders. Because of their diverse etiology, histology and clinical presentation, no single scheme of classification has gained acceptance.[88]

The Potter classification (Potter 1972),[89] does cover the most important conditions seen prenatally (Table 31.2).

Many of the terms used to describe kidney malformations, such as the Potter classification, are confusing since they are based on histology and do not take account of recent advances in molecular biology and genetics. A more straightforward approach is to divide the abnormalities into groups based on the underlying cell biology, such as aberrant early development or defects in 'terminal' maturation.[90]

The aberrant early development group includes dysplastic kidney[90]:

1. Large multicystic dysplastic (Potter type IIa).
2. Small organs with a combination of hypoplasia/dysplasia (Potter type IIb).
3. Severely obstructed kidneys (Potter type IV).

Table 31.2 Potter classification of cystic renal disease

Type I	Autosomal recessive (infantile) polycystic renal disease
Type II	Multicystic renal dysplasia
Type III	Autosomal dominant (adult) polycystic renal disease
Type IV	Obstructive cystic dysplasia

Kidney malformations associated with syndromes are also included within this category.[90]

Defects in terminal maturation are observed in polycystic kidney disease (PKD). Initial nephron and collecting duct formation is unremarkable in these kidneys, but there is a later cystic dilatation of these structures causing secondary loss of adjacent normal structures. The most common types are autosomal dominant and autosomal recessive PKD. Both may present prenatally.[90]

Polycystic kidney diseases

Two forms of PKD will be discussed in this chapter:

1. Autosomal recessive polycystic kidney disease (infantile) (ARPKD).
2. Autosomal dominant polycystic kidney disease (adult) (ADPKD).

Both diseases may present prenatally or during infancy.

Cysts only arise from collecting ducts in ARPKD, whereas they arise from all areas of the nephron or collecting duct in ADPKD. In addition, there are usually numerous small cysts in ARPKD whereas there are fewer, larger cysts in the dominant disease. Associated abnormalities in other organ systems are quite different in both conditions.[90]

Autosomal recessive polycystic kidney disease (Potter I)

This condition is characterized by symmetric enlargement of both kidneys secondary to renal collecting tube dilatation. This is associated with varying degrees of hepatic fibrosis and biliary ectasia.[91]

It is an autosomal recessive condition with an incidence of 1/40,000–50,000 live births.[92]

There is likely to be a defect in the collecting ducts resulting in the formation of cystic dilatations of the collecting tubules.[93] The hepatic fibrosis could be due to overgrowth of the biliary epithelium. The gene for ARPKD is located on chromosome 6p.[103]

Pathology The kidneys are symmetrically enlarged, and this is produced by cystic dilatations of the collecting tubules, which are arranged radially throughout the renal parenchyma.[93] The earlier-forming distal collecting tubules are more severely affected than the proximal collecting tubules. There is no proliferation of the connective tissue.

Table 31.3 Manifesations of ARPKD according to the subclassification of Blyth and Ockenden

Type	Proportion of dilated renal tubules (%)	Extent of portal fibrosis	Lifespan
Perinatal	90	Minimal	Hours
Neonatal	60	Mild	Months
Infantile	20	Moderate	10 years
Juvenile	<10	Gross	50 years

Clinically the disease has been classified into four subtypes[94] (Table 31.3).

Diagnosis The typical appearance is of enlarged kidneys showing increased echogenicity associated with small or absent bladder and oligohydramnios[95,96] (Figure 31.32).

These sonographic features may not be present until the third trimester, however, and it is well documented that fetuses with their condition may look absolutely normal at the 20-week scan. Thus, this condition cannot be excluded until well into the third trimester.[97–99]

A few cases diagnosed by transvaginal scanning at 12–14 weeks' gestation have been reported.[100]

Careful measurements of both kidneys are important to the diagnosis because affected kidneys have a faster growth profile than normal kidneys.[101]

Molecular genetics studies provide a useful adjunct to ultrasound for diagnosing ARPKD and these should be discussed with high-risk families. It is possible to make a prenatal diagnosis at 11–12 weeks gestation from chorionic villus sampling.

Magnetic resonance imaging (MRI) has also been used to diagnose ARPKD *in utero*, but this technique is not in regular use in most centers.[102]

Associated anomalies The main association is hepatic fibrosis.

Differential diagnosis The differential diagnosis for ARPKD is quite large. However, one important consideration is autosomal dominant polycystic kidney disease (adult), which can look identical except that liquor volume is usually normal. The other main diagnoses are outlined in Table 31.4.

Prognosis The outcome is predicted from the severity of the renal disease, with the poorest outlook for the perinatal type. Infants usually die from respiratory failure rather than renal problems, although aggressive ventilatory support and emergency nephrectomy may improve the outcome.

The outcome is progressively better with later presentation and decreasing severity of renal involvement.

Long-term complications include severe systemic hypertension, urinary tract infection and hepatic fibrosis with portal hypertension leading to hypersplenism and gastroesophageal varices.[104]

Figure 31.32 Autosomal recessive polycystic kidney disease. The images show enlarged kidneys with echogenic parenchyma and oligohydramnios. The bladder is not visible.

Management When scanning demonstrates bilaterally enlarged echogenic kidneys with oligohydramnios and there is family history of autosomal recessive polycystic renal disease, the outlook is likely to be very poor. In such a setting a termination of the pregnancy could be offered to the mother before viability.

When there is no family history and the amniotic fluid is normal, other conditions that have better prognosis should be considered. In such cases, conservative management is more appropriate.

The presence of associated abnormalities recommends karyotype. Follow-up scans are of value to assess liquor volume in pregnancy.

There is a 25% risk of recurrence.

Autosomal dominant polycystic renal disease (Potter III)

This condition is much more common than ARPKD. However, it is much less common or ADPKD to present prenatally or in early childhood. The ADPKD classically of both kidneys present cystic dilatation of the nephrons. It is the most common of the hereditary renal cystic disease, with an incidence of 1/1000 live births.[105]

The condition is caused by a mutation near the telomere of chromosome 16 in 90% cases.[106] Five percent of cases are caused by abnormality of chromosome 4.[107] Ninety percent of cases are linked to the *PKD1* gene on the short arm of chromosome 16[106] and 5% are linked to the *PKD2* gene on chromosome 4.[107]

Prenatal diagnosis is possible by gene probes from chorion sampling.[104]

Pathology It is a systemic disorder characterized by cysts formation in ductal organs, particularly the

kidneys and liver. Cysts may also be present within the pancreas, spleen and CNS.[88] In the kidneys only 5% of nephrons are cystic in the early part of the disease.

Diagnosis In adults, almost all patients present one cyst, at least, at age of 30 years.[108,109] The sonographic appearance is well known: enlarged hyperechogenic kidneys, with a mixture of small and large cysts[110] (Figure 31.33).

Some cases diagnosed prenatally have been reported. The most common sonographic finding is large kidneys.[111–113] The sonographic appearance is similar to the ARPKD: symmetrically enlarged and hyperechogenic kidneys. The bladder is generally present and the amniotic fluid is normal. The corticomedullary junction may appear accentuated or may be indistinct.[114] Some reports have described the presence of macroscopic cysts within the echogenic kidneys.[90]

Brun *et al.*[27] determined a new specific echographic pattern: moderately enlarged kidneys (1–2 SD > mean) with, in the majority of cases, a hyperechogenic cortex and relatively hypoechogenic medulla that occurs in the third trimester. This hyperechogenic cortex is probably related to the presence of multiple microcysts within renal cortex.

Sonographic diagnosis is usually made in the third trimester with a mean of 28 weeks.[114] Some cases of earlier sonographic diagnosis have been reported but mostly in cases with known family history.[115,116]

Follow-up scans are essential because in the second trimester the kidneys can look normal.

Very rarely, the condition can be unilateral.[117,118]

Differential diagnosis Several conditions may exhibit enlarged hyperechogenic kidneys. This echographic feature may correspond to different renal diseases with different outlooks and perinatal outcomes: obstructive dysplasia, multicystic renal dysplasia, autosomal recessive polycystic renal disease, genetical syndromes (Perlman sd., Beckwith–Wiedemann sd., Bardet–Biedl sd., Meckel sd.), nefroblastomatosi, renal vein thrombosis, toxic injured, infections (cytomegalovirus), isquemia, aneuploydy, and sometimes, normality.

In autosomal dominant polycystic kidney disease few cases are diagnosed prenatally. The diagnosis is based on family history, amniotic fluid, associated abnormalities and genetic analysis.

Associated anomalies The most important associated anomalies are cysts in the liver, spleen and pancreas. Noncystic anomalies include cardiac disease, skeletal anomalies, pyloric stenosis and intracranial aneurysms.[88] Tract urinary malformations associated with this condition have also been described.[114]

Prognosis The condition is often asymptomatic and usually presents in the fifth decade with hypertension and end-stage renal failure.[105]

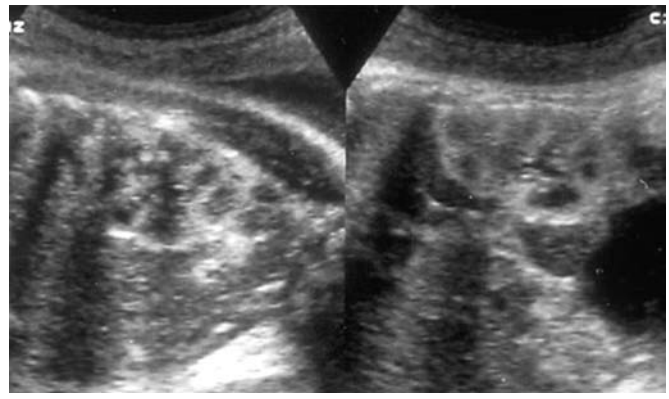

Figure 31.33 Adult polycystic kidney disease. Brightly echogenic kidneys with accentuation of the cortico-medullary junction and a small bladder with decreased fluid.

The outlook for those cases diagnosed *in utero* is difficult to determine because to date only 83 cases of adult-type polycystic renal disease presenting prenatally or in the first few months of life have been reported. MacDermott *et al.*[104] reported that in prenatal cases, 43% of babies die within the first year of life and 67% of survivors develop hypertension. The best indicators for outcome are the presence of oligohydramnios and the perinatal outcome from a previously affected sibling.

Management Management of the pregnancy depends in large part on the parents´ knowledge of the condition.

The diagnosis of this condition requires very careful counseling with regards to both the short-term and long-term outlooks.

Follow-up scans in the third trimester are of value to assess liquor volume.

There is a 50% risk of recurrence.

Dysplastic kidneys — multicystic renal dysplasia (Potter II)

The diagnosis is inferred from the 'bright' echogenic appearance caused by the lack of normal renal parenchyma and structurally abnormal kidneys.

Dysplastic kidneys can be of any size, ranging from massive distended with multiple large cysts up to 9 cm in diameter, which are commonly termed 'multicystic dysplastic kidneys' (MCDK), to normal or small kidneys, with or without cysts. Dysplasia can be unilateral or bilateral. MCKD is one of the most common causes of abdominal masses in the newborn.[90]

It is the most common form of renal cystic disease in childhood. It has an incidence of 1/3000 live births and is more common in boys.[119,120] The majority is unilateral, but it can be bilateral up to 23% of cases.[119]

MCDK are attached to atresia of the ureter and renal pelvis. This may be related to incomplete but severe obstruction to the kidney early in nephrogenesis.[121]

Figure 31.34 Multicystic dysplastic kidney disease. The kidney appears enlarged with multiple cysts. The contralateral kidney is normal.

Figure 31.35 Multicystic dysplastic kidney disease. The kidney appears enlarged with multiple cysts. The contralateral kidney is normal.

Pathology The kidney is replaced by multiple smooth-walled cysts of varying size.[88] Between the cysts is a dense stroma but usually no normal renal tissue.[122,123] Typically, the renal artery is either absent or very small.

Diagnosis The prenatal diagnosis for the unilateral condition is variable and depends on its severity. It is usually straightforward in the mid-trimester scan.

The classical presentation of MCDK is a multiloculated abdominal mass consisting of multiple thin-walled cysts, which do not appear to be connected. The kidneys are usually enlarged with an irregular outline and no renal pelvis can be demonstrated (Figures 31.34 and 31.35). Circumferential cysts may occasionally be detected in kidneys of more normal size, particularly in association with lower tract obstruction. Parenchymal tissue between the cysts is often hyperechogenic[90] (Figures 31.36 and 31.37). Bladder and amniotic fluid are usually normal in the unilateral condition.[120,121]

The bilateral form is usually diagnosed earlier because oligohydramnios is present and bladder is not seen. MCDK usually affects the whole kidney; however, occasionally, only part of the kidney is involved, usually the upper pole of a duplex kidney.[124]

Careful attention should be paid to assessment of the contralateral kidney because the incidence of contralateral renal anomalies is high (39%). A search should be made for nonrenal anomalies.[110]

There is a high association between dysplasia and obstruction: dysplastic kidneys are classically attached to atresic ureter; renal dysplasia is associated with lower urinary tract malformations.[90]

Color Doppler assessment may be useful in determining the diagnosis since the renal artery is always small or absent in MCKD and the Doppler waveform, when present, is markedly abnormal with reduced systolic peak and absent diastolic flow (Figure 31.38).

Figure 31.36 Multicystic dysplastic kidney disease. Parenchymal tissue between the cysts is often hyperechogenic.

Differential diagnosis includes upper urinary tract dilatations and other cystic abdominal masses.

Associated anomalies Associated anomalies are seen in the contralateral kidney in 30–50% of cases: vesicoureteric reflux is the most common, followed by renal agenesis, renal hypoplasia and pelviureteric junction obstruction.[125,126]

Detection of dysplastic kidneys should stimulate a detailed examination of the fetus for other structural abnormalities, including heart, spine, gastrointestinal, CNS, cleft palate, limb anomalies and umbilical cord

Figure 31.37 Multicystic dysplastic kidney disease. Parenchymal tissue between the cysts is often hyperechogenic.

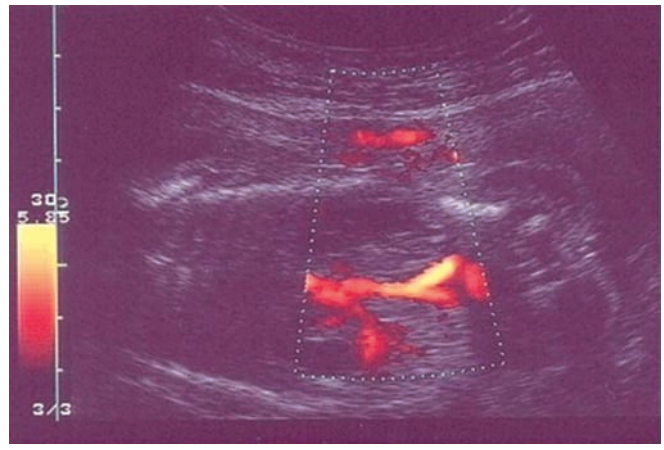

Figure 31.38 Multicystic dysplastic kidney disease. Color Doppler shows that the renal artery is always small or absent.

as up to 35% may have extra-renal anomalies. These are more likely to occur in fetuses with bilateral than unilateral MCDKD.[127] Chromosome analysis should also be discussed with the parents, particularly when structural abnormalities are detected or dysplasia is bilateral. Risks of chromosomal defects are low if there is isolated renal dysplasia.

Kazebnik *et al.*[127] reported 102 prenatally detected cases. In their experience the condition is unilateral in 76% of cases, 10% have normal karyotype, but in all cases they found associated nonrenal anomalies.

Prognosis Unilateral multicystic dysplastic kidney has a good outcome provided the contralateral kidney is normal. If an associated renal anomaly is present, the prognosis depends on the severity of the associated abnormality. The presence of multiple anomalies confers a poorer prognosis.

Bilateral multicystic kidneys have a very poor prognosis, and all babies succumb, in the early neonatal period, to pulmonary hypoplasia.

Management Unilateral multicystic kidney can be managed conservatively with follow-up scans in the third trimester to assess both the multicystic and contralateral kidney.

Bilateral multicystic kidney has a very poor prognosis, and a termination of pregnancy is an appropriate management strategy.

The risk of recurrence is small, about 2–3%, but it can be higher if it is associated with a genetic syndrome.

Obstructive cystic dysplasia (Potter IV)

It occurs secondary to obstruction in the first or early second trimester of pregnancy.[128]

The incidence of this condition is difficult to determine because only a small proportion of obstructed kidneys progress to renal dysplasia. There is an approximate incidence of 1 in 8000 live births, with 40% being bilateral dysplasia.[92,129]

This condition is caused by early renal obstruction.

Unilateral disease can be caused by a pelviureteral or vesicoureteric junction obstruction.

Bilateral obstructive dysplasia is caused by severe bladder outlet obstruction (urethral atresia or posterior urethral valves).

Pathology The kidney is usually small with disorganized epithelial structures surrounded by fibrous tissue. Cortical cysts are often present.[129]

Diagnosis The sonographic appearance is small echogenic kidneys with peripheral cysts. In the bilateral condition, bilateral hydronephrosis may be present, bladder with thick walls and usually collapsed and severe oligohydramnios may be seen.

The renal cortex assessment is very important. The presence of cortical cysts and hydronephrosis is suggestive of dysplasia.[129] Although increased echogenicity is a good sign of renal dysplasia, normal renal echogenicity does not exclude this condition[128] (Figures 31.39 and 31.40).

Occasionally, the obstructive dysplasia can affect part of a kidney.[130]

Differential diagnosis The differential diagnosis is established between multiple conditions, as shown in Tables 31.4 and 31.5.

Associated anomalies The main anomalies seen are cardiac and the VACTERL association (*v*ertebral anomalies, *a*norectal atresia, *c*ardiac anomalies, *t*racheo-*e*sophageal fistula, *r*enal anomalies and *l*imb abnormalities). Other less common associations are hydrocephalus, cloacal malformation, malrotation and ambiguous genitalia.[131]

Prognosis The prognosis depends on whether the condition is bilateral or unilateral. Bilateral disease

Figure 31.39 Obstructive cystic dysplasia. Peripheral cortical cysts and echogenic parenchyma.

Figure 31.40 Obstructive cystic dysplasia. Peripheral cortical cysts and echogenic parenchyma.

has a poor prognosis, and most of newborn succumb in neonatal period to pulmonary hypoplasia. In unilateral disease, the outcome depends on the presence of renal anomalies affecting the contralateral kidney and the presence or absence of associated abnormalities.

Management. Due to the very poor outcome of the bilateral condition, interruption of pregnancy can be offered to the parents.

Unilateral condition can be managed conservatively in the absence of contralateral kidney disease and associated abnormalities.

The condition is sporadic.

Echogenic large kidneys or 'bright' kidneys

Large 'bright', or hyperechogenic kidneys are occasionally seen at the time of a routine ultrasound scan or indeed later in pregnancy when a woman is scanned for another clinical indication.[132]

They represent a difficult diagnostic dilemma, particularly in the presence of a normal liquor volume, since their underlying etiologies are relatively diverse. A list of the more common underlying pathologies is shown in Table 31.6.[90] Only a few of these conditions can be identified prenatally, usually on the basis of associated abnormalities, liquor volume and targeted invasive test. In many instances, however, definitive diagnosis is dependent upon postnatal investigations.

Sonographic detection of large, 'bright' kidneys should stimulate a detailed examination of the rest of the fetus paying particular attention to the rest of the renal tract and other measurements. If the bladder is enlarged, with or without dilated ureters, then the findings reflect an obstructive uropathy. If the kidneys and all measurements lie above the 95th percentile, then an overgrowth syndrome (Beckwith–Wiedemann, Perlman, Simpson–Golabi–Behmel syndrome, etc.) could be considered (Figures 31.41 and 31.42). Karyotyping should be discussed, particularly when other malformations are detected.

If the fetus has isolated hyperechogenic kidneys and a normal karyotype with no evidence of renal tract obstruction, then the etiology lies between renal dysplasia, autosomal recessive polycystic kidney dysplasia, autosomal recessive polycystic dysplasia, nephrocalcinosis or a variant of normal.

Accurate prediction of the prognosis can be difficult, although liquor volume is a key indicator since reduced volume or its absence indicates that the outcome is likely to be poor and the pregnancy will frequently end in a neonatal death subsequent to pulmonary hypoplasia, as well as renal failure. In these circumstances, termination of pregnancy is a reasonable option.

In the presence of normal amniotic fluid, serial scanning should be undertaken to monitor the size of the kidneys and renal function as indicated by liquor volume.

Simple renal cysts

The incidence of simple renal cysts varies with gestational age. Scanning at 14–16 weeks' gestation is 1/1100[132] and at 20 weeks is 1/2400.[133]

The etiology is unclear, but there are two main theories[134]:

(1) They are retention cysts resulting from the obstruction of renal tubules secondary to local vascular damage or inflammation.
(2) The second to fourth generations of uriniferous tubules fail to degenerate or unite with later generations of collecting tubules, persisting as cystic collections.

The cysts are usually solitary and unilocular with no communication with the renal pelvis. The rest of the kidney is normal.[133]

Table 31.4 Echogenic kidneys: antenatal ultrasound appearances and clinical findings

Condition	Renal size	Cysts present?	Hydronephrosis	AF	Cysts in parents' kidneys	Family history	Associated findings
ARPKD	Large	No	No	↓	No	Yes, in sibling	Hepatic fibrosis
ADPKD	Large	Sometimes	No	Normal	Yes > 20 yr	Yes, in parent	Occasionally cysts in parents´ liver, spleen
Obstructive cystic dysplasia	Small	Often	Yes	Depends on degree of renal obstruction	No	No	Hydronephrosis usually urethral obstruction
Finnish type nephrotic syndrome	Large	No	No	Normal	No	Yes, in sibling	Raised serum AFP
Beckwith–Wiedemann syndrome	Large	No	No	Normal ↑	No	Occasionally	Macrosomia, large liver, macroglossia, omphalocele
Perlman syndrome	Large	No	Sometimes	Normal ↑	No	Yes, in sibling	Macrosomia, hepatoesplenomegaly ascites, micrognathia, depressed nasal bridge
Meckel Grubel syndrome	Large	Sometimes	No	↓	No	Yes, in sibling	Polydactyly encephalocele
Trisomy 13	Large	Sometimes	No	Normal	No	No	Facial clefting, holoprosencephaly, cardiac defects, polydactyly
CMV infection	Large	No	No	Normal	No	No	Microcephaly, hydrocephaly, intracranea calcification, large liver and spleen, hydrops
Renal vein thrombosis	Large, usually unilateral	No	No	Normal	No	No	Maternal diabetes, maternal pyelonephritis
Normal	Normal	No	No	Normal	No	No	

Table 31.5 Syndromes associated with renal cystic disease

Syndrome	Clinical features
Meckel Gruber	Large echogenic kidneys, polydactyly, encephalocele
Patau	Hyperechogenic large kidneys, polydactyly, holoprosencephaly, facial clefting
Jeune	Echogenic kidneys, dwarfism, small thorax
Beckwith–Wiedemann	Large echogenic kidneys, macrosomia, hepatosplenomegaly, macroglossia, omphalocele
Short rib polydactyly (Majewski type)	Large echogenic kidneys, dwarfism, polydactyly, small thorax
Laurence–Moon (Bardet–Biedl)	Renal cysts, retinal dystrophy, polydactyly, mental deficiency, hypogonadism
Zellweger	Cystic kidneys, hypotonicity, limb contractures, congenital cataracts, hypoplastic corpus callosum, heterotopia
Perlman	Macrosomia, hepatosplenomegaly, ascitis, micrognathia, depressed nasal bridge
Tuberosa esclerosis	Epilepsy, mental retardation, cutaneous lesions, cardiac rhabdomyomas (*in utero*)

Table 31.6 Conditions associated with large, 'bright' kidneys

	AF	Renal cysts	Renal pelvis dilatation	Macrosomy	Other abnormalities	Heart abnormalities	Inheritance	Alternative prenatal diagnosis
Dysplasia	N/Oligo	+/−	+/−	−	+/−	−	10%(AD)	−
Obstruction	N/Oligo	+/−	+	−	+/−	−	Sporadic	
ARPKD	N/Oligo	−	−	−	−	−	AR	DNA
ADPKD	N/Oligo	+	−	−	−	−	AD	DNA
Beckwith–Wiedemann	N/Poly	−	+/−	+	+	−	AD or Disomy	Cyto/DNA
Perlman	N/Oligo	−	+/−	+	+	−	AR	−
Simpson–Golabi–Behmel	?	?	?	+	+	+/−	X-linked	DNA
Trisomy 13	Oligo	−	+/−	−	+	+/−	Sporadic	Cyto
Meckel Gruber	Oligo	−	−	−	+	+/−	AR	DNA
Nephrocalcinosis	N	−	−	−	−	−	Sporadic	−

Diagnosis The cysts appear as a unilocular round or oval anechoic structure with well-defined borders, usually near the periphery of the kidney. Cysts vary in size (2–4 mm).[133]

The differential diagnosis is established between:

(1) Hydronephrosis of the upper pole moiety of a duplex kidney.
(2) Perinephric urinoma.
(3) Cysts arising from structures close to the kidneys (duplication or mesenteric cysts).

