122 Management of small-for-gestational-age fetuses: antenatal and intrapartum strategies

J. M. Carrera, F. Figueras, R. Devesa and J. Mallafré

Introduction

There is increasing opinion[1] that small-for-gestational-age (SGA) fetuses is an heterogeneous condition that includes several etiologic and clinical groups, namely (i) abnormal SGA, fetuses whose smallness is secondary to chromosomal, structural or infective abnormalities; (ii) intrauterine growth restriction (IUGR), fetuses with impaired placental function; and, by exclusion, (iii) normal SGA, fetuses that represent the lower spectrum of the weight distribution of the normal population.

Since the etiology and prognosis is different, the management of each category should also be completely different.

It seems obvious that the best treatment we can offer a fetus with growth retardation, whose circulation and homeostasis are progressively deteriorating, is extraction at the most appropriate time. A suspected delay in fetal growth confers vital importance to the management of the pregnancy to avoid as far as possible the dangers that threaten its life and well-being. The prognosis can be significantly improved by good prenatal supervision, the early identification of the growth anomaly, the diagnosis of possible congenital defects, the early detection in the fetus of phenomena of adaptation and decompensation as regards hypoxia, and the appropriate interruption of gestation where necessary.

For the correct management of SGA fetuses, the following factors must be taken into account:

(1) Gestational age and fetal maturity: not only to decide on possible interruption of the gestation, but also to use the most appropriate control procedure (for example, the use of cardiotocography before week 30 of gestation has not proved very useful).
(2) Basic or associated medical pathology. Treatment of the underlying disease can improve the fetal condition and postpone any need for extraction.
(3) Type of growth retardation (see earlier chapter).
(4) Existence or otherwise of a congenital defect. The approach to a case can be completely transformed by the existence of a (chromosomic or malformative) congenital defect, especially if it leads to a poor prognosis.
(5) Presence or otherwise of oligohydramnios, a key factor for some authors: it can indicate a significant congenital defect or placental insufficiency in the decompensation phase.
(6) Results of fetal control tests. These are governed by the preferences or facilities of each clinic (echography, cardiotocography, acoustic stimulation test, fetal movements study, umbilical Doppler, fetal hemodynamic pattern, biophysical profile, etc.).

Other authors in this book have already discussed the prenatal diagnosis of SGA, its detection in patients not at risk, along with the methods for establishing the state or condition of the fetus for the gestational age. In this chapter, we concentrate on the possibilities currently available, or under research, to improve the prognosis for these fetuses, or gain time until they become sufficiently mature to be extracted.

Over the last 20 years a host of medical and pharmacological means of theoretically improving nutrition and the fetal condition have been attempted. The concept of intrauterine treatment of growth retardation is particularly appealing, although its results have been less than convincing.

Primary prevention

Primary prevention is only achievable if the causes of the disease are understood and risk factors are likely to be manipulated.

Genuine primary preventive strategies for SGA include: smoking cessation programs, antirubella vaccination, counseling for prevention of toxoplasmosis, prenatal diagnosis programs (contributes to the early discovery of a significant number of the congenital defects associated with SGA), strategies aimed at reducing the number of multiple pregnancies in women on assisted reproductive techniques, and, finally, primary preventive strategies for pre-eclampsia-mediated IUGR (sperm exposure, prevention obesity and insulin resistance).[2]

Secondary prevention

Secondary prevention is aimed at detection and treatment of the preclinical phase of a disease. Therefore, it requires the availability of methods of early detection and means of intervention and correction of the pathophysiological changes. Maternal serum screening has proved disappointing for IUGR: elevated levels of alpha-fetoprotein and human chorionic gonadotrophin are associated with IUGR but are a very poor screening test (sensitivity about 5%).[3] Since IUGR is caused by uteroplacental insufficiency, which is considered to be secondary to the spectrum of complications caused by poor trophoblast invasion, IUGR can be associated with an increased resistance in the uterine arteries. Doppler evaluation of this vessel constitutes the most promising screening method for IUGR. Evaluation of this tool has been hampered by different criteria for growth restriction and for abnormal Doppler waveform, by discrepancies in the targeted population and by differences in instrumentation (use of color Doppler, transvaginal vs. transabdominal approach) among the studies. Nevertheless, a recent multicentric and massive population-based study[4] aimed at evaluating the role of transvaginal uterine artery at 23 weeks, has demonstrated an overall sensitivity for growth restriction of 16%. Nevertheless, when the event of interest is the occurrence of disease requiring delivery before 32 weeks (which represents the subgroup with significant perinatal morbidity and mortality), the sensitivity for pre-eclampsia-associated and no-pre-eclampsia-associated growth restriction is 93% and 56%, respectively, with specificities of 95%. It would be appealing to move the screening into early pregnancy, but despite the fact that it seems a promising strategy for pre-eclampsia, the sensitivity of uterine artery Doppler evaluation in early second trimester for growth restriction requiring delivery before 32 weeks is only 28% (12% for growth restriction without pre-eclampsia).[5] Hence, it seems that uterine artery evaluation identifies a subgroup with an increased risk for developing severe growth restriction.

Nevertheless, in order to achieve secondary prevention ways to correct this preclinical phase are required. Since the spectrum of complications caused by poor trophoblast invasion is characterized by reduced endothelial production of prostacyclin and increased production of thromboxane A2 by platelets and the enzyme cyclo-oxygenase, which plays a central role in this pathophysiological mechanism, can be inhibited by aspirin. Oral administration of low-dose aspirin might prevent or delay the onset of placental insufficiency. In recent years, clinical trials evaluating the efficacy of uterine artery based screening strategies and treatment with aspirin in pregnancies that are at risk, have yielded discouraging results both with 150 mg[6] and 100 mg,[7] with no significant reduction in the occurrence of growth restriction. Despite the lack of evidence for the usefulness of this secondary prevention strategy, identifying pregnancies at risk, may enable a closer surveillance during the late second trimester and third trimesters.

Tertiary prevention

In IUGR, tertiary prevention should be aimed to minimize the complications of this disease, namely, fetal morbidity and mortality. Proper antenatal care is the most important part of tertiary prevention. Although several physical and pharmacological strategies have been suggested, it seems obvious that the best treatment we can offer a fetus with growth retardation, whose circulation and homeostasis are progressively deteriorating, is extraction at the most appropriate time. Tertiary preventive strategies can be roughly divided into those focused on treatment (therapeutic strategies) and those aimed at optimizing the delivery timing (obstetric management strategies).

Therapeutic strategies

Nutritive supplements to the diet

All the fetal substrates originate from the maternal circulation, which means that, in theory, the maternal administration of food supplements would be the most physiological therapy and benefit the fetus, since the supply of many nutrients depends on the concentrations in both circulations.

Nutritional supplementation is indicated whenever the usual diet of the mother is considered to be clearly deficient. In practice, this is the case when the daily intake of calories is under 2200.[8]

In contrast, nutritional supplementation is not indicated, and can not only be ineffective but even detrimental, when the supposed growth retardation is due to phenomena such as pre-eclampsia or placento-funicular malformations.

Lechtig and coworkers[9,10] observed not only an increase in maternal and fetal weight when they supplemented the inadequate diets of a group of undernourished mothers, but also a clear improvement in the proportions of growth retardations at the age of 36 months.

Other authors[11] recommend the administration of arginine, tyrosine and perhaps cysteine – all fetuses show a low capacity for compensating for their deficits – to mothers in zones where these are normally found wanting.

The administration of folic acid and vitamin B_{12} can also be suggested, owing to their involvement in the metabolism of nucleic acids.

Rahia therapy

This consists of measures based on hygiene, and particularly rest. The renal and uteroplacentary circulation increases in the prone position, and especially on the side, as the uterine contractility decreases. On the other hand, complete rest considerably reduces the expenditure of energy, and it is possible that some energy substrates normally used in muscular exertion may now be placed at the disposal of the fetus.[12]

It is important that this rest is taken in the lateral position. Goodlin[13] emphasizes that rest in the supine position can cause an aortic–caval compression and interfere in the placental circulation.[14] Mengert and coworkers[15] demonstrated that compression of the caval vein through tying or compression with the fingers (e.g., in the course of a cesarean operation) produced retroplacental hemorrhage. In contrast, complete rest in the lateral position improved the functioning of the placenta, as demonstrated by the increase in concentration of urinary estriol.[16] This is an innocuous and cheap measure that has been widely used in recent years. Hospitalization can be useful from week 30 of gestation.[17] Despite these observations, the only clinical trial[18] aimed at evaluating the effect of bed rest for suspected fetal growth restriction, which included 107 women, did not observe differences between bed rest and ambulatory management for fetal growth parameters and neonatal outcomes.

Perfusions of dextrose and amino acids

Maternal perfusion with solutions of dextrose (or glucose) has been suggested.[17,19–21] This therapy was introduced after the observation that maternal hypoglycemia was associated with an increase in the incidence of small-for-gestational-age fetuses.[22–24]

There is evidence that insulin levels are markedly increased in many mothers of fetuses with a low weight for the gestational age, especially in the postprandial phase.[25] It is highly possible that the low level of human placental lactogen (HPL) contributes, in many cases, to the excessive anabolism, considering the lipolytic properties attributed to it.

Grumbach and coworkers[26] have verified the anti-insulin activity of human chorionic somatomammotropin or HPL. The low level of placental production of HPL can therefore noticeably affect the continuous supply of glucose to the fetus and consequently its development. In this respect, Spellacy and colleagues[27] believe that a disorder in the regulation of the secretion of HPL can be considered as a factor that induces fetal growth retardation.

All these findings point to the theoretical benefit of infusions of dextrose or glucose in those patients with permanent hypoglycemia, as well as in others with relatively rhythmic hypoglycemia resulting from postprandial hyperinsulinism.[28–45]

This type of therapy is currently used less, owing to a basic pathophysiological consideration: fetuses with extrinsic growth retardation suffer not only from hypoglycemia, but also from hypoxemia and academia.[46–48] The administration of glucose to the mother (or directly to the fetus) can increase acidemia, causing further deterioration in the fetus,[43,49] and most clinics have therefore abandoned this measure.

It has been noted that plasma levels of maternal amino acids which are low during the third trimester of gestation or during birth are associated with infants with a low weight or reduced head circumference.[50,51] This has given rise to attempts to administer perfusions of amino acids to these pregnant women,[52–55] but protein supplementation also involves potential risks. High concentrations of some amino acids can be toxic: there is a proven relationship between high levels of certain amino acids in the fetus and mental retardation (maternal phenylketonuria), as well as premature births and perinatal deaths.[56]

Maternal hemodilution

Despite the fact that numerous studies on animals have demonstrated the benefits of maternal hemodilution to the uteroplacental blood flow,[57] it has only come into use relatively recently in human medicine.[58] The main arguments put forward for the introduction of this therapy in the treatment of IUGR are the following:

(1) There is a statistically significant positive correlation between the maternal plasma volume and the weights of the fetus and placenta in cases of idiopathic growth retardation.[59]
(2) Doppler study of IUGR shows that a significant decrease in the resistance indices of the uterine artery and the fetal arteries is produced in therapy with hemodilution.
(3) Maternal hemodilution produces not only an increase in plasma volume but also reduced viscosity in the blood and an antiaggregant platelet effect in some colloids.[58]

Despite its potential benefits, it must be stressed that hemodilution without complementary oxygen

therapy can strikingly increase the fetal oxygen deficit by decreasing its capacity for transportation.[60] This would explain some of the failures of this technique.[61]

A Cochrane meta-analysis[62] aimed at evaluating the effectiveness of plasma expansion for the treatment of growth restriction failed to find any study which fulfilled the quality standards to be included, concluding that there is not enough evidence to evaluate the use of plasma volume expansion for suspected impaired fetal growth.

Betamimetics

It has been established that the administration of uterus-relaxing betamimetics produces effects beneficial to the uteroplacental flow and the mother–fetus exchange[63,64] and to the possibilities of postnatal survival.[65,66] These effects are probably due to various causes:

(1) Increase in maternal minute volume due to the chronotropic or positive inotropic effect,[67–70] which implies an increase in uterine flow. This justifies a greater placental output, along with the increase in circulating glucose also produced.
(2) Moderate increase in the flow in the uterine artery, with a parallel decrease in its vascular resistance, and at the same time an increase in the diastolic velocities in the umbilical artery.[71–73]
(3) Relaxation of the uterine musculature, with an increase in fetal well-being and a facilitation of exchange.[74]
(4) Vasodilatation of the villous capillaries, enabling the fetal blood to be increased in the placenta. This, along with the increase in cardiac expenditure, implies an increase in placental–fetal blood flow which enhances exchanges, especially those based on simple diffusion. Renaud and coworkers[68] observed a significant increase in cervical circulation in cases of fetal hypotrophy after using ritodrine, although there were no appreciable differences in normal cases.
(5) Raised glucose levels, both in mothers and fetuses, due to the stimulation of glycolysis. This has been repeatedly observed during childbirth.[75–78]
(6) Activation of pulmonary maturing, with a significant increase in the lecithin/sphingomyelin ratio in the amniotic fluid.[79–81] This property makes possible the (not infrequent) premature extraction of the fetus.
(7) Activation of cerebral maturing. There is growing evidence that babies born from mothers treated with betamimetics present neurological reflexes appropriate to neonates of a greater chronological age.

Despite the irrefutable scientific evidence to support this therapy, its efficacy in practice is difficult to prove. On the other hand, it has been suggested that the vasodilating effect of betamimetics could not only lower the blood pressure, but also induce a decrease in plasma volume, thus worsening the fetal situation.[59]

A Cochrane review[82] of clinical trials aimed at evaluating the effect of betamimetics in growth restriction, which included two studies of 118 women, observed that no statistically significant differences were found between the betamimetic groups and the control groups for low birth weight (relative risk 1.17, 95% confidence interval, CI 0.75–1.83), other anthropometric measures or neonatal morbidity and mortality.

Sedatives

Some experimental studies[83,84] suggest that chlorpromazine dilates the myometrial vessels. The combination of this effect with the general sedation induced in the patient, which is propitious for rest, can endorse its administration, especially in cases of toxemia. It has been suggested that this beneficial effect is due to a momentary reduction in the cerebral consumption of oxygen, which makes it more resistant to hypoxia.

Heparin and anticoagulants

The activation of the processes of coagulation has frequently been described in cases of fetal growth retardation.[85,86] At the same time, it was discovered that, in some cases of preeclampsia, intravascular coagulation and fibrin deposition were produced in various organs, as well as in the placental intervilli spaces[87–90]; some cases of fetal growth retardation associated with preeclampsia are related to a depletion in the platelet levels in the maternal blood, resulting from intravascular coagulation in the placenta, which gives rise to a localized deposit of fibrin and platelets.[91–93]

These findings led to attempts to treat growth retardation with anticoagulants.[94] Some studies showed good results after treatment with heparin,[95–97] above all when the treatment was introduced early on (between weeks 32 and 36). The results after that were always poor.

For the proponents of this treatment, heparin not only plays a preventive role, but also cures vascular parietal lesions by reducing the placenta's aggregating capacity and breaking up fibrin deposits. (Moreover, heparin has the advantage of not crossing the placental barrier.)

It is also possible to use low-molecular-weight heparins (sodium enoxaparine), which apparently do not cross the placental barrier when used in the second to third trimester of gestation, despite their low molecular weight.[98,99]

Acetylsalicylic acid

There are conclusive proofs that the reduction in uteroplacental perfusion and disturbances in the villous microcirculation are connected to an imbalance in the production of prostacyclin and thromboxane.

A host of studies over the last few years have demonstrated that acetylsalicylic acid at low doses irreversibly inhibits platelet cyclo-oxygenase, thus reducing thromboxane synthesis but without modifying the production of prostacyclin (PGI_2) of endothelial origin.[100–103] Owing to this irreversible inactivation, the inhibiting effect is accumulative with repeated doses, with the result that daily doses of 30–50 mg of aspirin provoke a complete suppression of the synthesis of platelet thromboxane in 7–10 days.[104]

A balance between thromboxane and prostacyclin is thus attained in both the maternal and the fetoplacental circulations, the vascular reactivity to the vasomotor agents is normalized and platelet aggregation is inhibited. It is still not completely known how aspirin acts.

For some authors, the reported effect depends on the dosage: low doses (100 mg) permit the inhibition of platelet cyclo-oxygenase without affecting the endothelial enzyme.[103,105] This ability to select the action is eliminated if the dose is increased.[103]

For others,[106,107] aspirin has been found to have a trophoblast-derived inhibitor action that permits the inhibition of the placental synthesis of thromboxane and the establishment of the physiological balance of prostaglandins.

Sibai and coworkers[108] and Pedersen and Fitzgerald[109] have shown that 20 mg of aspirin produces inhibition of platelet cyclo-oxygenase activity and permits the biological detection of salicylemia, but that the systemic concentrations of the salicylates induced are insufficient for stimulating the acetylation of endothelial cyclo-oxygenase.

The administration of aspirin at low doses results in:

(1) The modification of the synthesis of prostaglandins in the maternal circulation[100,101,108] and in that of the fetus[100–108];
(2) The modification of vascular sensitivity to angiotensin[105]; and
(3) The inhibition of platelet adherence to collagen, in conditions of stasis or slow blood flow.

In other studies[110,111] dipyridamol was also introduced as a complement; this inhibits phosphodiesterase, which impedes the degradation of cAMP, with an aggregant and vasodilatory effect (principally mediated by prostacyclin).

A significant decline has been noted in the incidence of delayed growth, with an increase in the weight of neonates born to mothers at high risk of IUGR,[110–112] irrespective of the use of dipyridamol. In contrast, differences were found with this treatment in the Italian study,[113] although this work is open to a number of methodological objections.

Another effect of therapy with aspirin at low doses (between 60 and 100 mg/day) is the reduction of the incidence of pre-eclampsia in women with a high risk of suffering from this, owing to their obstetric history,[114] an increased sensitivity to the pressor action of angiotensin II,[93] or anomalies in the Doppler scans of the uterine arteries.[115] However, further studies are required for definitive validation of these opinions.

A recent Finnish prospective randomized study on first-trimester low-dose aspirin administration in patients with abnormal uterine artery blood flow showed encouraging prevention of pre-eclampsia.[116] Although the rate of IUGR was not significantly affected there are several arguments that support the use of low-dose aspirin in high-risk pregnancies that are identified through abnormal uterine artery Doppler. The safety of aspirin in pregnancy has been documented in a large number of patients.[117] The severity of IUGR may be decreased[118] and a decline of maternal delivery indications for pre-eclampsia is likely to decrease the preterm delivery rate. Placental disease with severe IUGR may be the first manifestation of previously undiagnosed underlying thrombophilia.[119]

Atrial natriuretic peptide

The atrial natriuretic peptide (ANP) is an endogenous peptide with diuretic, natriuretic and vasodilatory properties.[120] It is synthesized in the right atrium. It has been reported that ANP is capable of provoking vasodilatation of the placental circulation in animals.[121]

In the animal model, the administration of ANP to guinea pigs in which IUGR was induced by the ligature of the uterine artery[122] significantly increased the blood flow to the placenta.

The concentrations of ANP in fetuses with IUGR are significantly higher than in fetuses with normal growth, suggesting an adaptive fetal response in an attempt to increase the blood flow.[123] Furthermore, it has been demonstrated that there are up to 80% fewer receptors for ANP in the arteries of placentas in IUGR compared to those of normal fetuses, which could demonstrate that an alteration in the placental receptors for ANP would be the etiopathogenic basis for some IUGR. More data should be obtained in this respect in the future.

Sexual steroids

Some obstetricians administer varying doses of progesterone and estrogens on a completely empirical basis.

Several authors[124–129] showed some years ago that progesterone reduces the excitability and contractility of the myometrium muscular fiber, thus contributing to uterine relaxation.

In fact, as Beydoun and coworkers have shown,[130] progesterone treatment on ovariectomized rabbits is capable of significantly increasing the fetal and placental weights through hyperplasia. Other studies have presented similar results with synthetase analogs.[131,132]

It must be remembered, however, that therapy with steroids can inhibit the fetal pulmonary surfactants. In fact, nowadays there is very little support for the continued use of sexual steroids for this indication.

Oxygen therapy

Oxygen is an essential component for fetal growth: a 20–40% oxidative metabolism is required to provide

the energy necessary for fetal growth.[133,134] In fact, it seems that hypoxemia must be the cause of the retarded growth observed in mothers who are carriers of hemoglobinopathy, cyanotic cardiopathy and asthma, or who live at very high altitudes, as occurs in animals subject to hypobaric hypoxemia.[135–137] Those fetuses with retarded growth on whom funiculocentesis was performed[138] revealed a partial pressure of oxygen lower than that of normal fetuses.

All the available studies refer to an intermittent administration of oxygen (10–120 min), which increases fetal respiratory movements[139] and active movements[140] and provokes a notable improvement in fetal circulatory distribution[141,142] as well as lower perinatal mortality.[143]

However, no studies have been able to demonstrate that this is useful in improving fetal oxygenation during pregnancy when it is carried out discontinuously, as it inevitably has to be.[144] On the contrary, there is evidence that it can reduce oxygenation by producing a uteroplacental vasoconstriction.[145,146] This side effect could be avoided by the supplementary administration of vasoactive drugs. Betamimetics would probably perform this task. Moya and coworkers[147] reported two cases of severe neonatal depression due to the alkalosis produced by hyperventilation during anesthesia.

Further arguments against oxygen therapy are:

(1) Oxygen increases the use of glucose and therefore aggravates hypoglucemia[148];
(2) Oxygen therapy increases cerebrovascular resistance and decreases peripheral resistance, which prejudices cerebral oxygenation and hypoglycemia[142]; and
(3) There is no evidence that oxygen therapy increases fetal growth or improves the transportation of nutrients across the placenta.[141]

Nowadays the administration of oxygen is considered to be justified only in those cases in which the 'oxygen test' was positive. This test consists of observing whether velocimetric changes are produced in the fetal aorta after administration of oxygen. If there is a notable increase in the diastolic velocities, oxygen therapy is indicated.[142]

A Cochrane meta-analysis,[149] aimed at evaluating the effectiveness of oxygen therapy in growth restriction, which included three randomized studies with 94 women, observed a significant reduction in perinatal mortality (relative risk 0.5; 95% CI 0.32–0.81) when compared with placebo. Nevertheless, a greater gestational age in the treatment group might introduce a bias which could account for the differences.

Intra-amniotic therapy

Various studies have stated that the supply of nutrients to the human fetus is restricted by growth retardation; autopsies have demonstrated a decrease in the reserves of glycogen and fat similar to that in undernourished children.[150] For this reason, the intra-amniotic injection of amino acids and glucose has been suggested for attempting to improve the nutrition of the fetus.[151–156]

There has been some debate as to whether the absorption by the fetus of the products deposited in the amniotic cavity takes place through diffusion across the amnios or through deglutition, digestion and absorption in the fetal digestive tract. Even when the former route is secure, experiments in cases of anencephaly,[157] with albumins marked with ^{131}I or with ^{51}Cr[158] demonstrate that digestive absorption is probably the preferred route.[159–161]

Experimental studies in animals have demonstrated that amino acids and proteins injected into the amniotic fluid are not only consumed by the fetus through absorption in the digestive tract,[159,162–164] but also passed on through the placenta and the umbilical cord.[153,165–167] For this reason, there is a marked increase in the weight of the placenta after intra-amniotic feeding.[168]

Overall, the studies on various animal species demonstrate that the supply of amino acids and glucose to the fetus can improve the fetal prognosis, regardless of the route used (intra-amniotic, intragastric or intravenous[159,162,164,168–171]). In contrast, the provision of lipids not only fails to enhance fetal nutrition but can also prove deleterious by aggravating the IUGR and respiratory difficulties.[172]

Repeated amniotic puncture multiplies the risks and complications, even more so in the frequent cases of severe oligohydramnios. Infection and premature birth are still more problematic, as the fetus itself is at stake.

Apart from the risks inherent in the technique, the administration of an excess of glucose can provoke a decrease in the fetal arterial oxygen content,[165,166,173] owing to the fact that glucose induces an increase in the consumption of fetal oxygen, as well as provoking lactic acidosis. This risk is greater if its administration is performed directly, as discussed below.

Direct administration of nutrients to the fetus

Various studies in animals have demonstrated the efficacy of this method. The direct administration to the stomach or intestine of sheep[174,175] of glucose and amino acids by means of a catheter rapidly increased their levels in the fetal blood, and produced an increase in weight in those fetuses previously experiencing delayed growth brought on by a limited maternal diet.[171] There is also an account of direct intravenous administration[176] which correlated the fetal weight with the daily concentration of nutrients administered.

There is only one case report of direct administration of nutrients in humans. Saling[177] administered amino acids and vitamins over 9 days by means of an intraperitoneal catheter to a fetus with growth retardation at 33 weeks of gestation, after which a spontaneous birth occurred without complications.

This treatment route requires a more complete experimental basis to demonstrate its efficacy in the face of its evident drawbacks, to make its evaluation possible in humans.

Intermittent abdominal decompression

This technique, first described by Heyns and colleagues[178] and recently modified by Shimonovitz and coworkers,[179] attempts to improve uteroplacental blood flow and, as a result, fetal oxygenation.

It consists of an adjustable plastic garment on a rigid support with a decompression mechanism that induces a decrease in the pressure round the maternal abdomen. Shimonovitz and coworkers[179] reported good results with intermittent applications of a negative pressure of 70 mmHg over 30 s at 1-min intervals, for a total of 30 min twice a day. An analytical overview of the studies published on this topic up to that point[180] reported a significant reduction in perinatal mortality.

Blecher[181] measured the placental blood flow before, during and after decompression, and noted that on 50% of occasions there was an increased blood flow, and this was particularly noticeable during decompression. Other authors[182–186] have also observed an increase in blood flow in cases with placental insufficiency on the flow curves, along with improvements in various hormonal tests. This technique could therefore produce an improvement in uteroplacental blood flow that could last for a certain time afterwards, provided that the placenta is not too insufficient.

Although this procedure has been virtually discarded in Western Europe, it is still practiced in Eastern European countries in the treatment of chronic fetal afflictions.[187,188] The recommended method is as follows: treatments of 8–10 h overall, made up of applications of 30–60 min/day (2 atm).

Pharmacology of prostacyclin/thromboxane balance

The work of Clark and coworkers[189] in animal experimentation demonstrates a clear increase in the blood flow in the uterine artery after the intra-arterial administration of prostacyclin, although this has not always been confirmed afterwards.[190,191] It does not therefore seem that the administration of prostacyclin can be useful for this purpose.

As regards thromboxane synthetase inhibitors, Van Assche and coworkers[192] have used dazoxiben, a product that inhibits the production of thromboxane A_2 in some cases of pre-eclampsia. The conditions under which it was applied (small number of patients, late administration) do not make it possible to draw any conclusions.

Nitric oxide liberators

The maternal administration of glyceryl trinitrate (GTN), an agent that releases nitric oxide, is capable of improving both the uterine and the umbilical circulation; this is verified in practice by a significant reduction in the pulsatility indices of both arteries.[193,194] This pharmacological action is especially evident in the cases of growth retardation associated with pre-eclampsia.

The pathophysiological explanation lies in the fact that pre-eclampsia gives rise to a reduction in the activity and production of nitric oxide, which has negative repercussions on the uteroplacental circulation. The GTN administered to the mother exerts a direct action firstly on the uterine vasculature, provoking its vasodilation and improving the provision of oxygen and nutrients to the intervillous space, and secondly on the villous microcirculation, thus also provoking vasodilatation here. In theory, the administration of GTN would be indicated in all those cases of growth retardation associated with pre-eclampsia in which the nitric oxide test (sublingual administration of 0.3 mg of GTN) has previously proved positive (decrease at 30 min of maternal blood pressure and the pulsatility indices in uterine and umbilical arteries).[195] However, further studies are required to determine whether this therapy is free of risks and proves capable of persistently improving uteroplacental vascular insufficiency in the cases mentioned. Until such studies are undertaken, the administration of GTN can be used as a diagnostic, but not a therapeutic tool.

Immunological treatment

It is theoretically possible that the inhibition of the secreting activity of B lymphocytes or the blocking of the peripheral action of immunoglobulins could occasion an improved fetal outcome in gestations that are complicated by the presence of antiphospholipid antibodies.

Edelman[196] reported on the administration of corticoids in 22 cases and noted a normalization of the plasma levels in anticardiolipin antibodies in 80% of pregnant women. Several authors[197–199] have recorded the results obtained from the administration of intravenous gamma-globulin in pre-eclamptic patients with fetuses with growth retardation and antiphospholipid antibodies. There is no question that the treatment reduced the plasma levels of these antibodies, but it is not clear whether it improved the clinical picture. The mechanism of action of the gamma-globulins is still open to debate.

Pharmacology of cerebral observation

Barbiturates were proposed some years ago[84] as a means of momentarily reducing the cerebral consumption of oxygen and, therefore, the vulnerability of this organ to hypoxia. Since then the majority of studies have shown that these drugs have very limited value in the intrauterine prevention of cerebral lesions.[200]

Our present-day understanding of the cellular consequences of hypoxia enables us to hold out some hopes for the *in utero* prevention of posthypoxic cerebral lesions, when fetal extraction – which continues to be the most expeditious therapeutic measure – is still not possible or has to be postponed owing to other circumstances.[201]

There are four possible pharmacological strategies: the avoidance of: (1) increased intercellular calcium; (2) excessive release of amino acid exciters; (3) pathological arachidonic acid cascade; and (4) oxygen free radicals.

Increase of intercellular calcium. An increase in intercellular calcium is the first biochemical link in the chain of events leading to neuronal death. This could theoretically be avoided, although only partially, by means of the administration of calcium channel antagonists, such as nifedipine, which has proved to be effective in the avoidance of local infarcts in rabbits,[202] flunarizine, which apparently provides a certain degree of cerebral tissue protection in rat fetuses afflicted by hypoxia[203,204] and lidoflazine, which, when administered in sheep after the hypoxic ictus, improved the prognosis of these lesions.[203]

The most promising of all these drugs is apparently flunarizine, since it has the most favorable action on the cerebral circulation and crosses the placental and hematoencephalic barriers with ease. However, these findings remain to be confirmed in human species and the administration strategy needs to be determined (before, during or after the hypoxic episode).

If the blockage of the calcium channels were to prove effective, this treatment could impede the subsequent activation of the phospholipases and the amino acid exciters, as well as the release of free fatty acids.

Excessive release of amino acid exciters

The avoidance of the release of, for example, glutamate or aspartate, can be achieved by pharmacologically inhibiting the receptors of certain amino acids (competitive antagonists).

The experimental use of rats and sheep has confirmed the neuropreventive possibilities of a broad-spectrum excitatory-amino-acid receptor antagonist, kynureic acid, which attenuates the cerebral lesion by up to 35%; an *N*-methyl-D-aspartate antagonist (N-receptor), MK-801; a glutamate release inhibitor, BW1003C87, which reduces the cerebral lesion by up to 50%; and, finally, an a-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor antagonist, identified as NBQX, which induced a reduction of 28%.[205,206] These antagonists can be used before or immediately after the hypoxic–ischemic ictus.[207]

Alternatively, non-competitive antagonists, such as phenciclidine, dextromethorphan or magnesium sulfate, have also been used. Propentophylline, which attenuates the excess of amino acid exciters, seems capable of reducing cerebral lesions by 28%. All these products have been used on various experimental animals (rats, cats, rabbits, sheep, lambs) with encouraging results, as already indicated, since their administration before and/or after provoked hypoxia significantly reduced neuronal lesions and the appearance of postischemic accidents.

Some of these drugs, such as BW1003C87, seem to play only a neuroprotective role if they are administered before the hypoxic ictus. The cerebral lesions in these cases are reduced from 98% to 45%.[206]

The drug with the most future appears to be MK-801 because, apart from its therapeutic actions, it easily crosses the placental and blood–brain barriers. However, more information is required on its potential toxicity[208] and its effects on the human fetus.

Pathological arachidonic acid cascade. Avoidance of this would reduce both the production of oxygen-derived radicals and the prejudicial effects of prostacyclin/thromboxane imbalance. Both these aims could theoretically be met by administering prostaglandin synthetase inhibitors and inhibiting cyclooxygenase with products such as indomethacin. Encouraging experiments have been carried out on adult animals (dogs, rats, cats), showing that the administration of indomethacin before the ischemic ictus improves postischemic reperfusion.[209] There are also well-known data on its gestational administration in the prophylaxis for premature births, because of its effects on the closure of the ductus arteriosus, the regulation of breathing and the reduction in amniotic fluid.

Indomethacin has recently been used at low doses as a neuropreserver in underweight neonates. It apparently achieves a significant reduction in the incidence of intraventricular hemorrhages, with no further consequences.[210] More information is required on its use in the fetus with this specific indication.

Another theoretical measure for avoiding prostacyclin/thromboxane imbalance could consist of the administration of the former at therapeutic doses. However, the studies available have not shown any appreciable benefits.[211]

Oxygen free radicals. Avoidance of these could be achieved either by eliminating their production or by eliminating their deleterious derivatives.

The first goal could be attained either by blocking xanthine oxidase, which catalyzes the degradation of hypoxanthine, or by inhibiting the lipid peroxidation that gives rise to the destruction of membranes. Alopurinol has been used in the first case, and has proved effective to some extent in the avoidance of cerebral edema in rats submitted to overall ischemia. The inhibition of peroxidation part can be attempted with 21-aminosteroids (U7400GF), although there is little information on this possibility.

The elimination of free radicals in animal experimentation has been attempted by two types of products: enzymatic antioxidants such as superoxide dismutase and catalase, and the free radical 'scavengers', a very heterogeneous group of drugs, which include methionine, mannitol, ascorbic acid and tocopherol.

The administration of the above-mentioned antioxidants before the hypoxic ictus has proved capable,

in the fetuses of both dogs and rats, of improving cerebral blood flow and the somatosensory potentials.[212]

However, at the moment, the use of vitamins C, E and C+E[213] has provided no *in vitro* evidence of any effect on lipid peroxidation or placental perfusion in normal placentas and patients with pre-eclampsia.

Finally, Gutteridge's group[214,215] also highlights the extracellular antioxidants, which include metal-bound proteins (transferrin, lactoferrin, haptoglobin, hemopexin, etc.), 'iron-oxidant proteins' (ceruloplasmin) and extracellular 'scavenger' proteins[216,217] such as extracellular superoxide dismutase and glutathione peroxide. The principal function of the extracellular antioxidants seems to be the deactivation of the catalysts needed for the formation of oxygen free radicals.[218,219]

Some studies[220,221] suggest that some malformations in diabetes can have as their pathogenic mechanism the excessive generation of oxygen free radicals, activated by a high concentration of glucose. It would thus be possible, at least experimentally, to avoid the teratogenic effect by means of the administration of free radical scavengers.[221,222] However, we lack documented information on their usefulness and lack of risks, and this prevents us from attempting to administer them in human gestation.

Obstetric management strategies

The association between IUGR and increased perinatal mortality, morbidity and impaired long-term neurodevelopmental outcome has received considerable attention in recent years. There is general acknowledgement in this pathology of a sharp increase in the cases of intrapartum fetal distress, the risk of neonatal depression (low Apgar scores), meconium aspiration and acidosis.[223] On the other hand, several studies[224–228] have shown that the ante- and intrapartum fetal mortality rate is significantly greater in small-for-gestational-age fetuses than in premature fetuses matched for weight.

Finally, the respiratory distress syndrome, necrotizing enterocholitis, intraventricular hemorrhage and periventricular leukomalacia have been reported to be increased in preterm growth restricted neonates.[229]

Since there is no effective fetal therapy for growth restriction, timing of delivery is an essential issue in the management of these fetuses. Delay could increase hypoxia and affect brain development, but early delivery carries the dangers of prematurity and the associated risk of cerebral palsy. During the last 30 years, obstetricians have been searching for a tool to prenatally predict these events of critical importance.

Decision to terminate gestation

A multicentric randomized controlled trial, the Growth Restriction Intervention Trial (GRIT),[230] aimed at comparing the effect of delivering early with delaying birth for as long as possible, has been recently published. A total of 588 fetuses between 24 and 36 weeks were randomized to immediate delivery or delayed delivery until the obstetrician was no longer certain. The study observed that when obstetricians were uncertain about timing of delivery, they were prepared to vary the timing by about 4 days, and although such delay caused some stillbirths, earlier delivery resulted in an almost equal number of additional deaths. Moreover, at 2 years of age, there was a trend toward more disability in the immediate delivery group. Although this study did not provide a detailed clinical guidance on the exact point at which compromised fetuses should be delivered, it stressed the critical importance of delivery timing. Arterial and venous Doppler parameters, biophysical variables and fetal heart rate analysis are used for this purpose. In addition, others factors such as maternal complications (especially in pre-eclampsia), severity of growth restriction, neonatal resources, parental opinion and, overall, gestational age, complicate the decision-making in those fetuses. Although the order in which alteration of Doppler and biophysical parameters take place has been clarified in recent studies,[231–233] the existing wide variation in policies is not surprising.[234]

Gestations in which systematic delivery cannot be justified. Various situations can be included in this category:

(1) Gestations with fetuses that are small for gestational age but normal. As already explained, these fetuses have a moderately low genetic growth potential, but are normal. They represent the lower spectrum of growth normality. From the biometric point of view, they are found in the lower centiles but their weekly increases are satisfactory, when using appropriate longitudinal standards to evaluate growth velocity.
(2) Fetuses with malformations or chromosomal anomalies. The strategy followed depends on the type of anomaly, the gestation period and the decision of the parents. When abortion is feasible, parents must be informed of this option. If the gestation follows its course (late diagnosis, refusal to interrupt), its management must be based on observation, irrespective of the fetal maturity or the results of tests to control the fetal condition. Each case must be studied and managed on its individual merits, with the opinion of the parents taken into account.
(3) Gestations with fetuses with an apparently IUGR, but which do not present oligohydramnios and have normal tests of fetal well-being. In these cases vigilant observation should be carried out, in strict accordance with each particular unit's control criteria (twice-weekly non-stress test, weekly echographic control, Doppler umbilical examination, oxytocin or funiculocentesis test if there are any doubts).

Gestations requiring delivery. The interruption of gestation must be normal practice, provided the fetus is viable (mature fetus or in the transitional maturing phase), in the following cases:

(1) Detention of fetal growth over a period of 3 weeks (evaluated with appropiate longitudinal standards) with pathological cerebroplacental ratio and likely fetal lung maturation.
(2) Presence of oligohydramnios (echograpic examination) or meconium amniotic fluid (amnioscopy) and likely fetal lung maturation.
(3) Doppler (persistent venous abnormal flow, reversed end-diastolic flow in the umbilical artery) or biophysical (persistent altered biophysical profile, silent or decelerative cardiotocography) criteria suggesting fetal decompensation and acidosis.
(4) Study of fetal blood biochemistry (funiculocentesis) indicating an irrefutably pathological acid–base balance.

The theoretical aim of the interruption is the extraction of the fetus before the centralization of the fetal blood flow reaches an advanced phase and can injure the fetus. In this regard, it is important, if Doppler is available, to follow the evolution of the hemodynamic changes taking place in the fetus (covered in other chapters in this book).

When the fetus is immature, an attempt must be made to accelerate its maturation by the usual means (administration of corticoids, etc.). Preterm IUGR/ARED fetuses exhibit divergent cardiovascular responses to prenatal steroids. Intensive Doppler-based fetal monitoring may identify a subset of fetuses prone to decompensation after maternal steroid administration. When abnormal venous Doppler studies are found, delivery may be more appropriate than steroids.[235] It must be remembered that the risks from IUGR can be intensified with prematurity.[236] If gestation has not reached 28 weeks, the decision to expel the fetus involves risk. The decision of whether to interrupt the gestation or not must always be studied in the light of each particular case.

In contrast with the classical statement that growth-retarded fetuses have an accelerated pulmonary maturation, current observations have suggested a higher incidence of respiratory distress in those fetuses when compared with preterm neonates with normal weight.[237] The study of the amniotic fluid in these fetuses shows a high quantity of surfactants and lipidic cells. However, it is possible that in some cases there is a delay, as a result of placental insufficiency, in the maturing of type II fetal alveolar cells, which are responsible for the production of surfactants.[238,239] Furthermore, it must be remembered that labor, and even some hours with broken membranes, improve the surfactant content in the amniotic fluid.

When we studied our practice of terminating gestations in our unit, we noted that our strategy has changed substantially over the last 20 years. In the first 5 years (1976–80) the number of births with a spontaneous onset was 70.3%, but by the last period this had been reduced to less than half this figure (28%), with a parallel increase in the number of inductions, and particularly in the number of elective cesarean sections.

Management and timing

Though clear guidelines supported by strong evidence cannot be provided, protocols for management of SGA fetus may be developed according to current knowledge. Although some recent management protocols have been published,[240,241] our local protocol is as follows:

(1) SGA (estimated fetal weight below the 5th centile with normal cerebroplacental ratio and normal uterine artery Doppler flow): excluding infectious and genetic causes, the perinatal results are good. Delivery should only be indicated for obstetrics or maternal factors. Weekly BPS and fortnightly Doppler evaluation should be performed.
(2) IUGR with normal fetal well-being tests (estimated fetal weight below the 5th centile with abnormal cerebroplacental ratio or uterine artery Doppler flow): weekly Doppler and BPS 2 times /week should be performed. Delivery beyond 37 weeks or when pulmonary maturity is proven could be considered.
(3) IUGR (estimated fetal weight below the 5th centile with abnormal cerebroplacental ratio or uterine artery Doppler flow) with significant blood flow redistribution (absent or reversed end-diatolic flow in the umbilical artery):
    a. beyond 34 weeks: deliver
    b. between 32 and 34 weeks:
        i. REDV: steroids and deliver in 24–48 h
        ii. AEDV: steroids, daily Doppler and BPS
    c. below 32 weeks: steroids, daily Doppler and BPS
(4) IUGR (estimated fetal weight below the 5th centile with abnormal cerebroplacental ratio or uterine artery Doppler flow) with proven fetal compromise (persistent increased ductus venosus waveforms pulsatility, low short-term variability in cardiotocography or oligohydramnios):
    a. beyond 32 weeks: deliver
    b. below 32 weeks: hospital admission, steroids, daily Doppler and BPS/8–12 h
(5) IUGR (estimated fetal weight below the 5th centile with abnormal cerebroplacental ratio or uterine artery Doppler flow) with fetal decompensation (persistent absent or reversed a-wave in the ductus venosus or persistent pulsatile

Table 122.1 Means of initiating birth in our unit during two different periods: 1976–80 and 1990–94

	1976–80	1990–94
Spontaneous onset (%)	70.33	28.2
Induction (%)	20.00	39.8
Elective cesarean section (%)	9.06	31.9

Table 122.2 Means of terminating birth in our unit during two different periods: 1976–80 and 1990–94

	1976–80	1990–94
Vaginal route (%)	84.19	55.5
Cesarean section (%)	16.80	44.4

umbilical vein + persistent BPS < 6/10, decelerative cardiotocography): deliver at a tertiary care center. In the subgroup under 28 weeks, each case should be evaluated by a multidisciplinary committee composed by an obstetrician and a neonatologist with experience in those cases, and taking into account the opinion of the parents: expectant management could be an option is these extremely preterm and compromised fetuses.

Elective route of birth

The literature reiterates the finding that two-thirds of fetuses with growth retardation can tolerate the stress of birth perfectly well, and, therefore, they are delivered by the vaginal route. A cesarean section should be performed in only one-third of gestations.[242,243] This is true in principle (Table 122.l) but in our present experience the total number of cesarean sections is 44.4% (Table 122.2). Nowadays, in most hospitals the number of cesarean sections in this category has gone up to 30–50%.[223,242,244]

The decision between induction of the birth or a cesarean section must be made on the basis of various criteria, especially: fetal condition (phase of fetal adaptation to hypoxia, decompensation phase), special obstetric features (parity, fetal presentation, pelvic and cervical conditions) and gestational age.

Generally speaking, the following situations lead towards an elective cesarean section

(1) IUGR in the phase of fetal adaptation to hypoxia (e.g. incipient centralization of blood flow, normoamnios or moderate oligohydramnios, abnormal uterine artery waveforms) with poor obstetric conditions;
(2) IUGR in the phase of fetal decompensation irrespective of obstetric conditions;
(3) SGA fetuses with malformations capable of causing mechanical dystocia (e.g., hydrocephaly, voluminous teratomas); and
(4) Progressive deterioration of the maternal condition (e.g., cardiopulmonary diseases, kidney diseases).

A recent study,[245] aimed at evaluating the prospect of vaginal delivery of growth-restricted fetuses with abnormal umbilical artery blood flow and negative oxytocin challenge test, has observed that the vaginal delivery rate was significantly lower in the abnormal flow group compared with the normal flow group, but in cases finally destined for a trial of labor the vaginal delivery rates were similar. There was no indication that any fetus was exposed to detrimental hypoxia or distress. These results should encourage obstetricians to perform trials of vaginal delivery when there is no unanimous indication for cesarean delivery.

Means of inducing birth

Once the decision has been made to interrupt the pregnancy through induction, this must be planned in the light of the fetal condition. It must be remembered that the reserves of glycogen and fat are severely depleted in a fetus with growth retardation, which has a greater or lesser degree of uteroplacental insufficiency. The hypoxic stress derived from labor can give rise to a rapid depletion of the scanty fetal reserves. This makes it necessary to establish an anaerobic defense metabolism, with subsequent metabolic acidosis.

For this reason, the induction of birth must be meticulous and avoid any hyperstimulation. In our unit we remain loyal in these cases to induction through amniotomy and the administration of oxytocin with a continuous perfusion pump.