Associated anomalies Most simple cysts are asymptomatic and rarely associated with structural or other abnormalities. Occasionally they are associated with[133,136,137]:

(1) Pelviureteric junction obstruction
(2) Posterior uretharl valves
(3) Turner syndrome
(4) Trisomy 13
(5) Trisomy 18
(6) Trisomy 21(5% are associated with simple renal cysts)

Prognosis The outcome is good for fetuses with simple cysts.[133]

When cysts do become symptomatic, simple aspiration under ultrasound control is the treatment of choice.[138]

Management Simple cysts seen in the first half of pregnancy can be followed up with scans during the third trimester. The majority resolve and those that persist do not need any postnatal investigations.

Renal tumors

Congenital renal tumors are rare. The incidence is 1 per 125,000 newborns.[139] The most frequent tumor

Figure 31.41 Meckel–Gruber syndrome. Distended abdomen due to the cystic renal dysplasia.

Figure 31.43 Neuroblastoma. Solid tumor and heterogenous.

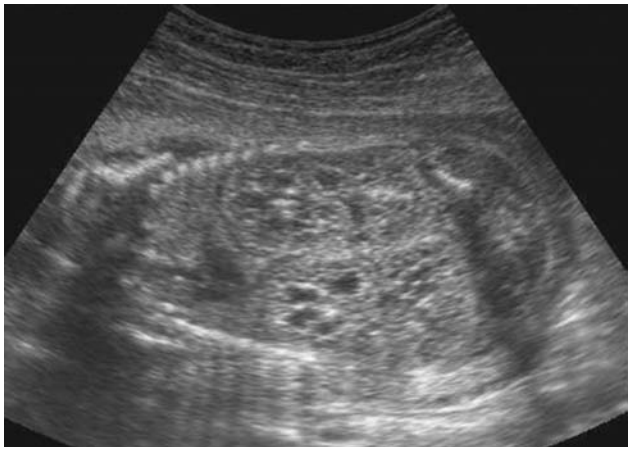

Figure 31.42 Large and bright kidneys with oligohydramnios.

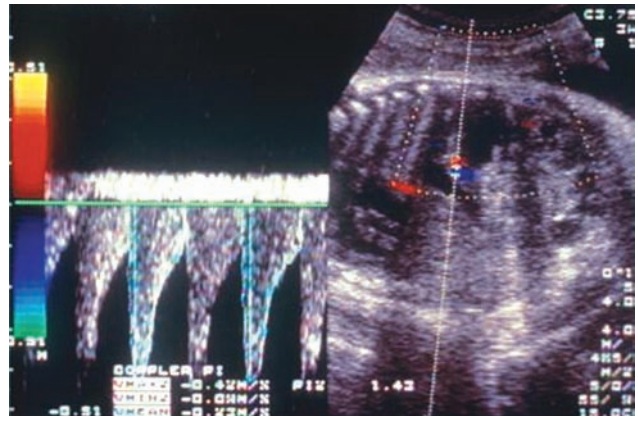

Figure 31.44 Neuroblastoma. Solid tumor and heterogenous. Color Doppler shows artery blood flow.

is the mesoblastic nephroma. It is a benign tumor that presents continuity with the normal nephrons. Wilms' tumor is rare in the fetus.

The etiology is unknown.

Diagnosis

The diagnosis will generally be made before the presence of a polyhydramnios and an abdominal mass at level of renal fossa in third trimester[140] (Figures 31.43 and 31.44).

- The mesoblastic nephroma is unilateral and on ultrasonography appears as a solid mass. Occasionally, cysts can be identified, many of them are located near the renal hilus, and almost all affect the renal parenchyma. On occasions, the tumor can be adjacent to the kidney and compress it. The mesoblastic nephromas is usually well defined
- It can have polyhydramnios in 70% of the cases, resulting from the polyuria secondary to the hypercalcemia[141]
- The hydrops is uncommon, and it has a poor prognosis[142]
- Wilms' tumor presents very similar echographic characteristics and an anatomopathological study should be carried out for its diagnosis.[143]

Differential diagnosis

- Neuroblastoma. It usually displaces inferior to the kidney
- Suprarenal hemorrhage
- Retroperitoneal teratoma
- Extralobar subphrenic sequestrum.

Associated anomalies

- The mesoblastic nephroma unusually associates to anomalies
- Wilms' tumor associates to anomalies in 15% of the cases: aniridia, genitourinary abnomalies and hemihypertrophy.[144]

Genetic markers

The genes WT1 and WT2 located in chromosome 11 have been implicated in the development of the Wilms' tumor, as well as the gene WT3 of chromosome 16 in Beckwith–Wiedemann syndrome and Denys–Drash syndrome.[144]

Prognosis

Treatment is surgical and it is usually curative. The presence of hydrops involves a very bad prognosis.[142]

Management

- During the pregnancy it is necessary to control the polyhydramnios to avoid premature childbirth and the premature rupture of membranes (PROM)
- Childbirth should take place in a tertiary level hospital, where there are neonatology unit, pediatric surgery and pediatric oncology.

This tumor appears sporadically.

32 Fetal echocardiography

C. Mortera and J. M. Carrera

Introduction

Prenatal diagnosis of fetal cardiovascular malformations is generally based on the use of ultrasound and echocardiography techniques during pregnancy.[1,2]

Anatomical cardiac anomalies[3,4] are identifiable throughout the use of two-dimensional (2D) echocardiography, providing fetal anatomical cardiac structures.[2,4] Current use of 3D echocardiography provides images that may improve the anatomical structural relationship.[5,6] However, Doppler echocardiography studies allow for additional dynamic information to the cardiologist[7] and interested obstetrician[8,9] in prenatal diagnosis. Consequently, the application of such methods in normal and abnormal fetal cardiac structures and function leads to an accurate congenital heart disease diagnosis inside the uterus.[10,11]

In order to successfully diagnose cardiac malformations throughout the use of fetal echocardiography, a number of integrated conceptual areas need to be thoroughly understood to achieve a complete cardiovascular diagnosis. First, a profound knowledge of cardiovascular fetal physiology[12] and anatomy as well as fetal cardiovascular pathology and cardiac rhythm disturbances is required. Second, it is required to understand the causes and concepts of heart failure to identify the signs and causes of fetal heart failure.[13]

However, the goal of prenatal echocardiography is to make a prediction of the pregnancy outcome, offering medical[14] and surgical cardiac prognosis about the short- and long-term surgical management.[15]

Fetal cardiovascular anatomy

The fetal cardiovascular system is developed during the first 9 weeks of gestation. Interestingly, the heart is the only organ in the fetus capable of functioning while it is being developed. The 'foramen ovale' and 'ductus arteriosus' are the only features that are different in a developed fetal heart[16] when compared to an adult heart. The right atrium is presented as a slightly larger cavity than the left atrium. The superior and inferior vena cava are identifiable as they meet with the right atrium. Pulmonary veins tend to be smaller in size due to the reduced pulmonary blood flow; however, they become apparent in mature fetuses.

The tricuspid and mitral valves present similar features under echocardiographic analysis (Figure 32.1). Two papillary muscles constitute the subvalvular apparatus of the mitral valve, while only one is observed in the tricuspid valve. The tricuspid septal leaflet is distinctly apparent because it attaches to the septum at a closer location than the mitral valve from the apex of the heart. This separation in valve positioning allows for effective visual recognition if the ventricles are pathologically inverted.

To ensure normal ventriculoarterial connections,[8,17] a 'crossing' by the pulmonary and aortic outflow tracts and arteries must be identified when examined with echo (Figure 32.2). A parallel position of both great vessels at their origin from the heart would mean a 'transposition of the great arteries'.[8]

In order to differentiate the aortic arch from the ductal arch (Figure 32.3), three supra-aortic vessels must be attached to the curve of the aortic arch before it extends into the descending aorta. The position beneath the ductal arch is recognizable by its continuity from the pulmonary artery into the ductus arteriosus and the descending thoracic aorta.

Fetal cardiovascular physiology

The normal fetal heart structure and blood circulation differ physiologically[12] from those of the adult. The placenta and the feto-placenta circulation become the major source of oxygen in the uterus during fetal life as opposed to the adult lung autonomous respiratory system.

Two major fetal intracardiac shunts appear, one at the foramen ovale level and the other at the ductus arteriosus. These allow for a *right to left* direction of the almost total fetal cardiac output. Approximately half of this circulatory blood volume will be sent to the placenta to be oxygenated, returning subsequently to the fetus, resulting in two major circulations: the fetal circulation and the feto-placental circulation.[16]

Feto-placenta venous circulation is characterized by the entry of the umbilical vein through the fetal

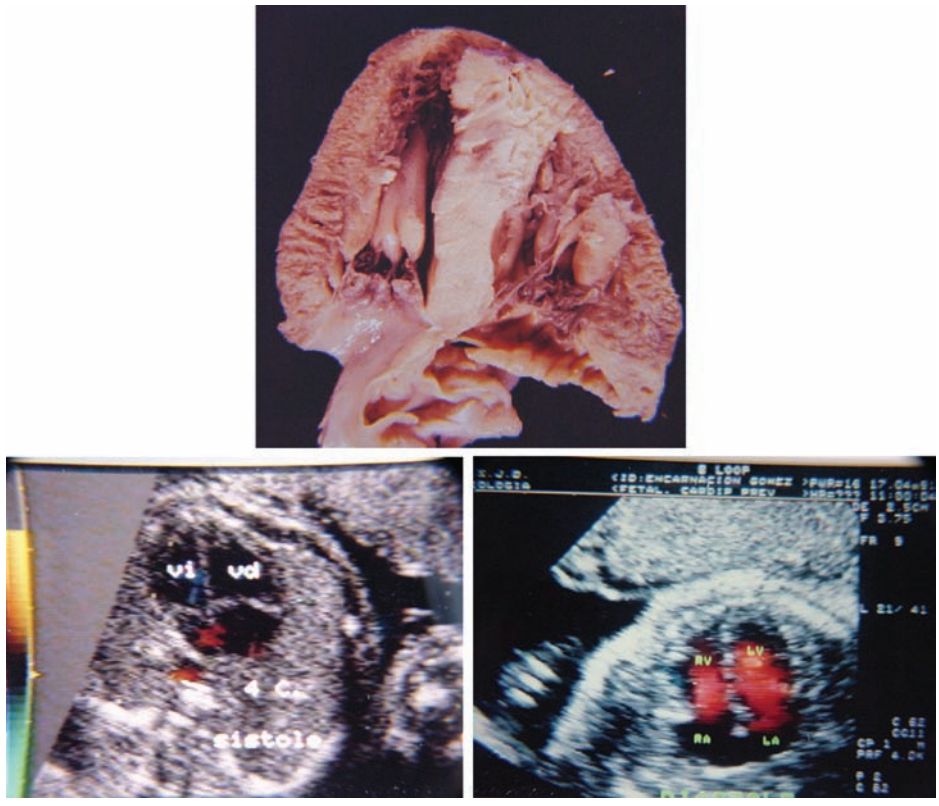

Figure 32.1 Normal four-chamber view. Systolic and diastolic color flow Doppler phases at the A–V valves. Anatomic correlation with the heart specimen.

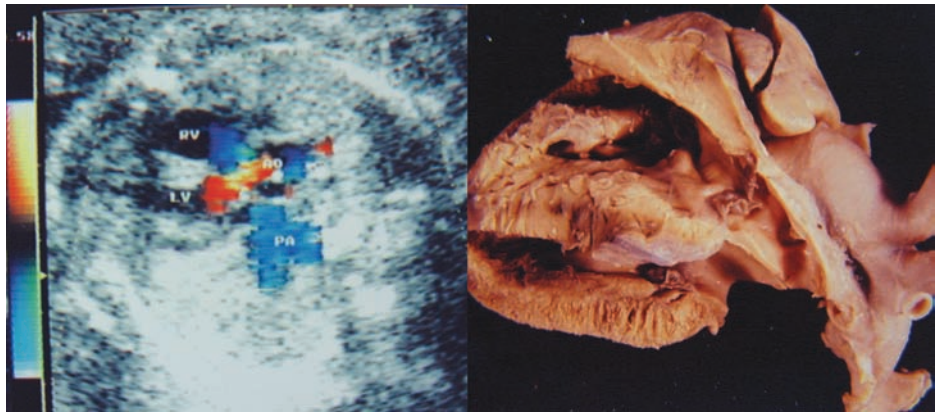

Figure 32.2 Normal longitudinal color flow Doppler cut at lateral dorsum. Crossing of the outflow tracts and arteries and anatomic correlation.

liver. Oxygenated blood travels from the placenta entering the fetus through the 'ductus venosus', which is an extension of intrahepatic umbilical vein. It has been found that the flow dynamics of the circulatory system in this specific area are crucial for the fetal oxygenation process. The diameter of the ductus venosus is reduced as it meets the inferior vena cava. This reduction in diameter accelerates the oxygenated blood, creating a directional jet toward the foramen ovale and left atrium. The entry of this oxygenated bloodstream is cyclically regulated by the fetal heart rate. The change in volume in the right atrial cavity imposes the cardiac filling pattern. This allows the oxygenated blood to be propelled through the left atrium and left ventricle toward the coronary arteries and fetal brain. Less oxygenated blood returning from the peripheral fetal body, coming from the superior vena cava and inferior vena cava, enters the right atrium, right ventricle and the pulmonary artery. At this last point most of the blood is diverted through the ductus arteriosus toward the descending aorta, leaving the pulmonary circulation at minimum flow.

The lower part of the fetal body has low oxygen requirements. This area is supplied by a part of the

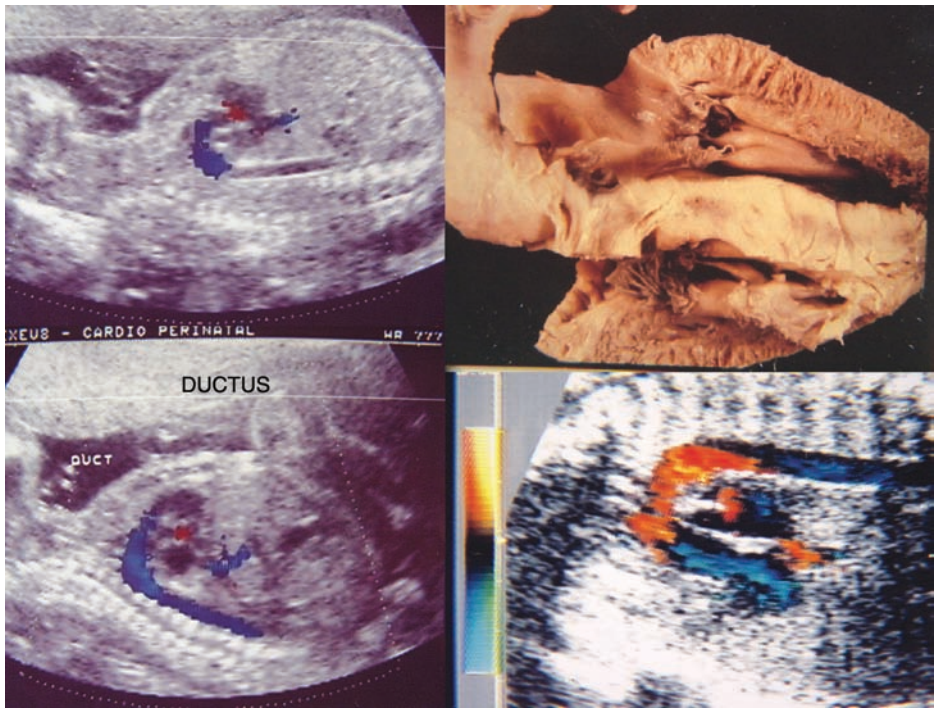

Figure 32.3 Normal aortic arch at posterior/anterior dorsum. Normal ductus arteriosus arch at posterior dorsum.

less oxygenated blood coming from the descending aorta. The rest of the blood at this level is directed toward the placenta through the umbilical arteries and umbilical cord. The blood oxygenation process takes place at the placenta, which is then returned to the fetus, closing the feto-placenta circulation.

Thus, two main circulatory systems are developed during the fetal life: fetal and feto-placenta circulation. Both the circulatory systems are maintained by the fetal heart. Consequently, high fetal cardiac output is required to keep both the circulations functioning. This translates into elevated heart rates (130–160 beats per minute, (bpm)), which are also partially imposed by the limited ventricular compliance of the fetal heart.

Another representative feature only present in the fetal circulatory system is the similar systolic pressure levels between the right ventricle/pulmonary artery and the left ventricle/aorta at a systemic level. Therefore, *right to left intracardiac shunts* are dependable on systemic vascular resistance as well as changes in cardiac and vascular blood volume adjustment.

Assessing the fetal heart

Instrumentation and technique

The study of the fetal heart requires the combination of several dynamic ultrasound techniques and sequential cardiac analysis.[18]

The intracardiac fetal echocardiographic studies require a range-gated 2D and pulsed Doppler to perform selective interrogation of blood flow across the A–V valves, ventricles and great arteries, ductus arteriosus, descending aorta as well as the aortic arch. The scanning should also include the hepatic duct and veins, the inferior vena cava, atrial flows, foramen ovale and when possible the pulmonary veins. The equipment should also include CW Doppler for sampling high-velocity jets.

Color flow mapping increases the diagnostic accuracy and understanding of fetal cardiovascular circulation.[8,9] Color flow display must be performed with the instrumentation settings at a high pulse repetition frequency in order to avoid aliasing. Intracardiac blood velocities are higher than in the periphery, therefore color Doppler settings must be set up at high frame rates, reduced angle and high filter to obtain good color resolution. However, diagnostic misinterpretation of color intracardiac Doppler may occur in complex congenital heart disease if previous analysis of 2D cardiac malformed anatomy has not been properly done.

(1) 2D echocardiography identifies anatomical structures, spatial relationship, position of the heart, myocardial thickness and myocardial function. The superimposition of color Doppler technique allows performing of selective cardiovascular flow dynamics in each heart structure.
(2) 'Pulsed Doppler' is used for selective flow studies in each cavity or vessel and the instrument setting has to be adjusted according to the sampling site. 'Continuous Doppler' is necessary to identify high-velocity blood signals as well as to quantify intracardiac and intravascular pressure gradients. 'Color Doppler' opacification of the

blood flow in cardiac cavities and vessels allows detection of abnormal turbulent accelerated flows produced by valve regurgitation and stenosis or other cardiac defects.

(3) 'M-mode color Doppler flow' is used to measure accurately the cavity size and vessels as well as to evaluate cardiac rhythm disturbances and cardiac function.

(4) Fetal position within the uterus must be understood to evaluate the spatial orientation of the different heart structures in order to trace the best Doppler signal and map the color flow Doppler displayed in anatomical position.

'Anterior dorsum' and 'posterior dorsum' are usually the best fetal positions to study the color flow displayed in the aortic arch and the aorta as well as the ductus arteriosus arch.

'Posterior dorsum' is the most favorable position to obtain the four-chamber view to evaluate the ventricular filling pattern across the A–V valves, obtaining information about atrial and ventricular size and anatomy, integrity of the atrioventricular septum and inlet septum, the A–V valves and atrioventricular connections.

'Lateral dorsum' identifies best the opacification of the right and left outflow tracts and outlet septum, as well as ventriculoarterial connections.

Transabdominal cardiac Doppler studies can be performed with adequate level of cardiac definition from 17 weeks of gestation onward, using a 3.5-MHz transducer. Cardiac scanning should include at least three anatomical and functional cuts to demonstrate structural and functional normal assessment.

Normal anatomic and functional fetal echocardiographic features

A number of normal features should be identified in the echocardiographic evaluation of the fetus:

(1) The normal position of the heart within the thorax is of levocardia (the heart is usually to the left, opposite to the liver and superior to the stomach). In the four-chamber view, the thoracic aorta should be in the left, in close proximity with the left atrium. The fetal heart lies in a more horizontal position due to the large liver.

(2) Septal integrity should be present, although weakening of the inlet/outlet septum may give the impression of a ventricular septal defect (VSD) in the early stages of pregnancy; no posterior confirmation has been possible, probably due to a transitional echo view, which cuts part of the left outflow tract and the interventricular septum.

(3) The patent foramen ovale should be a visible atrial communication of approximately the same size as the ascending aorta but no larger than 6 mm along pregnancy and with a detectable moving membrane.

(4) Normal separation between the septal leaflet implantation of the mitral and tricuspid valves should identify the right and left A–V valves (Figure 32.4).

(5) Myocardial contractility presents an out of systolic phase, paradoxical septal movement; however, movement of the anterior and posterior heart walls should be identified for evaluating ventricular myocardial movement and function.

(6) A pericardial space translucency may be visualized in the absence of a pericardial effusion.

(7) The heart rate should be between 120 and 180 bpm.

(8) Normal ventriculoarterial connections should be established when normal crossing of both ventricular outflow tracts and arteries is seen (Figure 32.2).[8]

(9) Normal vessel relationship is seen by the transverse three-vessel view from left to right – the pulmonary artery, the Ao and the SCV are seen in the same transverse plane.[19]

(10) The aortic arch should give rise to the three supra-aortic arteries.

(11) The ductus arteriosus arch should be identified as a vascular structure in continuity with the descending aorta, in a right-angle curvature when it meets the aorta.

(12) The superior vena cava and inferior vena cava should be visualized in continuity entering the right atrium.

(13) The pulmonary veins should be seen entering the left atrium.

Normal Doppler fetal hemodynamics

Peripheral venous return of the umbilical vein and ductus venosus

Doppler sample at the umbilical vein level shows that a low-velocity non-pulsatile wave form is slightly influenced by diaphragmatic respiratory movements. The intrahepatic umbilical vein continues with the ductus venosus as it meets the inferior vena cava. The diameter of the ductus venosus is reduced as it meets the inferior vena cava. This reduction in diameter accelerates the blood flow converting the non-pulsatile Doppler venous wave of the umbilical vein into a high-velocity triphasic wave form directly influenced by the cycling cardiac filling pattern. The first peak (S) represents the systolic cardiac phase; the second peak (D) represents the diastolic phase, which is followed by the atrial contraction inflection (A).

Right/left atrium and foramen ovale

Doppler interrogation of the foramen ovale demonstrates a right–left shunting. Premature closure of the foramen ovale has been described.[20] Doppler tracing in the pulmonary veins is also triphasic as in the systemic veins; the lowest-velocity deflection occurs

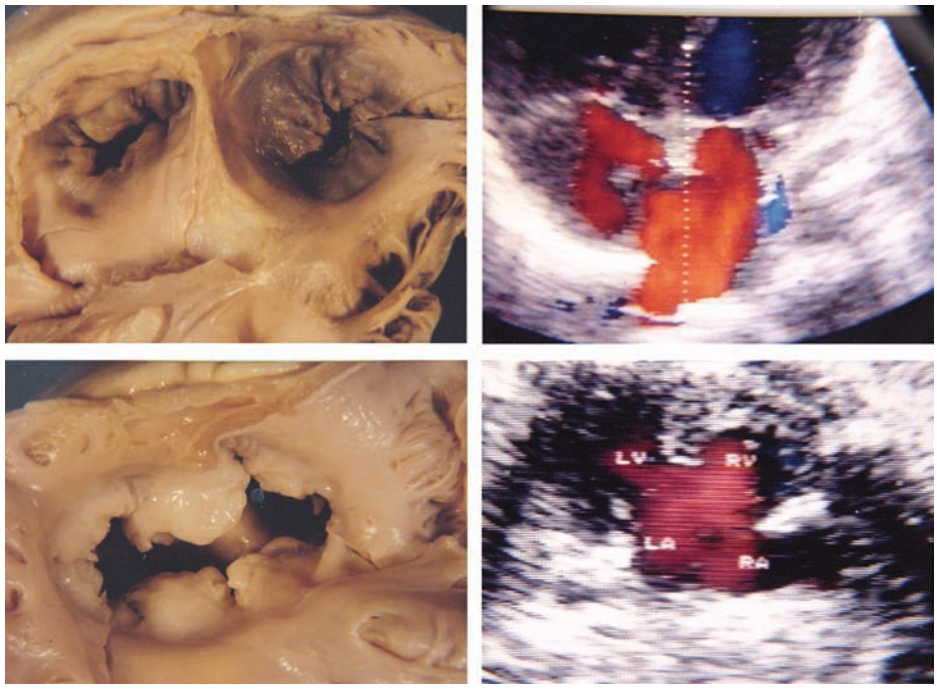

Figure 32.4 Inflow of the heart with two normal A–V valves. Color Doppler also identifies the PFO. Inflow of a heart specimen with one common A–V valve in atrioventricular septal defect. Echo/anatomy correlation.

during atrial contraction. Timing of the phases in the venous flow of the pulmonary veins may be useful in diagnosing premature atrial contractions.