The induction begins with a dose of 0.5 or 1 mU/min, which is doubled every 20 min until theoretically effective uterine dynamics are attained (three to four contractions every 10 min). The dosage is stabilized at this point, but with the maintenance of the infusion rhythm necessary for maintaining satisfactory dynamics. In the event that there is no sign of fetal distress, the drip is continued for 12 h. If the active period of the birth is not reached during this time, the induction must be considered a failure and a cesarean section will be decided upon.[244,246]

The administration of intracervical prostaglandins in order to mature the neck before the instillation of the oxytocin infusion is a procedure that we rarely use in this pathology, since resorting to it can produce hyperdynamics and secondary alterations to the fetal heart rate.[244,247,248]

Over the course of the last 5 years in our unit, something over a third of the inductions in growth retardation have terminated in expedient cesarean sections, owing to intrapartum fetal distress or failed induction; these figures are similar to those reported by other authors.[249]

Intrapartum control

Owing to the frequency of placental insufficiency in fetuses with growth retardation, causing a genuinely chronic fetal distress, it is clear that birth represents an excessive stress for many of them. For this reason, labor, whether begun spontaneously or induced, must be controlled by continuous cardiotocographic monitoring, at first externally and then internally when cervical conditions permit it. Any significant anomalies in the findings must be followed up with biochemical control, as in any other high-risk gestation.

The intrauterine pressure of the contractions is similar to that of a normal gestation,[250,251] therefore any alterations in the FCF observed in growth retardations during delivery are not conditioned by anomalies in the uterine dynamics. The presence of a higher number of these anomalies can be attributed to the frequent oligohydramnios and to the higher number of inductions (with their familiar iatrogenesis).

As regards the cardiotocographic readings, in our experience there are no significant differences (with respect to a control group) in the baseline of the FCF, or in the early decelerations; in contrast, the percentage of contractions that generate late decelerations is significantly greater in the group with IUGR, above all in the dilatation period. This has been endorsed by other authors.[252] These characteristics of the outline of the FCF explain why clinical control of the birth proves insufficient, since the baseline of the FCF remains practically unaltered.

As for the determinations of pH carried out during birth in our last series, on 10% of occasions the pH was less than 7.20; on 27.5% it ranged between 7.20 and 7.25, and on the remaining occasions (62.5%) surpassed the figure of 7.25. The figures for pathological and prepathological pH easily surpass those of any control group of normal births. It must be borne in mind that we performed 31.9% of elective cesarean sections on account of abnormally low fetal respiratory reserves. These figures are also very similar to others that are on record.[252]

This acute fetal distress is mostly a simple intensification of preexisting chronic fetal distress. For this reason, extrinsic (or type II) growth retardations, which generally have a vascular uteroplacental cause, exhibit differences in behavior during birth that are statistically significant with respect to other intrinsic (or type I) retardations.

The intensification of this chronic fetal distress is probably produced by different mechanisms:

(1) Exhaustion of the placental functional reserves due to spontaneous or induced contractions;
(2) Greater fetal vulnerability through the lack of subcutaneous fat and peripheral vasoconstriction motivated by the redistribution of blood towards more vital zones; and
(3) Reduction in the quantity of Wharton's jelly in the umbilical cord, which reduces its tonicity and facilitates its prolapse and compression.

Recently, a study[253] aimed at evaluating the role of pulsioximetry in growth-restricted fetuses, have found that fetal pulse oximetry is reliable, according to umbilical cord blood measurements and Apgar scores, reducing cesarean deliveries in cases of non-reassuring cardiotocographic patterns in those fetuses.

Obstetric anesthesia

Of all the various types of anesthetic procedures, it seems to us that peridural anesthesia is the most satisfactory in cases of growth retardation. This type of anesthesia avoids the administration of analgesics, anxiolytics and spasmolytics which are capable of depressing the fetus, and it is particularly useful in the frequent cases of association of toxemia and fetal growth retardation. In addition, it makes biophysical and biochemical monitoring more tolerable for the mother.

It must be taken into account that a fetus with IUGR has greater sensitivity to general anesthesia, owing to its hypoproteinemia. This characteristic, which means that the drug does not leave the general circulation with the same speed as normal, can occasion an increase in its concentration in the central nervous system, and this is translated into an increase in the number of neonatal depressions.[242,244] Furthermore, it seems that the hepatic capacity to metabolize the drug is also diminished, and there is a degree of renal incapacity for its elimination.

It also does not seem advisable to use paracervical anesthesia, as it is well known that this increases the number of bradycardias.

123 Growth-restricted newborns: characteristics and management

R. Baraibar and L. Sánchez

In order to provide correct postnatal care for low birth weight infants, it is important for the neonatologist to have adequate information on the antenatal history of a fetus affected by intrauterine growth restriction (IUGR). This includes the time at which IUGR was identified, the evolution and characteristics of cephalometric parameters, the presence of congenital anomalies or chromosome abnormalities, maternal diseases and toxic habits, uteroplacental function, hemodynamic changes (Doppler abnormalities in the umbilical or fetal circulation) and antepartum or intrapartum signs of fetal distress (characteristics of the amniotic fluid, abnormal fetal heart rate patterns or changes in blood pH).

The terms 'intrauterine growth restriction' (IUGR) and 'small-for-gestational age' (SGA) are related but not synonymous. IGUR refers to a process that causes a reduction in an expected pattern of fetal growth. This process results in an attenuation of fetal growth potential. SGA refers to an infant with a birth weight lower than a predetermined cut-off value.

Management in the delivery room and neonatal resuscitation

The birth process represents a risk situation for SGA infants, so the presence at the delivery of personnel trained in neonatal resuscitation (ideally, a neonatologist) is essential for many of these babies. The 'normal' SGA infant with smallness of a presumably genetic origin would probably not require any specialized care. The fetus would be born in good condition and the baby would remain with the mother, with the same protocols of perinatal care followed as for normal appropriate-for-gestational-age (AGA) infants.

For proper management of SGA infants with congenital defects, it is desirable that discussions are held between the parents and the obstetric team beforehand, about the possible postnatal viability of the fetus and the expected management after the birth, according to the evidence of prenatal studies (ultrasound pattern of congenital defects, fetal karyotype). It might be decided to avoid resuscitation maneuvers in cases of some chromosome abnormalities or multiple congenital anomalies associated with severe physical defects or neurological dysfunction. A complete and careful neonatal examination, however, is required to confirm morphological anomalies associated with the chromosomal defect. A thorough fetal postmortem examination would also be required.

In cases of less severe congenital defects, management will vary in relation to the characteristics of each type of malformation. In the hypotrophic SGA infant, the higher probability of perinatal asphyxia and meconium aspiration should be taken into account, as well as the early appearance of hypothermia, hypoglycemia, acidosis and anemia/polycythemia. Neonates with congenital infections may present a highly compromised clinical condition (hydrops, coagulation disorders, heart failure, liver failure, etc.) and may require aggressive resuscitation. However, others may be asymptomatic. Isolation measures will be necessary for some SGA newborns with viral infections.

Immediate neonatal examination

The SGA infant should undergo a careful physical examination, especially when reliable information on the circumstances of gestation is not available. This includes the following:

(1) Infant's weight and height, measurement of head circumference and ponderal index$_1$ with calculations on a population-based weight/gestational-age curve. It is useful also to know paternal height, because it has been shown that very low paternal height has an influence on the weight and height

of the neonate[1] [ponderal index = (weight × 100)/height^3], where weight is in grams and height is in centimeters.

(2) Clinical evidence of malnutrition, when possible accompanied by measurement of the quadriceps skin-fold thickness and the mid-arm circumference. It is well known that the greatest severity of malnutrition produces the highest occurrence and intensity of clinical manifestations (asphyxia, hypoglycemia, hypocalcemia and polycythemia) in the neonatal period.[2–4]

(3) Description and careful recording of major and minor congenital defects. An attempt should be made to recognize clinically relevant associations, sequences or syndromes.

(4) Clinical evidence of intrauterine malnutrition: the hypotrophic SGA infant frequently appears as an 'alert' neonate – thin, dry, with soft tissue wasting, the eyes open and the skin desquamated and wrinkled and sometimes covered or impregnated with meconium. The extremities seem to be more lengthy, with large hands and feet. Occasionally, the skin color is plethoric, but in cases of perinatal asphyxia it may appear pale, owing to peripheral vasoconstriction. In all cases, data of the physical and neurological examinations in combination with reference tables,[5] should be used for assessing the gestational age of the newborn infant.

Other tests that should be considered include the following: for non-hypotrophic SGA infants, karyotyping, skeletal radiographic survey and complete ultrasound screening (heart, brain, abdomen) for SGA infants with congenital defects; serum immunoglobulins, serological tests for congenital infections, investigation of cytomegalovirus in urine and DNA testing if specific intrauterine infections are suspected (cytomegalovirus, toxoplasm). Further tests are acid–base balance, serial serum glucose levels, calcium, hemogram with erythroblast count, coagulation tests, serum creatinine and liver enzymes for hypotrophic SGA infants.

Main clinical symptoms of SGA newborns

Perinatal asphyxia

It is well known that IUGR associated with placental insufficiency causing malnutrition and chronic hypoxia places the fetus in a condition in which stress derived from even an uncomplicated birth cannot be properly supported. Lin and colleagues[6] have shown statistically significant differences in Apgar scores at 1 and 5 min and mean pH values between AGA and SGA neonates. Thornberg and coworkers[7] have reported a series of 42,203 live infants in which the population of SGA babies was clearly overrepresented in the birth asphyxia group. Following the recommendations of the American Academy of Pediatrics, the American Heart Association[9] and European Resuscitation Council,[10] it is very important to ensure that all necessary equipment and personnel trained in neonatal resuscitation are present at the delivery of growth-restricted babies. It is necessary to have results available of acid–base status in umbilical cord vessels during resuscitation and glucose levels during the first minutes of life, in order to determine the exact requirements of oxygen, bicarbonate and glucose.

Although some of SGA infants requiring neonatal care suffered from postasphyxia metabolic acidosis, restoration can frequently be achieved by oxygen therapy, adequate ventilatory support and prevention of heat loss. Bicarbonate administration should be limited to patients with laboratory evidence of sustained metabolic acidosis and decreased blood pH levels. Spencer and associates[11] have shown that, in severely acidotic term newborns not requiring resuscitation, SGA infants showed less improvement than AGA babies of the same gestational age. In the SGA group, spontaneous rise of pH was slower, and there was a smaller fall of the $PaCO_2$ with no changes in base deficits. Since respiratory and heart rates did not differ between AGA and SGA infants, the clinical observation did not identify babies who were less efficient at compensating for acidemia.

Serial sampling is required for the monitoring of blood glucose. Rapid and uncontrolled infusion of hyperosmolar glucose solutions, particularly in preterm SGA babies, should be avoided. Simmons and coworkers[12] found that, in uteroplacental insufficiency states, glucose transport is differentially altered in the lung and brain of SGA fetuses. Although glucose transport was decreased in type II pneumocytes, lung fibroblasts and lung tissue, glucose transport was not altered in brain tissue and glial cells; this may contribute to the phenomenon of 'brain sparing'.

Clinical symptoms of hypoxic–ischemic damage in SGA neonates can be assessed similarly to those in AGA babies. In general, 0.26% of the SGA newborns had abnormal neurological symptoms on neonatal examination. These figures, however, may vary across studies in relation to the suitability of perinatal care. The risk of neurological sequelae correlates better with late Apgar scores and severity of neurological symptoms than with early Apgar scores. Meconial aspiration, pulmonary hypertension (secondary to asphyxia and aggravated by polycythemia), and acute hemorrhagic pulmonary edema are more common in hypotrophic SGA groups than in the general population.[13] Treatment of hypoxic–ischemic encephalopathy, pulmonary hypertension and meconial aspiration is described in Chapter 7.

Neonatal hypoglycemia

The incidence of hypoglycemia in SGA infants is extremely variable, depending on different factors, such as the severity of intrauterine malnutrition

Table 123.1 Treatment of hypoglycemia in small-for-gestational-age infants (hypoglycemia = glycemia of < 30 mg/dl in full-term infants, < 20 mg/dl in preterm infants and < 40 mg/dl in term newborns after the first 24 h of life

Asymptomatic newborn infants
(1) Attempt oral feeding (bottle, oral tube) with 5–10% dextrose solution or sugar-fortified hypoallergenic milk formula, 10 ml/kg. Control serum glucose levels at 30–60 min
(2) Remember that 10% solutions are hyperosmolar and may be poorly tolerated
(3) Consider the intravenous route initially when birth weight is < 1500 g, oral intake is poorly tolerated or there are symptoms

Symptomatic newborn infants
(1) Preferably use the intravenous route: 0.25–1 g/kg (2.5–10 ml/kg) of 10% dextrose; also: 1–4ml/kg of 25% dextrose (higher concentrations are inadequate) at a rate of 12 ml/min
(2) Continue at a rate of 4–8 mg/kg per min of 5 to 10–15% glucose solution according to fluid requirements, tolerance and infant's condition
(3) Add sodium and chloride after the first 12 h and potassium after the first 48 h when superimposed deficiencies are not present
(4) Do not give glucagon. The indication of corticoids (hydrocortisone 5 mg/kg per day orally or intravenously, or prednisone 2 mg/kg per day orally) is exceptional

Note: Measurement of blood sugar levels by means of colorimetric strips should not be used for diagnostic purposes and only for the systematic screening of infants at risk. Results obtained should be confirmed by laboratory assay of plasma or serum glucose concentrations. Glycemia in whole blood is 15 mg/dl lower than in plasma or serum

(expressed as birth weight < 3rd centile, ponderal index < 10th centile and skin-fold thickness < l0th centile); associated perinatal complications (e.g., asphyxia); suitability of clinical control of the neonate during the first hours of life; and early oral or intravenous glucose supplementation. In different studies, the incidence of neonatal hypoglycemia varied between 40% and 67% in preterm SGA infants and between 10.7% and 24% in full-term SGA babies.[14,15] Singhal and coworkers[16] demonstrated that SGA babies had a sevenfold increased risk of manifesting hypoglycemia compared with AGA babies, and approximately two-thirds of the hypoglycemic babies had one or more risk factors, including birth asphyxia (24%), diabetic mother (24%), respiratory distress (14%) and septicemia (12%). Other contributing factors are hypothermia and inadequate neonatal transport. In this study, carried out in New Delhi,[12] a total of 60% of SGA babies were asymptomatic, although it has been established that babies with few symptoms and moderate hypoglycemia may be followed by adverse neurodevelopmental outcome.[17] The most common symptom observed was lethargy (81%), jitteriness (67%), respiratory abnormalities (42%), hypotonia (40%) and seizures (30%).

The etiopathogenetic mechanism of hypoglycemia in SGA infants involves a marked decrease in the energy reserves that are the substrates of gluconeogenesis and glycogenolysis.[19] Treatment of hypoglycemia demands adequate administration of glucose (Table 123.1).[20,21] In the SGA infant, however, there is a defect in the intermediate metabolism of this substrate administered postnatally.[22] Glycerol, lactate and amino acids (alanine) are sources of glucose production in case of glycogen deficiency. In the SGA neonate, these substances are increased even in the presence of hypoglycemia; this indicates a deficiency or abnormality of gluconeogenic liver enzymes, in particular phosphoenolpyruvate carbokinase. Although other enzymatic inducers of gluconeogenesis, such as glucagon and catecholamines, may also be reduced in SGA babies, the administration of glucagon to correct low blood sugar levels is not considered appropriate in these infants with reduced glycogen stores.[23,24] Intravenous hydrocortisone, which would decrease the peripheral consumption of glucose by decreasing insulin levels and increasing alanine production, may be useful in extreme situations,[25] provided that a sufficient amount of proteins is concurrently infused.

In contrast to the hyperinsulinism found in newborns from diabetic mothers, hypoglycemia in SGA babies progresses during the first hours of life unless SGA has been accompanied by severe malnutrition, prematurity or perinatal asphyxia, in which case blood sugar levels decrease immediately and rapidly after birth. Serial sampling over the first 24–36 h is required for prompt detection of hypoglycemia and intervention. Special attention should be paid to babies being breast fed or when facilities for monitoring blood sugar are unsatisfactory or unavailable.[26] In these cases, the eventual oral intake of 5% water–dextrose supplement or sugar-fortified hypoallergic milk formulas until sufficient milk secretion is produced and normal glucose levels are attained should be recommended.

Hypocalcemia

A higher incidence of hypocalcemia in SGA infants than in AGA babies has not been clearly established.

Sator-Kulic[27] showed normal values of serum calcium ions in SGA infants on the first and the third days after birth. Only hypotrophic SGA infants or neonates who have suffered from perinatal asphyxia would have a higher incidence of low serum calcium levels. In these cases, calcemia should be determined within 12 and 24 h after birth. Routine assay of serum calcium in asymptomatic full-term SGA infants is not required.

Hypothermia

The hypotrophic SGA neonate has a greater cephalic volume and total body surface in relation to his or her weight, so that there is a greater heat loss than in the AGA baby. In the full-term SGA infant, in contrast to the preterm AGA infant, radiant and convective heat losses may be reduced by the ability to diminish body surface area by a flexion posture of the extremities. Although the term SGA infant has a greater thermogenic capacity than peers of the same weight and lower gestational age, this is established at the cost of caloric expenditure that cannot be maintained for a long time.[28] The scarce subcutaneous fat prevents correct thermal insulation, and the scarce brown fat stores prevent a correct response to the initial cold stress. Therefore, prompt and complete drying of the infant after birth, and wrapping in thermal paper after resuscitation, maintaining the baby under a radiating heat source, is crucial.

Nourishment problems: necrotizing enterocolitis

The need to feed the hypotrophic SGA infant early, together with a frequently complicated perinatal period, imposes demands on the bowel that often cannot be satisfied. Although some studies[29] have not found differences in the gastric residual volumes of breast milk between healthy preterm SGA and AGA infants with gestational age of 28–36 weeks, vomiting and regurgitation are sometimes observed in hypotrophic term SGA babies orally fed at high rates with milk or glucose.

Perinatal asphyxia causes a redistribution of blood flow to different organs with relative ischemia in some. Mesenteric ischemia together with tissue hypoxia and hyperviscosity, especially in the very early preterm hypotrophic SGA infant, predisposes to necrotizing enterocolitis (NEC). Several studies demonstrate a trend toward an increased incidence of this entity.[30,31] In the study by Kurscheid and Holschneider,[32] 30% of the 73 patients treated for NEC were SGA infants. In these cases, feeding (in the form of elementary formulas) should not be started until the achievement of a stable hemodynamic status, absence of gastric retention, normal abdominal palpation and spontaneous passage of meconium. In the Vermont Oxford Nerwork (VON) study, including 19,759 very low birth weight (VLBW) neonates prenatal corticosteroid use was not associated with decreased risks of NEC.[33]

A potential protective role against NEC of different feeding strategies, like use of breast milk or continuous vs. bolus feeding in preterm and SGA newborns has been suggested but not evidence based.[34,35]

Preterm SGA infants have higher metabolic rates than AGA babies because of their faster growth rate and larger brain size.[36] In addition, they absorb dietary nutrients less well, particularly fat and proteins. It has even been shown that, in term SGA infants,[37] serum concentrations α-lactalbumin are significantly higher than in AGA infants of similar gestational age. This indicates that IUGR causes a delayed postnatal decrease in macromolecular absorption and delayed intestinal maturation.

To satisfy caloric requirement, 150 cal/kg/day should be reached from the seventh day of life.

Studies on iron status in infants of low birth weight[38] have shown that, at birth, preterm AGA infants had higher serum ferritin concentrations than preterm SGA babies. Preterm infants who were not supplemented with iron, irrespective of their adequacy for gestational age, showed evidence of iron deficiency before 4 months of age.

With respect to the effect of IUGR on postnatal weight change in preterm infants, Bauer and associates[39] reported significantly higher weight loss and body water loss during the first week of life in preterm AGA infants than weight-matched preterm SGA babies. Loss of weight and total body water in AGA infants was accompanied by a greater diuresis than in SGA infants at the same amount of fluid intake. Fluid requirements of full-term SGA infants are 80–90 ml/kg on the first day of life, reaching 10–150 ml/kg/day after the first week. Fluid requirements in preterm SGA babies, however, should be calculated daily and individualized according to the presence of associated conditions and the type of heat source under which the baby is maintained.

Cerebral hemorrhage and ischemic brain damage

In a study of the impact of prematurity and IUGR on neonatal hemorrhagic and ischemic brain damage, carried out by Amato and colleagues,[40] a higher incidence of peri- and intraventricular hemorrhage (IVH) in the AGA group (36.8%) than in SGA babies (18.5%) was reported. In both groups, however, a significantly higher incidence of cerebral hemorrhage was found in babies of <1000 g in body weight compared with babies of >1000 g in body weight. Ischemic brain lesions (periventricular leukomalacia) were equally distributed between AGA and SGA babies (10.5% vs. 3.7%) independently of body weight category.

If only extremely low birth weight babies are considered, most of studies have demonstrated a greater incidence of IVH in SGA newborns compared to AGA ones. According to the VON data comparing SGA and AGA VLBW neonates,[33] the odds ratio in SGA was 1.13 for IVH and 1.25 for severe IVH. In this case, the prenatal use of steroids seemed to have a protective role.

Respiratory distress syndrome and other prematurity-related pathologies

Although initial studies suggested that IUGR-related fetal stress would protect SGA infants against severe respiratory distress syndrome (RDS) by stimulating fetal lung maturity,[41] recent investigations do not seem to confirm this.[30,42,43] Thompson and colleagues[44] compared neonatal ventilatory requirements and outcome in 135 very early preterm SGA infants to those from controls matched for gestation age and gender. Although there was no significant difference in the median duration of mechanical ventilation, more SGA infants required ventilation and were ventilated because of RDS. However, in a subgroup also matched for mode of delivery, differences between the two groups were not encountered. Ley *et al.* have shown a higher incidence of RDS among preterm SGA infants born before 29 weeks gestation with the use of fetal growth standards, based on ultrasonically estimated fetal weights, but not in SGA infants born between 29 and 32 weeks' gestation.[45] In the large VON cohort,[33] RDS is also slightly increased (odds ratio 1.19) in SGA born before 30 weeks of gestation compared to AGA of the same gestational age.

In the study of Schiff and colleagues,[43] 127 pre-eclamptic women who had undergone amniocentesis for pulmonary maturity assessment were matched for gestational age, sex, race and infant gender with non-hypertensive women with preterm labor who had undergone the same procedure. There were no significant differences between SGA and AGA infants born to women with pre-eclampsia in comparison with their matched controls in the incidence of an immature result and respiratory distress syndrome.

In VLBW infants (less than 1500 g or born before 30 weeks' gestation), the condition of being SGA seems to confer also an additional risk of other prematurity-related morbidities,[33–45] like ductus ligation, chronic lung disease and retinopathy of prematurity.