Increase in right atrial or ventricular filling pressure may lead to right heart failure. This increase in resistance to umbilical venous flow accentuates the atrial contraction and the corresponding Doppler inflection wave at the 'ductus venosus', creating a negative deflection wave that may exceed the zero line at the venous return; this Doppler form should be recognized as a sign of heart failure.

The less oxygenated blood returning from the peripheral fetal body, coming from the superior vena cava and inferior vena cava as the blood enters the right atrium, presents a Doppler venous flow with the triphasic waveform related to the same cardiac filling cycle; this waveform exhibits more pronounced atrial inflection but less flow velocity than the waves obtained in ductus venosus.

Inflow heart and atrioventricular valves

Doppler interrogation of the inlet heart examines the diastolic filling function. Doppler waveforms through the tricuspid and mitral valves are similar, representing the ventricular filling pattern: the first peak E is followed by the A wave. Due to atrial contraction an increase in A occurs in the early phases of pregnancy and may represent a transient restricted compliance of the ventricles; normal velocity across the A–V valves increases along pregnancy. High heart rate may produce single wave changes in morphology. A–V valve stenosis or volume overload alters the morphology and increases velocity across the valves.

Regurgitation of an A–V valve is detected within the atrial cavity. Although quantification of a regurgitant flow by Doppler is difficult, detection of a significant regurgitant jet in fetal life represents a considerable hemodynamic dysfunction.[13]

The integrity of the atrioventricular septum in continuity with the inlet septum should be seen as color Doppler fills the ventricles. Weakening of the inlet septum may give the impression of a VSD in the early stages of pregnancy; but no posterior confirmation has been possible, probably due to a transitional echo cut; however, an A–V septal defect has to be excluded (Figure 32.4).

Outflow heart, semilunar valves and arteries

Color Doppler has become an extremely effective tool in identifying crossing flow patterns vs. parallel flows at the arterial level. The different color opacification of each artery indicates opposing flow directions that represent normal crossing of the pulmonary and the aortic outflow tracts and arteries[8] and normal ventriculoarterial connection (Figure 32.2). A single color representation in both arteries identifies the parallel relationship of the great arteries, being the most frequent anatomical arterial relationship seen in transposition of the great arteries (Figure 32.5). However, careful attention should be paid to fetal spatial orientation in the uterus in lateral dorsum to evaluate arterial crossing relationship by color Doppler.[21]

Color Doppler also gives information about the integrity of the outlet septum when both the outflow tracts are identified. Subarterial and infundibular VSD will be seen during this examination.

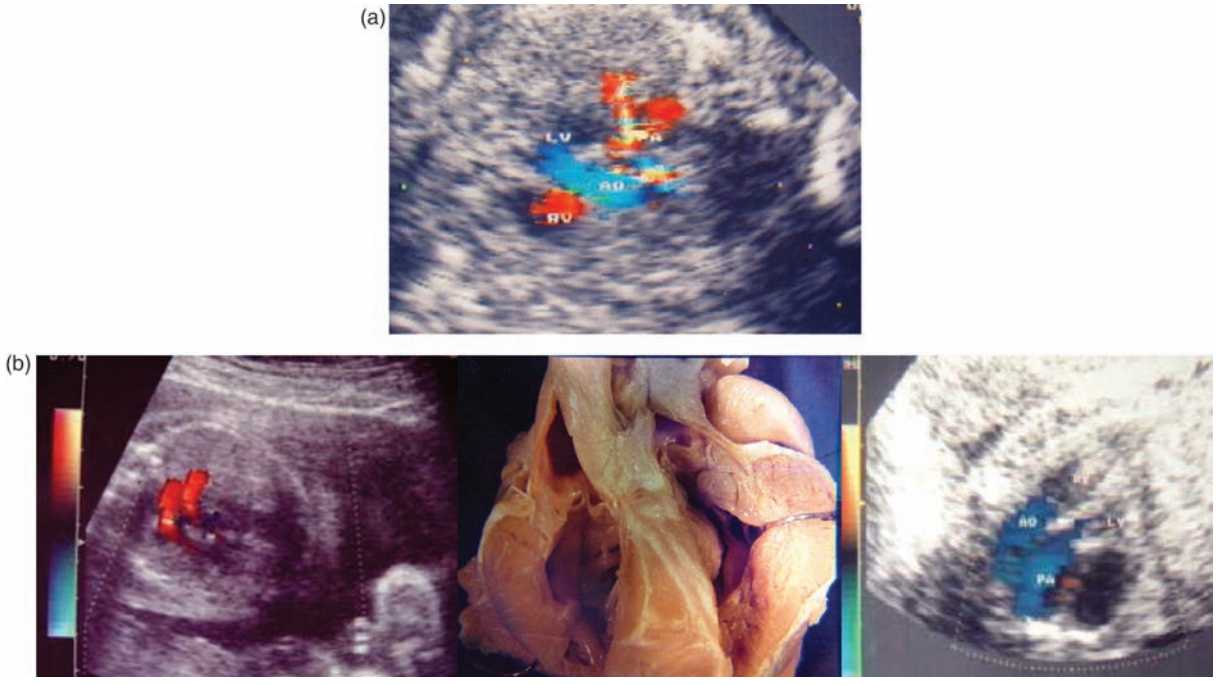

Figure 32.5 (a) Normal outflow right and left ventricular tracts and arteries. The opposite code opacification shows the normal crossing relationship. (b) Heart specimen from a transposition of the great arteries. Color flow Doppler shows parallel opacification of both arteries.

Semilunar valve systolic flow examination by Doppler not only allows measuring of time intervals to assess systolic function, but may also give information about the presence of valve stenosis or regurgitation. Blood velocity across a semilunar valve should not exceed 130 cm/s; an increase above this velocity could be due to valvular stenosis or increased blood volume. A turbulent high Doppler flow is usually produced by valve stenosis; the degree of obstruction is the key for measuring the severity of this lesion. In fetal life, each semilunar valve allows the passage of approximately half of the blood volume that will transverse the valve after birth; this reduced blood volume will cause an underestimation of the obstruction and of the valve pressure gradient, making the fetal assessment difficult. Valvular regurgitation produces a backward flow into the left or right ventricular outflow tract, which in the fetus with normal heart rate (>130 bpm) represents structural valvular dysfunction.

Ductus arteriosus and the descending aorta

The pulmonary artery receives approximately half of the total blood flow ejected by the right fetal heart. At this point most of the blood is diverted through the 'ductus arteriosus' toward the descending aorta, leaving the pulmonary circulation at minimum flow. The ductus arteriosus is a vascular structure in continuity with the descending aorta, forming almost a right-angle curvature when it meets the aorta; the ductus at this level may impose a degree of flow restriction; however; this is compensated by the active systolic contraction of the right ventricle. Doppler waveform shows a slight increase in systolic velocity as the ductus meets the aorta. However, an abnormal increase in systolic and diastolic velocity above 130 cm/seg. is produced during ductal constriction with marked elevation of systolic and diastolic velocity. Patients under indometacin treatment should be Doppler controlled to detect signs of ductal constriction (Figure 32.6) and medication should be stopped. A sudden increase in ductal constriction leads to increase in afterload with tricuspid regurgitation.[22,23]

Systolic arterial Doppler wave in the abdominal aorta is followed by continuous diastolic flow as blood entering the intra-abdominal umbilical arteries goes into the umbilical cord toward the placenta.

Abnormal anatomical and functional echocardiographic fetal features

Abnormal features of echocardiography include the following:

(1) Malposition of the heart is established when atrial and visceral organs (liver/stomach) are seen in the wrong position: the usual place for these structures is termed as 'situs solitus'. 'Situs inversus' involves reversal of the normal atrial and ventricular positions. 'Situs ambiguous' describes an undefined medial visceral position. Dextrocardia, mesocardia, levocardia are terms that define the location of the cardiac apex.
(2) Comparative disproportion between atrial and ventricular cavities, as well as arterial size, may lead to demonstration of pathological dilatation

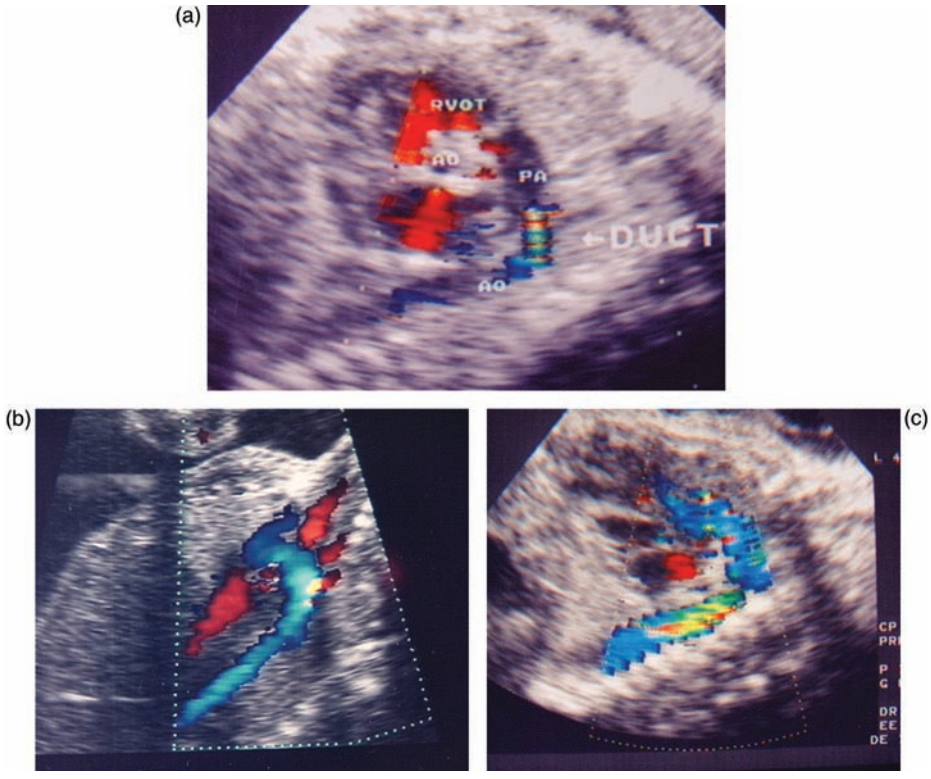

Figure 32.6 (a) Ductus arteriosus constriction under indometacin therapy. Color flow Doppler shows a turbulent ductal flow. (b) Normal aortic arch. (c) Coarctation of the Ao. Color flow detects a turbulent flow at the descending aorta.

(15) Arrhythmias; taquyarrhythmia, bradycardia.

Fetal cardiovascular pathology. Identification by 2D echocardiography and color Doppler

Congenital heart disease appears as a result of 'structural malformations' developed during the early phases of fetal life.[2,3] The severity of each malformation marks the future prognosis of the newborn, with perinatal death as high as 50%,[4] when congenital heart

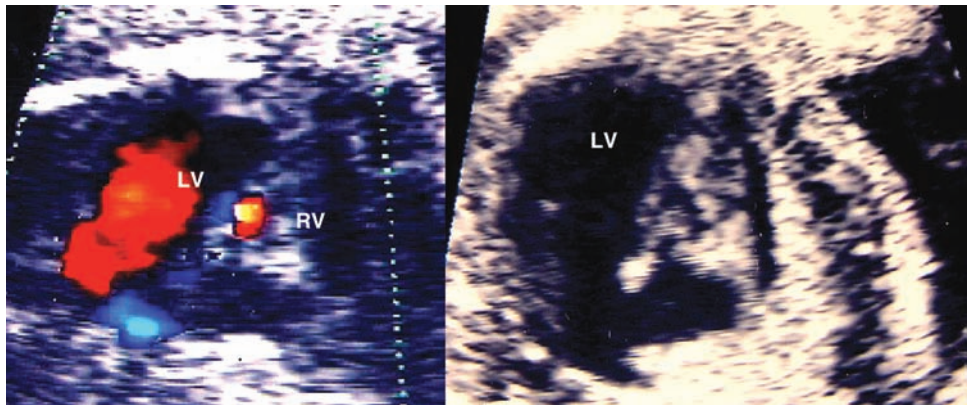

Figure 32.8 Tricuspid atresia and hypoplastic right heart. The Color Doppler helps to identify a small right ventricular cavity.

disease has been diagnosed in fetal life.[24] Chromosomal abnormalities may be found in as high as 42% of the fetal cases referred because of congenital heart disease.[25] However, 'functional cardiac anomalies' may occur as a transitory disturbance during fetal intrauterine growth and usually present a good prognostic outlook at term.

In an attempt to simplify congenital heart disease complexity, cardiac malformations may occur at two basic levels following a segmental approach:[7]

(1) The inflow level, including malformations at systemic and pulmonary veins, atriums, atrial septum, inlet valves, inlet/trabecular septum and ventricular cavities.
(2) The outflow level, which includes ventricles, outlet septum, outflow tracts, semilunar valves and arteries.

Inflow level

The veins are identified by using the four-chamber view as they meet the right and left atriums. Anomalous connections of the systemic veins as well as pulmonary veins may be visually identified.[26] The relative sizes of the right and left atriums should be compared. Usually, the right atrium is larger than the left atrium. Early closure or reduction of the foramen ovale[20] (atrial septal aneurysm) may be identified as well as a distended foramen. The ventricles should be of similar size although right ventricular dominance may be normally present.

Congenital cardiac malformations and conditions at inflow level include:

(1) Anomalous venous connections of the systemic venous return or the pulmonary veins.
(2) Atrial septal defects: ostium primun, ostium secundum and sinus venosus defects and patent foramen ovale with septal aneurismatic membranous septum.
(3) Atrioventricular valve anomalies: mitral/tricuspide atresia, mitral/tricuspid stenosis/hypoplasia (Figures 32.8 and 32.9). Atrioventricular valve regurgitation. Single common valve, Ebstein's anomaly.
(4) Ventricular development: hypoplastic left heart, hypoplastic right heart, single ventricle (univentricular heart), single inlet, double inlet, atrioventricular canal complete and partial, and ventricular inversion (atrioventricular discordance) corrected transposition.
(5) Ventricular septal defect: inlet portion (perimembranous), trabecular (muscular) and apical.
(6) Pericardium (effusion).
(7) Myocardium: ventricular anatomy (right ventricle heavily trabeculated containing the tricuspid valve with a confluent papillary muscle/left ventricle smooth endocardial walls with the mitral valve and two well-defined papillary muscles. Left ventricular myocardial contractility, function and hypertrophy.
(8) Cardiomyopathies: hypertrophic (diabetes, etc.), dilated (endocardial fibroelastosis, etc.).
(9) Cardiac tumors.

Outflow level

Color Doppler has become an extremely effective tool in identifying 'crossing flow patterns' vs. 'parallel flows'.[8] The different color code opacification of each artery indicates opposing blood flow directions that represent normal ventriculoarterial connections (Figure 32.5).[4] The key to the diagnosis is to demonstrate the origin of the pulmonary artery arising from the left ventricle and the aorta arising from the right ventricle.

Single color code opacification in both arteries identifies parallel arterial relationship, which represents a discordant ventricular–arterial connection, so-called transposition of the great arteries (Figure 32.5). Single opacification of one single arterial trunk, truncus.

Congenital cardiac malformation and conditions at the outflow level include:

(1) Aortic valve/pulmonary valve: atresia, stenosis and regurgitation.
(2) Hypoplastic aortic arch/pulmonary trunk.

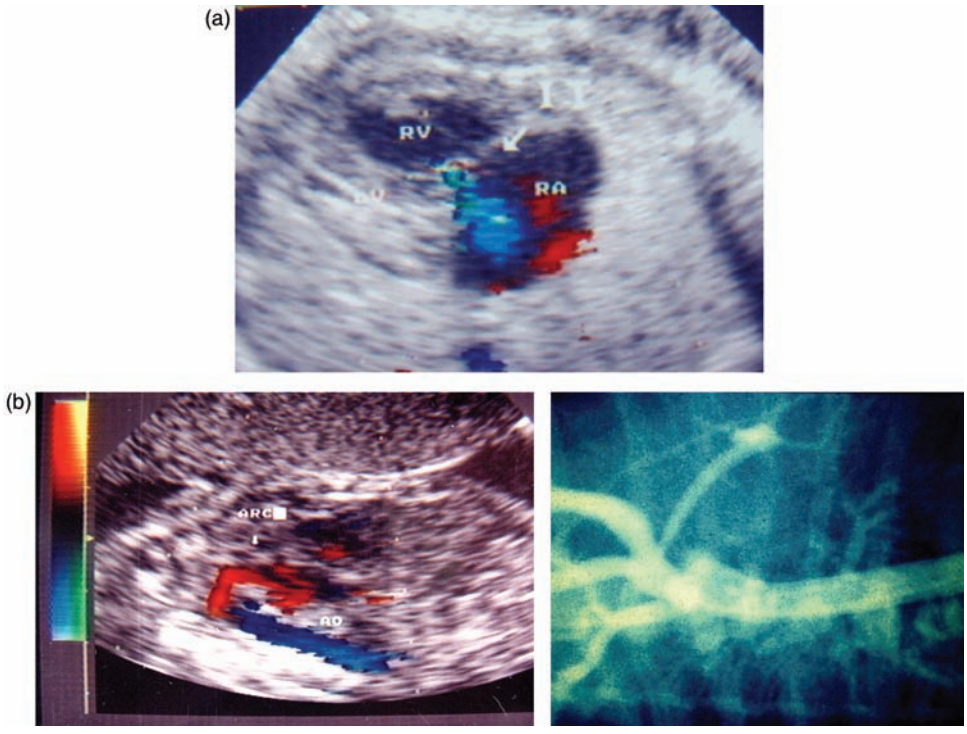

Figure 32.9 Hypoplastic left heart syndrome with mitral atresia and aortic atresia. (a) Single ventricular cavity corresponding to the right ventricle. Tricuspid regurgitation is seen. (b) Echocardiograph/angiogram to show the retrograde aortic arch opacification as no blood is ejected through the aortic valve.

(3) Coarctation of the aorta (Figure 32.6)/aortic arch interruption.
(4) Coronary artery anomalies.
(5) Absent pulmonary valve syndrome.
(6) Single arterial trunk (truncus arteriosus).
(7) Tetralogy of Fallot (Figure 32.10)/pulmonary atresia + VSD.
(8) Double-outlet right ventricle (Figure 32.11).
(9) Double-outlet right ventricle and transposition of the great arteries (Figure 32.11).
(10) Ventricular septal defect: infundibular, perimembranous, subarterial and trabecular.
(11) Aorto/pulmonary window.
(12) Anomalies of the aortic arch.
(13) Hypoplastic aortic arch and coarctation of the aorta (Figure 32.6) vs. interrupted aortic arch.

The diagnosis of structural and functional heart disease is possible during fetal life, although, not always with the amount of precision required. There are a number of congenital heart malformations that are extremely difficult to establish before birth as the fetal heart is not yet fully adapted to the future adult circulation that will take place after birth.

In the newborn with congenital heart disease, as the pulmonary circulation and lung oxygenation process begin, cardiac malformations will develop further. The intracardiac fetal shunts will close down as pulmonary artery pressure is reduced to one-quarter of the systemic pressure.

During pregnancy some fetal heart defects such as ostium secundum atrial defect, anomalous pulmonary venous return and some small ventricular septal defects will be impossible to evaluate. Also, in some cases of Fallot's tetralogy in which fetal pulmonary blood obstruction is not yet well established during the prenatal period, it may be difficult to identify the obstruction as the main functional/anatomical feature of this malformation. During fetal life, malformations and vascular anomalies such as persistent ductus arteriosus, aortopulmonary window, coarctation of the aorta and interruption of the aortic arch are extremely difficult to diagnose because no dysfunctional changes take place before birth, although indirect cardiac signs such as enlargement of the right heart cavities have been described.

Coronary artery anomalies are also difficult to suspect. The diagnosis of atrioventricular or semilunar valve stenosis is similarly difficult; the degree of obstruction to blood flow is the key to measuring severity in these lesions. In fetal life, each cardiac valve allows the passage of only half of the blood volume that will transverse the valve after birth because of the fetal intracardiac circulation pattern; this reduced blood volume will cause an underestimate of the obstruction and valve pressure gradient making the diagnosis by Doppler difficult.

Diagnosis and prognosis of fetal heart failure

The echocardiographic examination of the cardiovascular system provides much information about the

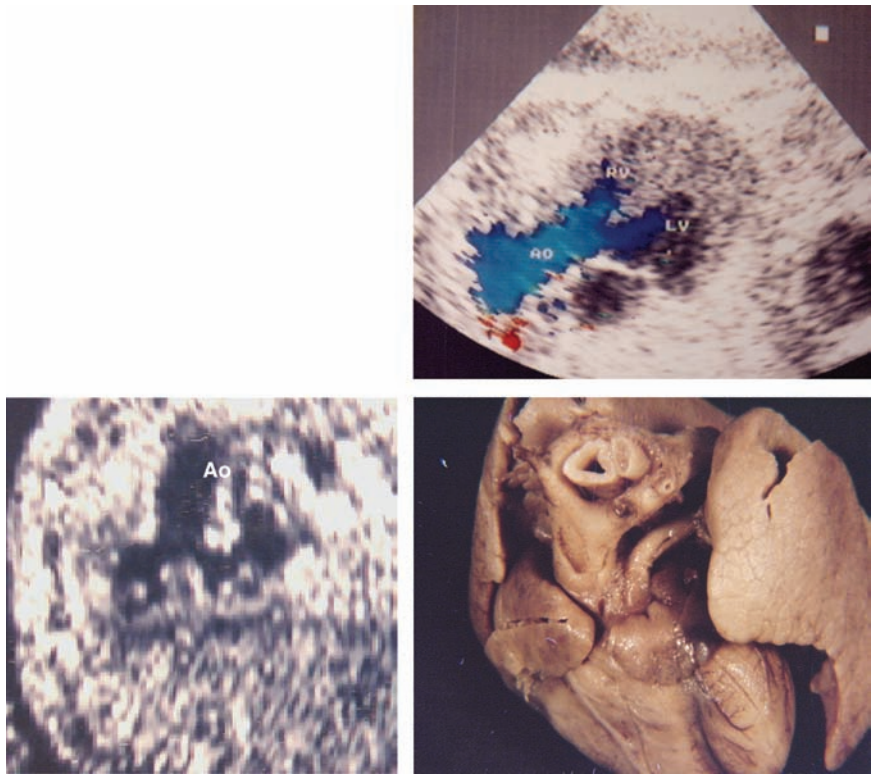

Figure 32.10 Tetralogy of Fallot. The heart specimen shows reduced pulmonary artery compared to the ascending aorta. A double aortic arch was present as well. Aortic–septal overriding can be seen by echocardiography, demonstrating the subarterial VSD.

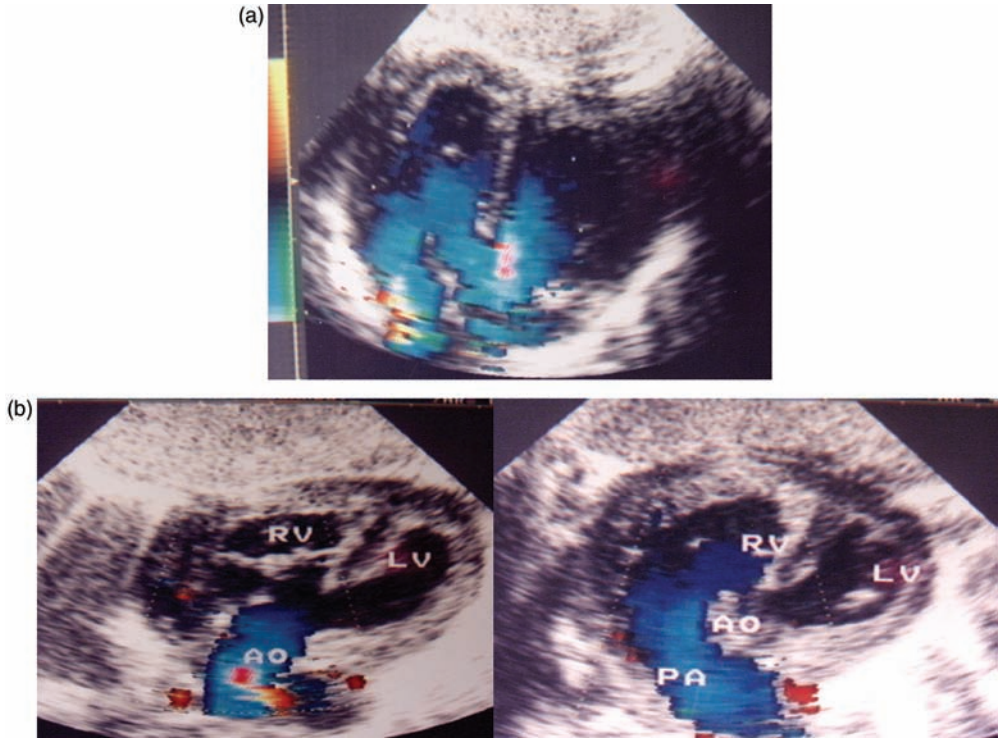

Figure 32.11 Double-outlet right ventricle. (a) Two parallel outflow tracts and arteries are seen coming from the right ventricle with subpulmonary VSD in double-outlet right ventricle with TGA. (b) Double-outlet right ventricle with normally related arteries with subaortic VSD.

well-being of the fetus. Heart failure is established when low cardiac output produces inadequate tissue perfusion. This results in a series of complex hormonal reflexes and vascular adaptations to improve direct flow to the vital organs. Peripheral vasoconstriction increases the fetal systemic resistances in response to cardiovascular stress with excess production of catecholamines and naturetic factor together with other complex humeral agents to maintain arterial redistribution of fetal cardiac output for the survival of the fetus.

The diagnosis of fetal heart failure is established through the analysis of a number of cardiovascular features:

(1) The cardio-thoracic size. Cardiomegaly is the universal sign of heart failure. This is measured using the CT cardiac/chest circumference ratio. Normal, < 0.5.
(2) Myocardial function. Assessment of cardiac function by global myocardium fiber shortening fraction is calculated by using the difference between the diastolic and systolic dimensions divided by the diastolic diameter. Normal, > 0.30.
(3) Increased atrial reversal contraction at the venous Doppler triphasic pattern in the hepatic duct and inferior vena cava. This may be a sign of increased end diastolic ventricular pressure. Increased A:S ratio peak atrial reversal divided by peak ventricular systole (Figure 32.12). Normal values should be less than 7%. In the fetus with congenital heart disease the venous filling patterns should be normal with the exception of tricuspid/pulmonary atresia with intact septum of restrictive filling compliance lesions.
(4) Analysis of Doppler detection of valve leak at the heart.

Fetal cardiac arrhythmias

Fetal cardiac disrrythmias[27,28] are rhythm disturbances caused by irregular cardiac beats, 'extrasystoles', or by regular accelerated tachycardias produced by ectopic heartbeats greater than 180 bpm. On the contrary, bradycardia are slow regular heart rhythms, below 80 bpm.

Cardiac disrrythmias account for 1–2% of rhythm alterations during pregnancy. Fetal arrythmias are also associated with a higher incidence of congenital heart disease. However, irregular cardiac rhythms caused by extrasystoles account for 80–85% of benign rhythm disturbances in normal fetus with no need for specific treatment. Management of these disrrythmias during pregnancy only requires maternal rest and withdrawal of stimulants.

Taquy-bradycardias[29] are frequently a cause of heart failure and hydrops. They usually require *in utero* treatment via maternal administration of antiarrhythmic agents, premature delivery and cardiac pacing of the newborn as in the case of congenital heart block.

Classification of cardiac arrhythmias

Irregular heartbeats (Figure 32.13)

Extrasystoles

Extrasystoles constitute the most frequent arrhythmia in the fetus and in the newborn; no treatment is required, only observation.

They have been associated with high fetal catecholamines, maternal hyperthyroidism and stimulants.

Sinus arrhythmia

In this disorder, there is variability between the sinus atrial contractions. It is recognized by the variable space between Doppler pulsed waves.

Premature atrial contraction

Premature atrial contraction is the most frequent ectopic arrhythmia often causing extrasystoles. It may be the origin of supraventricular tachycardia.

Premature ventricular contraction

Premature ventricular contractions are ventricular ectopic beats; they are rare in the fetus.

Regular fast heart rate

Sinus tachycardia

This is a persistent cardiac rhythm above 160 bpm but below 200 bpm, that may be related to the fetal response to catecholamines, anemia, etc.

Pathological tachycardias

They are regular fast heart rhythms above 200 bpm, divided into two main groups: supraventricular and ventricular tachycardia.

(1) Supraventricular tachycardia (Figure 32.14) includes:
- *Atrial tachycardia*, produced by an ectopic atrial beat.
- *Atrial flutter*, a rapid atrial contraction of 300–400 bpm. The atrial activity is blocked at the atrioventricular (A–V) node with ventricular response of 220 bpm. The p wave can be identified at the movement of the atrial wall by m-mode echo.
- *Intranodal tachycardia*, the most common fetal and newborn tachycardia, it presents with a ventricular response between 220 and 280 bpm and a 2/1 atrioventricular block.
- *Atrioventricular tachycardia with accessory pathway*, with conduction via the Kent or Mahian intranodal and extranodal pathway conduction. In the Wolf–Parkinson–White syndrome, tachycardias are produced by a

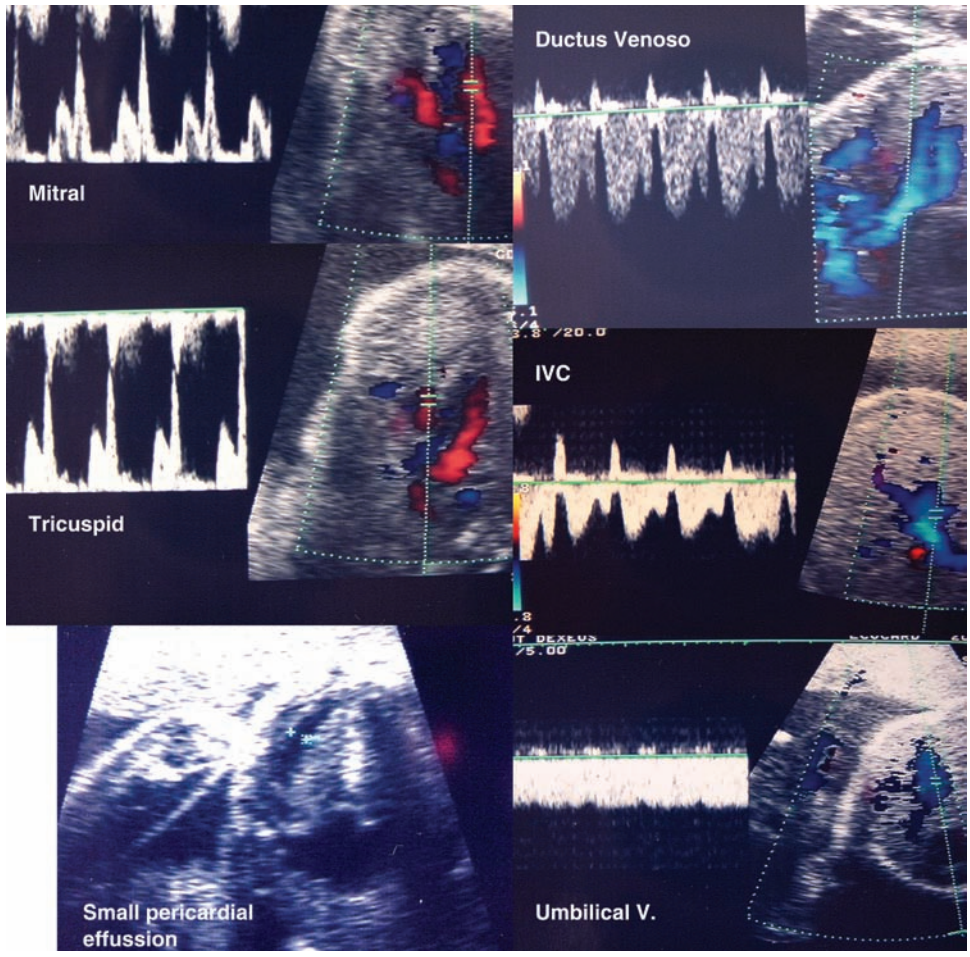

Figure 32.12 A number of Doppler signs can predict fetal heart failure: increased 'a' in A–V flow; deep diastolic phase at ductus venosus flow; prominent and negative 'a' wave at the inferior vena cava; small pericardial effusion; pulsatile deflection at the umbilical flow.

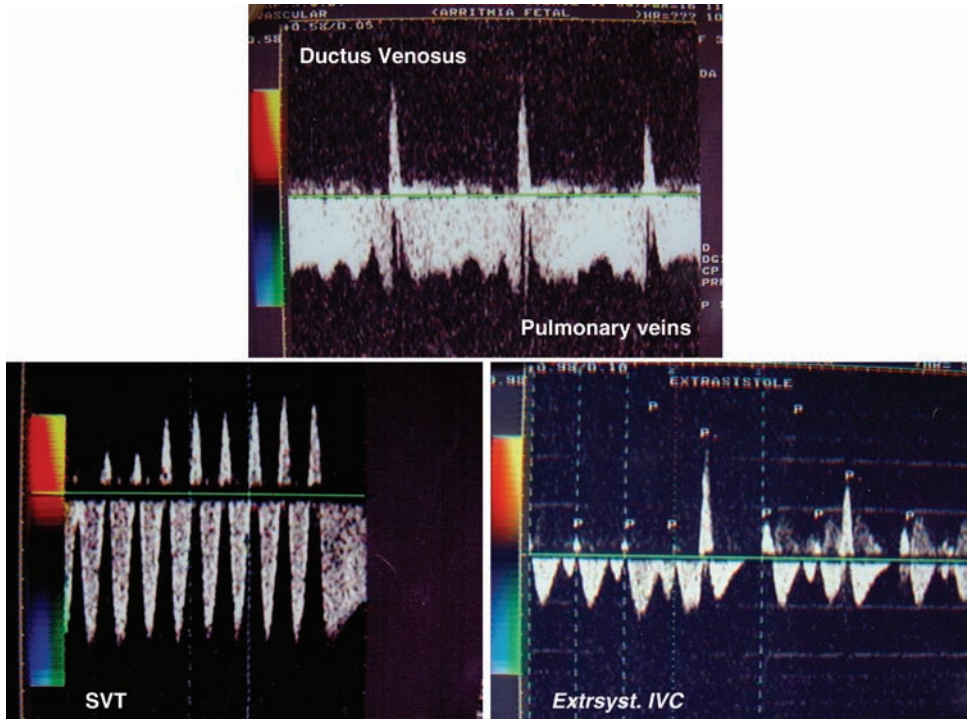

Figure 32.13 Supraventricular ectopic beats seen at ductus venosus flow and inferior vena cava (negative deflections) and run of supraventricular tachycardia.

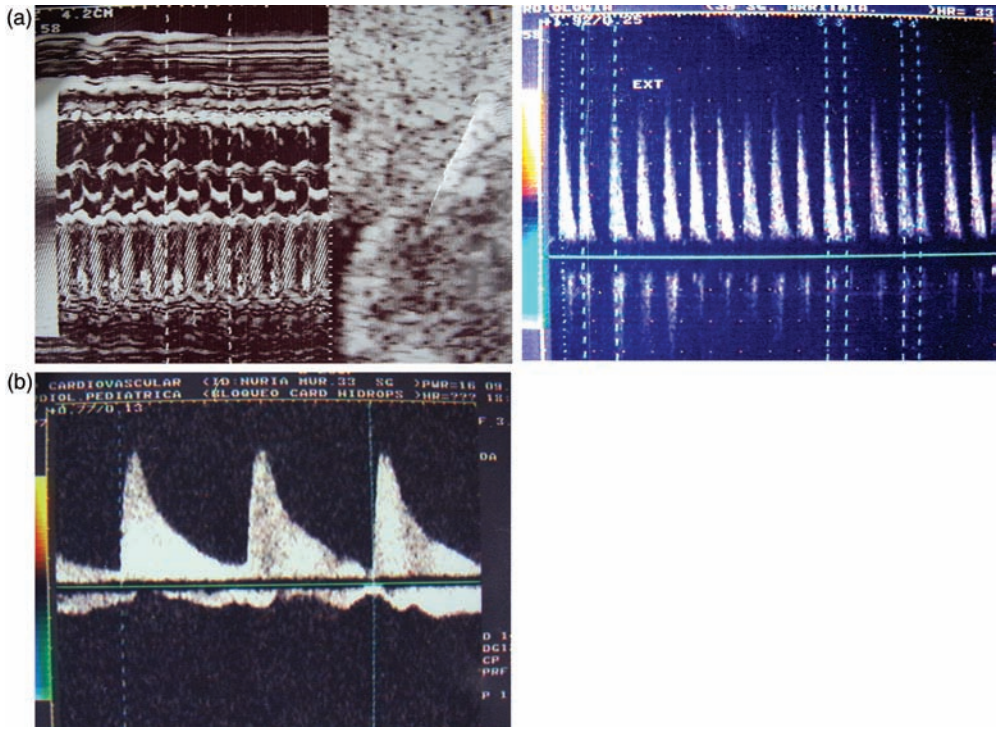

Figure 32.14 (a) Supraventricular tachycardia using M-mode echocardiography to establish a 2/1 atrioventricular rate comparing the atrial wall movements and the aortic valve opening. (b) Ventricular bradycardia in a congenital complete A–V block.

circular re-entry mechanism; atrial activity is not visualized by echo; therefore, no specific diagnosis of this syndrome can be reliably made *in utero*.

(2) Ventricular tachycardia are rare in the fetus and newborn and are usually associated with myocardial dysfunction or intramyocardial tumor. The ventricular heart rate is not as fast as in the supraventricular tachycardia and is in the range of 180 bpm. This disrrhythmia may present runs of tachycardia with irregular heartbeats and no relationship can be established between atrial and ventricular contractions.

Regular slow heart rate

Bradycardias

Bradycardia is a slow cardiac rhythm with heart rates below 80 bpm. The bradycardia includes the following:

(1) *Transient sinus bradycardia* can occur during ultrasound examination. In this situation vagal stimulation over the head of the fetus may produce transient bradycardia with spontaneous recovery. Persistent bradycardia may be the consequence of fetal hypoxia or congenital heart block with or without structural congenital heart disease.

(2) *Congenital heart block* is the result of a delay or a block in the transmission of atrial electrical impulse along the atrioventricular conduction system. Three degrees may be present.

- 'First-degree block' is produced by a delay in the A–V conduction system; it is not recognized by echo.
- 'Second-degree heart block' occurs when an incomplete A–V conduction delay results in an isolated atrial impulse, which is not conducted through the A–V node, resulting in a missed ventricular contraction.
- 'Third-degree heart block' produces an atrioventricular dissociation. The atrial contraction is independent of the ventricles; it follows the sinus beats at atrial rate of 150 bpm. Atrioventricular conduction is blocked and ventricular contraction is established at an autonomous ventricular rate of 50–60 bpm (Figure 32.14). Atrioventricular dissociation is the usual presentation of congenital heart block.

Congenital heart block and persistent fetal bradycardia are associated either with congenital heart disease or with a structurally normal heart. However, a normal fetal heart and congenital heart block can be related to autoimmune maternal disease as lupus erythematosus,[30] Sjogren's syndrome and rheumatoid arthritis, not always diagnosed before pregnancy. Anti-Ro and anti-LA antibodies are most likely to be detectable in maternal blood.[31]

Congenital heart block with heart rates above 60 bpm seems to have a reasonable outcome. A pacemaker should be implanted in the newborn when ventricular heart rate is below 70 bpm. Fetal hydrops and heart failure are related to slow ventricular heart rate below 50 bpm. Fetal management should include maternal administration of terbutaline or sympathomimetics agents, as well as premature delivery and pacemaker implantation in the newborn.[32]

33 Three-dimensional ultrasound in prenatal medicine

E. Merz

Introduction

During the past two decades three-dimensional (3D) ultrasound has evolved from a relatively tedious laboratory technique to a highly sophisticated technique for daily routine examinations, particularly in prenatal diagnosis.

In 1989 the first commercially available ultrasound scanner (Combison 330) with special 3D probes for transabdominal and transrectal scanning was launched by Kretztechnik AG, Austria.[1] This system allowed fully automated volume acquisition and multiplanar reconstruction of the 3D data set in three orthogonal planes. Due to rapid developments in computer and transducer technology, image quality and processing speed improved tremendously in the following years. With the latest 4D technology of Voluson® 730 Expert (GE Medical Systems Kretz Ultrasound), volume acquisition and volume display can be accelerated in such a way that the fetus can be visualized three-dimensionally in real-time. This gives the examiner a direct impression of the fetal surface and movements.

Additional 3D/4D techniques have been developed within the past 2–3 years: glass body rendering, volume contrast imaging in the A and C planes (VCI-A and VCI-C, respectively) and spatio-temporal image correlation (STIC).

Technical aspects

All 3D/4D ultrasound examinations consist of four main steps:[2,3] (1) data acquisition, (2) 3D/4D visualization, (3) volume analysis/image processing and (4) storage of volumes, rendered images or image sequences (cine clips) (Table 33.1).

Table 33.1 Steps required in transvaginal and transabdominal 3D ultrasound (after Merz[3])

Data acquisition
- Orientation in the 2D image
- Definition of the region of interest (ROI)
- Volume acquisition

3D visualization
- Multiplanar display
- Surface-rendered image (surface mode, light mode)
- Transparent image (maximum mode, x-ray mode)
- Vascular image (combination of surface or transparent rendering and color Doppler)
- Animated image (rendering of image sequences)

Volume/image processing
- Electronic scalpel
- Filtering
- Contrast and brightness control
- Color image

Storage of volumes, rendered images and image sequences

3D data acquisition

For volume acquisition, the ultrasound beam has to be moved over the object of interest. This procedure can be performed manually with external acquisition systems or automatically with internal acquisition systems.

External acquisition systems

These freehand systems do not require a specially designed transducer. The scans are performed using a freehand technique with a conventional 2D probe, whose position and movement in space are tracked by an add-on system.[4–6] However, the freehand systems are not able to achieve 4D ultrasound.[3]

Internal acquisition systems

These systems use specific probes with a fully automated scanning technique.[1,3,7] The automated scanning movement can be achieved by using mechanical gears and/or electronic scanning techniques such as steered phased arrays and/or curved/linear arrays in which different groups of elements are excited.[1] These probes can be used for 3D and 4D ultrasound as well.

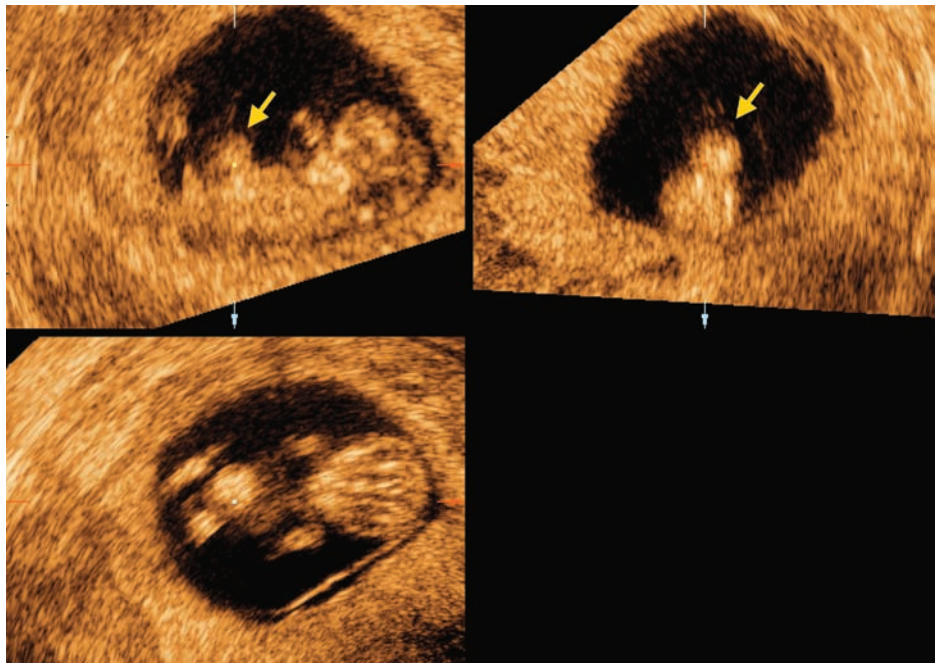

Figure 33.1 Fetus with physiologic umbilical hernia (←) (9 weeks) in the multiplanar display. Upper left, midsagittal scan; upper right, transverse scan; lower left, coronal scan.

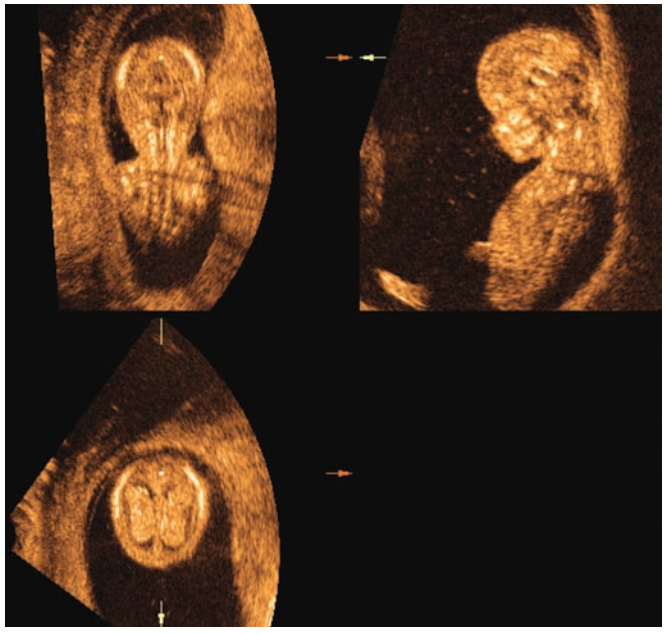

Figure 33.2 Multiplanar display of a fetus at 13 weeks of gestation. Upper left, coronal scan; upper right, midsagittal scan; lower left, transverse scan of the head.

Figure 33.3 Surface view of a fetus at 12 weeks of gestation.

3D display

In contrast to conventional 2D ultrasound, which provides only one gray scale imaging mode to demonstrate the fetus, present 3D technology offers the ability to review the fetus in several different display modes:

Triplanar (= multiplanar) mode

The triplanar mode allows reslicing of acquired volumes in any direction.[3,8,9] Thus, any arbitrary plane can be shown, even image planes that are not accessible with conventional 2D ultrasound. The simultaneous display of all three perpendicular sectional planes provides an ideal basis for a detailed tomographic survey of the fetus and allows the demonstration of a specific plane to be precisely controlled (Figures 33.1 and 33.2).

Surface mode

The surface mode can provide 3D images of the outer and inner fetal surfaces (Figures 33.3–33.5, 33.15).[2,3,10,11]

Figure 33.4 Surface view of a fetal face at 32 weeks of gestation.

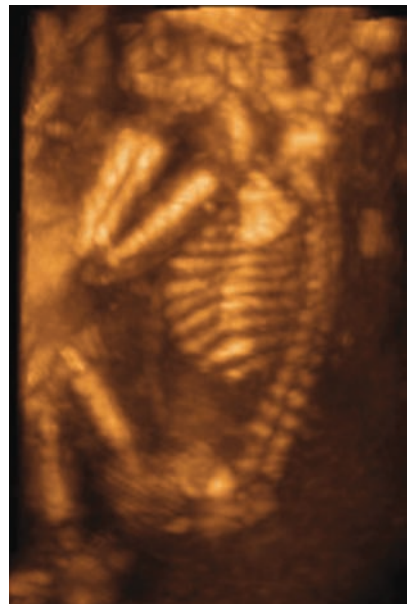

Figure 33.6 Transparent view (maximum mode) of a normal fetal skeleton at 20 weeks of gestation.