Polycythemia and coagulation disorders

It is well known that chronic tissue hypoxia induces an increase in plasma erythropoietin concentration in human fetal life and this response stimulates fetal erythropoiesis. Increased plasma erythropoietin concentrations in SGA fetuses have been documented as early as 26 weeks' gestation.[46] The degree of increase was significantly associated both with fetal acidemia and, more strongly, with fetal erythroblastosis. Furthermore, a more accurate assessment of tissue oxygenation in SGA newborns may be obtained by determining the erythroblast count rather than blood pH values. Perinatal asphyxia and placental vascular changes may cause disturbances in placental–fetal exchange, which may induce changes in the total blood volume and subsequent deterioration of the hemodynamic status. The risk of manifesting polycythemia (hematocrit > 65% in peripheral blood) in SGA infants was between threefold[18] and 25-fold[47] greater compared with AGA babies (0.5%). Although about one-third of polycythemic infants had one or more symptoms, on neurodevelopment follow-up the development indices of both asymptomatic and symptomatic cases were found to be comparable.[47]

In healthy preterm SGA neonates, no correlation was seen between serum levels of vitamin K_1 and plasma levels of coagulation factors II and X. After the administration of 1 mg vitamin K_1, no accelerated increase in coagulation factor activities was seen.[48]

Kupferminc and colleagues studied the increased prevalence of inherit or acquired thrombophilias in woman with mild severe IGUR. The trombophilias significantly increased were factor V Leiden mutation, prothrombin gene mutation and protein S deficiency.[49]

Biochemical, metabolic and compositional changes in SGA infants are shown in Tables 123.2 and 123.3.

Mortality

The perinatal mortality rate among IUGR infants is 10–20 times the rate among AGA infants.[58]

Compared with AGA babies, fetuses affected by IUGR have a higher risk of death antenatally, whereas SGA infants have a higher risk of death in the neonatal period. Although the perinatal mortality of SGA babies ranges between 50% and 60%, their neonatal mortality is lower than that of preterm AGA infants of the same weight. When crown–heel length was used to classify growth patterns,[59] proportionate IUGR with short crown–heel length had a significantly greater mortality than disproportionate IUGR infants with normal crown–heel length. When the ponderal index was used for classification, there were no statistically significant differences in mortality between the two groups. At present, however, actual mortality rates are difficult to assess, given that pregnancy termination is a frequent decision in severely malformed fetuses with harmonious IUGR diagnosed antenatally; the majority of fetuses with normal karyotype and harmonious IUGR are healthy infants. IUGR due to uteroplacental insufficiency with adequate perinatal obstetric control should have mortality rates in such infants hardly higher than those of AGA infants.

In a study of 28-day survival rates of 6676 neonates with birth weights of 1250 g or less,[60] predictors of survival in descending order of significance in the multivariate analysis were gestational age and birth weight,[61,62] sex, race, single birth and SGA. In the study of Kilpatrick and colleagues,[63] singleton SGA neonates had a significantly greater perinatal mortality than twin SGA neonates matched for gestational age at delivery at 30 weeks or more. The effect of birth weight discordance in preterm twin gestations was studied in 122 live born twin sets delivered between 25 and 30 complete weeks' gestation.[64] Preterm twin gestations with > 30% birth weight discordance were associated with a higher incidence of infant death (25%), congenital anomalies (37.5%), SGA infants

Table 123.2 Biochemical and metabolic changes in small-for-gestational-age infants (modified from Babson and Kagas[50])

Carbohydrate and fat metabolism
Neonatal hypoglycemia
No changes in K_t (rate constant for glucose metabolism)
Decreased, increased or no change in insulin
Decreased, increased or no change in free fatty acids and glycerol[51,52]
Decreased or no change in *b*-hydroxybutyrate
Decreased hepatic gluconeogenesis
Decreased urinary epinephrine after hypoglycemia
Decreased levels of HDL-cholesterol, reduced activity of lecithin: cholesterol–acyl transferase[153]
Decreased insulin-like-growth factor-II (IGF-II)[53]
Increased lactate, pyruvate, alanine and glucagons
Increased or no change in ketone bodies
Increased levels of VLDL and lipoprotein lipid content[51]
Increased levels of IGF-I and IGF-binding protein-1[54,55]

Proteins and collagen
Decreased or no change in total protein and prealbumin
Decreased OH-proline turnover early and increased later
Decreased N-terminal propeptide of type III procollagen[56]
Increased ammonia, urea and uric acid
Increased uronic acid turnover

Immunocompetence[57]
Decreased IgG
Decreased humoral or cellular bactericidal capacity
Decreased phagocytic index
Decreased lysozyme
Decreased humoral and cellular immunocompetence
Increased IgM in some cases

Hematology
Increased hematocrit, erythroblast (H.l) count, erythrocytic volume and viscosity
Increased fetal hemoglobin
Increased erythropoietin
Increased, decreased or no change in prothrombin and partial thromboplastin time
Increased reticulocyte index but no change in reticulocyte count
Decreased platelets

Miscellaneous
Decreased serum ionic calcium
Decreased, increased or no change in amniotic fluid L/S ratio
Decreased, increased or no change in O_2 consumption
Increased cortisol or ll-OH corticosteroids
Increased or no change in human growth hormone

Table 123.3 Compositional changes in small-for-gestational-age infants (from Babson and Kagas[50])

Placenta
Decreased or no change in weight and DNA
Decreased, increased or no change in RNA
Decreased heat-stable alkaline phosphatase, glycogen, glucose and oxygen use
Decreased fibrinolysis (urokinase pathway)
No change in protein/DNA
Increased or no change in RNA/DNA, nitrogen or protein
Increased RNA polymerase, protein synthesis from proline and leucine and increased aromatization, glycogen use

Liver
Decreased weight and glycogen
No change in DNA and protein/DNA

Muscle
Decreased protein and fat
Decreased, increased or no change in total water and extracellular water
Decreased, increased or no change in DNA
Increased intracellular water
Decreased RNA, RNA/DNA, protein/DNA
Decreased zinc, potassium, magnesium and increased sodium

Brain
Decreased weight, especially cerebellar
Decreased cerebellar DNA, myelin lipid, galactolipid sulfotransferase and glucosaminoglycans

Heart
No change in DNA and protein/DNA
Decreased sarcoplasm and glycogen

Adrenals
Decreased fetal zone

Water
Increased total body water, extracellular water, intracellular water and plasma volume

(32%), Apgar score of < 7 at 5 min (33%) and periventricular leukomalacia (17%). The gestational age rather than the degree of discordance is a predicting factor for less favorable neonatal outcome.[65,66] Jacobs and colleagues,[67] using the 1995–97 Centers for Disease Control and Prevention's Matched Multiple Birth file, examined the association between increasing intratriplet birth weight discordance and risk of fetal death and smallness for gestational age and found also a positive association if the discordance was greater than 29%.

The main causes of death in full-term SGA infants included perinatal asphyxia, congenital anomalies and diseases related to poorly controlled metabolic problems, whereas in preterm SGA infants these were RDS, HIV infection and NEC.

Somatic growth disorders

Growth of SGA infants with chromosome abnormalities, multiple major birth defects or intrauterine symptomatic infections affecting the central nervous system is usually severely compromised, with overall and unequal degree of impairment of weight, height and head circumference. Results of different studies on postnatal somatic growth in SGA infants are inconsistent, probably owing to the heterogenicity of all newborn infants considered to be small for dates.

Type, severity and earliness of IUGR have been related to SGA features.[68–72] It has been shown that newborn infants were thinner and shorter than the general population when their IUGR began before 34 weeks' gestation, and that these characteristics persisted throughout the growth period. When IUGR began earlier, before 26 weeks' gestation, growth

Table 123.4 One-year catch-up growth (%) of small-for-gestational-age (SGA) infants with distinct anthropometric alterations at birth (from reference 18)

	Weight < 10th centile	Weight + height < 10th centile	Weight + HC < 10th centile	Weight + height + HC < 10th centile
Weight	79	62	65	38
Height		69		33
Head circumference			100	66
Ponderal index*	81	75	80	45

HC, head circumference. At birth: height < 10th centile, 53%; HC < 10th centile, 30%; ponderal index < 10th centile, 57%; *in 17.5% of SGA infants, when the ponderal index was > 10th centile at birth, it decreased to below the 10th centile by 1 year

impairment was still greater and may even have affected the head circumference. These infants were less susceptible to recuperation, and frequently suffered disorders associated with neurological development. IUGR of late onset was less severe and generalized, and showed a more rapid process of recuperation. However, considering IUGR as a whole, most studies indicated that intrauterine growth-restricted infants had a tendency to be thinner and shorter,[18,68,73–83] but others disagreed.[84–91] It is generally accepted that undernourished neonates (low ponderal index or disharmonious) recuperate sooner, whereas neonates apparently not undernourished (normal ponderal index or harmonious) remain thin, are of short stature and have a reduced cranial perimeter[18,92–95]; the more severe the malnutrition, the more time required for recuperation.[96] However, some authors consider that, although most infants with low ponderal index can grow faster during the first months of life, diminished height, weight and head circumference remain at the long-term follow-up.[97,98] Others consider that early nutrition of SGA infants is especially important,[99] as is catch-up growth during the first months of life, as predictors of recovery.Other authors, however, do not share this opinion.[77–79]

In full-term twins in which the weight of the smaller was < 2000 g and 25% less than that of the larger, Babson and Kagas[100] found that this difference persisted in relation to both physical development and intellectual capacity at the age of 8 years. On the other hand, Philip[101] showed that full-term twins with 20% discordant birth weights could attain the same height and head circumference at the age of 1 year, although remaining thinner. Differences by gender have been found in some studies. In a longitudinal follow-up of growth in 123 SGA children,[102] the boys showed an extremely fast weight catch-up, 85% of them reaching a weight greater than −2SD at the age of 3 months and all of them remaining above this level at 4 years of age. Such a fast catch-up growth was observed in only two-thirds of the girls, but at 4 years of age 85% of the girls were also above −2SD. Length catch-up was more gradual than weight catch-up. Acceleration of head growth may be more prominent in SGA males.[103] A recent longitudinal study about the outcomes of VLBW infants from birth to 20 years, found females having greater catch-up in growth than males. The negative effect of neonatal illness on 20 years' height attainment was greater among males.[104] According to some authors, head circumference may grow in parallel with, or faster than, weight or height.[71,104] Karlberg and Albertsson-Wikland[105] followed a singleton birth cohort ($n = 3650$) of full-term SGA infants from birth till they reached final height at about 18 years of age. SGA infants were found to have a sevenfold higher risk for short final stature in comparison with the non-SGA group. At 18 years of age, 22% of the total short population were short at birth, whereas when birth weight was used to define SGA, only 14% of the 18-year-old short population were light at birth. It is concluded that the vast majority (> 86%) will achieve catch-up in height during the first 6–12 months of life. Of the remaining non-catch-up infants, about 50% remain short in final height.

One-year catch-up growth of SGA infants with different anthropometric abnormalities at birth is shown in Table 123.4.

The role of preexisting or persistent hormonal defects in the postnatal growth processes of SGA infants is unclear.[50] Insulin plays a critical role in fetal growth. A significant correlation between linear growth velocity and insulin release after glucose overload has been reported.[106,107] In the study of Samaan and colleagues,[53] SGA infants had lower insulin-like growth factor-II (IGF-II) levels than AGA and large-for-gestational-age infants. These results suggest that IGF-II may play a major role in fetal growth. On the other hand, the mean serum IGF-I levels in SGA infants were significantly higher than in AGA infants, but not in their respective mothers. This indicates that the production of IGF-I in the maternal and fetal compartments is independent and that circulation of IGF-I across the placenta is unlikely. The concentration of IGF-I and insulin-like growth-factor-binding protein-1 (IGFBP-1) in the umbilical vessels at delivery showed an inverse correlation with birth weight, so that significantly higher values were found in SGA infants

than in AGA neonates.[87] IGFBP-1 might inhibit the action of IGF-I in both the maternal and the fetal compartments, and the rise in IGFBP-1 could be a primary factor in retardation of fetal growth.[54,55] A positive correlation between C-peptide levels in cord blood and neonatal weight, ponderal index and maternal weight gain during gestation were also observed in SGA infants.[108] N-terminal propeptide of type III procollagen (PIIINP) concentration in cord serum of SGA infants was significantly lower than in AGA infants.[56] PIIINP assay may serve as a dynamic biochemical indicator of deviant fetal growth as the PIIINP results were also related to the severity or duration of IUGR. The lowest values were obtained in non-malformed SGA infants with small head circumference, known as an index for the chronicity of fetal nutritional deprivation.[90] Somatomedins seem to play a role in fetal growth.[109,110]

Some studies report the effects of growth hormone (GH) therapy in children with short stature secondary to IUGR,[110] showing significant results in patients with normal secretion of endogenous growth hormone when doses three times higher than in cases of growth hormone insufficiency were given.[111,112]

In July 2001, growth hormone GH was approved by the US Food and Drug Administration for the long-term treatment of growth failure in children who are born SGA and do not achieve catch-up growth by 2–3 years of age, at doses of 0.24–0.48 mg/kg/week.[113] The objectives of GH therapy in short SGA children are: catch-up in early childhood, maintenance of normal growth in childhood and achievement of normal adult height .Higher doses (up to 0.48 mg/kg/week) are more effective for the short term, but its advantages over lower doses on the long term is not yet know. Only adult height results of randomized dose–response studies will give a definite answer.

Whether measures of GH secretion provide clinically useful information for the routine treatment of short children who were born SGA is controversial. Arguments that favor evaluation for GH deficiency come from data suggesting that many short patients who were born SGA have diminished GH output, evidenced by low levels of spontaneous GH secretion, and depressed circulating concentrations of markers of GS secretion, such as IGF-I. Thus, the lack of catch-up growth in some cases might be attributable to reduced GH secretion.

However, standard laboratory GH stimulation tests do not predict growth response in most patients who are SGA. The present recommendation is that test of GH release only is performed when GH deficiency is suspected on clinical or biochemical backgrounds.

Neurological development and outcome: postnatal behavior

It has been widely recognized that SGA infants constitute a high-risk group for neonatal neurological problems, sensoral and neurodevelopmental sequelae and behavioral disturbances.[114–121] As early as in the neonatal period, deficits in muscular tone with decreased cephalic control, diminished spontaneous activity and poor and incomplete primary reflexes with a lower degree of impairment of tendon reflexes may be observed.[122] In a study in which the influence of IUGR on heart rate during sleep was assessed,[123] sympathetic and parasympathetic heart rate control was clearly different between SGA and AGA newborn infants, with a shorter RR interval and lower amplitude of heart rate variability in all bands of the polygraphic recordings. Circadian rhythmicity is established more slowly in growth restricted infants than in normal children.[124] Excretion of melatonin, also rhythmically and age related, is delayed in growth restricted infants.[125] During active and quiet sleep, Curzi-Dascalova and coworkers[126] and Riese[127,128] demonstrated significant modifications in the establishment of respiratory rhythm control (more central respiratory pauses, higher apnea index, and time spent with periodic breathing), dissimilar patterns for behavioral stability, reactivity and activity during sleep, significantly higher incidence of vigorous limb movements and right hand-to-mouth movements, more spontaneous smiles and a trend to more spontaneous startles. Abnormal responses in neurobehavioral performance at 40 weeks' conceptional age,[129] as well as two patterns of spontaneous general movements unique for the SGA infant might be used to discriminate between healthy and neurologically suspect newborn infants.[130]

When brainstem auditory evoked responses were examined in SGA children from birth to 6 years of age and compared with those of AGA children, Jiang and coworkers[131] demonstrated that I–V, I–III and III–V conduction intervals showed similar developmental trends. However, the III–V/I–III ratio followed a developmental course that differed markedly from that in AGA children. The ratio decreased slightly with age up to 2 years and was persistently smaller than in normal children after 1 year, indicating that the relative development of early and late brainstem conduction time deviates from normal.

Neurological development in SGA infants during the first years of life has been extensively studied. Fitzhardinge and Steven[114] considered that SGA infants constitute the second group in neurological sequelae following preterm infants with intraventricular hemorrhage (7% of neonates with a birth weight of < 3rd centile had neurological sequelae and up to 16% had mild deficits classified as minimal brain dysfunction). Preterm SGA neonates would be those at highest risk. In a neurological follow-up study of 37 SGA newborn infants,[132] 8% of the group had severe neurological sequelae at 1 year of corrected age. The statistical analysis showed a high correlation between subnormal weight gain and neurological and developmental abnormalities at 1 year. In a case–control study in which the risk of cerebral palsy in connection with

IUGR was analyzed,[133] the risk in SGA infants was significantly increased in term and moderately preterm infants. The most common abnormalities were tetraplegia, diplegia and dyskinetic cerebral palsy.[134] In full-term severely growth-retarded infants, a relationship was found between skull circumference < 3rd centile and the presence of minor neurological dysfunction at the age of 6 years, whereas body measurements, behavior at home and at school and school achievement were not related.[135]

In long-term follow-up studies, a higher prevalence of auditory problems in relation to IUGR has not been found, although speech disorders (delay in the onset of speech, poor and immature language, defects in articulation, etc.) have been documented by different authors.[53,136] With respect to visual defects, although 18% of male and 10% of female SGA infants in the study of Fitzhardinge and Steven[114] needed visual correction, these figures were similar to those found in the general population. According to the study of Getz and coworkers,[137] being SGA does not pose an additional risk for the development of grating acuity or binocular visual field size over the first 4 years of life in preterm children. Other studies[138,139] reported delayed visual directed prehension and abnormal visual brainstem evoked potentials.

Although minor motor dysfunctions, subtle neurodevelopmental and attention deficits, hyperactivity, failure at schools despite normal intelligence and increased fears have been reported,[80,140–142] it is difficult to ascertain whether these findings occur more frequently in SGA children.[115,143] The family environment may play an important role in the first developmental stages.

Recent studies point out the relation between reversal end-diastolic flow velocities (EDFVs) on antenatal assessment, with a wide range of problems at school age. Absence of EDFV is well recognized as a marker of fetal compromise which is associated with acute perinatal sequelae but not related with adverse neurodevelopmental outcome. This suggests that reversal EGFV could represent intrauterine decompensation which may have adverse effects on the developing brain.[144]

In a comparative study of the physical and developmental status of preschool SGA children, Pryor[145] found that mothers were less likely to have breastfed their babies and reported higher incidences of eating problems and visits to a general practitioner than those with AGA children. For all subjects, breast feeding was correlated with higher Stanford–Binet scores, and environmental factors appeared more salient for the progress of SGA children at this age than biological factors. At age 13, adolescents born SGA scored significantly lower than the AGA group on the WISC-R scales, and at the age of 15, they were rated by parents as having more behavioral problems.[146] Mothers' education has been associated with SGA infants' academic abilities,[147] and improper mothering behavior has also been postulated as a factor associated with behavioral disturbances in SGA children.[148,149]

It is generally considered that perinatal complications are important determinants of major neurological sequelae, whereas less severe behavioral problems in the long term would be more related to IUGR *per se*. The time of onset of IUGR (before 27 or before 34 weeks' gestation) has been associated with the degree of impairment of school performance; reading, writing and drawing abilities; creative and imaginative activities; and reasoning capacity.[150] More severe behavioral disturbances were observed in very early growth-retarded children and have been related to their short stature; boys were more irritable and anxious, and felt more unhappy and worried about their relationships with other children, whereas girls were more blubbering and irascible, and adopted defiant and intimidating attitudes against their schoolmates.

Smedler and colleagues[151] reported that healthy VLBW SGA infants aged 8–11 years scored significantly lower on measures of visuospatial ability, nonverbal reasoning, strategy formation and gross motor coordination, and they had also more behavioral and educational problems than control AGA infants matched for age, sex and socioeconomic background. These developmental deficits began to be increasingly evident at an early school age. Being born SGA at term is associated with poorer school performance at 12 and 18 years,[152] according to data obtained in a French regional cohort. Lagerstrom and coworkers[153] found that girls born SGA showed lack of school motivation and concentration difficulties both at age 10 and at age 13. These authors further observed that SGA children had lower scores than controls in WISC test performance and full scale scores at the age of 10 years; preterm SGA infants also had lower scores in the verbal scales.[154] Results from the British Birth Cohort in which school performance was assessed at 16 and 26 years were published recently.[155] At 16 years, those born SGA demonstrated small but significant deficits in academic achievement, and the teachers were less likely to rate those who were born SGA in the top 15th percentile of the class compared with those who were born AGA. At 26 years, the adults who were SGA did not demonstrate any differences in years of education, but they were less likely to have professional or managerial jobs and reported lower income than the AGA participants.

Adult conditions related to IUGR

Evidence that the quality of fetal growth and development has strong and, in widely varying populations, reproducible effects on susceptibility to many common adult human diseases has only been acquired relatively recently.

A further general point to be made in relation to studies in this area as they relate to human disease is

the extremely crude nature and limited scope of the observations available reflecting the quality of human fetal growth and development at the present time. There is no such thing as a 'normal' birth weight. At the present, there is no way of knowing what the optimal fetal growth potential is of any particular child. The relationship of the prevalence of a disease to birth weight is often continuous throughout the range of birth weights. Studies in experimental animals have indeed shown that it is possible to expose pregnant women to particular insults, which do not change the birth weight of the offspring but yet do change their phenotype in other respects.[156]

Individuals who were born small-for-gestational age are a group of people who appear to be at increased risk of the detrimental consequences of obesity. In the cohort study of Ong and colleagues,[89] children who showed catch-up in weight or length between 0 and 2 years were heavier and taller than other children at 5 years, and had greater body mass index, percentage body fat, total fat mass, and central fat distribution, which are variables of childhood size linked to metabolic markers for risk of disease in adulthood and are predictive for adulthood obesity.

It appears that both poor fetal and early postnatal growth are separately linked to the risk of poor glucose tolerance as an adult.[156]

Adult hypertension and other cardiovascular disease, in people who were born small-for-gestational age, has been attributed to fetal adaptations to maternal undernutrition or placental dysfunction that permanently alters growth characteristics, postnatal metabolism and physiology.[157,158] The mechanisms underlying the programming of hypertension are likely to be multifactorial; however, a role for the kidney and the endotelium in the maintenance of raised blood pressure has been reported.[159] In some studies, postnatal physiological adaptation and maturation if IGUR infants is slower than normal and therefore they remain in a physiologically immature state for longer, the higher rates and greater cortisol excretion could be precursors to hypertension and cardiovascular disease seen in adult.[160]

The programming of the endocrine axes might occur during critical phases of fetal development and might thus be affected by intrauterine growth restriction. A northern Spanish group[161] has indicated associations between reduced fetal growth and the occurrence of precocious adrenarche, pubarche, hyperandrogenism, polycystic ovary syndrome and hyperinsulinism. However hyperandrogenism and precocious pubarche were not confirmed in a large Dutch study.[162] Both studies reported a lower number of follicles in the ovaries in girls born SGA. Most studies show that children born SGA start their puberty at a normal age but relatively early, within the normal range. Age at menarche seems comparable with controls.[163]

Intrauterine and early postnatal environments could have long-term consequences for infectious disease risk, as well as risk of other diseases with an immunologic component, including asthma and allergy, autoimmunity-related diseases and neoplasia. The success of immunization programs that target adolescent and young adults (e.g., tetanus and hepatitis B) could be affected.[164] A recent study of Hasselmar and colleagues[165] report a similar frequency of allergic diseases in SGA-born subjects as in controls deviating from the primary hypothesis of a protective effect on allergy development in the subgroup of IUGR subjects.

The underlying mechanisms explaining links between fetal growth and cancer are not clear but could well include permanent changes in growth factor expression and sensitivity.[156]

124 Macrosomia: concept and epidemiology

E. Fabre, R. González de Agüero, J. L. de Agustín and A. Ezquerra

Introduction

The term macrosomia describes the condition of infants with birth weight of ≥4000 g, regardless of gestational age. Further subdivisions of macrosomia have been commonly used: mild macrosomia (4000–4499 g), very macrosomic (4500–4999 g) and extremely macrosomic (≥5000 g). However, other cutoff levels have also been used in the definition of the macrosomic fetus: birth weight of ≥4100 g[1], 4500 g[2] or 4536 g (10 lb).[3] Although weight is easy to determine, this criterion fails to reflect the influence of gestational age on birth weight.

Birth weight–gestational age tables are convenient methods to demonstrate the relationships between birth weight and perinatal outcome. The 10th and 90th percentiles of birth weight are common arbitrarily chosen limits of appropriate weight for gestational age (AGA). Large for gestational age (LGA) is defined as born with a weight ≥90th percentile for gestational age, and small-for-gestational age (SGA) as born with a weight <10th percentile (Figure 124.1). However, because birth weights normal-for-gestational age may vary with geography and ethnicity, an infant that is LGA according to a set of normative data derived from one population may not meet the criteria derived from another population.

Although macrosomia has traditionally been defined on the basis of birth weight, not all macrosomic fetuses have the same anthropometric characteristics. It has long been recognized that the infant of a diabetic mother typically has a disproportionate increase in such insulin-sensitive tissues as adipose tissue, liver and muscle, but not in others such as bone, skull and brain, in which growth is relatively insulin insensitive.[4] In addition to differences in weight/length ratios, infants of diabetic mothers also differ in body composition and weight distribution from those of non-diabetic mothers. Fetal macrosomia in diabetes mellitus is characterized by organomegaly and increased adiposity and fetal muscle mass. Both fetuses and neonates of diabetic mothers have a significantly smaller head circumference than that of fetuses and neonates of gestational age-matched non-diabetic mothers,[5] but abdominal circumferences of LGA infants of diabetic mothers are significantly greater than those of LGA infants of non-diabetic mothers.[6] Among neonates weighing over 4000 g, the shoulder circumferences of infants of diabetic mothers were found to be significantly greater than those infants of non-diabetic mothers.[5] The disproportionate increase in the size of the abdomen and shoulders compared to the cranium contributes to the potential for traumatic vaginal delivery. The amount of subcutaneous fat present in the infant of a diabetic mother may be an indicator of the degree of glycemic control achieved during gestation.

Estimation of body composition, lean body mass and fat mass is a further anthropometric refinement in the assessment of growth. Lean body mass represents metabolically active tissue and is relatively stable *in utero* in relation to the alterations in the maternal metabolic milieu, while fetal fat mass accumulation may be more sensitive to factors that affect fetal growth.[7] In the normal-term neonate, lean body mass represents an average of 86% of total body weight and explains 83% of the variance in birth weight. In contrast, neonatal fat mass constitutes only 14% of birth weight but explains 46% of its variance.[8] Macrosomia in the fetus of a diabetic mother may represent the accumulation of excessive fetal fat as opposed to lean body mass.[9] Sparks[10] described a comparable rate of accretion of lean body mass in SGA, AGA and LGA fetuses but considerable variation in the accretion of fetal fat. Fat accretion in SGA fetuses is considerably less than in the AGA fetuses, which in turn is less than that of the LGA fetuses. Estimates of body composition, however, are rarely used to assess normal fetal growth, because of methodological difficulties. The ponderal index has been used as an estimate of the degree of obesity or thinness of an infant. Although birth weight is used in the derivation of the ponderal index, this explains only 22% of the variance in birth weight and correlates poorly with estimates of percentage body fat.[8]

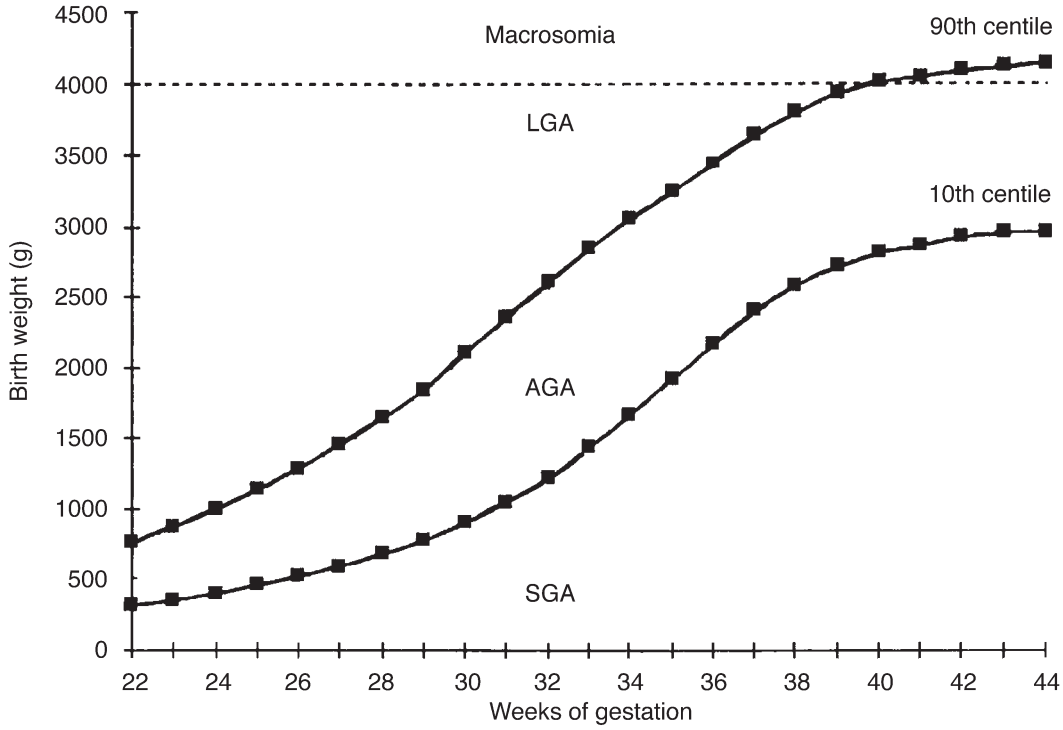

Figure 124.1 Increase in body weight of fetuses during the second half of gestation according to menstrual age. LGA, large; AGA, appropriate; and SGA, small-for-gestational age.

Epidemiology

Epidemiological factors

Women delivering macrosomic infants tend to be obese, tall, older and have increased parity.[11] It is also interesting that the macrosomic infant is more often male[12,13] (Table 124.1). Maternal factors that may predict macrosomia in the infant include previous history of macrosomia, obesity, prolonged pregnancy and diabetes mellitus.[2,13,14] Studies of pregestational and gestational diabetic women have demonstrated a similar relationship between macrosomic neonates and the aforementioned factors of risk.[15,16]

Fetal syndromes with genetics determination

There are different fetal syndromes which can determine a genetical growth acceleration. Their incidence is normally quite low. Most common ones are:

Beckwidth-Wiedemann syndrome, is characterized by a consistent set of symptoms including macroglossia, visceromegaly, macrosomia, umbilical hernia or omphalocele and neonatal hypoglycemia. Although most cases appear to be sporadic (85%), the etiology is generally accepted as genetic. Families with more than one affected relative have been reported, and linkage studies in these familial cases have located the gene on the short arm of chromosome 11 (11p15.5). This region contains the insulin-like growth factor, Type 2 (IGF2 gene), and the product of this gene is a major fetal growth factor.[17]

Nesiodioblastosis, autosomal recessive inheritance (11p15.1, 10q23.3, 7p15-p13), the main feature is a proliferation of beta pancreatic islets, producing hyperinsulinism and neonatal hypoglycemia.[18]

Sotos syndrome, in this syndrome, also called cerebral gigantism, babies are generally significantly larger and heavier than average, caused by excessive pre-natal and early post-natal growth. Characteristics include macrocephaly with accelerated bone maturation, delayed development and language problems, widely spaced eyes, prominent jaw, and high arched palate. Intelligence varies from normal to mild learning disability. Most cases are sporadic mutations. Once established, inheritance is autosomal dominant (5q35).[17]

Weaver syndrome, characterized by accelerated growth and advanced bone age (evident at birth), unusual craniofacial appearance, hoarse low-pitched cry, and hypertonia with camptodactyly, caused by mutations in a gene called NSD1 (5q35). The same gene is mutated in more than three-quarters of patients with another overgrowth disorder called Sotos syndrome.[17]

Nevo syndrome, Nevo syndrome is caused by mutation in the gene encoding lysyl hydroxylase and is therefore allelic with, or in the view of some, identical to, the kyphoscoliotic type of Ehlers-Danlos

Table 124.1 Prevalence of macrosomia and odds ratios for selected factors (from Larsen *et al.*[13])

	Macrosomic infants (%)	Adjusted odds ratio (95% confidence interval)*
Body mass index		
≤25th	4.8	0.58 (0.55–0.62)
25th to < 75th	8.1	l.00*

42	14.7	1.55 (1.45–1.66)
Sex of infant		
Male	11.2	1.00*
Female	6.7	0.52 (0.50–0.54)

* Multiple logistic regression with body mass index, height, ethnicity, smoking, maternal age, previous live births, gestational age and infant sex in the model

syndrome. Some of the characteristics are increased growth, kyphosis, prominent forehead, volar edema, spindle-shaped fingers, wrist drop, talipes, hyperbilirubinemia, generalized hypotonia and autosomal recessive inheritance (1p36.3–36.2).[17]

Congenital hyperinsulinism, is a clinically and genetically heterogeneous entity and causes severe hypoglycemia in neonates. The clinical heterogeneity is manifested by severity ranging from extremely severe, life-threatening disease to very mild clinical symptoms, which may even be difficult to identify. Most cases are caused by mutations in the cromosome 11p15 coding for either of the two subunits of the beta-cell. Recessive mutations of the beta-cell genes cause diffuse HI, whereas loss of heterozygosity together with inheritance of a paternal mutation causes focal adenomatous HI. Other cases are caused

by mutations in gene coding for the beta-cell enzymes glucokinase (GK), glutamate dehydrogenase (GDH), and SCHAD.[19]

Maternal weight gain and prepregnancy weight

Maternal prepregnancy weight, as well as maternal weight gain during pregnancy, are directly related to birth weight. Underweight women tend to deliver infants with lower mean birth weights, and heavier women tend to deliver infants with higher mean birth weights.[20] A very important risk factor for macrosomic fetuses is maternal obesity.[3] Among women not selected on the basis of glucose intolerance, univariate analysis demonstrates a greater frequency of infant macrosomia among obese than among non-obese mothers.[21] After adjustment for factors known to be important predictors of birth weight, such as maternal age, smoking, race, height, parity, gestational age and infant gender, the odds of delivering a macrosomic infant are 2.2 times higher in severely overweight mothers than in those of normal weight[13] (Table 124.1). Among gestational diabetics, a positive association has also been demonstrated between birth weight and maternal prepregnancy body mass index, percentage ideal body weight and absolute weight.[22]

The evidence also indicates that women with large gestational weight gains are at increased risk for infants of high birth weight.[23] Low prenatal gain is associated with a more than doubled risk of SGA, and high prenatal gain gives a doubled risk of LGA.[24] Several studies have found a linear relationship between birth weight and maternal weight gain at all levels of prepregnancy weights,[25] whereas others have reported that, as prepregnancy weight increases, the importance of maternal weight gain diminishes.[26] Maternal weight gain significantly increases birth weight for women with body mass indices of $\leq$135% of the standard before pregnancy, with an equal effect in underweight and ideal-weight women and slightly less for moderately overweight women. However, weight gain during pregnancy has no significant effect on birth weight for very overweight women.[27] Compared to obese women who gained 7–11.5 kg, obese women who lose weight or do not gain weight are at higher risk for delivery of infants under 3000 g or SGA infants and those who gain more than 16 kg are at twice the risk for delivery of infants weighing 4000 g or more (Figure 124.2).[28] Nonetheless, obese women clearly have infants that are larger than those of non-obese women for the same weight gain.

Previous fetal macrosomia

The tendency to repeat increased birth weight in subsequent pregnancies is well accepted. Bakketeig and colleagues[29] found that the risk of an LGA infant was 48% in the second birth if the first was LGA, compared to a risk of 16% if the first birth was AGA. Infants with birth weight of $\geq$4500 g are 7.0 times more likely (95% confidence interval 5.4–9.1) to have a subsequent macrosomic sibling than are infants with smaller birth weight, after controlling for pregnancy smoking status, parity and gestational age. Race, maternal age or marital status and diabetes mellitus do not materially affect this relationship. The overall prevalence of macrosomic infants subsequent to previous macrosomic birth is 22%, a proportion that does not vary notably with parity, or when paternity changes between successive births. Mothers with one macrosomic infant are at marked risk for repeating macrosomic births.[30]

Post-term pregnancies

A recognized but often overlooked consequence of the prolonged pregnancy is fetal macrosomia. The postdate fetus should continue growing, although at a reduced rate, in the absence of uteroplacental insufficiency. Thus, an otherwise healthy fetus may become macrosomic with continuation of the pregnancy. Large, often macrosomic fetuses are more common in post-term pregnancies and predispose to dysfunctional labor, shoulder dystocia and operative deliveries. Boyd and coworkers[14] found a 16% incidence of macrosomic infants at 41 weeks' gestation and a 21% incidence at 42 weeks' gestation, both significantly increased when compared to the 8.2% incidence reported at less than 41 weeks' gestation. Similar results were reported by Arias,[31] who also found a 23.8% incidence of macrosomia in fetuses of more than 41 weeks' gestation. Figure 124.3 shows a continuous increase in the number of infants with birth weights of $\geq$4000 g for each week interval after 40 weeks' gestation. Usher and coworkers[32] reported that post-term fetuses are also more often macrosomic, with a birth weight of 4000 g or more in 23% of primiparas and 40% of multiparas at 42 weeks or later compared to 9% and 14%, respectively, at term. Chervenak and colleagues[33] reported an incidence of macrosomia at 42 weeks' gestation of 25.5%, significantly higher than 6% of macrosomic infants in the group of patients delivered between 38 and 40 weeks' gestation. In general, infants delivered at 42 weeks' gestation are three to seven times as likely to weigh more than 4000 g than those delivered before 41 complete weeks' gestation.

Diabetes mellitus

It is well known that infants born to diabetic mothers have an excessive size and weight at birth. Macrosomia has long been considered the hallmark of diabetic fetopathy. Maternal hyperglycemia induces fetal hyperglycemia, which in turn stimulates fetal endocrine pancreatic islets and insulin release; the persistent fetal hyperinsulinism promotes glucose uptake by fetal tissues and increases fetal growth, with resultant macrosomia.[34] The incidence of macrosomia in pregnancies complicated by diabetes is more than twice that for non-diabetic women.[14] Diabetes is more frequently

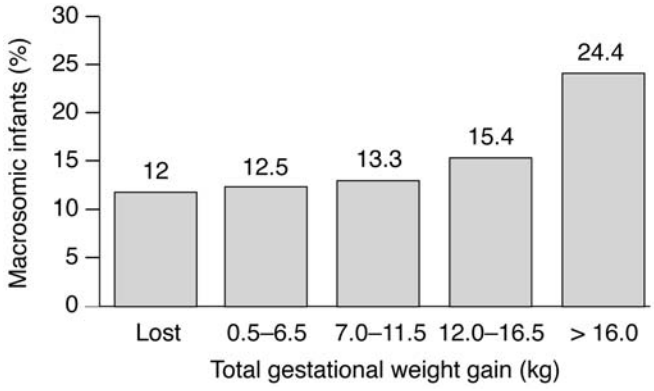

Figure 124.2 Incidence of macrosomia by total gestational weight gain in obese women. Data from Edwards *et al.*[28]

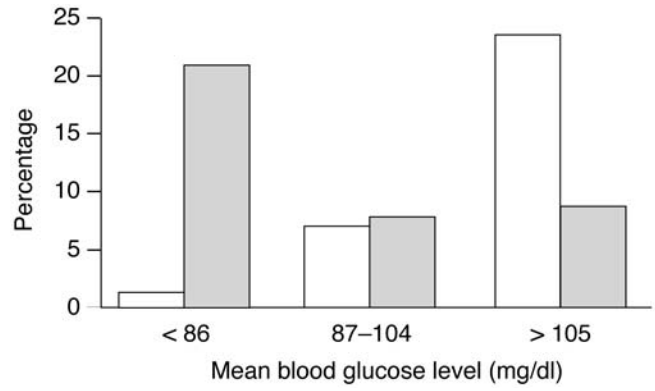

Figure 124.4 Association between neonatal size and level of glycemic control in gestational diabetes. Open bars, large; and shaded bars, small-for-gestational age. Modified from Langer *et al.*[39]

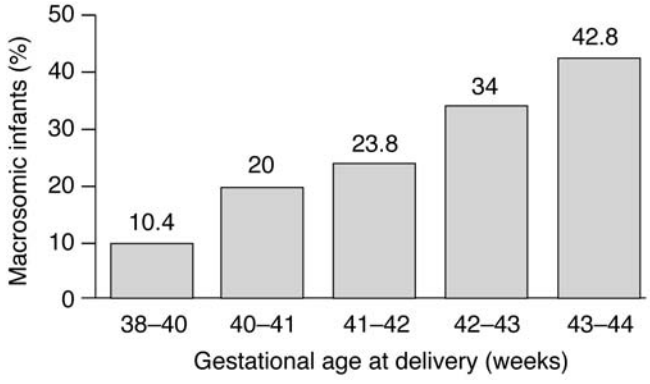

Figure 124.3 Incidence of macrosomia by gestational age at delivery. Data from Arias.[31]

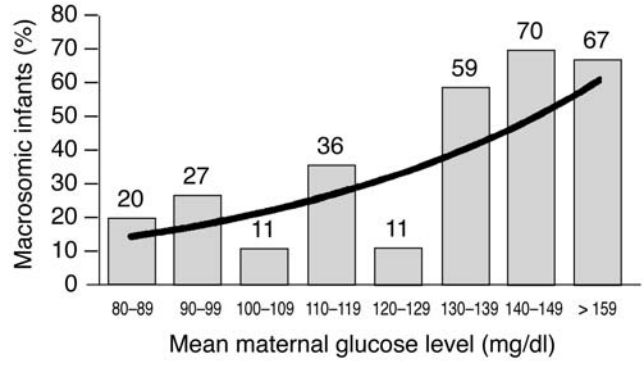

Figure 124.5 Incidence of macrosomia in relation to mean maternal glucose level. Data from Willman *et al.*[40]

present among mothers of infants whose birth weights exceed 4000 g than among those with lower birthweights.[3,14] However, when the gestational age is controlled, LGA infants are born with equal frequency to diabetic and non-diabetic mothers.[35] Inconsistencies in these findings may be explained by the influence of factors other than maternal diabetes on birth weight.[22]

In recent years tight glycemic control became a standard of care in the management of the pregnant diabetic in order to reduce perinatal mortality and morbidity. This resulted in the reduction of perinatal mortality to rates comparable to those observed in the normal population. In contrast, the incidence of perinatal morbidity as reflected by metabolic disorders and macrosomia remains relatively high. Although maternal hyperglycemia is clearly a factor implicated in the development of macrosomia, the evidence is often conflicting. Several investigators[36] have reported an association between maternal glucose control and macrosomia, but others have not been able to substantiate this finding.[37] Fetal growth appears to be affected by many factors in addition to maternal glucose levels. In non-diabetic women, maternal factors that have been shown to be related to macrosomia include parity, maternal size, weight gain and prolonged pregnancy.[14] Other determinants of birth weight that have been linked to excessive fetal size in non-diabetic women include fetal sex, history of a large infant and race.[38]

In a large study of patients with gestational diabetes, the relationship was examined between optimal levels of glycemic control and perinatal outcome (334 gestational diabetic women and 334 subjects matched for control obesity, race and parity).[39] Three groups were identified on the basis of mean glucose level throughout pregnancy. In the group with high levels ($\geq$105 mg/dl) the incidence of LGA infants was approximately twofold higher than in the control group. Also, the incidence of LGA infants was 21-fold higher in the group with high mean blood glucose levels than in the group with low mean blood glucose levels ($\leq$86 mg/dl), and fourfold higher than in the group with intermediate mean blood glucose levels (87–104 mg/d1). No significant difference was found between the control and the mean blood glucose category of 87–104 mg/dl in the incidence of SGA or LGA infants (Figure 124.4). Willman and colleagues[40] reported that there is a non-linear relationship between maternal glucose concentration and excessive fetal growth and that the incidence of macrosomia is not consistently increased until the mean glucose concentration is equal to or higher than 130 mg/dl (Figure 124.5). Also, the results of this study

indicate that macrosomia among diabetic women is multifactorial in origin and not singularly the consequence of maternal hyperglycemia. Specifically, maternal obesity, maternal insulin requirements (which reflect greater insulin resistance and greater abnormality of fatty acid and lipid metabolism), maternal glucose level and history of a large infant are associated with fetal macrosomia. Therefore, factors known to be associated with excessive fetal size in non-diabetic women must also be considered when women with well-controlled diabetes inexplicably give birth to macrosomic infants.

In some studies of the relationship between maternal glucose concentrations and fetal macrosomia, there is an implicit assumption that the risk of the latter exists only for those who equal or exceed the threshold values defining gestational diabetes on a glucose tolerance test (GTT). However, this is probably not the case, as is suggested by a demonstrated risk of macrosomia among women exhibiting lesser degrees of glucose intolerance. In infants of women with diabetes, macrosomia is thought to occur because of fetal hyperinsulinemia due to maternal hyperglycemia. The same hypothesis has been used to explain the increase in neonatal birth weight found in studies of pregnant women with minor degrees of glucose intolerance. The exact degree of maternal glucose intolerance associated with fetal macrosomia is not well defined. As any criteria for the diagnosis of diabetes are arbitrary, their use lies in their clinical value. One may question whether the results of currently used screening tests accurately predict the patient's risk for fetal overgrowth.