Figure 33.5 Surface view of a fetal ear at 38 weeks of gestation.

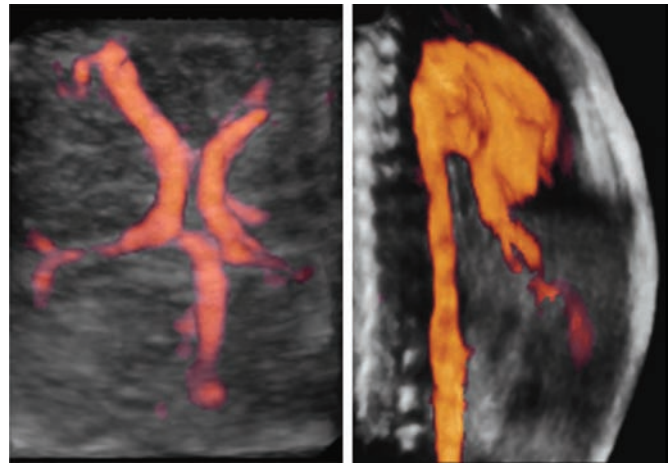

Figure 33.7 Glass body rendering: the combination of transparent mode and power Doppler displays the vascular system of the fetus. Left, circle of Willis (35 weeks); right, fetal heart and aorta (30 weeks).

For this purpose the region of interest has to be framed with a volume box. For many years this volume box was only variable in size but nowadays it is variable in size and shape. Various rendering algorithms (surface mode, soft surface mode, light mode and soft light mode) can be used in surface rendering, either individually or in different combinations.[3]

A basic requirement for all 3D surface rendering is the presence of an adequate fluid pocket in front of the structure being imaged. Overlying or adjacent structures such as the placenta, fetal limbs and loops of the umbilical cord tend to obscure the structure of interest and must be removed with the electronic scalpel.[12]

Transparent mode

The transparent mode provides a complete survey of the fetal skeleton (Figure 33.6).[13,14] Two different rendering algorithms (maximum mode and x-ray mode) can be used, either individually or in combination with the smooth surface mode or the gradient light mode.

Glass body rendering

The combination of 3D color Doppler or power Doppler and gray-scale 3D images enables the physician to analyze the fetal vascular system (Figure 33.7).

3D cine mode

In order to obtain an overall 3D impression of the object of interest, a certain number of rendered views are displayed in a fast sequence. In this way the observer can see the object of interest rotating on the screen. The 3D cine mode can be used with the surface mode, the transparent mode and the glass body rendering.

4D display

4D ultrasound

With the acquisition of up to 35 volumes/s, both the surface and the movements of the fetus can be demonstrated on the screen. This enables the parents to observe the movements of the fetus and allows the examiner to study the behavior of the fetus. The 4D cine loop allows the examiner to scroll back through volumes to achieve the best surface demonstration of the region of interest (Figure 33.8). For 4D volume rendering, two rendering modes are always applied simultaneously.

Figure 33.8 Surface-rendered view of fetal yawning at 32 weeks. The 4D cine loop allows scrolling back to the most interesting movement.

4D cine sequence

A 4D image cine sequence can be created with a Voluson® 730 series machine in the real-time 4D mode. After storage as an AVI file, such a sequence can be shown with a movie program in any personal computer.

DiagnoSTIC™

STIC is a new technique for assessment of the fetal heart, based on the automatic acquisition technology. It allows off-line multiplanar analysis of the fetal heart. For DiagnoSTIC™, a slow-motion (7.5, 10 or 12.5 s) volume scan of the fetal heart is performed. The data are then rearranged and stuck together by correlation of its temporal and spatial domains. An EGC trigger is not necessary. The result is a 4D real-time data set presenting one heart cycle in motion. This data set can also be rotated and analyzed in the triplanar view while the heart is beating at any stage of the cycle.

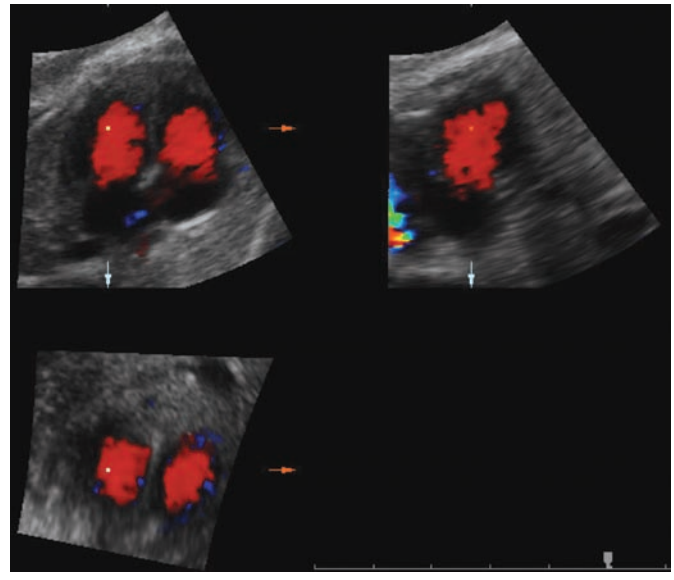

Figure 33.9 Fetal heart at 36 weeks. The STIC technique combined with color Doppler displays blood flow in all three orthogonal planes at the same time.

STIC-color (spatio-temporal image correlation with color Doppler)

In this technique the STIC technique is combined with color Doppler information. This facilitates the recognition and confirmation or exclusion of congenital heart defects (septal defects, transposition of the great vessels, etc.) (Figure 33.9).[3,15–18]

Volume contrast imaging

In VCI the probe is applied in the same way as in conventional 2D ultrasound and so is an easy approach to 4D, even for the novice. This volume rendering process is based on thick slice tissue data[3] and it is possible to select a slice thickness between 3 and 20 mm. Displayed as a thick slice, the VCI technique allows a 4D volumetric data acquisition.

The development of this tool has facilitated a marked improvement in tissue contrast resolution in real-time and therefore enables inhomogeneous areas or subtle lesions to be detected. It provides additional information simultaneously with conventional 2D imaging, without the processing time of off-line 3D reconstruction. In VCI technology a mixture of surface mode and transparent maximum mode rendering is employed.

Volume contrast imaging in the A plane

VCI-A provides the examiner with an easy 4D approach. It reveals the same anatomical region as in the 2D ultrasound image, but the tissue contrast is better with VCI-A (Figure 33.10).

Volume contrast imaging in the C plane

VCI-C allows an easy 4D real-time approach in the coronal plane of the region of interest (Figure 33.11). VCI-C offers great potential in prenatal diagnosis because it scans planes that are not accessible with conventional B-mode scanning. This is particularly important when the fetus is in an unfavorable position.

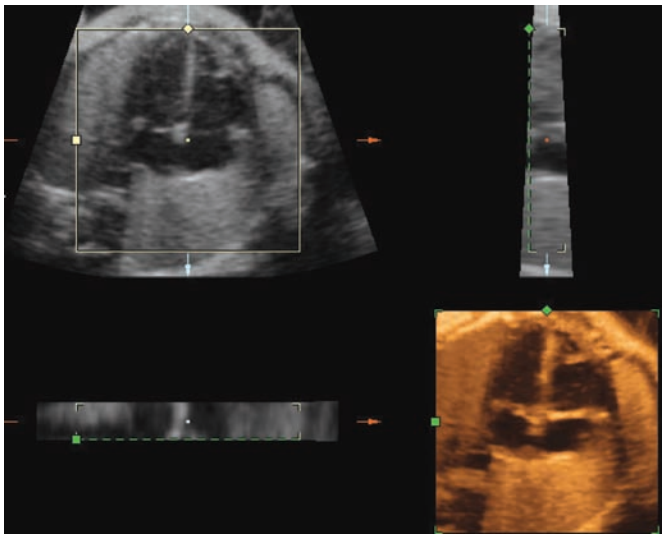

Figure 33.10 VCI-A of the fetal heart (29 weeks). This technique shows the same anatomical region as in the 2D ultrasound (upper left), but the contrast is better in VCI-A (lower right).

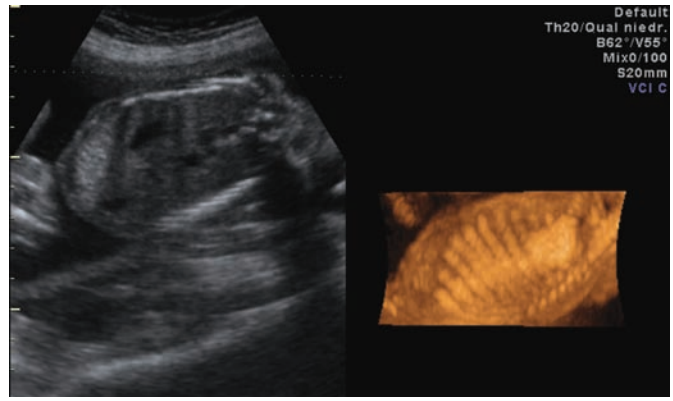

Figure 33.11 VCI-C. This simple technique yields detailed morphologic information of the plane perpendicular to the marked green line in the conventional 2D plane. Here: 3D information of the fetal chest in the tangenti view (20 weeks).

Volume/image processing

In many cases the acquired data sets require post-processing. In order to obtain a high-quality surface image, adjacent or overlapping structures that are obscuring the fetus have to be removed with an electronic scalpel. Low-level echoes in the amniotic fluid may be filtered out by increasing the threshold value. In color Doppler the angio threshold removes small motion artifacts and color noise.

Image brightness and contrast can be set to any desired value in all 3D/4D display modes just as in 2D ultrasound. In glass body rendering, the color and gray-scale areas can be adjusted independently of one another. All changes are immediately visible on the monitor. These interactive control features make it easy to display any object with optimal brightness and contrast.[3,19]

Storage of volumes, rendered images and image sequences

Long-term storage

3D/4D ultrasound gives us the capability to store volumes, rendered images, 3D and 4D cine sequences digitally. Today, various media are available for the long-term storage of these volumes, such as removable hard disks, magneto-optical disks and DVD.

When findings of interest are stored digitally on non-degrading media, the examiner can retrieve the volumes at any time and navigate through them in the absence of the patient.[7] This is of particular value in the diagnosis of fetal anomalies, as it enables the examiner to take the time to fully scrutinize equivocal findings without upsetting the patient by lingering at a particular site with the probe, which is often a problem in conventional 2D examinations.[3]

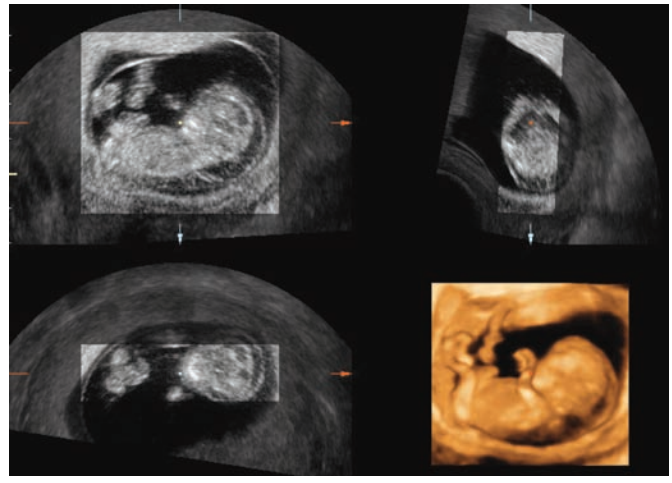

Figure 33.12 Multiplanar demonstration of a fetus with increased nuchal translucency thickness of 6.2 mm (→) (11 + 4 weeks). Karyotype: trisomy 18. Upper left, precise midsagittal scan; upper right, transverse scan at neck level; lower left, coronal scan; lower right: surface view.

Clinical applications

For the examination in the first trimester the transvaginal 3D/4D probe is usually applied, and for the second and third trimester examinations, the abdominal 3D/4D probe is used. If the fetus is in a cephalic presentation the transvaginal 3D/4D probe can also be used in the second or third trimester to assess the fetal brain in a higher resolution.[9,20]

The advantage of all the different 3D/4D rendering modes is that it is possible to visualize the normal embryonic and fetal development at all stages.[21–23] The first view of the fetal face has an important psychological effect on the parents to whom the detailed

Figure 33.13 Surface-rendered view of a small cleft lip at the right side (38 weeks).

Figure 33.15 Surface-rendered view of a fetus with left-sided hydrothorax at 30 weeks of gestation. The fetal chest has been partly 'removed' with the electronic scalpel, displaying the surface of the small left lung.

Figure 33.14 Surface-rendered view of the left hand with postaxial hexadactyly (←) (31 weeks).

images are much better recognizable than the 2D pictures. With the use of glass body rendering (3D and power Doppler) even the vascular system can be observed by the parents.

For the sonographer, however, the detection of a fetal malformation is of more importance.[24–33] Despite the fact that with conventional 2D ultrasound examinations most of the fetal abnormalities can be detected by the experienced examiner, 3D/4D ultrasound provides additional information, particularly for the experienced examiner.[7] 3D ultrasonography can depict many image planes that are inaccessible with conventional 2D ultrasound. In the first trimester the triplanar demonstration is particularly helpful in the verification of a true midsagittal section, which is necessary for an exact nuchal translucency (NT) measurement (Figure 33.12).[34–36] In NT demonstration and measurement, the examination time can be dramatically reduced, especially in case of an unfavorable fetal position, and the quality of the requested image can be improved.[36]

In the second and third trimesters the photo-realistic surface view of the fetus offers interesting opportunities for the detection of abnormalities, especially in subtle

defects (Figures 33.13 and 33.14).[24–33] In some cases it is also possible to find defects that were not revealed with conventional 2D ultrasound.[7] In other cases the surface mode can also provide impressive 3D images of the inner fetal surfaces (Figure 33.15).

4D ultrasound provides an excellent real-time 3D view of the fetus. With the STIC technique, even 4D fetal echocardiography has become a reality. The triplanar demonstration of the beating heart enables a comprehensive assessment of the fetal heart morphology including the great vessels. Due to the fact that the volume can be rotated and resliced in all dimensions even complex anomalies of the fetal heart can be demonstrated precisely. The combination of STIC and color Doppler allows an exact control of the cardiac blood flow while the heart is in motion (Figure 33.16).

The interactive display in 3D/4D ultrasound is particularly useful for the detection of specific abnormalities, making it possible to identify fetal surface abnormalities and define the extent of a defect in all dimensions. The same applies to the targeted exclusion of fetal anomalies. Particularly in cases with an increased recurrence risk, the various display options of 3D/4D ultrasound provide a selective exclusion of a fetal defect and parents can see for themselves that the 3D surface image demonstrates a normal fetus.

34 Ultrasound-guided fetal invasive procedures: current status

J. M. Troyano, M. Alvarez de la Rosa and I. Martinez-Wallin

Since the early 1980s various forms of fetal puncture (fine needle aspiration) have been used for diagnostic purposes.[1–5] In the beginning, the only possible way of entering the fetal environment was with the help of a fetoscope, but the spectacular development of ultrasonography has permitted the invasion of the intrauterine environment using tools that are increasingly safe, especially in the tighter sections. Needles with improved characteristics have been developed that are now being used in new biopsy techniques.[3,6,7]

Fetal puncture for diagnosis is technically possible, provided it is done by adequately trained hands, but the essential problem lies in establishing the correct procedure, which is not quite defined yet.[8]

Technique generalization

Whatever the location of the fetal puncture, a certain number of requirements are imperative.

(1) The operator must have sufficient working experience in invasive echography.
(2) The room should be fit to be used for surgery: it is necessary to have an aseptic room for echographic intervention. A sterile wrap is recommended for the ultrasound probe. We use a surgical glove for an airtight seal.
(3) The characteristics of the surgical equipment used for obtaining samples are described in the following.

As the tendency is to obtain samples with maximum diagnostic utility and minimal risk to the integrity of the pregnancy, it is of utmost importance, with few exceptions, to use needles no smaller than 18 g.

It is clear that the tools used will not always be harmless. A simple example is the device still used for skin biopsies for diagnosing some types of *genodermatosis*, which consists of a pair of clipper forceps measuring 2.5 mm in size.

These methods often require the use of an anesthetic, and in some cases general anesthesia, before incision of the maternal abdomen using a scalpel and introduction of a guiding trocar sheath of the thickness of a Verre's needle.

The complications arising from the use of 2.5-mm-thick needles and the transabdomen forceps method are similar to those of the fetoscope. Further, the method itself is highly variable: a great variety of needles of relatively small size (18-g standard) are available, giving very good biopsies, including samples of skin and samples of visceral solid areas (Figure 34.1).[2,7]

Among the organs that are intrauterinally reachable, the most difficult to sample, after the skin, is the kidney, essentially due to the histological constitution of the parenchymal stratum.[9]

Only those samples that include the corticomedular stratum are considered satisfactory. Getting such samples is affected by the fetal availability in respect of its intrauterine position, the distance and the interposed tissue to the kidney (skin, muscle) and perirenal fat and the very capsule.

The use of a 14–16-g catheter with isometric aspiration techniques with constant vacuum in these cases allows us to obtain acceptable samples in 69–80% of all instances, while the use of a 18–20-g catheter gives acceptable specimens only in 25–30% of cases. This means that isometric (fine needle) puncture–aspiration techniques do not always offer the results hoped for with solid organs, mainly the kidney; wider catheters need to be used, which is far from the 'harmless philosophy' that should prevail in these processes.

Figure 34.1 Different types of needles and system for fetal biopsy.

For these cases and others that could occur, depending on the tissue characteristics, the use of equipment such as an *aspiration biopsy set* yields cylindrical specimens of a maximum length of 2–5 mm. The set includes an 18-g bisided trocar syringe in all its circumference, acting as a circular blade, and a conical sheath with vacuum suction embolous contriving through its interior. It allows optimal safety conditions and histological quality comparable with those of the *Tru-Cut* method.

Of all the viscous solid organs within reach, the one that offers the least problems is the liver. Its spongy tissue constitution and its great size and volume in the fetal abdomen allows optimal accessibility and consequently offers samples in practically 100% of cases, using a conventional fine needle of 18–20 g.

The obtaining of muscle tissue samples presents one of the greatest difficulties due to the topographic and anatomical characteristics of the skeleton and the important motor innervation. For this reason it is necessary to correctly select the spot and the muscular area least susceptible to the formation of indelible functional lesions.

The most accessible topographic areas are the external faces of the thighs, but the vastus externus muscle is technically more accessible (Figure 34.2); it is a zone covered by the subtrochanteric fascia-lata descending in an oblique direction toward the fetal femur, The use of the *sure cut* system's 18-g needle with vacuum aspiration allows a success rate of over 75%. Conventional spinal needles with complementary aspiration with a 50-cc syringe vacuum allow us to obtain samples only with great difficulties.

When the puncture area has liquid characteristics, the echographic view is wide ranged, allowing a large field of action.

(4) In general, technically it is preferable to choose the most direct route, avoiding any obstacles, avoiding the placenta entirely if possible.

(5) Once the crucial point to puncture has been determined, the needle should be introduced within the field of view of the probe, frame by frame, until the fetus is reached.

(6) It is recommended to locate the puncture point approximately without making direct contact with it in the first instance, and to determine the angle of the needle at the chosen spot. It is of the greatest importance to enter with a single *sudden jab* to avoid sudden fetal jolts or movements.

(7) It is advisable in all *free-hand* fetal punctures for the operator to take into account the dynamic variations of the fetal position.

(8) For better manipulation, an assistant should be in charge of carrying out the isometric aspiration process at a prudent distance, approximately 1 m away from the surgical table, placing a serum of the same length between the needle and the syringe.

(9) Except in circumstances such as pericardic and pleural overflow that need an operating time of about 15–30 min, the procedure should be carried out without any anesthesia.

Aspiration in cystic disorders will fundamentally orientate the diagnosis. Aspiration on ovarian cysts is only indicated in cases that are complex due to the dynamic volume or due to rare structural types, with the aim of therapy rather than diagnosis.

We take suspicious chylous collections only where the presence of high lymphocyte concentrations gives

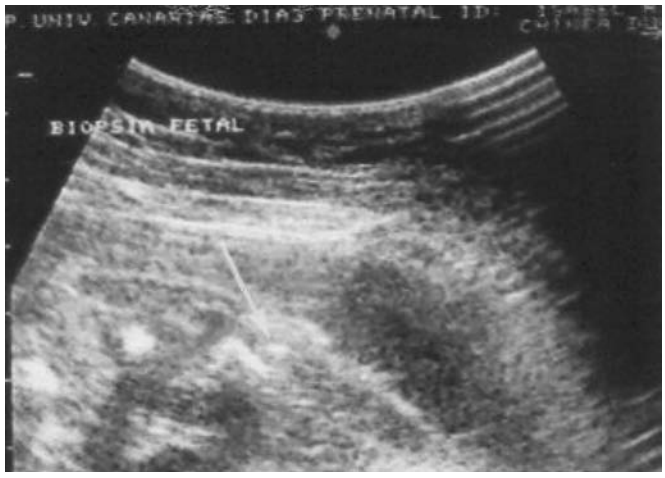

Figure 34.2 Subtrochanteric muscle biopsy: echographic monitoring. The arrow indicates the puncture position oblique to the fetal femur.

Figure 34.4 Ventriculocentesis: obtaining cephaloraquideus liquid determines the presence of viral bodies through polymerase chain reaction.

Figure 34.3 Cystic lynphangioma: percutaneous puncture determines qualitative and genetic characteristics (lymphocytes).

a practically certain diagnosis and a genetic study is possible in very few days, justifying this type of procedure (Figure 34.3).

Puncturing pericardic discharges has diagnostic as well as therapeutic aims.

Among brain punctures, the most representative, *ventriculocentesis*, allows us to carry out serological marker studies in RCL, independent of any derived therapeutic attitude, although the efficiency of the derivative procedures in hydrocefalia is uncertain (Figure 34.4).

Of all the structurally cystic processes, the obtaining of fetal urine in dilated urological pathology has the greatest diagnostic value. The biochemical analysis of fetal urine allows us to distinguish irreversible tubular lesions and normal renal function.

There is no doubt that the incorporation of biological molecular techniques and DNA studies allows us to establish in many of cases, alterations of any determined genetic locus[10–13].

Occasionally, we may find that we do not have enough material to base a prenatal diagnosis upon due to a lack of family records of deceased relations. In such cases the absence of this information constitutes a serious obstacle to the diagnosis, as it must then be based on only on a small corionic-villi, funicular or amniotic sample.[11,14]

In such a situation sampling directly from the fetal tissue is of special relevance for the diagnosis or for ruling out any suspicion of family inheritance.

> The taking of fetal samples by biopsy techniques is justified only in cases when the prenatal diagnosis of any specific pathological illness is not possible, or is frankly difficult, using any of the existing conventional techniques.

Liver biopsy

Technique

Fetal transabdominal aspiration-puncture using 18-g needles with a conic catheter or spinal needles of the same thickness with isometric vacuum aspiration using a 50-cc syringe and serum system. Once introduced into the fetal kidney, soft, brief *inward–outward* movements should be made in the same direction as the puncture.

The aspiration system should be extracted first and the needle last to avoid contaminating any other tissue. The spot to be punctured should be situated between the belly button and the edge of the ribcage. This fate is helped by the physiological hepatomegaly, introducing the needle approximately 1 cm under strict echographic monitoring. Preferably the external third of the right lobe should be chosen as it offers a minor principal vascularization; if not, the suprahepatic vessels should be avoided (Figure 34.5).

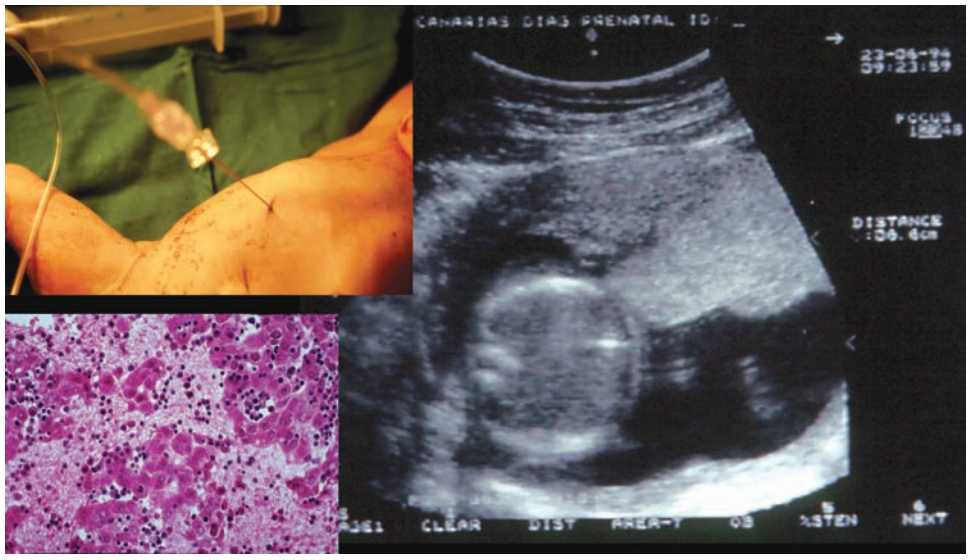

Figure 34.5 Liver biopsy: echographic monitoring and histological samples of fetal liver (19 weeks). Extramedullar hematopoietic foci can be detected.