The relationship between maternal glucose concentrations and fetal macrosomia has been explored in several publications. Some have failed to demonstrate any significant relationship. Others have found a positive relationship between maternal glucose levels and fetal macrosomia. One of these reports showed that patients who had elevated 1-h glucose screening test values and normal GTT (group study) results delivered macrosomic neonates (11.9%) significantly more often than those having normal glucose screens (6.4%). When the data were corrected for other macrosomia risk factors (advanced age, high parity, obesity, race and prolonged gestation) there was still a significantly higher frequency of macrosomia in the study group.[41] Another report demonstrated a trend of increasing birth weight with increasing 1-h glucose screening test values.[42] Women who have only one elevated value on a GTT have macrosomic neonates significantly more often (18.0%) than those having normal glucose screens (6.6%) (odds ratio 2.28; 95% CI 1.77–5.37), a relationship that persisted after controlling for risk factors.[43] The incidence of neonatal macrosomia in infants of mothers who had only one abnormal value in a 3-h GTT (20%) was greater than in those of normal values (12.4%); however, after adjustment for gestational age, there were no differences in birth weight and LGA percentage.[44]

Apart from glucose, many others factors are involved in fetal growth. Recently many studies have shown the correlation of blood cord levels of insulin-like growth factors (IGFs), IGF binding proteins (IGFBPs), leptin, and interleukin-6 (IL-6) with intrauterine growth.[45–47]

Incidence and perinatal mortality

In general, infants weighing more than 4000 g account for almost 10% of deliveries, while those of 4500 g or more account for about 1% of all deliveries.[3] The Spanish Perinatal Mortality Survey of the Perinatal Medicine Section of the Spanish Obstetrical and Gynecological Society recorded data of 597,585 births at hospital – with known birth weight and gestational age – in different Spanish regions from 1980 to 1992.[48] In the period surveyed, the incidence of infants weighing more than 4000 g was 6.7%, and 0.8% of infants weighed more than 4500 g. This is similar to the published rates of macrosomia. In a revision of 10 studies published from 1931 to 1980, the incidence of fetal macrosomia ($\geq$4500 g) was between 0.6 and 1.9%.[3] Recent stastistics from the European Union show a significant variation in percentages of higher birth weights. In some countries like Denmark or Sweden, babies weighing more than 4500 g account for more than 4%, in others like France, Greece, Portugal or Luxembourg, the average is less than 1% of total live births.[49] Data obtained from the Center of Disease Control in the United States show a progressive decrease of the incidence of macrosomia, from 10.2% in 1996 to 9.2% in 2002 for babies over 4000g at birth (Tables 124.3 and 124.4).[49–51] Few epidemiological reports exist on the tendency over time regarding fetal macrosomia incidence. In the Spanish Perinatal Mortality Survey the macrosomic rate has decreased over recent years. From 1980 to 1992 the incidence of large infants ($\geq$4000 g) diminished from 8.6% to 5.8%, and the incidence of infants weighing more than 4500 g decreased from 1.0% to 0.6% (Table 124.2). The incidence of infants weighing more than 5000 g remained stable, at round 0.1%.

The association of fetal growth abnormalities with perinatal morbidity and mortality is of interest to both obstetricians and neonatologists. The few studies of fetal overgrowth have shown that perinatal mortality plotted against birth weight follows a U-shaped distribution, even when controlled for the length of gestation. Perinatal mortality increases at the extremes of birth weight at each gestational age (Figure 124.6). Table 124.2 shows the mortality rates during the perinatal period in macrosomic fetuses. In the whole period surveyed, the fetal mortality rate in fetuses weighing more than 4000 g was very similar to that observed in fetuses weighing between 2500 and 3999 g (3.2 vs. 2.8/1000 births). A similar result was observed in the early neonatal mortality rate (1.5 vs. 1.6/1000 live births) and perinatal mortality rate (4.8 vs. 4.4/1000 births). However, when the mortality rates during the perinatal period between those born weighing over 4500 g and

≥5000 g	5396 (0.1%)	5498 (0.1%)	6208 (0.2%)	6069 (0.2%)	5941 (0.2%)	5941 (0.2%)	6268 (0.2%)	< .0001

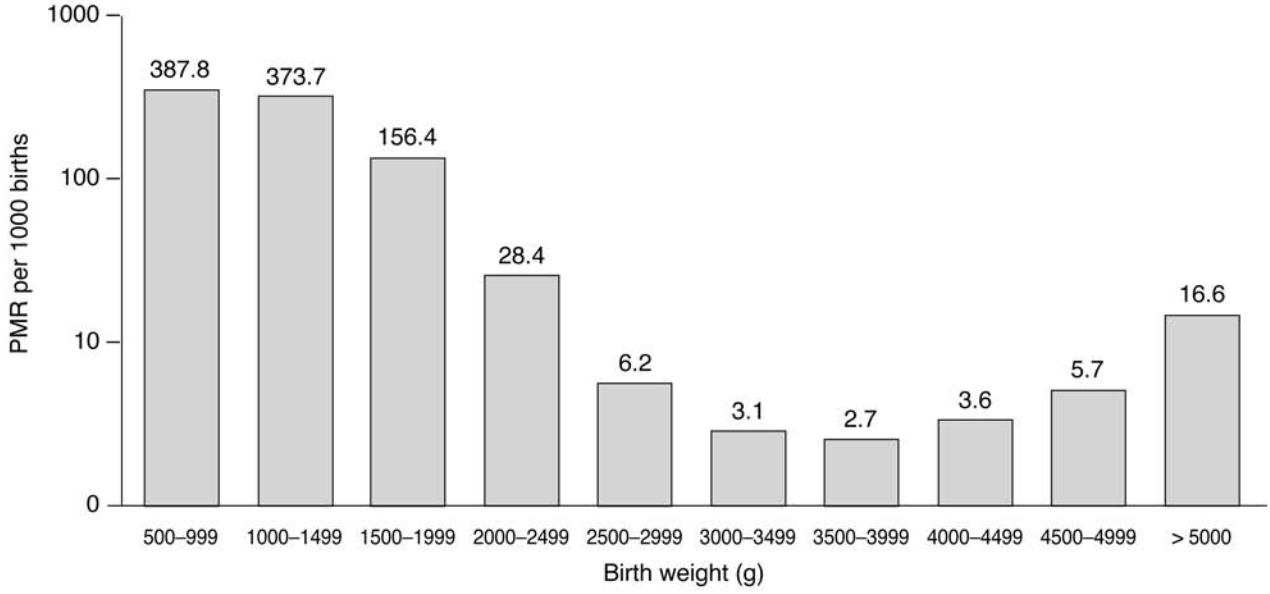

Figure 124.6 Perinatal mortality rate (PMR) for birth weight groups in those born at term (37–41 weeks' gestation) from the Spanish Perinatal Mortality Survey of the Perinatal Medicine Section of the Spanish Obstetrical and Gynecological Society from 1980 to 1992.

those born weighing in the range 2500–3999 g are compared, it is observed that fetal mortality rate is 2.8 times higher (7.8 vs. 2.8/1000 births), early neonatal mortality rate is 3.2 times higher (5.1 vs. 1.6/1000 live births) and perinatal mortality rate is 2.9 times higher (12.9 vs. 4.4/1000 births). The prognosis for the very large fetus, although substantially improved in recent years, remains less than desirable. From 1980 to 1992 in those born weighing more than 4500 g, the fetal mortality rate diminished from 9.2 to 6.6/1000 births, the early neonatal mortality rate from 6.2 to 3.9/1000 live births and the perinatal mortality rate from 15.4 to 10.4/1000 births. In other studies, a full-term infant weighing more than 4500 g was shown to have a risk of mortality three to four times higher than an infant of average birth weight.[52]

It is important to recognize the relatively high incidence of macrosomia, because of the complications associated with this condition. These include increased maternal and fetal trauma, shoulder dystocia resulting in Erb's palsy, perinatal asphyxia, meconium aspiration, increased rate of labor disorders, operative delivery and postpartum hemorrhage.[3] The incidence of shoulder dystocia directly relates to increasing fetal size. The overall incidence of shoulder dystocia varies between 8% and 10% with fetal weights of 4000–5000 g and is as high as 20–30% with fetal weights of more than 4500 g.[53] The risk of shoulder dystocia for LGA newborn (>4000 g) is 1.6% (OR = 22.3; 95% CI 16.7–29.8; P <0.001). The presence of maternal diabetes also increase the risk until 0.6% (OR = 2.8; 95% CI 2.0–4.0; P <0.001). Combining risk factors such as LGA, diabetes mellitus and vacuum delivery increased the risk for shoulder dystocia to 6.8% (OR = 32.6; 95% CI 10.1–105.8; P <0.001) (Figure 124.7).[54] Among infants of diabetic mothers, over two-thirds of shoulder dystocia cases occur in those weighing 4000 g or more.[55] Neonates experiencing shoulder dystocia have significantly greater shoulder-to-head and chest-to-head disproportions than do macrosomic neonates delivered without shoulder dystocia.[5] Fetal injuries, ranging from brachial plexus injuries to clavicular and humeral

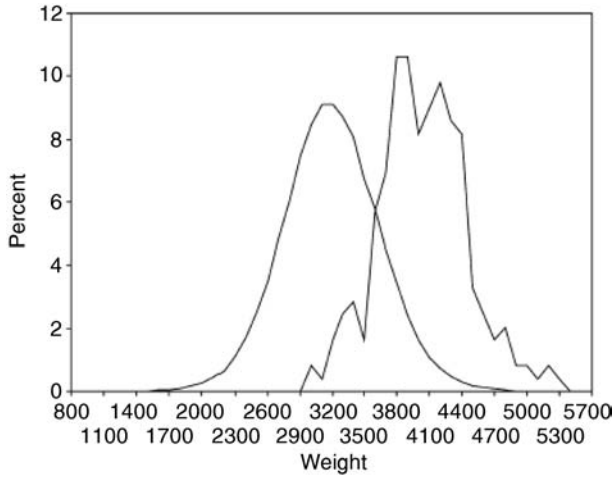

Figure 124.7 Birth-weight distribution among patients with shoulder dystocia (right curve; mean 4081.5 ± 416.1) and without shoulder dystocia (left curve; mean 3240.6 ± 449.2) from Sheiner *et al*.[54]

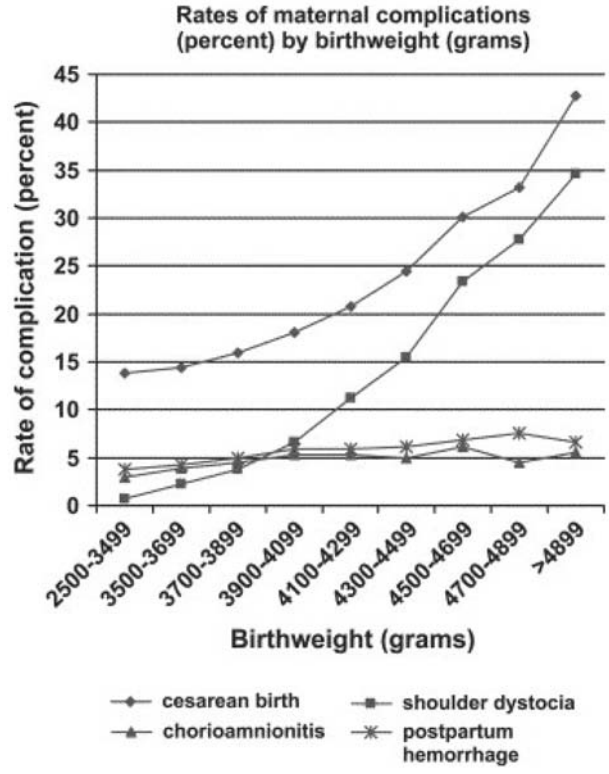

Figure 124.8 Rates of maternal complications (percent) by birth weight (g) from Stotland *et al*.[62]

fractures, are recognized complications of shoulder dystocia. However, most of these injuries appear to be transient, and permanent neurological injury or true asphyxia is uncommon. The management of large-for-date fetuses must be based not only on the estimated fetal weight, but also on functional criteria, and the mode of delivery will depend on a balance being struck between fetal and material risk, and the wishes of the parents.[56–61]

Several investigators have advocated for routine cesarean delivery when the fetus reaches a "macrosomic" weight, although there has been no consensus on what that weight should be. Benedetti and Gabbe[63], for example, considered an infant to be macrosomic when it was in excess of 4000 g, given the significantly increased risk of shoulder dystocia in this group. Alternatively, some investigators have suggested that the most appropriate fetal weight indication for cesarean delivery should be 4500 g, although others, such as ACOG (level C evidence), have recommended 5000 g.[64] But nowadays, among uncomplicated pregnancies, there is sufficient evidence that suspected macrosomia is not an indication for induction or for primary cesarean delivery. For pregnancies complicated by diabetes, with a prior cesarean delivery or shoulder dystocia, delivery of a macrosomic fetus increases the rate of complications, but there is insufficient evidence about the threshold of estimated fetal weight that should prompt cesarean delivery (Figure 124.8).[62–65]

125 Etiology and pathogenesis of fetal macrosomia

F. Carmona and V. Cararach

Introduction

Macrosomia is the term used to define fetuses that present excessive weight at birth; however, there is no agreement on what is the maximum weight that can be considered normal at the moment of birth since the limits defined by different authors vary between 4000 and 4500 g.[1–3] The currently most widely accepted definition considers gestational age as well as weight; the the word macrosomia includes 'fetuses that are large for their gestational age' (birth weight above the 90th percentile of weight distribution for their gestational age).[4] However, with regard to the possible prevention of problems during delivery the limit is set at 4000 g.

Fetal development and growth are regulated by many factors, which include the fetus's own characteristics, the maternal environment, placental function, and the availability of nutrients for the fetus. There is a close correlation in normal pregnancies between fetal weight and gestational age, such that fetal growth may be considered as the result of the relationship between genetic potential for growth and external influences that may modulate it. During early pregnancy, fetal growth is due to an increase in the number of cells (hyperplasia), while in the third trimester it is principally a result of an increase in cell size (hypertrophy).

Since fetal needs in later pregnancy are greater, the external influences (particularly the placenta if its capacity is diminished) are more important and thus the rate of fetal growth tends to diminish after the 30th week in multiple pregnancies and after the 36th week in single pregnancies, making differences in fetal size during the third trimester more obvious than in earlier stages of the pregnancy.[5,6]

In this chapter, we review the main factors involved in the genesis of macrosomia.

Factors involved in fetal growth

Genetic factors

The basic determining factor for the size of different species is genetic in character. Nevertheless, the mechanisms that control growth, are not well known. In fact, birth weight varies widely: weight among percentiles 10 and 90 in the Hospital Clínic de Barcelona for 40-week newborns varies between 2900 and 3980 g; of this variation, 20% is believed to be attributable to the fetal genotype; maternal height and weight exert considerable influence on the final fetal weight.[7,8]

In only a small percentage of cases does macrosomia form a part of a genetically determined syndrome and there is no prenatal diagnostic test that can specifically identify this subgroup of patients. Although they are uncommon, we shall briefly describe the particular syndromes, which include macrosomia among their characteristics.

Beckwith–Wiedemann syndrome

Only 200 cases have been recorded in the literature since it was first described.[9] Newborns are characterized by excessive weight (mean birth weight 4000 g), macroglossia, linear creases in the outer ear, and, in a high percentage of cases, omphalocele. Hydramnios and prematurity are common and embryonal cancers of infancy and early childhood are also frequent. Macrosomia is mainly at the expense of the muscular and subcutaneous tissues, and in many cases there is hyperinsulinemia at birth; many cases (30–35%) show neonatal hypoglycemia. The majority of infants with hypoglycemia will be asymptomatic and have resolution of this condition within the first 3 days of life and less than 5% will have hypoglycemia beyond the neonatal period requiring either continuous feeding or a partial pancreatectomy.[10] It is also common to find an increase in the number of red blood cells, hyperviscosity, and dyspnea with, in some cases, slight to moderate mental retardation, which may improve if the condition is diagnosed and treated appropriately during the neonatal period. The neonatal complications are very similar to those presented by the offspring of diabetic mothers. There are descriptions of an increase in the number and affinity of erythrocyte insulin receptors and it has been suggested that the excessive growth is the consequence of an increased response to normal or slightly increased

insulin concentrations,[11–13] resulting in hypoglycemia among newborns, which is often serious and produces convulsions. Treatment with hydrocortisone may improve the situation. Diagnosis must be regarded with suspicion until the birth, when macrosomia, omphalocele, and macroglossia can be diagnosed.[14]

Recent studies have identified the majority of genes associated with the Beckwith–Wiedemann syndrome in the 11p15 region and the genotype of persistent hyperinsulinemia–hypoglycemia of childhood also in the 11p15 region may provide a molecular basis for hypoglycemia in the Beckwith–Wiedemann syndrome involving abnormal methylation of either H19 or LIT1, which encodes unstralated RNAs on 11p15.[15] Prenatal diagnosis could be made in suspected cases studying by PCR the polymorphic loci on 11p 15.15 in the fetus, by amniocentesis or by chorionic villus sampling, or in both parents.[16]

Soto's syndrome

This occurs sporadically but familial cases with dominant autosomic heredity have been known with defects in the *NSD1* gene in nearly 60% of the patients.[17] The affected fetuses present macrocephaly, dolichocephaly, and prognathism with moderate to severe mental retardation in 83% of the cases. Fourteen percent of the affected newborns present abnormal glucose tolerance tests.[18] Prenatal echographic examination reveals the existence of a heavier-than-expected fetus with a cephalic perimeter/abdominal perimeter ratio that is greater than normal (similar to what happens in cases of asymmetric growth retardation).

Gillian Turner's syndrome

This is a recessive X-linked syndrome characterized by mental retardation, increase in genital size, and varying degrees of macrosomia. There may be cerebral gigantism

Weaver's syndrome

This is a rare syndrome characterized by accelerated skeletal maturation, unusual facies, and camptodactylia.[19]

Nesidioblastosis

This condition is characterized by the existence of a diffuse proliferation of the islets of Langerhans with a relative increase in beta cells. It has been suggested that the primary defect may be an alteration in the organization of the islets, which impedes the usual pancreatic regulation of insulin secretion, which is done by other hormones, such as somatostatin. The only efficient long-term treatment is the surgical resection of 95% of the pancreas. Although the etiology is unknown, it seems to be a recessive autosomic defect in pancreatic development. Newborns have a phenotype very similar to the offspring of diabetic mothers, with macrosomia due above all to hypertrophy of the muscular and subcutaneous tissue.

Other syndromes

Other genetic alterations have been related with fetal overgrowth. A recent report describes four children from two unrelated families presenting with macrosomia and a terminal duplication of the long arm of chromosome 15. In all cases, chromosome analysis of the parents showed a balanced translocation involving 15q26.1-qter.[20] Another report describes a case of non-diabetic macrosomia associated with Simpson–Golabi–Behmel syndrome.[21]

Fetal hormones

The genome controls fetal growth; the fetal hormones translate genetic information into real stimuli for growth. However, the exact mechanisms by means of which this control and regulation are carried out have not yet been established.

Insulin

This hormone plays a very important role in postnatal life, mainly in the metabolism of carbohydrates. During intrauterine life, however, insulin is the most important hormone in the regulation of fetal growth. Given that insulin cannot pass through the placental barrier, the only source of insulin found in the fetal plasma is its secretion by the fetal pancreas. Insulin is present in fetal plasma as early as 8–9 weeks' gestation, although it is relatively inactive until about the 20th week when fetal insulin response to glucose becomes evident;[22] the response to exogenous glucose depends on fetal glucose levels, which regulate the sensitivity of the beta cells of the pancreas.[23] Thus, chronic fetal hyperglycemia accelerates the development of insulin-secreting mechanisms in such a way that the offspring of diabetic mothers are predisposed to develop an insulin-secreting response similar to that of an adult.[24]

The insulin receptors in the fetal liver reach their maximum levels between weeks 19 and 25 of pregnancy; however, the maximum affinity of these receptors is reached later in pregnancy.[25]

Hyperinsulinemia induces the storage of glucose in the form of glycogen, lipogenesis, and the utilization of amino acids as an energy source. Experiments performed in rhesus monkeys on the effect of insulin on fetal growth have shown that this hormone produces organomegaly, increase in fetal and placental weight, and an increase in the crown–rump length (CRL).[26] In clinical practice, the importance of insulin in the control of fetal growth is better understood if it is kept in mind that in macrosomic syndromes, such as maternal diabetes, Beckwith–Wiedemann syndrome, and nesidioblastosis, hyperinsulinemia is very common.

Several human studies support the relationship between insulin and fetal macrosomia even in non-diabetic mothers. Akin *et al.* studied 20 non-diabetic mothers and their macrosomic infants with the appropriate-for-gestational age control group. Levels

of hemoglobin A1c were similar in both the groups but the C peptide levels were significantly higher in macrosomic infants, suggesting that these infants were more likely to have hypersinsulinemia that were normal-sized infants and this hyperinsulinemia was not caused by the disregulation in glucose metabolism.[27] Valensise *et al.* determined the maternal plasma levels of C peptide in 206 consecutive patients submitted for an oral glucose tolerance test. They showed that a C peptide cutoff at 2.9 ng/ml resulted predictive for patients delivering large-for-gestational age newborns (OR = 3.42; 95% CI = 1.59–7.39).[28]

Insulin-like growth factors (IGFs)

This is a group of peptides with structural similarities to the proinsulin chain of amino acids.[29] They were previously known as somatomedins and may act through endocrine, paracrine, or autocrine mechanisms.[30] Their effect is to promote fetal growth though any of the following mechanisms: (a) stimulation of glucose metabolism; (b) DNA synthesis; and (c) cellular proliferation. There are two main IGFs: IGF I and IGF II, which can be detected from the 13th week of pregnancy and cannot cross the placenta; fetal and maternal IGF I levels increase as pregnancy advances and correlate with fetal and placental weight;[31] it is not possible to describe a similar relationship between IGF II and fetal weight, though it has been shown that the levels of this peptide in the amniotic fluid do not change during pregnancy.[32]

At the cell level also, two types of IGF receptors have been identified.[33] Type I receptors are very similar to insulin receptors, whereas type II receptors are IGF-specific. Two different transporting proteins have also been described, though the exact mechanism by which they act is not well known.

Animal models have shown that growth factors play an important role in the fetal growth. This role has been studied through transgenic animal models. Thus, growth hormone (GH)-deficient mice have been mated with IGF-I transgenic mice and their offspring have had normal body weight and linear growth, suggesting that IGF-I plays a larger role than GH in fetal growth.[34] Mice whose IGF-II gene has been eliminated are severely growth retarded *in utero* and have small placentas, but they survived and grew normally after birth. Mice with deleted IGF-I are also very small but have a normal placenta and they had severe postnatal arrest and neonatal death. This suggests that IGF-I plays a large role in prenatal as well in postnatal growth; however, IGF-II affects placental growth, and thus fetal size, but it is not essential for postnatal growth.[35]

Other hormones

The effect of the GH on fetal growth is minimal, since the liver is the only fetal tissue that expresses receptors for this hormone. Leptine is a hormone that plays an important role in the regulation of the fetal weight. The umbilical plasma levels of leptine are correlated with the birth weight and with the umbilical concentration of insulin, thus confirming that role.[36] The effect of other hormones on fetal growth is also minimal.

Maternal and environmental factors

There are certain factors that have been associated empirically with macrosomia. They include previous history of macrosomia, multiparity, maternal obesity, the mother's age, height, excessive weight gain during pregnancy, prolonged pregnancy, and prolonged labor.[37–40] Recently, a birth weight prediction equation based on maternal and pregnancy-specific characteristics, which achieved accuracy of prediction comparable to that obtained using ultrasonic fetal biometry, has been validated.[41] It has also been recently stressed that, in gestational diabetes pregnancies, the association of maternal glucose values and fetal macrosomia is limited to the fasting glucose levels between 32 and 35 weeks, while maternal obesity appears to be a strong risk factor of macrosomia throughout pregnancies with gestational diabetes.[42] In this sense, it has been described that the occurrence of obstetric complications, including macrosomia, parallels the level of obesity, but even moderate overweight amplifies the risk.[43]

To study the influence of these factors, we used a retrospective study of 22,745 births (of more than 20 weeks) in the Hospital Clínic de Barcelona between 1980 and 1992. To reduce difficulties of interpretation, we eliminated pregnancies in diabetic patients, which left 21,298 pregnancies, which we allocated as follows:

Group 1: 500–2499 g (those with a low birth weight, totalling 1462 cases or 6.9%)
Group 2: 2500–3999 g (those with normal weight, totalling 18,748 cases or 88%)
Group 3: 4000–4249 g (first macrosome fraction, totalling 697 cases or 3.3%)
Group 4: 4250–4449 g (intermediate macrosome fraction, totalling 275 cases or 1.3%)
Group 5: over 4500 g (totalling 116 cases or 0.5%)

To describe and evaluate the distribution of the cases we used Habermann's contingency tables.