If the diagnosis being sought is histological, the sample should be preserved in formaldehyde; if it is enzymatic, the sample should then be sealed airtight in carbonic snow.

The gestational age recommended is around 20 weeks, provided that the hepatic metabolism and main enzymatic processes are well or are practically established.

Indications

The indications are prenatal diagnosis, mainly of enzymatic alterations and of lethal metabolic characteristics.[15,16]

Deficiencies of ornitil transcarbamylase (OTC): This mitochondrial enzyme of the urea cycle is synthesized in the liver or the intestines. Sex-linked disorders tied to the sex are revealed in the screening data of mothers who have urine excretion of orotic acid.

Primary hyperoxaluria (PH): This is severe, charted renal insuffiency of rapid evolution that is characterized by the presence of calcic oxalate deposits in the renal tubule, microlithiasis and interstitial fibrosis. The hepatic level is accompanied by a total absence of alanine and inactivity of the catalytic gliosilate aminotransferase and immunoreactive proteins. This leads to death.

For diagnosis it is very important to have the previous family clinical history.

Carbamoyl phosphate synthetase deficiency: This is an enzymatic defect of the urea cycle with recessive autosomic inheritance.

Other autosomic recessive disorders may be detected by means of hepatic biopsy, including the following:

(1) Non-ketotic hyperglycinemia
(2) Prenatal diagnosis of infantile neuronal ceroid-
(3) lipofuscinosis
(4) Biliary atresia (type I cysts)
(5) Long-chain 3-hydroxyacyl-CoA dehydrogenase.[17–20]

Table 34.1 Experience with seven prenatal punctures for liver biopsy

	Number of cases
Reasons for biopsy	
OTC diseases in the same family	4
Previously affected brother	1
Mitochondrial respiratory deficit	1
Non-ketotic hyperglycinemia	1
Results	
Prenatally confirmed diagnosis of OTC deficiency	2
Prenatally non-confirmed diagnosis with neonatal exitus by hyperammonemia	1
Prenatally confirmed as non-affected fetuses	4

Complications

Prenatal liver biopsy has a few risks at the tissue level, due to its visceral characteristics. These risks are derived from major vascular tears, which involve great bleeding, resulting in fetal death. In our experience (seven prenatal punctures), we have observed no complications (Table 34.1).

Fetal puncture in the evaluation of renal status

The correction of a theoretic renal obstruction problem is possible, in spite of the difficulties and risks that it holds, even if in the majority of cases it is not necessary. We should start by stating that an ultrasound

Figure 34.6 Fibrocortical dysplasia associated with corticomedullar cyst and renomegaly.

Table 34.2 Fetal nephrouropathy. Echographic prediction

Tissue marker	Sensibility (%)	Specificity (%)
Corticomedular cysts	70	100
Hyperecongenity	60	90
Hydronephrosis	75	70
Hydronephrosis + cysts	90	100

echography diagnosis of the obstructed renal pathology does not necessarily imply an irreversible function alteration. In this sense the amniotic volume can be used as an indirect marker of the actual renal function, but this does have the inconvenience that it includes the possible measuring of the intrinsic clearance function.

When taking into account the possibility of practicing an intrauterine derived therapy, it must be noted that this can only be justified in a fetus in whose kidneys there has been no irreversible damage. However, this makes it essential to establish a precise evaluation of the renal function in order to adequately select those fetuses that will benefit from prenatal therapy.

The most conflictive situation is renal dysplasia. Fibrosis, dysplasia and cartilaginosis are found simultaneously in this condition, frequently associated with corticomedular cysts, although not always so (Figure 34.6).

Approximately 90% of all kidney dysplasias are associated with dilated or obstructive disorders. It can be remarked that in these cases any derived therapeutic action is unnecessary.

High-resolution echography has become the leading kidney evaluation process; however, it does have a few diagnostic limitations (Table 34.2).

In our experience the obstruction of a kidney without visible cysts or hyperechos does not, however, exclude dysplasia. This quite alarming fact occurs approximately in 25–30% of all cases.[8–21]

From this we can deduce that echography on its own cannot be used to diagnose all renal dysplasias, and for this reason fetuses with pelvic dilation are subsidiary of derived drainage.

A biochemical study of fetal urine is important data for management of these fetuses. The composition of the fetal urine stays constant, practically throughout the pregnancy and with hypotonic characteristics. This fact automatically demonstrates an optimal and reliable renal function and in contrast iso- or hypertonic urine indicates a deficiency in renal function with an infastous prediction.

The biochemical markers that are closely related to the renal function are defined by Na^+, Cl^- and osmotic urine.

Another determining factor in the normal renal clearance function derived from the near high reabsorbing tubular activity is establishing specific proximal tubular lesion selective markers.

These markers correspond to lysosomal proteins exclusive of the proximate tubular structure and become expressed by *N*-acetyl-D-glucosaminidase (NAG). Low molecular weight proteins filtered by the glomerular system and reabsorbed practically in their totality by the proximal tube, if present in fetal urine and in the amniotic fluid in large quantities (higher than 8 U/l), are indicative of tubular tissue destruction.

The detection of β-2 microglobuline would be interpreted in the same manner (Figures 34.7 and 34.8).

We found that the levels of biochemical markers are significantly low in physiological urine in comparison with cases affected with irreversible renal disorder. The same outcome is found with the tissue markers NAG and β-2 microglobuline (Table 34.3).

When we compare the relationship between the ionic concentrations and the osmolarity (Na^+ and Cl^-) of the fetal urine and those of the amniotic liquid, we do not find significant differences between fetuses with conserving and fetuses with pathological functionalities. But comparing the levels of NAG and β-2 microglobuline, a significantly greater concentration of the two markers has been observed in the amniotic liquid of the affected fetuses (Tables 34.4 and 34.5).

The increase in concentration of NAG and β-2 microglobuline is possibly due to the cumulative effect of the amniotic clearance mechanism.

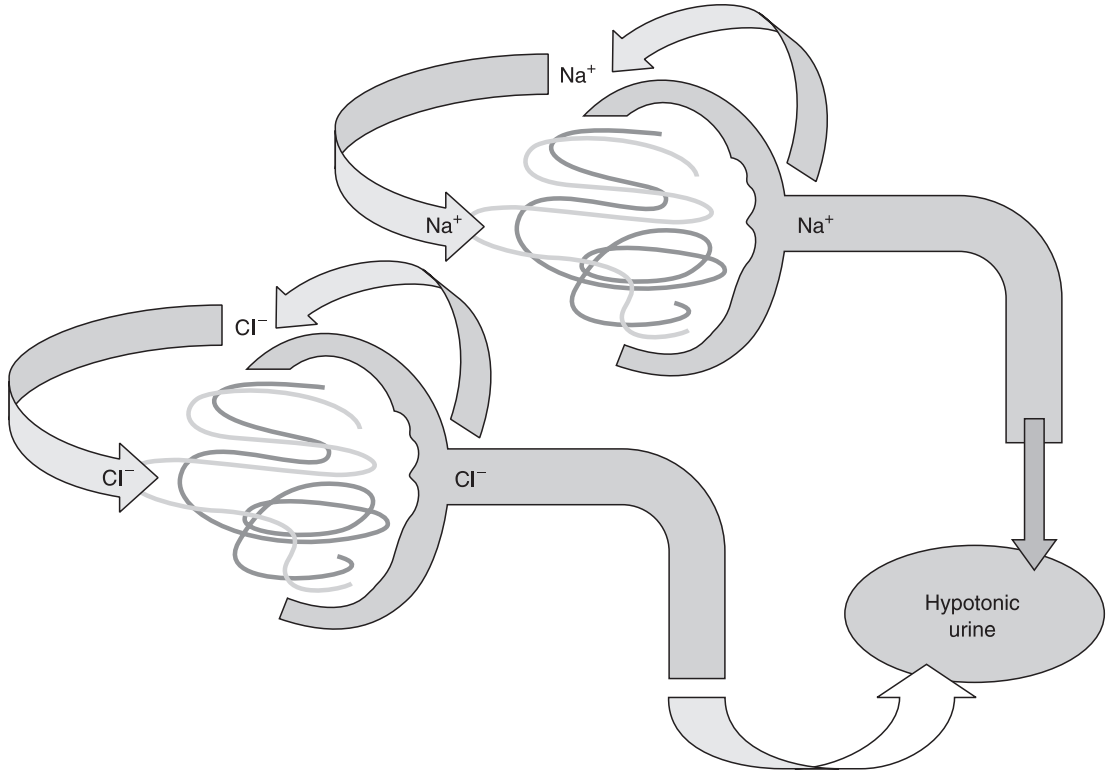

Figure 34.7 Biochemical markers that have a close relation with a renal function are defined by the NA+, Cl– and osmotic urine derived from the near high reabsorbing tubular activity. Fetal urine characteristics remain constant, practically throughout the pregnancy, with hypotonic features.

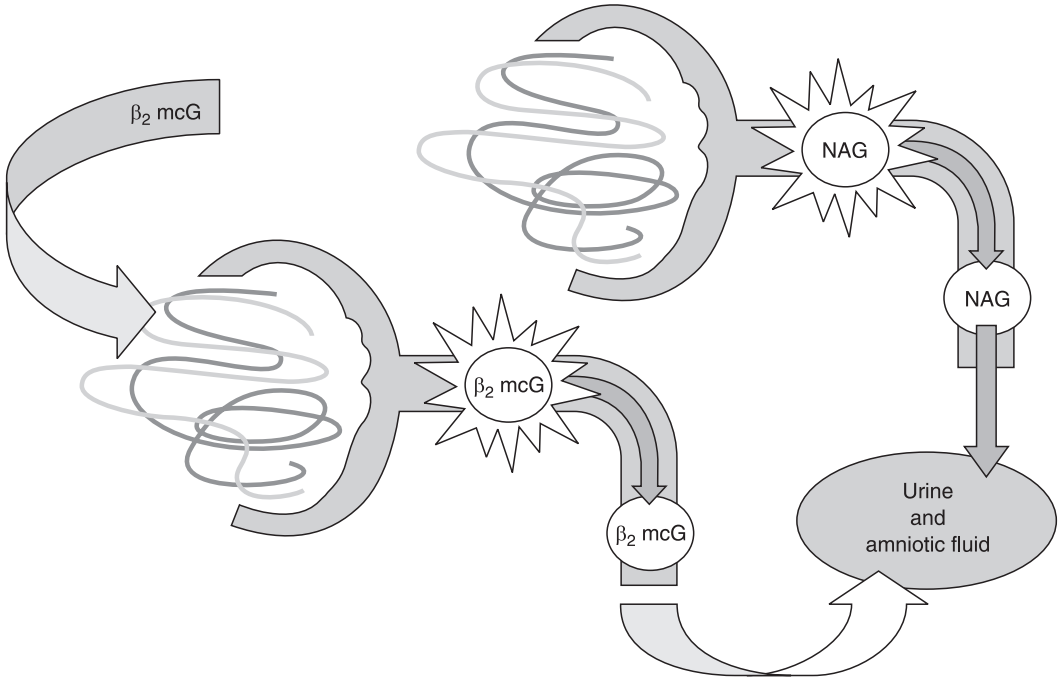

Figure 34.8 A determining factor of a normal renal clearance function corresponds to lysosomal proteins exclusive of the proximate tubular structure (NAG); if it is present in fetal urine and in the amniotic fluid in large quantities, it is indicative of tubular tissue destruction. *β*-2 Microglobuline would be viewed similarly.

Table 34.3 Fetal urinary aspiration: pathological biochemical markers and their values

	18–20 weeks	20–30 weeks	> 32 weeks
Na^+ (mEq/ml)	120.0	126.44 ± 11.50	139.60
Cl^- (mEq/ml)	119.0	132.50 ± 7.18	141.00
OsM (mOsm)	240	261.50 ± 24.20	281.00
NAG (U/l)	18.0	25.83 ± 0.85	25.73
β–2 Microglobuline (ml/l)	26.0	38.97 ± 1.30	38.72
K^+ (mEq/ml)	3.1	3.41 ± 0.66	3.90
Creatinine (ml/l)	1.2	2.54 ± 0.83	3.70

Table 34.4 Physiological values: urine vs. amniotic liquid

Urine/amniotic liquid	18–20 weeks	20–30 weeks	> 32 weeks
Na^+ (mEq/ml)	42/137	42/140	47/140
Cl^- (mEq/ml)	23/109	47/109	41/108
OsM (mOsm)	98/267	102/273	102/271
NAG (U/l)	2.0/3.6	2.7/3.62	2.0/4.69
β-2 Microglobuline (ml/l)	4.7/4.5	5.1/5.0	5.3/5.8
K^+ (mEq/ml)		41/140	
Creatinine (ml/l)		1.9/.6	

Table 34.5 Pathological values: urine vs. amniotic liquid

Urine/amniotic liquid	18–20 weeks	20–30 weeks	> 32 weeks
Na^+ (mEq/ml)	120/132	126.4/140	139.6/140
Cl^- (mEq/ml)	119/107	132.5/149	141/158
OsM (mOsm)	240/267	261.5/273	281/296
NAG (U/l)	18/16.9	25.83/20.34	25.73/20.8
β-2 Microglobuline (ml/l)	26/22.3	38.9/28.74	38.72/30.0
K^+ (mEq/ml)	3.1/138	3.4/140.6	3.9/148
Creatinine (ml/l)	1.2/0.7	2.54/0.82	3.7/0.9

This opens the field of study of nephrouropathies through the determination of these and other parameters in the amniotic liquid, without the need for an invasive study of the fetal urine.[21]

The K^+ and creatinine concentrations are different in their predictive evaluation as there is a large clearance effect in the placenta and great variability in its ionic charge, which makes the potassium filtration very dispersed; on the other hand, 90% of the K^+ concentration is intracellular.[8,21]

In summary, we can venture in Table 34.6 a prediction of renal viability in relation to the parameters described, taking into account the fact that these values are applicable to any gestational age.

Intrauterine determination of the characteristics of fetal urine offers the possibility of absolute diagnosis of normal renal clearance function.

Table 34.6 Fetal urine: biochemical markers applicable to any gestational age, echographic image indications and amniotic liquid volume to determine the renal function status

Prediction	Bad	Good
Echographic image	Hyperecongenity + cyst	Normal echography
Amniotic liquid	Oligoamnios	Normal
Fetal urine

NAG	> 8 U/l	< 8 U/l
β-2 Microglobuline	> 4 mg/l	< 4 mg/l
K^+	Indifferent	Indifferent

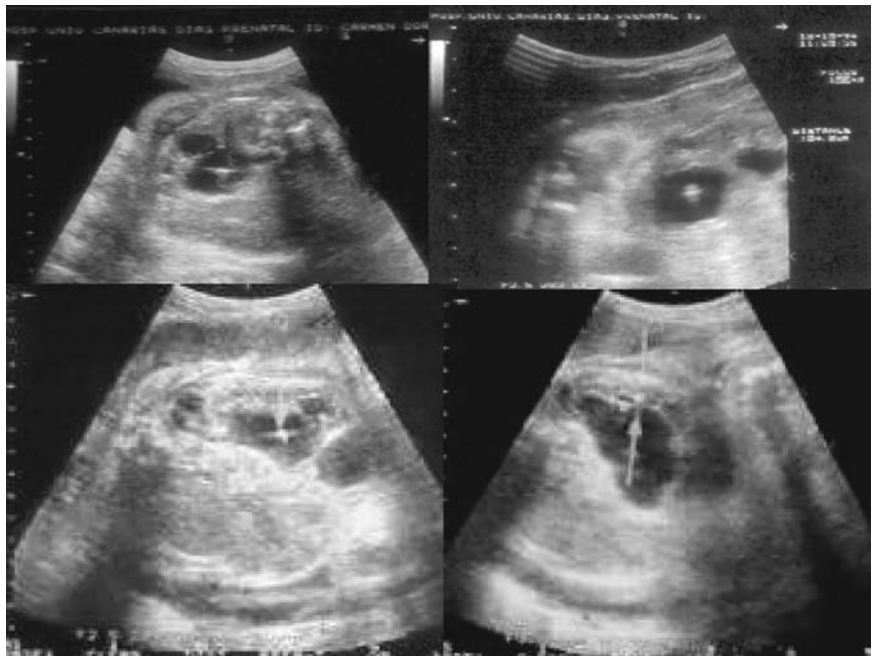

Figure 34.9 Aspirative nephrostomy: echographic monitoring.

Urine aspiration puncture for diagnosis is technically feasible, using conventional 18-g spinal needles having an aspiration system connected to a 20-cc syringe. The way to approach this depends on the fetal position available.

With the posterior back position we will not find any great inconvenience in puncturing the bladder, whilst for a lateral or anterior back position a nephrostomic aspiration is chosen (Figure 34.9).

In neither are there any noticeable complications, at least in our experience.[8,21]

Nephrostomic aspiration allows us firstly to reevaluate the echostructural characteristics of the expanded kidney parenchyma and, secondly, as long as we use the 16-g sure cut aspiration system, to carry out at the same time a renal biopsy without any technical difficulties.

For this, once the nephrostomic urine aspiration has been carried out, without taking the needle out move it toward the renal parenchyma and carry out the aspiration with a *swinging* movement over the corticomedular area.

Obtaining samples of 2-mm length is enough for detection of the histological characteristics that define a kidney dysplasia.[8,9,21–23]

However, once the technical problems involving tissues have been solved, the use of 16-g catheters from the aspiration biopsy set (Figure 34.3) allows us to obtain samples in 65% of cases. If conventional 18-g catheters are used, samples are obtained in only 30% of the cases though they are safe (J. Troyano and I. Donald, unpublished observations).

Skin biopsy

As already stated in the general section about fetal biopsies, skin biopsy entails the most serious difficulties in obtaining adequate or sufficient samples that will allow correct histopathological diagnosis or prediction.

The most important aspect is the obtaining of valid samples; for this we need at least 1-mm strips of skin and no smaller in surface area and that also include a layer of the epithelial stratum, comprising conjunctive areas and basal membrane. Only in this way can an acceptable reading be obtained.[24]

The second aspect to be taken into account is the surgical biopsy material. We have already indicated previously that the use of 2.5-mm clipping tongs (forceps/clippers), introduced into the amniotic environment using a trocar, will allow the obtaining of skin samples in 100% of all cases, and it is true that the residual skin lesions, and any pregnancy complications there may be, will not provide any noticeable benefits in relation to the diagnostic data.

The use of conventional needles and isometric aspiration, using the *slice* technique, which consists in inserting the needle sideways over the skin and making *scratching* or *scraping* movements, this will allow us to obtain skin strips of optimum quality with minimum damage to the integrity of the pregnancy (Figure 34.10).[25–28]

The third aspect to consider is the place selected for taking the sample, as depending on the disorder that we aim to diagnose prenatally, the biopsy area

Figure 34.10 Left: Skin biopsy in fetal abdomen, scratched sideways. Right: Mature histological cutaneous samples in which keratohyalin and hemidesmosomes are detected.

will be different. The same area of fetal skin wrap will not always be valid or suit the purpose of the biopsy.

Technique

Skin samples should, if possible, be taken from different areas of the fetus.

The pregnancy stage recommended for this is around 20 weeks, as after this time, the pilose follicles begin to develop and keratinization mechanisms set it. A study of the elements involved in the keratinization (keratohyalin and tonofibers), gives preliminary indications of the disorder.

On the other hand, at this stage in the pregnancy the dermoepidermal junction has definitively been established, and the gradual rise of intercellular desmosomes is a great help for the diagnosis of different forms of epidermolysis.

The sequence should follow the following steps:

- Echographic monitoring
- If possible, the placenta must be avoided
- Take into consideration the fetal position as on some occasions it will be necessary to obtain samples from different skin areas
- Rigorous sterilization
- Optional local anesthesia, depending on the surgical timing
- Oblique needle incidence in the thickness and surface of the skin, making a scraping or scratching movement without pulling back
- Try to obtain at least 1-mm strips. The use of vacuum needles allows the collection of various fragments from the interior without the need for withdrawing the needle
- Immediately, proceed to wash the samples in saline serum for the histological staining and fixing process or for electron microscopy analysis.

Indications

Indications are most frequently based on diagnosis of some type of genodermatosis or congenital dermoepidermic disorders, of dominant autosomic transmission and recessive types, the majority being lethal in the short or medium term.

Figure 34.11 Keratinization disorder.

These disorders can be classified as follows:

- *Bullous epidermolysis*: Fetuses with large blistered areas that, once the blisters break, set off intensive erosive zones with a fast loss of electrolytes are affected[6,10,29,30]
- *Anhidrotic ectodermic dysplasias*: Recessive disorder linked to the sex. The fetuses are born without pilose follicles, without any hair or sudoriparous glands. They develop hyperthermic through disregulation and general dryness syndromes[31]
- *Keratinization disorders*: Also called *collodion baby syndrome*, characterized by the appearance of *reptilian skin* due to epidermic membranes that are *shed quickly*. Severe and lethal dehydrating disorders[32,33]
- *Pigmentary atopies*: Ocular syndromes with severe intolerance to light and early or premature development of skin cancers.[31,34,35]

The diagnostic problems faced with these dermatoses are due to the development of a lesion which has different topographic origins, and so the need to select

Table 34.7 Diagnoses possible from fetal skin biopsies

Keratinization disorders: The puncture spot is in the trunk and buttocks (Figure 34.11)
Harlequin fetus
Collodion baby
Sjögren–Larsson syndrome
Congenital icthyosis

Ampollous diseases: The puncture spot is in the waist, skin folds, abdomen and buttocks (Figure 34.12)
Herlitz ampollous junctional disease
Hallopeau–Siemens ampollous dermolytic disease
Inverse dystrophic ampollous disease
Cockayne–Touraine dystrophic ampollous disease

Pigmentary disorders: The puncture spot in the skin of the head (scalp) (Figure 34.13)
Negative tirosinase oculocutaneous albinism
Chediak-Higashi disease
Anhidrotic ectodermic disease

Figure 34.12 Ampollous disease.

Figure 34.13 Pigmentary disorder (scalp lesions).

the puncture spot has to be in accordance with the illness that one is trying to detect.

The diagnostic possibilities of skin biopsies are summarized in Table 34.7.

It is essential to have an objective family history in order to determine the biopsy spot.[34,36,37]

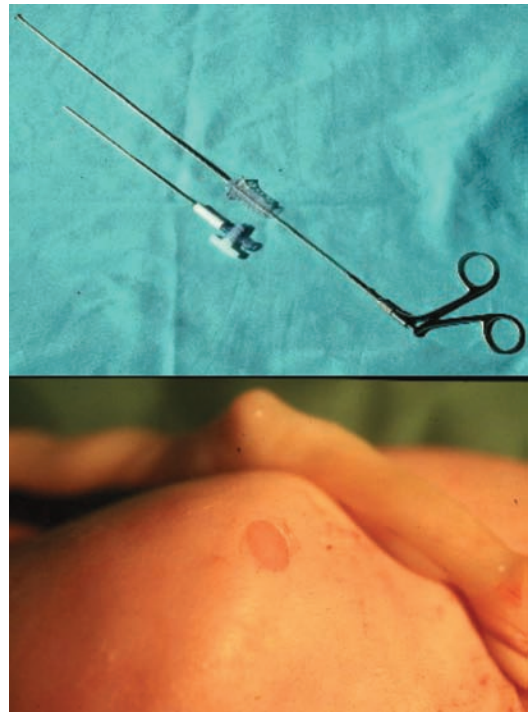

Figure 34.14 Residual cutaneous lesion after biopsy with clipper system.

Figure 34.15 Subtrochanteric muscle biopsy: detection of dystrophine by immunofluorescence indicates healthy muscle.

Complementary requirements

The study of the samples will be based on the ultrastructural features stated previously. A great deal of experience in fetal dermatology using electron microscopy is required to make the diagnosis.