With regard to age there is a significant increase in cases of macrosomia (Table 125.1) after the age of 35, except in certain weight groups in ages above 40 in which, although there is a clear increase in frequency, it does not reach significant values due to the low number of cases in the group. Similar results are observed with parity. Beginning with the group with two or three previous pregnancies, there is a significant increase in frequency of macrosomes in all groups (Table 125.2). The same is found with maternal height when it is above 1.60 m and, especially when it is above 1.65 m (Table 125.3), with weight increase above 20% (Table 125.4), with a history of macrosomia (Table 125.5), and with fetal sex (Table 125.6). In the majority of cases, these factors increase the frequency

of macrosomia by two or three times, but the history of macrosomic previous fetuses increases macrosomia by nearly seven times.

Table 125.7 compares macrosomic newborns with newborns of normal weight, showing a statistically significant association between macrosomia and parity, maternal age, gestational age, maternal height and weight, and the maternal history of previous macrosomes. The implications of this and of other similar studies are that older women, obese women, multiparous women, and those with prolonged pregnancies each belong to a group with high risk of macrosomia, which is compounded when more than one is present at the same time. This is especially important in the selection of the group of pregnant women at risk of macrosomia, for whom we can consider adopting preventive attitudes toward the complications connected with this pathology.

The origin of macrosomia in diabetes

Since its description 150 years ago, macrosomia has been one of the main components of diabetic

Table 125.7 Epidemiology factors related with macrosomia in the Hospital Clínic de Barcelona (from Sack[1])

	Birth weight (kg)			
Factor	**< 2.5**	**2.5–4**	**> 4**	***p*[2]**
Parity				< 0.0001
Nuliparous	7.8	88.5	3.7	
Parous	6.2	87.5	6.2

fetopathy. It has been known for some time that the weight of the offspring of an untreated diabetic mother is 140% higher than that of the controls, but this increase is distributed asymmetrically in that CRL is increased by 112%, heart size by 175%, liver by 180%, lung and spleen by 130%, the adrenal glands by 160%, and the pancreas by 110%; the kidneys and the brain do not increase in size.[44] Moreover, the increase in weight is due to the increase in both the size and the number of cells.[44] In addition, the data from the Clinic Hospital of Barcelona mentioned above confirm that the distribution of macrosomes is significantly greater in diabetic compared with non-diabetic patients (data not shown).

The problem of excessive fetal growth in the diabetic pregnant woman is complex and may be the consequence of an abnormal supply of nutrients to the fetus. In the early 1950s Pedersen established the hypothesis that served for more than 30 years to explain fetal weight gain in diabetic mothers;[45] as a result of the characteristic hypoinsulinemia diabetic patients present hyperglycemia. The glucose easily crosses the placenta through a diffusion mechanism and reaches the fetus, 75% of the levels present in the mother's circulation. These high fetal blood glucose levels are an additional stimulus for the fetus, which responds by increasing insulin secretion, which causes fetal hyperinsulinemia, which in turn causes increases in hepatic glycogen and the synthesis of triglycerides in the adipocytes, all of which leads to increased weight and macrosomia.

This hypothesis was later extended by Freinkel and Metzger,[46] who examined the role played by other nutrients. In their model (Figure 125.1), reduction in maternal availability of insulin leads to an increase in maternal levels of glucose, which furthermore is underused. This produces changes in the levels of all maternal nutrients, with high plasmatic levels not only of glucose but also of lipids, some amino acids, and ketones. Placentary structure and function may be altered, allowing an abnormal mixture of nutrients to reach the fetus. This contributes to anabolism

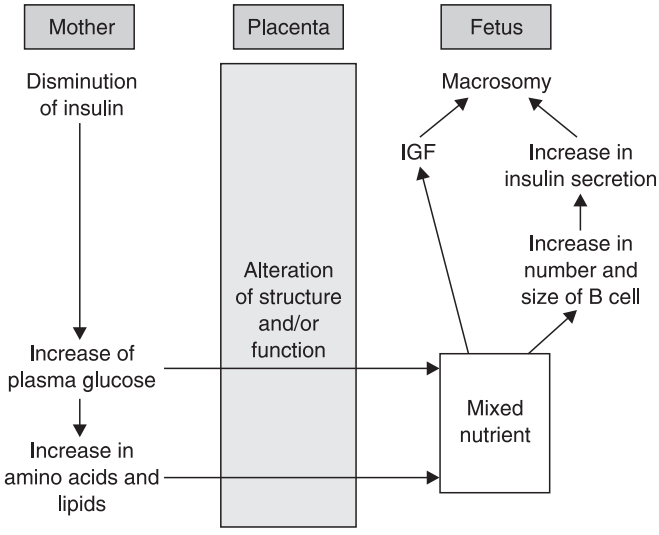

Figure 125.1

during the second half of pregnancy and produces excessive and premature insulin secretion, which leads to the growth in all the insulin-dependent organs.

We have recently investigated if there is any relationship between plasma lipid alterations and neonatal birth weight in pregnancies complicated with gestational diabetes mellitus (GDM). Between June 1994 and December 1995, 107 pregnancies complicated with GDM and 69 normal pregnancies were prospectively evaluated. The non-diabetic patients had normal O'Sullivan test during the early third trimester of their current pregnancy (26–29 weeks' gestation). GDM was diagnosed by a 3-h oral glucose tolerance test performed at 28–31 weeks' gestation. All women were studied after an overnight fast, between the 31st and the 34th gestational weeks. The levels of plasma cholesterol, triglycerides, high-density lipoproteins, and low-density lipoproteins were measured and their correlations with the birth

Table 125.8 Plasma lipid level in both groups studied

	Gamma	Control*	*P***
Cholesterol (mg/dl)	256.5 ± 52.7	240.8 ± 47.6	0.04
Triglycerides (mg/dl)	208 ± 69.1	170 ± 64.4	0.001
Hypercholesterolemia	52 (48.6%)	30 (42.3%)	NS
Hypertriglyceridemia	86 (80.4%)	39 (54.9%)	< 0.01
Hyperlipemia	93 (86.9%)	47 (66.2%)	0.002

*Results are mean ± SD or *n* (%); **Student's test or chi-square test as appropriate

Table 125.9 Fetal birth weight in normal and GDM pregnancies by plasma level of cholesterol and triglycerides

	Plasma level*		
Parameter	**Normal**	**High**	***P*** **
GDM group			
Cholesterol (mg/dl)	3099 ± 464	3190 ± 606	NS
Triglycerides (mg/dl)	2682 ± 697	3226 ± 470	0.01
Normal group			
Cholesterol (mg/dl)	3195 ± 437	3301 ± 362	NS
Triglycerides (mg/dl)	3154 ± 362	3248 ± 445	NS

*Results are mean ± SD; **Student's test

weight was determined in both the groups studied. The prevalence of hyperlipemia (hypertriglyceridemia and/or hypercholesterolemia) was greater among the GDM patients (Table 125.8), because a very high rate of hypertriglyceridemia is seen in these patients (85% vs. 56% in non-diabetic patients). The mean birth weight correlated positively with the plasma triglyceride level in the GDM patients but not in the non-diabetic group. The cholesterol did not correlate with the birth weight in the GDM group or in the normal patients group (Table 125.9 and Figures 125.2–125.5).

Clinical studies have shown that macrosomia may be associated with even minimal levels of hyperglycemia.[47,48] Freinkel and Metzger consider that other, as yet unidentified, defined growth factors may also contribute to excessive weight increase. The role of IGFs, among others, has been analyzed.[31,32]

The fetal pancreas is microscopically visible from the fourth week of embryonic life and insulin is detectable, as has been reported, from 7 to 10 weeks, albeit at levels much lower than those detectable in later stages of pregnancy. *In vitro* studies have shown that fetal pancreatic beta cells are functional from the 14th week of pregnancy, responding to amino acids, to ions such as Ca^{2+}, and to factors that increase intracellular cyclic adenosine monophosphate (cAMP), such as theophylline and glucagons.[49] Other studies have also shown that these cells release insulin in response to stimulation with glucose[50] in such a way that there is clear evidence to suggest that insulin may be a physiological regulator of glucose metabolism and fetal growth.[51]

Functional maturation of beta cells in fetuses of diabetic mothers is more premature than in fetuses of mothers with normal glycemia metabolism.[52] These studies emphasize the importance of understanding the physiological impact of early sensitivity to glucose: if this premature pancreatic maturation occurs, the onset of macrosomia may be much earlier than was previously believed.

Placental synthesis of substances such as human chorionic somatomamotrophin may influence nutrient availability. Likewise, decidual production of prolactin and lipotrophin, a precursor of the adrenocorticotropic hormone, and of endorphins may play a role in the modulation of fetal growth. Also, the hypothalamus–pituitary axis, which is well developed in the later part of pregnancy, may segregate peptides that promote fetal growth. Thus, fetal size at birth is a result of the integration of a system of three compartments: mother,

placenta, and fetus. In a recent paper,[53] it has been hypothesized that fetal macrosomia could be the result of a placental defect because the placenta is interposed between both fetal and maternal compartments and it has its own glucose metabolism. One characteristic feature of the human placenta in diabetes is the increased deposition of glycogen. Neither hyperglycemia nor hyperinsulinemia increase the glycogen content in the trophoblast. Since the glycogen increments in diabetes are predominantly located around fetoplacental vessels, it is tempting to assume a fetal origin of glucose making up the glycogen deposits. In fat, glucose can be transported back from the fetus into the placenta and this reflux is increased in diabetes. Therefore, in conditions of fetal glucose levels exceeding the demand for sustaining fetal growth and metabolism, glucose can be stored in the liver and other fetal tissues. Once these stores are saturated, glucose is extracted from the fetal circulation by the glucose carriers GLUT1 and GLUT3 on cells surrounding the fetoplacental vasculature and stored therein, again in the form of glycogen. These processes might be under the control of fetal insulin, because insulin injected into the fetal circulation increases placental glycogen stores. Fetal macrosomia would then occur only when fetal hyperglycemia exceeds the placental capacity to store excess fetal glucose. Thus, according to this hypothesis, the placental failure to protect the fetus would cause the 'unexplained' phenotypic changes occasionally found in fetuses born to well-controlled diabetic women.[53]

Finally, the appearance of macrosomia is multifactorial and is probably due to an excessive supply of nutrients to the fetus, together with the action of other growth-promoting factors. However, the accumulated evidence suggests that fetal hyperglycemia may not be the only stimulus responsible for fetal hyperinsulinemia; in fact, in humans, glucose is just one of the substrates involved in the production of insulin and, although it is one of the most important, other nutrients seem to be also important.

126 Macrosomia: obstetric management

B. Serra, J. M. Carrera and J. Mallafré

Introduction

As we have seen in an earlier chapter in this section, macrosomia is related to an increase in maternal and fetal complications. These include dystocia, prolonged birth, operative delivery, shoulder dystocia and postpartum hemorrhage. However, we must remember that a significant number of the mothers in these cases are diabetic, and this in itself increases fetal vulnerability.

It is also the case that the larger the fetus, the greater the duration of the birth, and the greater the risk of cephalopelvic disproportion and shoulder dystocia.

Management of the pregnancy

In our opinion there are three significant factors during pregnancy:

(1) *Prophylaxis of the macrosomia*, in particular the early detection and treatment of gestational diabetes (O'Sullivan's test, etc.). Appropriate advice on hygiene and diet should also be given to avoid obesity and a weight increase of over 20% during pregnancy. Finally, the remaining factors involving a risk of macrosomia must be evaluated thoroughly (age, parity, size, past history, prolonged gestation, etc.).

(2) *Evaluation of fetal weight*, bearing in mind not only the clinical evaluation of fetal size (uterine height over 34 cm at term or 32 cm in week 35), but more particularly the echographic estimate of fetal weight (biparietal diameter, head and abdominal circumferences). If the biometric values remain over the 90–95th percentiles, it is essential to establish the diagnosis of a probable macrosomia, but the following statements can be made regarding the accuracy of ultrasound in predicting fetal macrosomia:[1]

   (a) Independent of the formula used the relative accuracy of the estimated fetal weight decreases with increasing birth weight.
   (b) Ultrasound biometry, used to detect macrosomia, is characterized by low sensitivity, low positive predictive value and high negative predictive value. Thus, ultrasound's main value is to rule out the diagnosis.[2]
   (c) The positive predictive value can be increased making serial measurements.[3]
   (d) The measurement of fetal parts may not be very accurate in cases of combined maternal obesity, oligohydramnios and anterior placenta.
   (e) Every prenatal diagnosis center should use its own growth curves to select its particular cutoff value to predict macrosomia.
   (f) The time elapsed between the fetal weight estimation and delivery may influence the accuracy and precision of the estimate.
   (g) To date, none of the management algorithms based on ultrasonographically estimated fetal weight has shown any efficacy in reducing the incidence of shoulder dystocia or brachial plexus injury.

Although three-dimensional ultrasound and MR techniques have been used to assess fetal weight, they are still under investigation.

(3) *Prepartum obstetric strategy*, on which opinions are divided. While some authors[4] consider an induced birth inappropriate for avoiding any possible mechanical problems, since the risks can outweigh the benefits, others[2] favor induction from week 38 onwards if conditions are favorable (Bishop's test over 7). Their justification is that, if the birth is brought forward by 2 weeks, an increase in fetal weight of between 200 and 400 g may be avoided. In any case, the majority of authors agree that when the fetal weight is calculated as being over 4500 g, an elective cesarean section must be considered.[4–6]

Management of the birth

The decision regarding the route of delivery will depend on the estimated size of the fetus and the local

conditions, as well as on whether the mother is diabetic.[2,7]

If the estimated fetal weight is over 4500 g, the cesarean option should be chosen, regardless of any other considerations, apart from cases of mothers admitted in labor.

If the mother is diabetic, a cesarean section should be indicated if the suspected fetal weight is 4000 g or more. According to Langer and colleagues,[8] 84% of shoulder dystocias are thus avoided. It must be borne in mind that a cesarean section for extracting a macrosomic fetus has associated risks, since the uterus may be torn if the uterine incision is insufficient.

If the fetal weight is under 4500 g, the mother is not diabetic and the local conditions are acceptable (cephalic presentation, multiple pregnancy, mature neck, etc.), a vaginal delivery should be attempted.

The intrapartum management depends on the evaluation of the dilatation and the expulsion. If the evolution is slow and there appears to be an intrapartum risk of shoulder dystocia, it is necessary to resort to a cesarean section. Extractions with forceps or vacuum must be avoided in all cases. The delivery of an apparently macrosomic fetus is considered as high risk, and it is essential that both an anesthesiologist and a neonatologist are in attendance in the delivery room. The staff present at the birth must be absolutely sure of what to do if a shoulder dystocia should suddenly appear.

Shoulder dystocia

A shoulder dystocia occurs when the bisacromial diameter of the fetus is too large for the maternal lower pelvic strait and the foremost shoulder of the fetus encounters the obstacle of the pubic bone once the head is already outside. Such a dystocia can occur in a birth that had been evolving normally up to that point, although it is usually preceded by a prolonged expulsive period. It seems that its incidence is higher in obese patients. The diagnosis can be suspected if the head, after being released, seems to go back in and wedge itself firmly against the perineum. If slight downward pressure does not succeed in dislodging the shoulder, then the diagnosis is confirmed. This is the cue for taking the following steps:[3]

(1) Forced flexion of the legs on the abdomen. The upward rotation of the symphysis can free the affected shoulder (McRoberts' maneuver). If this is unsuccessful:
(2) Wide half-lateral episiotomy. Begin or intensify anesthesia. Clean the fetal mouth and nose.
(3) Manual pressure on the suprapubic region to try to pass the shoulder under the pubic symphysis (Hibbard's maneuver), while the index finger of the other hand pulls away from the rear axilla to allow the rearmost shoulder to progress through the concavity.
(4) If the above maneuver is unsuccessful, apply pressure to the fetus' rear scapula and try to rotate it sideways and upward (Woods' maneuver). If this succeeds, then the rearmost shoulder will end up below the symphysis and will emerge first. In other words, the rearmost shoulder will become the foremost one.
(5) If this maneuver is fruitless, then the fetus' upper arm must be moved rapidly onto its thorax and brought out. The foremost shoulder will be then dislodged and lie below the symphysis.
(6) If this also fails, then a cleidotomy must be considered.

These maneuvers are easy to describe, but difficult to perform with dexterity.

Shoulder dystocia is associated with fetal asphyxia, death and residual complications, such as brachial plexus complications (Erb's paralysis), diaphragmatic paralysis and fractures in the humerus and clavicle. As for the mother, these cases usually give rise to hemorrhages in delivery, hematomas and vaginal tears and, in extreme cases, uterine rupture.

127 Macrosomia: neonatal aspects

E. Doménech and N. Marta Díaz-Gómez

Definition

Neonatal growth is assessed using anthropometric measures taken immediately after birth.[1,2] Newborns (NBs) with a birth weight between the 10th and 90th percentiles on the intrauterine growth curves are considered appropriate for gestational age (AGA) and those lower than the 10th percentile are small-for-gestational age (SGA).

An NB is considered large-for-gestational age (LGA) when its weight is greater than the 90th percentile for gestational age on intrauterine growth curves,[3] although some authors advocate two standard deviations above the mean of birth weight for gestational age. The term macrosomic is used when the birth weight exceeds 4000 g. Some authors[4] believe that the term macrosomic should refer to those whose weight is greater than or equal to 4500 g (1.7% of all NBs).

Certain infants are constitutionally large due to favorable combinations of genetic potential and maternal environment.[5] Normal intrauterine growth is affected by gender and race. Female neonates are smaller than males, and black neonates are smaller than whites, at each estimated gestational age. Thus, to classify a neonate as LGA we have to use intrauterine growth curves that are gender and race specific.[6] Altitude (> 4000 ft) may also negatively affect fetal growth.[6] Ouzilleau *et al.*,[7] using Canadian standards curves, have established the 90th percentile as 4200 g for boys and 4000 g for girls born at 40 weeks of gestational age.

In addition to weight, some have argued that neonatal body proportions have a role in defining macrosomia and predicting its complications. Fetuses with macrosomia of diabetic mothers have a greater shoulder to head circumference ratio, which increases the risk of shoulder dystocia. Disproportionate macrosomia (ponderal index exceeding the 90th percentile in relation to gestational age and sex of the reference population) has been associated with an increased likelihood of neonatal complications among infants of diabetic mothers,[8,9] and also with an increased likelihood of hypoglycemia in infants of non-diabetic mothers.[10]

Incidence

The overall incidence of macrosomia (≥ 4000 g) is 8% of all NBs and as much as 26% when they are infants of diabetic mothers (IDMs),[3] and appears to be increasing.[11] This increase is correlated with an increase in gestational diabetes, although a high percentage of infants with macrosomia are born to non-diabetic mothers.[8] In a study performed in Montreal, of 57,199 non-malformed singleton live births at or after term between 1978 and 1996, Kramer *et al.*[11] observed an increase in mean NB weight with a corresponding rise in the percentage of LGA. The increase was largely the result of a rise in prepregnancy body mass index, gestational weight gain and gestational diabetes, post-term deliveries as well as a substantial reduction in maternal cigarette smoking and changes in sociodemographic factors.

Endocrine factors that influence fetal growth

A brief review of fetal growth facilitates the understanding of some of the physiologic and pathologic events responsible for neonatal macrosomia.

Intrauterine growth depends on the interaction of maternal, placental and fetal endocrine factors. In normal placental function and a normal maternal environment, the fetal genome is the central controller of growth.

Several hormone and growth factors influence fetal growth. The more relevant are insulin, the insulin-like growth factor (IGF) system, adipocytokines, ghrelin, placental growth harmone (GH), placental lactogen and leptin.

Insulin-like growth factors

It is believed that IGF-1 is a major determinant of fetal growth and the role of the other possible endocrine regulators is likely to be mediated in part by the IGF system.

Table 127.1 Values of GH, IGF-1 in AGA, LGA or SGA full-term infants

	Cord blood			At first week of life		
	LGA	AGA	SGA	LGA	AGA	SGA
Weight (g)	4025 ± 223	3269 ± 376	2200 ± 2990	4011 ± 217	3270 ± 331	2179 ± 211
Seric GH (ng/ml)	16.8 ± 10.8	19.5 ± 20.1	24.0 ± 4.9	20.6 ± 9.3	40.9 ± 28.9	44.8 ± 22.0
Urine GH (ng/kg/day)	—	—	—	1.2 ± 2.7	2.9 ± 3.5	6.4 ± 4.5
Seric IGF-1 (ng/ml)	74.2 ± 29.3	63.5 ± 25.1	9.4 ± 5.8	37.9 ± 29.5	28.1 ± 28.0	20.3 ± 16.1

LGA, large-for-gestational age; AGA, appropriate-for-gestational age; SGA, small-for-gestational age; GH, growth hormone

IGF-1 circulates bound to one of six IGF-binding proteins (IGFBPs), which modulate IGF activity. IGF-1 and their binding proteins are synthesized in the liver and are also produced locally by most tissues, where they act in an autocrine or paracrine manner. The local IGF-1 production is very important for organ development during fetal life.

Han *et al.* have shown that IGFs, especially IGF-2, are present in placental trophoblasts and fetal membranes from as early as 6 weeks. Animal studies have demonstrated that IGF-2 is important in fetal growth during early gestation whereas IGF-1 is the predominant growth-promoting factor in late gestation.[12] IGFs lead to abnormal growth when genetic variation in expression is present.

The IGFBP-3 binds more than 95% of the IGF in serum. One of the main IGFBPs, IGFBP-1, is a potential inhibitor of IGF-1 action. The levels of IGFBP-1 vary in inverse proportion to insulin levels. The levels of IGF-1 and IGFBP-3 in the perinatal period are low and the levels of IGFBP-1 are high, compared with older children and adults.[13]

Whereas in the child and adult both GH and nutrition control the synthesis of IGF-1 and IGFBP-3, in the perinatal period the nutrition status is probably the main regulator of their secretion. This could be explained in part by the immaturity of the GH receptors during this period.[14,15]

IGFBP-1, an important IGF-binding protein in pregnancy, is the predominant IGFBP in decidual cells, amniotic fluid and fetal plasma. Its concentration in the maternal circulation increases during pregnancy. In the circulation IGFBP-1 normally exists in a highly phosphorylated (p) state; however, during pregnancy non-phosphorylated (np) isoforms of IGFBP-1 are found. Gibson *et al.*[16] have demonstrated that human decidualized endometrium produces both npIGFBP-1 and pIGFBP-1, and that in the presence of IGF-2, npIGFBP-1 was preferentially produced. Since npIGFBP-1 has decreased affinity for IGF-1, these effects should enhance IGF-1 bioavailability and are likely to represent an important mechanism for controlling fetal and maternal tissue growth.