It is essential to have an objective family history knowledge in order to determine the prenatal dermoepidermic structural markers.

It is recommended that previous samples be maintained for use as a *study bank*.

Complications

Presently the tendency is to propose minimally invasive techniques using conventional needles **7** (38).

The use of conventional needles does not pose more risks than amniocentesis. On the other hand, trocar techniques and 2.5-mm biopsy provoke around 5% of miscarriages due to iatrogenic amniorexis, although some indelible fetal skin lesions have been described similarly (Figure 34.14). This does not occur in cases where the *scalp* technique is carried out with the use of conventional needles.

Muscle biopsy

This is carried out preferably for prenatal diagnosis of Duchenne's muscular dystrophy (DMD), although it is also possible to detect other hereditary myopathies as long as there is some clinical family history of these disorders.[11,38,39]

For the diagnosis of DMD, it is usual for DNA analysis to be used. When the recombinations within the DMD gene or the DNA analysis are not sufficiently informative or if it is not clear from the family history if there are possible carriers, direct examination of the muscle and its analysis is the only way to give an objective prenatal diagnosis.

The marker used is dystrophine; its determination by means of immunofluorescence allows us to differentiate the features of affected muscles from those of the healthy ones. The absence of this protein from the skeletal muscles is practically pathognomonic of DMD[11,14,39,40] (Figure 34.15).

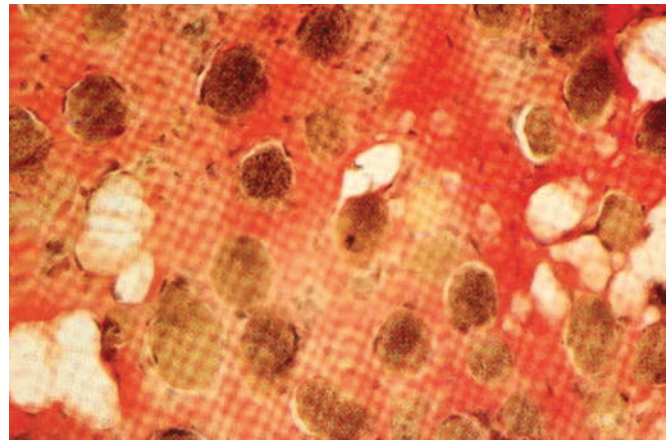

Figure 34.16 DMD with degenerated muscle as an associated sign: fat and connective infiltration, morphological cellular alterations and leucocyte infiltration.

At other times prenatal diagnosis of DMD may be impossible when there is only one previously affected male in the family, and there is no identifiable deletion.

The absence of dystrophine in a skeleton muscle, is in itself sufficient for determination of screening of the DMD. Nevertheless this diagnosis can be reinforced by detecting a rise in phosphocreatinkinase of more than 10 times its normal value in fetal blood.

Among the possibilities that can reinforce a prenatal DMD diagnosis or prediction we have:

- Sex linked
- High values of phosphocreatinkinase
- Absence of dystrophine
- Degenerated muscle
- Fat infiltration
- Connective infiltration
- Nuclear and cellular morphological alterations (Figure 34.16).

Technique

Any skeletal muscle is suitable, preferably the external face of one of the thighs or knuckles, avoiding topographic places with innervation or vital vascularization; indelible functional lesions will thus be avoided. The use of conventional 18-g needles or, even better, the sure cut method that has been described previously is preferred[8,38,41–43] (Figure 34.2).

Subtrochanteric punctures are carried out in a descending manner, as oblique as possible, orientated toward the fetal femur (Figure 34.2).

The puncture success rate is 75%.

It is essential to determine muscle dystrophy by immunoflourescence, being advisable but not determining the detection of phosphocreatinkinase and the study of the muscular structure at a morphological muscular level, fat and connective infiltration.

No complications are described.

The fetus may be studied using invasive techniques. These techniques are only justified when there are serious situations such as the possibility of an inherited illness or there is any other disorder detected during pregnancy; the need for diagnosis through biopsy is particularly important in the latter. Thoracocentesis, pericardiocentesis and other thoracoabdominal punctures are primarily carried out for therapy, and extracted material is studied for its components.

Other punctures on fetal tumor formations (sacrococcygeal teratomas, solid cervical teratomas, etc.) or liquid collections, such as pericariocentesis, do not have an acceptable justification from a therapeutic or diagnostic point of view, as echographic evaluation and currently used biophysical methods (color Doppler among these) give an acceptable identification of their vascularization and origin, including suspicious neoplasms[44,45] (A. Kurjak, unpublished data).

In agreement with our philosophy, we would like to express this thought:

> *The fetus has been endowed by nature to confront several inconveniences provided by its 40 weeks of development. It is a real 'Titan' that can face any adversity, and its adaptability is exceptional.*
>
> *Let us not disturb it!*
> *Let us not invade its privacy aggressively!*
> *Let us observe it minutely. When it needs us, which generally happens in few occasions, it will advise us; then let us help it.*
>
> J. M. Troyano-Luque (1993)

35 The role of ultrasound examination of the cervix in pregnancy

P. Rozenberg and Y. Ville

Introduction

Preterm delivery is the main cause of perinatal mortality and morbidity.[1] Its prevalence has been stable for the last 20 years accounting for 5.9% and 11% of all deliveries in France and in the USA, respectively.[2–4] This is mainly due to poor therapeutic results and the inadequacy of the diagnostic criteria for preterm labor. Risk scoring for preterm birth has both low sensitivity and positive predictive value.[5–8] Only 15% of women with a previous history of preterm delivery will do so in a subsequent pregnancy.[8] Routine digital cervical examinations during pregnancy increase the risk for admission in hospital without decreasing the incidence of prematurity.[9] In threatened preterm labor as defined by painful contractions, cervical changes on digital examination and frequency of contractions both remain poor predictors of preterm delivery.[10–13]

Different strategies have been developed to refine the risk of preterm delivery, including the use of transvaginal sonography (TVS) to measure and examine the length and shape of the cervix. TVS has been studied in three different populations: (1) symptomatic women with threatened preterm labor, i.e. regular and painful contractions together with changes on digital examination of the cervix; (2) asymptomatic women at high risk of delivering prematurely, as defined by a history of preterm delivery, late miscarriage, conization, maternal exposure to diethylstilbestrol (DES) during fetal life, uterine malformation or a current multiple pregnancy; and (3) asymptomatic women without any relevant history.

Threatened preterm labor

The risk of preterm delivery is significantly associated with two ultrasound features: shortening of the cervical length and cervical wedging

Cervical length (CL) measured by TVS, < 20, < 25, or < 30 mm, on admission had positive and negative predictive values (PPV and NPV, respectively) of 100% and 72%, 70% and 82%, and 65% and 100%, on preterm delivery, respectively. These patients delivered preterm despite tocolytic therapy during hospitalization.[14] Thus, the risk of preterm delivery is especially high in women whose CL on admission is < 20 mm, whereas a CL ≥ 30 mm is reassuring. Preterm delivery is also significantly associated with the presence of cervical wedging together with a short CL. This led to sensitivity, specificity, PPV, and NPV of 100%, 74.5%, 59.4%, and 100%, respectively.[15]

Ultrasound examination is more accurate than digital examination of the cervix in preterm labor

In preterm labor with intact membranes, Gomez *et al.*[10] showed that despite cervical dilatation of < 3 cm, CL and cervical wedging ($P < 0.005$) were highly predictive of preterm delivery, but digital examination of the cervix (dilatation and effacement) failed to do so. Survival analysis demonstrated a shorter admission-to-delivery interval for patients with an abnormal CL ($P < 0.005$). In preterm labor following completion of a course of IV tocolysis, cervical sonography performed better than digital examination to predict delivery before 36 and even 34 weeks, with a best cut-off of 30 mm on receiver operating characteristic (ROC) curve analyses.[11,16] The PPV and NPV were of 15% and 36%, and 97% and 100% in singleton and twin pregnancies, respectively, when assessed at between 23 and 33 weeks. When analyzed for delivery before 37 weeks, this held true for singletons but not for twins.

The comparison of cervical fetal fibronectin (fFN) assay and TVS of the cervix to predict preterm delivery remains a controversial issue

We found that prediction performances of vaginal fFN assay ≥ 50 ng/ml and of a CL of ≤ 26 mm in threatened preterm labor at between 24 and 34 weeks were similar

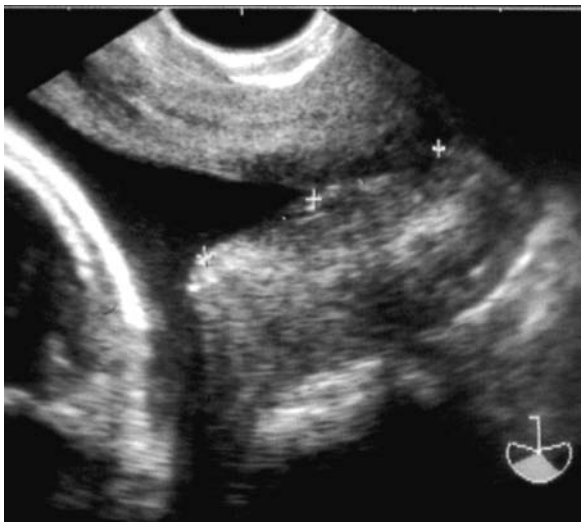

Figure 35.1 Dilatation of the IO.

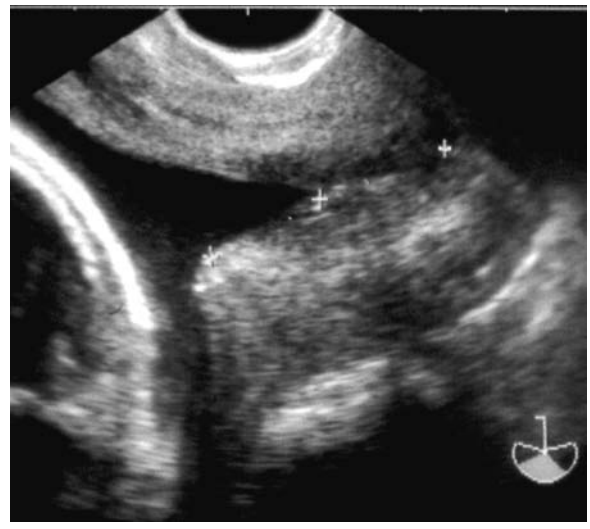

Figure 35.2 Sacculation of the membranes into the cervix.

with a high NPV of 86.6% and 89.1%, respectively.[17] The combination of both tests performed better with an NPV of 94.4% but the positive predictive value remained at around 50% although the odds ratio (OR) for delivering before 34 weeks was high (13.9; 95% CI, 3.7–52.2).

Rizzo *et al.*[18] reported that cervical fFN $\geq$60 ng/ml performed better than the association of CL and the presence of funneling on ultrasound. Furthermore, in patients with cervical fFN $\geq$60 ng/ml a shorter admission-to-delivery interval was found in the presence of an abnormal cervical index.

More recently, multiple logistic regression analysis found that only positive fFN testing (OR 11.25, $P=0.005$) and functional CL $\leq$20 mm (OR 8.18, $P=0.027$) were independently associated with preterm delivery.[19] In the group with CL of 20–31 mm positive fetal fFN was found in 71.4% of patients delivered within 28 days and in 7.4% delivered after 28 days ($P=0.001$). fFN testing could therefore be performed only in patients with a short cervix to discriminate further those at true high risk of prematurity, with sensitivity, specificity, PPV, and NPV of 86%, 90%, 63%, and 97%, respectively, in predicting delivery within 28 days.

Asymptomatic women at high risk of preterm delivery

There are four types of clinical studies addressing this issue: (1) observational studies examining the natural course, (2) observational studies examining the course of those treated with cervical cerclage, (3) non-randomized interventional studies, and (4) randomized interventional trials.

Observational studies of ultrasound features suggestive of cervical incompetence

Three ultrasound features are suggestive of cervical incompetence.

Dilatation of the internal os (IO) (Figure 35.1) was the first ultrasound feature suggesting cervical incompetence and thus increased risk of preterm delivery. Dilatation of the IO > 5 mm before 30 weeks' gestation is associated with preterm delivery in 33.3% vs. 3.5% when the IO remained closed ($P<0.01$). Digital cervical examination noted dilatation of the IO in only 10 of the 26 (38.5%) patients in whom ultrasound showed cervical dilatation.[20]

Sacculation or prolapse of the membranes into a shortening cervix (Figure 35.2), either spontaneous or induced by transfundal pressure, can be seen even when digital cervical examination shows a long and closed cervix.[21]

Another study, in which ultrasound examinations were performed at between 15 and 24 weeks, compared three methods to detect cervical incompetence: transfundal pressure, coughing, and standing.[22] The transfundal pressure was the most predictive (sensitivity, specificity, PPV, and NPV of 83.3%; 97.2%; 88.2%; and 95.8%, respectively).

Shortening of the cervix in the absence of uterine contractions is also suggestive of cervical incompetence. A CL < 10th percentile (22 mm) and funneling at the IO (Figure 35.3) at between 16 and 30 weeks were associated with delivery within 2–4 weeks and before 35 weeks [33% vs. 0 ($P=0.01$); 67% vs. 0%, ($P<0.001$); and 100% vs. 19%, $P<0.001$, respectively].[23] Within this high-risk group, women with medical or obstetrical complications (including multiple gestation and ruptured membranes), symptoms of preterm labor, and history of incompetent cervix

Figure 35.3 Funneling with shortening of the functional cervical length.

Figure 35.4 Increase in cervicle length after cerclage is often a temporary result.

that required cerclage were excluded. A short cervix or funneling beyond 20 weeks of gestation was also associated with an increased risk of preterm delivery before 35 weeks but not with an increased risk of delivering within 2–4 weeks following TVS.

Prospective longitudinal evaluation of a large cohort of 469 high-risk pregnancies by TVS and transfundal pressure on 1265 occasions at between 15 and 24 weeks[24] compared various sonographic cervical parameters to predict spontaneous preterm birth. ROC curve analysis showed that CL $\leq$25 mm alone performed as well as a combination of risk factors, CL, funneling, and transfundal pressure. The sensitivity for delivery at <28, <30, <32, and <34 weeks' gestation was 94%, 91%, 83%, and 76%, respectively, while the NPV was 99%, 99%, 98%, and 96%, respectively. Shortening of CL at weekly assessment helps in differentiating cervical competence from cervical incompetence in high-risk women (-0.3 vs. -4.1 mm/week; $P<0.001$).[25] Ultrasound diagnosis of cervical incompetence was defined as progressive shortening of the endocervical canal to 20 mm or less before 24 weeks' gestation.

In this high-risk group, CL $<$25 mm by TVS of the cervix performs better than CL $<$16 mm by digital cervical examination in assessing the risk of delivery before 35 weeks with relative risks of 4.8 and 2.0, respectively.[26]

In multiple pregnancies at between 24 and 28 weeks, a CL $\leq$25 mm by TVS was the best predictor of preterm delivery before 32 weeks, before 35 weeks, and before 37 weeks.[27] There is a continuous increase of 5–17% and 80% for this risk with CL shortening down to 40 and 20, and 8 mm, respectively.[28] CL of $\leq$20 mm seems to perform as well as any combination of clinical and ultrasound features at predicting preterm birth,[29] whereas CL $>$35 mm before 26 weeks seems to accurately identify a subgroup of twin pregnancies at low risk for premature delivery (3–4%).[30,31]

Although series are smaller, the predictive value of TVS of the cervix seems to hold true in triplets.[32,33] CL of $\leq$25 mm between 21 and 24 weeks' gestation was the best cutoff for the prediction of spontaneous preterm birth $<$28 weeks' gestation (86%, 79%, 40%, and 97% for sensitivity, specificity, PPV, and NPV, respectively).[34]

Follow-up studies in cervical incompetence diagnosed by TVS and treated by cerclage

It has been established that cervical cerclage is followed by a measurable increase in CL (Figure 35.4). This applies to both rescue cerclage[35,36] and elective procedures.[35,37,38] However, the relation of this increase with outcome is controversial and the longer the precerclage CL the more likely a delivery near term.[39] The value of CL shortening following cerclage is also controversial. A decrease of at least 10 mm is significant to predict delivery before 36 weeks.[36,37,40] However, this may not be significant when 34 weeks is considered as a cutoff.[38]

The value of non-randomized interventional studies based on ultrasound diagnosis of cervical incompetence is controversial

TVS together with transfundal pressure can be used in high-risk women to define cervical incompetence at between 16 and 24 weeks whenever this causes dilatation of the IO or protrusion of the membranes.[41]

Serial TVS suggests that evidence for cervical incompetence can be established by 24 weeks.[42] In a retrospective analysis, Kurup and Goldkrand[43] compared the outcome in three categories of cerclage: elective cerclage indicated by the patient's history, ultrasound-indicated cerclage performed in asymptomatic patients with cervical changes by ultrasound, and rescue procedure performed in symptomatic

patients. This shows that the performance of ultrasound-indicated cerclage in terms of preterm delivery rate and gestational age at delivery was better than emergency procedures. The benefit of cerclage in this group is, however, uncertain when compared to elective cerclage on the basis of a relevant history.[44,45] This, therefore, suggests that a new indication for cerclage can be defined as cervical changes on serial TVS in a high-risk group.

Randomized trials assessing ultrasound-based indications for cerclage in high-risk women

There are two such randomized trials published and their results are apparently contradictory. Althuisius *et al*. studied patients with a history of delivery before 34 weeks with suspected cervical incompetence or preterm rupture of membranes at < 32 weeks without preceding contractions.[46] In subsequent singleton pregnancies, they were randomized into two groups, with a 1/2 ratio, for either prophylactic cerclage ($n=23$) or a follow-up cervical TVS ($n=44$). In the follow-up group, a CL < 25 mm before 27 weeks led to a second randomization for either therapeutic cerclage or expectant management. The obstetrical characteristics of the prophylactic cerclage and observational groups were similar. There was no significant difference in the rate of delivery before 34 weeks (13.0% vs. 13.6%) in these two groups. A CL < 25 mm before 27 weeks was found in 18 (41%) patients in the observational group with a mean CL of 18.2 ± 5.9 mm at a mean gestation of 19.1 ± 2.9 weeks. The incidence of deliveries < 34 weeks was significantly lower in the therapeutic cerclage group when compared (1/10 vs. 5/8) with the bed rest group ($P=0.04$).

There might therefore be a double benefit in performing cerclage for ultrasound indication only among asymptomatic patients at high risk:

- First, this would allow a significant reduction in the amount of prophylactic cerclage. Indeed, in this study, cerclage was performed in only 40% of the cases.
- Second, therapeutic cerclage before 27 weeks may reduce the incidence of premature delivery before 34 weeks among patients with a CL < 25 mm.

More recently, Althuisius *et al*.[47] published the final results of their trial on 35 women with definite risk factors of cervical incompetence and shortening of the cervix down to < 25 mm at before 27 weeks; 19 were allocated randomly to the cerclage group and 16 to the bed rest group. Both groups were comparable for mean CL and mean gestational age at the time of randomization. Preterm delivery before 34 weeks was significantly more frequent in the bed rest group than in the cerclage group (7 of 16 vs. none, respectively; $P=0.002$). The compound neonatal morbidity, defined as admission to the neonatal intensive care unit or neonatal death, was significantly higher in the bed rest group than in the cerclage group (8 of 16 vs. 1 of 19, respectively; $P=0.005$).

The other randomized trial by Rust *et al*.[48] led to different conclusions but addressed a different population. Screening in the general population and detecting 25% cervical funneling or CL < 25 mm at between 16 and 24 weeks were randomized into cerclage group or expectant management by Rust *et al*. Except for the cerclage, all patients were treated identically before and after randomization. Cerclage did not affect the perinatal outcome in any of the two trials.

Several differences between these studies[47,48] may explain these contradictory results. Low-risk patients were screened for a short CL to be included in the Rust trial. In Althuisius', all but one patient had risk factors for cervical incompetence.

The main difference is therefore the initial selection of potential candidates. In the Rust trial, measurement of the CL was performed in patients who had risk factors for preterm birth. In Althuisius' trial, it was performed in patients who had risk factors for cervical incompetence.

All three trials included patients with short CL, which implies a high risk of preterm delivery but not necessarily a high risk of cervical incompetence. Rust *et al*. hypothesized that these ultrasonographic findings of the cervix during the second trimester demonstrate a potential final common pathway of multiple pathophysiological processes, such as infection, immunologically mediated inflammatory stimuli, and subclinical abruptio placentae. This hypothesis is supported by a 14.8% incidence of abruptio placentae in their study. Abruptio placentae were not found in any of the women in Althuisius' study. This difference in the prevalence of abruptio placentae confirms that the study populations in both trials are basically different.

TVS of the cervix in clinical trials in the general population

There is a relation between the risk of preterm delivery and the functional length of the cervix in the general population. In a prospective multicenter observational study, Iams *et al*.[49] performed TVS of the cervix in women with a singleton pregnancy at 24 weeks ($n=2915$) and 28 weeks ($n=2531$) of gestation. Delivery before 35 weeks occurred in 126 (4.3%) of the 2915 patients examined at 24 weeks. CL was normally distributed at 24 weeks (35.2 ± 8.3 mm) and at 28 weeks (33.7 ± 8.5 mm). The risk of preterm delivery was inversely correlated with the length of the cervix.

Heath *et al*.[50] measured CL by TVS at 23 weeks in 2567 singleton pregnancies in women attending routine antenatal care. The risk for delivery at 32 weeks decreased from 78% at a CL of 5 mm to 4% at 15 mm and 0.5% at 50 mm.

To *et al*.[51] measured the CL in 6819 singleton pregnancies at 22–24 weeks and looked for the presence of funneling to evaluate possible additional risk. Funneling of the IO was present in about 4% of pregnancies and

the prevalence decreased from 98% when the CL was 15 mm to less than 1% at lengths > 30 mm. The rate of preterm delivery was 6.9% in those with funneling compared to 0.7% in those without funneling ($P < 0.0001$). However, logistic regression analysis demonstrated that funneling did not provide a significant additional contribution to CL in the prediction of spontaneous delivery before 33 weeks.

Taipale *et al.* and Hassan *et al.*[52,53] confirmed the relation between the risk of preterm delivery and the functional length of the cervix but showed the limitations of this screening method in the general population. Indeed routine TVS of the cervix performed between 18 and 22 weeks helped to identify patients at risk of preterm delivery; nonetheless, the low prevalence of preterm births in these populations (2–3%) at low obstetrical risk is a limitation to the development of such a method of screening, which would bring either a high false-positive rate if the cutoff is 29 mm (3.6%) or a low sensitivity if the cutoff is 15 mm (8.2%).[52,53]

Non-randomized interventional studies among patients in whom ultrasound images are suggestive of a shortened cervix reported encouraging results.[54] CL was ≤15 mm in 1.6% of the cases at 23 weeks in an unselected population of singleton pregnancies.[54] The attending physician decided upon performing a cerclage or expectant management. The two groups did not differ in ethnic or obstetrical characteristics. The median CL was 10 mm in both groups. In the cerclage group, the prevalence of preterm delivery before 32 weeks was 5%, whereas it was 52% in the expectant management group.

There is one randomized trial among patients with ultrasound images suggestive of cervical incompetence that was initiated following the results of Heath's study. To *et al.*[50] chose a cutoff CL of < 15 mm at 23 weeks in the general population, with an overall low incidence of preterm deliveries. In their study, CL was the measured indicator. Randomization into cerclage or expectant management did not lead to any difference in the mean maternal age or in neonatal morbidity.

Conclusion

TVS of the cervix is an objective evaluation of cervical biometry as well as an anatomical survey looking for funneling and protrusion of the membranes through the cervix. Dynamic functional examination of the cervix evaluates the changes in the IO in response to uterine contractions or transfundal pressure. It has the advantage of screening for dilatation of the IO even when the external os is unchanged. Similarly, it enables early detection of shortening of the supravaginal portion of the cervix, which is not amenable to clinical examination. We can hope that this early diagnosis will improve the efficacy of tocolytics.

TVS is a more discriminant approach than digital examination of the cervix in terms of both PPV and NPV. Among high-risk symptomatic patients (threatened preterm delivery), the data in the literature are sufficient to justify the systematic use of TVS for a more accurate evaluation of the risk of preterm delivery before any decision of hospital admission.

Cervical ultrasound may also be useful in selecting patients with complete or partial cervical incompetence among asymptomatic women at high risk (history of preterm delivery, late miscarriage, conization, maternal DES treatment, uterine malformation, or a current multiple pregnancy). Among asymptomatic patients at high risk, progressive cervical incompetence may be a primary uterine condition that could trigger premature labor. Looking for funneling or protrusion of the membranes into the cervix is therefore extremely useful. In their absence, cervical incompetence should be sought by transfundal pressure. Compared with a single cervical measurement at 16–18 weeks and 6 days' gestation, serial measurements up to 23 weeks 6 days significantly improved the prediction of spontaneous preterm birth.[21,25,66] A shortened cervix, although non-specific and rarely observed in the absence of uterine contractions, could also be the only warning of cervical incompetence. On the basis of Guzman's studies, ultrasound surveillance of such patients should begin by the 15th week.

In the general population, TVS of the cervix should be a useful complement to ultrasound examination performed at 22–24 weeks of gestation and help clinicians to better identify patients at low risk of preterm delivery (NPV = 96.7% and PPV = 47.6%).[53] High-risk patients as defined by short CL or the presence of cervical funneling could benefit from weekly cervical ultrasound assessment in order to define further intervention including cerclage, tocolytics, and steroids injection for lung maturation.

36 Labor and puerperium

A. Mulic-Lutvica and O. Axelsson

Labor

There is no doubt that labor is a dangerous period of our life and may result in birth-related disorders. Preterm and postdate deliveries, multiple gestations, preterm rupture of the membranes, intrauterine growth disturbances, breech presentations and intrapartum bleeding are associated with considerable perinatal morbidity and mortality. Healthy newborns with expected good quality of life are the main goal of modern obstetrics. Numerous different methods have been developed to achieve this goal. One of the most widely used is without doubt ultrasound. Although the value of ultrasound in antenatal care is well established, it is surprising that the clinical knowledge of its advantages during the intrapartum or postpartum period is sparse. Nowadays, however, it is becoming increasingly common for obstetricians to use bedside ultrasound and to have ultrasound equipment permanently available in labor and delivery suites. By means of an ultrasound admission test, a selection of high-risk patients should be made. The uterus with its contents, including the fetus, placenta, umbilical cord and amniotic fluid, as well as the cervix, can be assessed in detail by ultrasound (Figure 36.1). Even the maternal pelvis has become the subject of growing interest among sonographers. Ultrasound can also be useful during the performance of some obstetrical procedures including external version of a breech fetus, intrapartum twin management, or manual or instrumental placental evacuation as well as for confirmation of an empty uterus after the completed procedure. Intrapartum ultrasound imaging is difficult due to discomfort in women caused by pain, supine hypotension and loss of the 'acoustic window' after rupture of the membranes, low station of the presenting part and lack of appropriate ultrasound equipment in the labor and delivery suite as well as inadequately trained examiners.[1–3]

Ultrasound admission test

Laboring women with inadequate or no prenatal care should be carefully examined with ultrasound when arriving at the labor and delivery unit.

Diagnosis of fetal life or death

Ultrasound diagnosis of fetal life or death is simple, prompt and accurate. The fetal heart should be identified and the absence of fetal heart motion by real-time ultrasound and/or color Doppler implies fetal death. A completely quiescent fetus without body or breathing movements is an additional sign of fetal death. If the fetus has been dead for several days, the ultrasound signs of fetal death are oligohydramnios, overlapping skull bones, hyperflexion of the spine and the presence of hydrops.

Fetal number

The presence of two separate heads, two spines and two heart motions is enough to identify a twin pregnancy. However, it is rare but not impossible to miss a multiple gestation even by ultrasound in a busy labor and delivery room, and especially if one of the fetuses is dead. Moreover, as the number of fetuses increases, the accuracy of intrapartum ultrasound diagnosis decreases. One of the possible explanations may be crowding and shadowing of one fetus by another, which creates a very confusing ultrasound image. Therefore, a thorough systematic approach should be adopted. All quadrants of the uterus must be explored in order to avoid missing a multiple gestation. Furthermore, ultrasound can be used to estimate the amount of amniotic fluid, and to give information on fetal presentation, growth discordance, signs of hydrops and fetal malformations. A correct intrapartum diagnosis and painstaking management of delivery with the assistance of ultrasound are essential for an optimal outcome in cases with multiple gestations.

Fetal presentation

The presenting part of the fetus, be it head, breech, shoulder or compound presentation, can be simply and accurately diagnosed by ultrasound. It should always be done before labor induction, cesarean sections, preterm deliveries, deliveries of multiple gestations and in cases of planned vaginal deliveries after previous cesarean sections.

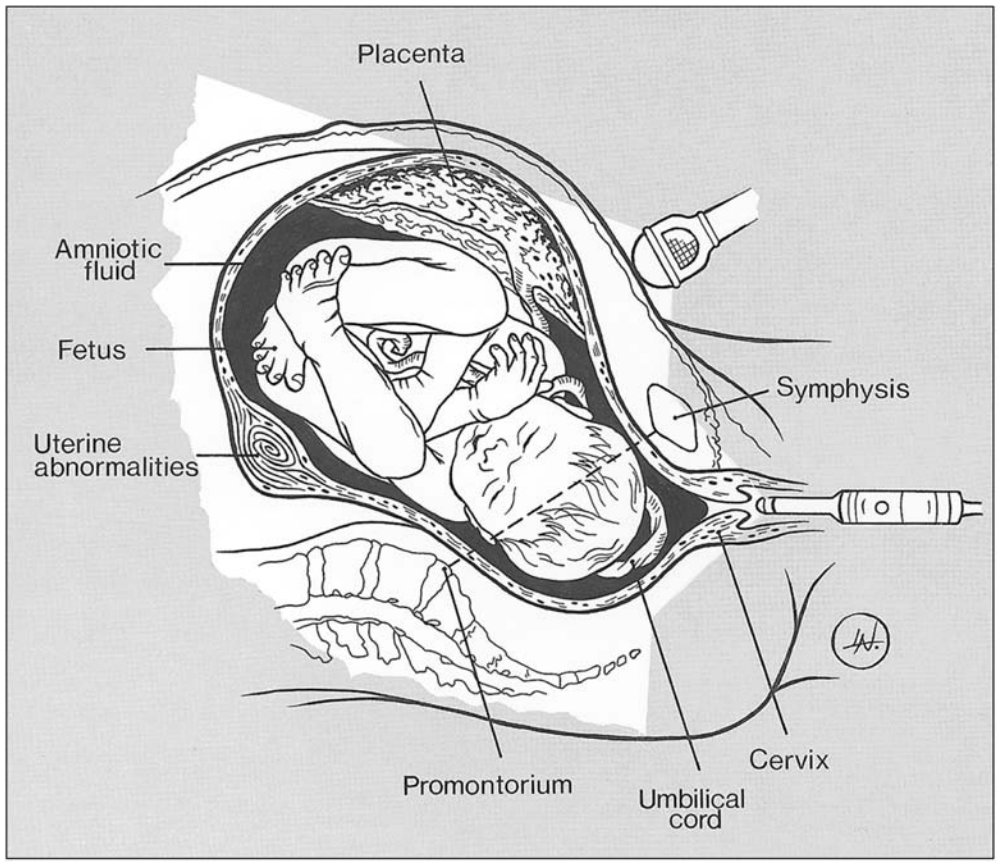

Figure 36.1 Potential use of intrapartum ultrasound.

Placenta location

Intrapartum vaginal bleeding and transverse lie are diagnoses in which ultrasound can be of assistance to confirm or rule out placenta previa or low-lying placenta. Prior to cesarean delivery, ultrasound can be an aid to locate the placenta and help to decide the type of uterine incision.

Intrapartum assessment of amniotic fluid

Ultrasound has made it possible to assess the amount of amniotic fluid. Several semiquantitative methods for evaluation of amniotic fluid volume, such as the largest vertical pocket and amniotic fluid index (AFI), have been published. A single largest vertical pocket of < 2 cm was labeled as oligohydramnios and a pocket of > 8 cm as hydramnios. Phelan and coworkers[4] described a four-quadrant method to measure the amount of amniotic fluid. A value of AFI < 5 cm was designated as oligohydramnios and a value of AFI > 24 cm as polyhydramnios. The umbilical cord and fetal limbs should be excluded from the measurement.[4–6] Since its introduction in clinical praxis, AFI has been widely accepted as an accurate method to estimate amniotic fluid volume. In antepartum surveillance, an AFI < 5 cm was considered to be associated with an increased risk of adverse pregnancy outcome and cesarean section for fetal distress.[7–9] Likewise, an intrapartum AFI < 5 cm was considered to be associated with neonatal metabolic acidosis.[5,10] Premature rupture of membranes, growth deficiency, postdate pregnancy and fetal renal anomalies are related to a reduced amount of amniotic fluid. A marked reduction in amniotic fluid increases the risk of cord compression and fetal death during labor, especially in postdate pregnancies.[6] Oligohydramnios in early labor should alert the obstetrician, and it is recommended that careful intrapartum surveillance be used. However, in the past several years AFI has been questioned as the appropriate method of defining oligohydramnios. Results from randomized trials showed that the use of AFI compared with the largest vertical pocket was associated with a significantly higher rate of suspected oligohydramnios.[11] The use of the test may increase interventions without improving neonatal outcome.[11,12] A meta-analysis of 42 reports found only one study that correlated intrapartum AFI with the rate of umbilical arterial pH < 7.00.[13]

Moreover, Moses[14] showed in a randomized study of 499 pregnancies that neither the AFI nor the single-pocket technique that was undertaken as a fetal admission test intrapartum identified a pregnancy that was at risk of an adverse outcome. As regards amnioinfusion for umbilical cord compression, in a

systematic review of 12 studies it appears to reduce the occurrence of variable decelerations, lower the use of cesarean section for suspected fetal distress and is associated with a reduction in puerperal infection.[15–17] Amnioinfusion can also reduce the incidence of meconium aspiration.[17,18] Hofmeyr[18] performed a systematic review of two studies of 285 women related to prophylactic vs. therapeutic amnioinfusion for oligohydramnios in labor. There is no advantage of prophylactic amnioinfusion over therapeutic amnioinfusion carried out only when fetal heart rate (FHR) decelerations or thick meconium staining of the liquor occurred.[18] Likewise, in one study of 66 women serial amnioinfusion for preterm rupture of membranes did not detect significant differences concerning cesarean section rate, low Apgar score or neonatal death rate. The author does not recommend the use of serial amnioinfusion for preterm rupture of membranes.[19] Ultrasound may be useful to monitor this procedure.

Fetal malformations

Preterm labor, breech presentations and multiple gestations imply an increased risk of fetal malformations. Ultrasound can be used to look for fetal malformations in these clinical situations. The detection of an unsuspected fetal malformation may change the obstetrical management.[20] Anencephaly or infantile polycystic kidneys have a dismal prognosis, and cesarean section should be avoided on fetal indications. The vaginal probe and a diagnostic amnioinfusion may permit a definitive diagnosis of bilateral renal agenesis or Potter syndrome with severe oligohydramnios. That diagnosis is not possible with the poorer resolution of the transabdominal (TA) approach.[21] In addition, color Doppler ultrasonography is useful to demonstrate the presence or absence of renal arteries. Diaphragmatic hernia as well as some structural or functional abnormalities of the fetal heart may require prompt surgical or medical treatment after delivery, so an accurate diagnosis before delivery is a prerequisite for appropriate neonatal management. Conjoined twins or sacrococcygeal teratoma may cause soft tissue dystocia, and cesarean section should be advised. In addition, ultrasound detection of a severe fetal malformation in preterm labor can exclude the need for tocolytic therapy.

Estimation of fetal weight

Accurate knowledge of fetal weight in early labor is important. Many clinical situations in an acute care setting require quick decision making, often based on estimated birth weight. Intrauterine growth retardation, preterm labor, post-term gestations, suspicion of macrosomia and twin and breech presentations are some of the clinical situations in which prediction of fetal weight may influence the management decision. Clinical estimation of fetal weight by abdominal palpation may be highly inaccurate, especially in the extremes of fetal size.[22,23] Since the introduction of ultrasound in obstetrics, a variety of equations using biparietal diameter (BPD), head circumference (HC), abdominal diameter (AD), abdominal circumference (AC) and femur length (FL) have been evaluated to find the most accurate way to predict fetal weight. It is now generally accepted that ultrasound estimation of fetal weight is more reliable than clinical estimation. Ultrasound has contributed to an improvement in estimation of birth weight,[22–26,29–31] although a few reports have questioned its accuracy.[27,28] The accuracy of ultrasound estimation of fetal weight is $\pm$10–15%. To avoid errors caused by a low station of the fetal head and molding or dolichocephaly in breech presentations, formulas based on FL and AC or adjusting BPD using cephalic index or HC should be used intrapartum.[24,25,29–32] In spite of inherent difficulties, the accuracy of intrapartum estimations of fetal weights performed by the house staff in a busy labor and delivery unit is comparable to that reported by more experienced examiners.[24,25] Furthermore, Pattersson[24] found that amniotic fluid volume, cervical dilatation or station of the fetal head did not influence the accuracy of intrapartum estimation of fetal weight.

Fetal well-being during labor

The biophysical profile (BPP)

Several methods for assessing the fetal well-being and identifying a fetus at risk of intrauterine death or injury have been evaluated. Manning[33,34] originally described the BPP. The ability to see the fetus, its activities and environment yielded the concept of the 'fetus as a patient'. The four components included in the BPP based on ultrasound parameters are fetal breathing movements, fetal body movements, fetal tone and AFI. A reassuring BPP score of > 8 confers a high probability of perinatal survival, and it accurately predicts antepartum umbilical venous pH.[34,35] FHR and fetal body movements are the most sensitive indicators of impending asphyxia antepartum. Oligohydramnios is associated with chronic fetal stress, and the absence of fetal body movements is predictive of impending fetal demise.[34] As labor progresses, a decrease in the fetal motor activity is a normal finding.[36,37] Fetal apnea is also a normal phenomenon during labor and has no adverse prognostic significance.[37] Sasson *et al.*[38] did not find a correlation between the intrapartum BPP and umbilical pH. Chua and coworkers[39] tried to select the best screening test to identify fetal compromise during labor. They concluded that women in early labor with an equivocal admission test should be assessed by an additional test like AFI, umbilical artery Doppler or vibroacustic stimulation, which might be of some help to detect a fetus with an increased risk of adverse outcome. Although observational studies[33–35,40] found that BPP score gives the best

prediction of both acute and chronic fetal compromise, a systematic review of RCTs (four studies of 2849 patients) do not support the use of the BPP as a test of fetal well-being in high-risk pregnancies.[41] However, the power of these studies is not strong enough to prove that the BPP score is without value.[42] Kim *et al*.[40] has recently found that cessation of any ultrasound component of BPP intrapartum significantly increased the risk of cesarean delivery and admission to the neonatal intensive care unit.

Intrapartum Doppler

Antepartum Doppler studies have shown an association between Doppler velocimetry and fetal well-being,[43] and the use of Doppler for antepartum surveillance in high-risk pregnancies can significantly reduce perinatal mortality in these cases.[43–46] The first intrapartum Doppler studies were performed with continuous and pulsed wave Doppler. Later, color Doppler and the transvaginal (TV) approach came into use. The most commonly examined vessels are the umbilical artery, uterine artery, fetal middle cerebral artery and aorta. There are three semiquantitative parameters that evaluate velocity waveform: pulsatility index (PI), resistance index (RI) and systolic/diastolic ratio (S/D). Uterine contractions, fetal breathing movements and frequent alterations in maternal position during painful contractions, as well as engagement of the fetal head in the bony pelvis, may make it difficult to get intrapartum Doppler signals.[47] Fairlie and colleagues[48] have, however, shown that the reproducibility of umbilical artery Doppler recordings during labor was comparable to the corresponding reproducibility from antepartum recordings. There is no significant change in the umbilical artery resistance during normal labor.[47–50] Neither amniotomy nor oxytocin infusion changes the umbilical artery resistence.[48] Likewise, epidural block with enough replacement has no negative effect on the S/D ratio.[51] Although Feinkind and coworkers[52] found that intrapartum screening with Doppler was sensitive enough to identify the fetus at risk of poor perinatal outcome, its use as a labor admission test is uncertain. At least two studies observed that intrapartum umbilical artery Doppler velocimetry is not a good predictor of fetal distress among unselected patients.[53,54]

Only in a high-risk population has a correlation been observed between the umbilical S/D ratio and umbilical cord pH.[48,52] The intrapartum umbilical artery S/D ratio might be of help in differentiating between variable decelerations caused by hypoxia or by mechanical occlusion.[55] It can also distinguish between true- and false-positive intrapartum late decelerations.[56] In the uterine arteries and their branches, a markedly reduced blood flow during normal labor has been noticed by several investigators.[47,49,51] Apart from intrauterine growth retardation and pre-eclampsia, preterm labor is also associated with a significantly higher uterine artery S/D ratio, probably due to decidual vascular abnormalities.[51] The few studies on fetal aortal blood flow have shown decreased flow during labor if intrapartum analgesia with pethidine and with a paracervical block were used.[47,57] In cases with no analgesia or with epidural blocks, an increased intrapartum fetal aortic blood flow was noted.[57] Doppler studies of fetal cerebral blood flow in labor may help to explain the pathophysiology of intrapartum asphyxia. Published data are, however, considerably controversial.[58–62] The aims of future investigations should be to elucidate the possible factors influencing the waveform pattern and the possible reasons for discrepancy in current reports.

Term and preterm premature rupture of the membranes (PROM, PPROM)

In cases of PROM, ultrasound assessment may be of diagnostic help in the labor and delivery unit. The amniotic fluid volume assessment, BPP and cervix status are ultrasound parameters of importance for evaluation of fetal well-being as well as for estimation of the conditions for induction of labor. To look for evidence of subclinical infection, a diagnostic amniocentesis may be performed. In patients with PROM, it has been shown that the overall BPP of the healthy fetus is not altered.[63,64] The most important parameters to evaluate fetal well-being are the amount of amniotic fluid and fetal breathing movements. Thus, PROM with severe oligohydramnios is accompanied by variable decelerations due to cord compression, an increased risk of metabolic acidosis, chorioamnionitis and a higher rate of cesarean section.[9,63–65] It seems that FHR alone and BPP are poor predictors of intrauterine infection. In a prospective study of 225 pregnancies complicated by PPROM with delivery between 24 and 32 weeks' gestation, AFI < 5 cm was the only significant risk factor independently associated with early-onset neonatal sepsis and chorioamnionitis.[66] Nowak also concluded that oligohydramnios might be associated with increased risk of chorioamnionitis.[67] While Vintzileos[68] recommended frequent estimation of the BPP as a simple test to predict the fetus at risk of developing sepsis, and questioned amniocentesis as a method to detect the fetus at risk of infection, Yoon[69] found amniotic fluid white blood cell count to be the best predictor of positive amniotic fluid culture, histological and clinical chorioamnionitis and neonatal morbidity. In a review of 12 studies, Hofmeyr found that amnioinfusion to prevent infection in women with membranes ruptured for more than 6 h was associated with a reduction in puerperal infection.[19] Amnioinfusion for umbilical cord compression in labor reduced FHR decelerations, cesarean section for suspected fetal distress, neonatal hospital stay > 3 days and maternal hospital stay > 3 days.[15] The assessment of fetal age, weight and presentation is important

when determining optimal management. Tsoi *et al.*[70] studied 101 women presented with preterm prelabor amniorrhexis. He measured cervix length by TV ultrasound and concluded that prediction of delivery within 7 days is provided by cervical length, gestation and presence of contractions at presentations.

Threatened preterm labor

More than 70% of the women presenting with threatened preterm labor do not progress to active labor and delivery. When confronted with a potential of preterm labor, ultrasound evaluation can provide important information, such as gestational age, fetal weight, presentation, BPP and the status of the cervix. Doppler velocimetry can detect cases associated with uteroplacental impairment. Severe fetal malformations and placental abruption should be excluded prior to the institution of tocolytic therapy. Gestational age and birth weight are the most important predictors of neonatal survival. None of the various formulas for estimation of fetal weight seems to have superiority when applied to preterm labor.[71] In very-low-birth weight fetuses, ultrasound estimation of fetal weight is very accurate and correlates with neonatal survival.[72] Fetal presentation can drastically change the delivery management. The value of the BPP to predict impending preterm delivery has been studied.[73] The individual biophysical parameters, especially fetal tone rather than the total score, demonstrate a strong relationship with the time interval to delivery.[74] It has been shown that the presence or absence of fetal breathing movements might be helpful in differentiating between true and false preterm labor.[73] Rising fetal prostaglandin levels during either term or preterm labor affect the fetal respiratory center, and provide a possible explanation for the cessation of fetal breathing movements during labor.[75,76] A recently published systematic review regarding the accuracy of absence of fetal breathing movements in predicting preterm birth confirmed that the absence of fetal breathing has the potential to be a useful test in predicting preterm birth both within 7 days and within 48 h of testing.[77] Future research is needed.

Cervical sonography allows determination of cervical length, funneling, the cervical index (funnel length + 1/endocervical length), originally described by Andersen and colleagues,[78] and dynamic changes in cervical anatomy.[79] With the TV approach, errors due to a low presenting part, maternal obesity or an overdistended bladder can be avoided.[80] The transperineal or translabial approach is a good alternative for departments where vaginal probes are not available in the labor and delivery suite. Prolapse of the amniotic sac through a dilated internal cervical os can also be observed and has been described as the 'hourglass membranes'.[81]

Although ultrasound assessment of the cervix seemed to be better than digital examination to predict preterm delivery,[78–83] qualitative analysis of nine studies using a cervical length cutoff of 18–30 mm showed that TV ultrasound assessment of cervical dilatation or length has poor predictive value.[84] The sensitivity for predicting preterm birth varied from 68% to 100% and the specificity ranged from 54% to 90%. In the most recently published studies of women with threatened preterm labor, cervical length cutoff of <15 mm seemed to have a higher probability to predict preterm delivery within 7 days.[85,86] Thus, sonographic measurement of cervical length helps to distinguish between true and false labor and to avoid overdiagnosis of preterm labor.[85,86]

Intrapartum vaginal bleeding

Two major clinical causes of vaginal intrapartum bleeding, which may require ultrasound expertise, are placenta previa and placental abruption. The TA approach may result in high false-positive (2–7%) and false-negative (2–8%) rates for placenta previa, depending on the time of scanning.[87,88] An overdistended bladder, maternal obesity, the posterior location of the placenta, the presence of fresh blood clots and an acoustic shadowing from the fetal head are the factors that make the diagnosis of placenta previa difficult. Considerable improvement has been achieved by TV ultrasound, where a false-positive rate of 1% and a false-negative rate of 2% have been observed.[87] The focal zone of the vaginal probe is 2–8 cm, which provides optimal imaging of the internal os. It is enough to insert the probe at a distance of 2 cm remote from the external os to avoid severe bleeding.

Tan *et al.*[89] studied the role of TV sonography in the diagnosis of placenta previa and performed TV sonography in 70 women diagnosed to have placenta previa by TA sonography. The diagnostic accuracy of the TV approach was 92.8%, compared with 75.7% for the TA route. They concluded that TV sonographic localization of the placenta is superior to the TA approach for types 1 and 2 placenta previa, but no better for types 3 and 4. TV color Doppler seems promising in the diagnosis of placenta previa accreta.[90,91] The ultrasound appearance of placental abruption can vary. A high false-negative rate is a problem. The normal anechoic retroplacental area with signs of venous flow identified by pulsed Doppler should not be interpreted as a placental abruption.[92] Nyberg *et al.*[93] reported results of 57 cases of placental abruption, retrospectively reviewed. The location of the hemorrhage was subchorionic in 81%, retroplacental in 16% and preplacental in 4% of the cases. The fetal mortality rate was 20% with a placental abruption including 20% of the placenta. The ultrasound findings varied with the size and location of the hematoma, as well as with the time of the sonogram. Furthermore, the risk of fetal demise was greater in retroplacental and preplacental cases than in cases with subchorionic hematoma. In most of the

cases with clinically suspected abruption, ultrasound findings are negative.[94] It is likely that the free passage of blood through the cervical os prevented the formation of a hematoma large enough to be visualized.[95] An acute hemorrhage is usually hyperechoic to isoechoic, and then gradually becomes anechoic during the following 1–2 weeks.[95,96] Rivera *et al.*[97] suggest that the use of ultrasound and non-stress testing in the expectant management of placental abruption could result in a decrease in maternal and perinatal mortality and morbidity. It must, however, be remembered that a negative ultrasound finding should not postpone essential treatment when there is a clinical suspicion of placental abruption.

Dystocia in early and late labor