We observed the highest levels of IGF-1 in LGA infants of non-diabetic mothers (Table 127.1), and the lowest in the SGA, and the reverse occurred with the levels of GH.[17–19] These findings coincide with those of other authors.[14,20]

Insulin

The role of insulin is thought to be permissive in fetal growth and is demonstrated by the phenotypes that characterize the extreme of insulin secretion. Neonates who are hyperinsulinemic have macrosomia, whereas severe growth restriction accompanies hypoinsulinemia. Hyperinsulinemia causes a decrease in IGFBP-1 levels, which increase IGF-1 bioavailability, and consequently accelerates fetal growth. Also, insulin itself may exert a direct mitogenic effect by binding to the IGF-1 receptors.[8]

Adipocytokines

Adipose tissue produces and secretes a number of hormones, collectively called adipocytokines. These include leptin and adiponectin, both of which are important in modulating metabolism and energy homeostasis.

Leptin, a hormone secreted by adipocytes and syncytiotrophoblast cells of the placenta, has been associated with intrauterine growth. This hormone is detectable in fetal umbilical cord blood at concentrations comparable with those found in adults. Plasma leptin levels in cord blood correlate with birth weight and their levels are significantly higher in LGA compared with AGA infants and are decreased by conditions that lead to low birth weight, such as maternal smoking and prematurity, although the mechanism by which it may by related to fetal growth remains unknown.[21] Christou *et al.*[22] found that the relationship between cord leptin levels and birth weight was independent of insulin and the IGF system.

Adiponectin is exclusively expressed and secreted from adipose tissue and is important in glucose and lipid metabolism. Plasma adiponectin levels decrease as adiposity increases in children and is inversely related to insulin, leptin and body weight. The role of adiponectin in fetal growth has not been clearly determined. Tsai *et al.*[23] have reported that high adiponectin levels are present in cord blood and are positively correlated with birth weight and adiposity. This suggests that adiponectin may be involved in regulating fetal growth.

Ghrelin

Ghrelin is secreted by the fundus of the stomach, the hypothalamus and the placenta. This peptide is closely associated with glucose metabolism and body mass. Hyperglycemia and insulin decrease plasma ghrelin. Fasting ghrelin concentration is decreased in patients with obesity. Insulin resistance and hyperinsulinism, commonly reported in obese subjects, have been proposed to explain part of this relationship.[24]

Farquhar *et al.*[25] have demonstrated the presence of ghrelin in cord plasma samples of NBs. They also found that its concentrations were inversely related to both birth weight *z*-score and glucose concentration. Plasma ghrelin levels in cord blood were 40% higher in SGA compared with AGA and LGA neonates, suggesting that ghrelin may play a physiological role in intrauterine malnutrition.

Placental lactogen and placental GH

Endocrine functions of the placenta include the synthesis of growth factors and hormones involved in cell reproduction and differentiation. Human placental lactogen, which is synthesized and secreted by the syncytiotrophoblast cells of the placenta, plays an important regulatory role in fetal growth, by stimulating the production of IGF-1 in the fetus and by increasing the availability of nutrients to fetal tissues.[26] On the other hand, placental GH has metabolic activities comparable to those of pituitary GH and is an important regulator of maternal IGF-1. Placental GH and maternal IGF-1 do not cross the placenta. Their effects on fetal growth are presumably mediated by effects on placental metabolism and substrate supply to the fetus.[27]

Causes of macrosomia

For proper management of macrosomia we should identify its possible cause. There are many possible causes for exaggerated fetal growth.

Congenital disorders

There are several congenital disorders associated with macrosomia, such as Sotos syndrome (cerebral gigantism), Carpenter syndrome, Weaver syndrome, Nevo syndrome, Nesidioblastosis, Beckwith–Wiedemann syndrome, Perlman syndrome, Marshall syndrome, Ruvalcaba–Mahre syndrome and some transpositions of the large arteries.

Hyperinsulinemia is a primary cause of macrosomia for many of these patients. Abnormalities in IGF secretion also have a significant role in many of these infants.

Nesidioblastosis (autosomal recessive disorder with hyperplasia of the β cells of the pancreas) is a life-threatening form of hypoglycemia that starts during the neonatal period in most cases and is caused by hyperinsulinism. Its diagnostic criteria are an extremely high demand for carbohydrates (> 15 g/kg/day), inadequately high plasma insulin level and an inhibited production of ketone bodies. The acute use of octreotide (somatostatin analog) produces prompt elevation of blood glucose, even in patients who fail to respond to diazoxide (5 mg/kg/dose, every 6 h) and hydrocortisone (25 mg/kg/day). In addition, it may be possible to avoid the need for partial or subtotal pancreatectomy by the long-term use of octreotide.[28]

Infants with Beckwith–Wiedemann syndrome (macrosomia and hyperinsulinism) may present (see Figure 127.1) typical phenotypic hyperinsulinemia features such as macroglosia, visceromegalia and omphalocele, as well as embryonic tumors and overproduction of IGF-2. These patients have anomalies in the short arm of chromosome 11 (replications, trisomies) where the insulin and IGF-2 genes are found, and in the neighboring genes including oncogene *H-ras* and the gene associated with Wilms tumor.

Other intrinsically fetal causes of accelerated growth are infrequent: twin receptors of a parabiotic pair are the most commonly cited. The NB with hydrops fetalis and with some fetal tumors (neuroblastoma, teratomas) also may have excessive weight for gestational age.

Diabetic pregnancy

The most common and best-known cause of LGA infants is the diabetic mother. In the USA, 0.2–0.3% of pregnancies are complicated by preexisting diabetes, and another 1–5% involve gestational diabetes.[29]

As a rule, the infant of a diabetic mother will be large for its gestational age, plump and born covered in an abundant layer of vernix caseosa, with a plethoric aspect, reddishness and cushingoid facial aspect, presenting limited motility and drowsiness during the first hours of life.

In the groups D, E and F of the White classification of diabetes with vasculopathy, there is often a placental insufficiency, which may give rise to children with normal or low birth weight.

The incidence of macrosomia in IDMs is approximately 25–30%, although we have found a decrease from 22.1% to 8.6% in recent years.[30] Fetal growth acceleration in LGA fetuses of diabetic mothers starts in the second trimester, from 18 weeks, and increases

Figure 127.1 An infant with Beckwith–Wiedemann syndrome showing macroglosia, visceromegalia, macrosomia and umbilical hernia.

progressively as the gestation advances, reaching maximum differences in the third trimester.[31]

Macrosomia in these NBs could be attributed to the excessive transferral of glucose from the mother to the fetus inducing fetal hyperglycemia. The fetal pancreas responds with a hypertrophy of the cells of the pancreatic islets and hyperplasia of the β cells, which produce fetal hyperinsulinism, which is accepted as the principal mediator of macrosomia, neonatal hypoglycemia and other perinatal morbidities. Hyperaminoacidemia also has an intrauteral stimulating effect on the development of β cells and of the anabolic actions of the insulin, which could be mediated by the release of IGFs.[32] Fetal anabolism is facilitated in this way, with fatty expanses constituting most of the fetal mass increase.[33]

Organomegaly is selective, with the kidney, heart, suprarenal and bone length enlarged, which are increased in proportion to weight, but brain size does not increase (corresponding to its gestational age), so the head may seem disproportionately small.

Fetal hyperinsulinemia and excessive fetal growth are significantly associated with antepartum maternal hyperglycemia in diabetic pregnancy.[34] Gold *et al.*[35] have shown that first- and second-trimester HbA1 levels were associated with macrosomia and that periconceptional glucose control was most predictive of birth weight in type 1 diabetic pregnancy. A possible explanation could be that early programming of fetal growth by elevated maternal glucose levels during the periconceptional period may result in subsequent LGA babies.

A much improved quality of glycemic control in pregestational diabetic pregnancy has brought a marked improvement of perinatal outcome, with a reduction of premature deliveries and severe neonatal morbidity. However, the fact that fetal macrosomia remains five to six times higher than normal suggests that the glycemic threshold for enhanced fetal growth is closer to normal than it is for other fetal and neonatal complications.

Other causes of macrosomia

The birth of an infant of great weight increases the possibility of subsequent diabetes in the woman affecting future births. Many macrosomic infants have non-diabetic mothers.[3,36] Infants of large, tall and heavy mothers, of women who are obese prior to pregnancy or those who gain excessive weight during this period may be large. The rate of LGA infants is three times higher in multiparous than in primiparous mothers.[4,37]

In a retrospective study of 33,000 live NBs, 1.7% were considered macrosomics (neonatal weight of 4500 g or more).[4] Among the isolated high-risk factors for the existence of macrosomia were postmature pregnancy (15.4%), morbid obesity (10%), insulin-dependent diabetes (9.2%), gestational diabetes (6.4%) and obesity (5.6%).

Body composition

Different techniques have been used to assess body composition in neonates. It is possible to make a fair estimate of the body fat mass of the NB by using an anthropometric model that includes skin fold measure, by bioelectrical impedance analyses or by dual-energy x-ray absorptiometry. Using these techniques it has been shown that infants with macrosomia have a different body composition from that of the AGA infants at birth,[38] and others[39] have reported that LGA infants had significant higher total body fat, expressed as absolute amounts or as a proportion of body weight, and lower lean body mass. Maternal diabetes exaggerated these body composition changes (Table 127.2).

The effect of maternal diabetes on fetal bone mass is controversial. Hammami *et al.*[39] comparing 47 LGA neonates, 11 of them born to diabetic mothers, with 47 gestational age-matched AGA infants, found that LGA neonates have higher bone mineral content.

Table 127.2 Anthropometric measurements, body fat mass and body lean mass, estimated by bioelectrical impedance analyses, in term newborn infants from diabetic and non-diabetic mothers

	Infants of non-diabetic mothers			Infants of diabetic mothers	
	SGA ($n=21$)	AGA ($n=150$)	LGA ($n=29$)	AGA ($n=30$)	LGA ($n=20$)
Weight (g)	2162 ± 199	3121 ± 326	4030 ± 338	3223 ± 443	4093 ± 420
Length (cm)	45.8 ± 1.4	49.6 ± 1.6	53.0 ± 1.4	49.4 ± 1.9	51.8 ± 1.7
Head perimeter (cm)	32.3 ± 0.7	34.1 ± 1.1	35.9 ± 0.6	34.2 ± 1.6	35.4 ± 0.8
Arm perimeter (cm)	8.2 ± 0.5	9.9 ± 0.8	11.0 ± 1.0	10.3 ± 0.8	11.8 ± 0.9
Sum of four skin-folds (mm)	13.1 ± 1.8	17.6 ± 2.7	19.8 ± 2.7	20.0 ± 3.5	24.3 ± 3.2
Total body lean mass (g)	2125 ± 187	2636 ± 291	3501 ± 379	2693 ± 293	3325 ± 344
% body weight	97 ± 1	85 ± 7	87 ± 6	85 ± 9	82 ± 8
Total body fat mass (g)	53 ± 33	484 ± 251	525 ± 248	530 ± 341	768 ± 407
% body weight	3 ± 1	15 ± 7	13 ± 6	15 ± 9	18 ± 8

LGA, large-for-gestational age; AGA, appropriate-for-gestational age; SGA, small-for-gestational age

Other authors found that infants of diabetic mothers have low bone mineral content (BMC) and high bone resumption marker at birth[40–42] and that infant BMC correlated inversely with poor control of diabetes in the mother, specifically first-trimester maternal mean capillary blood glucose concentration, suggesting that factors early in pregnancy might have an effect on fetal BMC.[42] Lower BMC and high bone resumption markers in infants of diabetic mothers could be related to the low vitamin D levels that have been found in NB of diabetic mothers than in control subjects.[43]

Neonatal complications

These apparently 'beautiful' NBs should be assessed by the neonatal specialist early on, as they may be more likely to present certain diseases, and should not be given an early discharge.

They should be screened for: glycemia, calcemia, hematocrits, bilirubin and, if they have respiratory distress, a gasometer and thoracic radiography scan should be carried out to detect cardiac or respiratory disorders. Other complications include increased risk of cesarean section, protracted labor, lacerations of the birth canal and hemorrhage in the mother, shoulder dystocia, brachial palsy, perinatal asphyxia and skeletal injuries in the infants.

Over the last 20 years significant reductions in complications have been achieved. However, recent reports have shown that even in Western countries, morbidity and mortality rates remain higher than in AGA infants.

The perinatal mortality rate is higher for infants weighing more than 4000 g, and this perinatal mortality is higher in the USA than in Norway;[44] however, we have not found this, except in IDMs.

Table 127.3 shows the morbidity and mortality rate in our environment (Canary Islands), based on a sample of 12,311 NBs, classified as AGA, LGA or SGA.

Obstetric trauma and perinatal asphyxia

Although NBs are getting bigger, the maternal pelvis has not been reported to do so. Macrosomia is associated with an increased rate of selective cesarean delivery (33.9%, almost three times that of control infants, obstetric trauma and perinatal asphyxia.[8]

In the macrosomic NB, except for infants of large mothers, obstetric trauma (clavicle fracture, Erb paralysis or paralysis of the frenic nerve) is common when they are born by vaginal route, as a consequence of the elevated presence of shoulder dystocia. Cesarean delivery is also more common in macrosomic than in normal birth weight.[8,45] Spontaneous rather than induced labor is associated with a lower chance of cesarean delivery among those fetuses with macrosomia. On the other hand, frequencies of shoulder dystocia, 1-min Apgar scores less than 7, and abnormal umbilical blood gas determinations are not different between vaginal and cesarean delivery.[46] Vaginal delivery seems a reasonable alternative to elective cesarean and a trial of labor can be offered.[47]

Sonographic methods for the diagnosis of macrosomia were developed in hopes of improving clinical estimates. However, the relative error associated with these methods limits their use in clinical practice. Serial sonographic measurements that are above the limits chosen to define macrosomia increase the likelihood that a birth weight will be macrosomic and could help to answer weight-related clinical questions such as mode and timing of delivery, especially for patients with diabetes.[48] Recently, Tisi *et al.*

demonstrated that mothers giving birth to LGA infants had a lower concentration of protein in amniotic fluid at 12–20 weeks' gestation compared with mothers of AGA infants, suggesting that amniotic fluid proteins might emerge as biomarkers of fetal growth.[49]

Hypoglycemia

Hypoglycemia is a very frequent complication in IDMs. Thirty to forty percent of IDMs present hypoglycemia after birth. The risk is higher in macrosomic infants of poorly controlled diabetic women and in cases of maternal hyperglycemia during delivery.[50]

Hypoglycemia in infants of diabetic mothers could be attributed to fetal hyperinsulinism, which is secondary to maternal hyperglycemia. After birth, with the source of glucose discontinued, this neonatal hyperinsulinism leads to hypoglycemia. In these infants a transitory intensified pancreatic response has been demonstrated, although temporarily, when using glucose solutions and intravenous arginine,[51] which suggests that the hypoglycemia is mainly due to neonatal hyperinsulinemia. After birth, there is a rapid drop in glycemia levels, with persistently low concentrations of free fatty acids, glycerol and hydroxybutyrate.[52]

Other endocrinological observations in IDMs are a reduction in the release of catecholamines and of the blood levels of glucagon after birth, which are less raised than in normal controls.[53]

Hypoglycemia most frequently occurs between 1 and 5 h of life, when the maternal glucose contribution has disappeared, but levels of circulating insulin remain raised.

IDMs that present hypoglycemia have raised C-peptide levels and free insulin at birth.[54] In infants of diabetic mothers, C-peptide should be determined in cord blood to define degree of hyperinsulinemia and glucose at birth (in cord blood or in plasma no later than 30 min after birth) and at regular intervals thereafter (before feeding at 1, 3, 6, 12, 24, 36 and 48 h of life) for detection of neonatal hypoglycemia. Monitoring may stop if normal plasma glucose levels are found on at least two consecutive measurements.

LGA NBs of non-diabetic mothers are also considered at increased risk for hypoglycemia. As happens with infants of diabetic mothers, chronic fetal hyperinsulinemia may be one of the causes of neonatal hypoglycemia in LGA infants of non-diabetic mothers. C-peptide concentrations in the cord blood of 29 macrosomic neonates born of non-diabetic mothers were higher than in 23 control infants whose birth weight was AGA, and there was a significant direct correlation between birth weight and C-peptide concentration. Six of the macrosomic infants studied (20%) had hypoglycemia in the first 24 h of life, compared with none of the infants born with appropriate weight.[10]

Because hypoglycemia in the immediate NB period is common in LGA infants, it has been recommended that these neonates should be routinely monitored for blood glucose levels. However, recently, Rooy *et al.*[55] have demonstrated that although low blood glucose levels did occur in LGA infants, this was offset by a

normal ketone body response, equivalent to those observed in infants who were AGA. The authors argue that neonatal ketogenesis is a normal adaptive response that enables the transition from fetal to infant metabolism, and that LGA infants whose mothers did not have documented diabetes do not represent a high-risk group of abnormal neonatal adaptation. In view of this, routine blood glucose monitoring and routine formula milk supplementation for LGA infants are not recommended.

Under normal conditions at birth, the glucose levels in plasma of the umbilical cord correlate with the values of the mother. In nearly all cases, the levels of glycemia diminish in the first 2 h of life, and later increase and stabilize. It is not uncommon to observe an isolated value of hypoglycemia, and because of this, the diagnosis of this entity must be based on two consecutive low values on analysis made at an interval not greater than 30 min.

Hypoglycemia is defined by serum glucose values of less than 40 mg/dl (2.2 mmol/l) for full-term infants.[56]

In clinical practice, the primary detection of serum glucose is made with colorimetric strips impregnated with chromogen, but the blood sugar levels measured in this way are 10% less than those assessed by the current oxidase glucose method and they may overestimate the low glucose levels, and at times not identify the hypoglycemia.[45,57]

The diagnosis of hypoglycemia cannot be based on glucose measurement with reagent strips. Strip hypoglycemia (less than 40 mg/dl), should be verified in the laboratory.

In symptomatic hypoglycemia (defined as hypoglycemic signs and symptoms that disappear after glucose administration) we may find variable clinical manifestations: convulsions, apnea crises, hypotonia, lethargy, food rejection, wheezing and irregular breathing patterns, cyanosis, weak cry, etc.; it should be taken into account that at times intense hypoglycemia presents an asymptomatic course, with the possibility of causing irreparable cerebral damage.

We may differentiate between three situations requiring more control: asymptomatic IDM with normal glycemia, asymptomatic infants with hypoglycemia and symptomatic hypoglycemia:[30,52]

(1) In asymptomatic IDMs with normal glycemia in the first hour of life the early initiation of breastfeeding, in the first 30–60 min after delivery, can prevent hypoglycemia. Breast feeding should be frequent, at least 10–12 times per 24 h, and the infant should be put to the breast at the earliest signs of hunger (crying is a late sign of hunger).[58]
(2) In asymptomatic infants with risk factors,[56] continue breast feeding (every 1–2 h) or feed expressed breast milk or substitute (10–15 ml/kg). Recheck blood glucose concentration before subsequent feedings until the value is stable. If the plasma concentration is less than 2.0 mmol/l (36 mg/dl), a close surveillance should be maintained, an intervention is recommended if the neonate is unable to suck, does not tolerate the early and frequent feedings described above, common situations in IDMs, or if glucose is low despite feeding, or if abnormal clinical signs develop, the infant should be hospitalized. Begin intravenous glucose infusion of 4–8 mg/kg/min, according to the course of the glycemia. Repeat serum glucose within 30 min and serially thereafter until stable > 2.5 mmol/l (45 mg/dl). Then, continue breast feeding or bottle feeding and slowly reduce intravenous infusion.
(3) In cases of NBs with symptomatic hypoglycemia and/or weight < 2000 g, or respiratory difficulty, or glycemia < 20–25 mg/dl (1.1–1.4 mmol/l) or no increase 20–30 min after oral attempts, intravenous glucose (10%) should be administered, and one or more intravenous bolus of 200 mg/kg of 10% glucose should be administered, subsequently continuing with perfusion at a rate of 6–8 mg/kg/min and then adjusting infusion rate to maintain glycemia above 45 mg/dl. Encourage frequent breast feeding after relief of symptoms. As the amount of enteral feeding increases, the intravenous glucose supply is reduced progressively; avoid the sudden withdrawal of a significant parenteral contribution with a risk of reactive hypoglycemia developing.

The lack of hypoglycemic response to the intravenous glucose supply or its persistence over more than 48 h necessitates administration of 5 mg/kg/day of hydrocortisone, divided in three doses, and one should ascertain if there are other reasons to justify the prolonged hypoglycemia.

In these macrosomic NBs it is not easy to place the peripheral venoclysis. At times, it is interrupted by extravasation, producing a reactive hypoglycemia in hyperinsulinemic patients. Thus, central silastic catheters are commonly used, introduced through peripheral route. In the case of a symptomatic IDM on whom peripheral venoclysis cannot be performed because of lack of experience or means, 30–100 μg of glucagon/kg should be administered (to a maximum of 1 mg) by intramuscular or subcutaneous route. The increased glycemia that this provokes may last 2–3 h (or perhaps less, due to hyperinsulinemia reactive to postglucagon hyperglycemia), which permits the NB infant to be transferred to the appropriate center.

Congenital malformations

The association between isolated congenital anomalies and macrosomia has been evaluated in a retrospective study on 31,897 neonates with congenital anomalies, of whom 1800 were LGA (5.8%). Five anomalies were significantly associated with high birth weight: talipes calcaneovalgus, hydrocephaly, combined angiomatoses, hip subluxation, and non-brown-pigmented nevi.[59]

Table 127.4 Neonatal morbidity and mortality rates of infants of pre- or gestational diabetic mothers, related to the overall newborn population (1999–2003)

NBs	Total infants (%) (n=12,311)	Infants of diabetic mothers (%) (n=549)	Macrosomic infants ≥4000 g (%) (n=678)	Macrosomic infants of diabetic mothers (%) (n=47)

NB, newborn; AGA, appropriate-for-gestational age; LGA, large-for-gestational age; SGA, small-for-gestational age

Diabetic pregnancies are associated with an increase in congenital anomalies. The rate of congenital malformations in IDMs is two to eight times higher than that of the general NB population.[8,29,60] However, the offspring of diabetic males have the same incidence of malformations as the general NB population and gestational diabetes does not represent a risk of congenital malformation.

Approximately, 40–50% of perinatal mortality in IDMs (it is increased two- to fivefold compared with the general population) is attributable to serious congenital malformations. The congenital anomalies seen in diabetes affect multiple organ systems. The most common abnormalities are seen in the cardiovascular system (6.1% live births) and in the central nervous system (2.5% live births).

Sacral agenesis and syndrome of caudal regression (agenesis or hypoplasia of the femora and sacral agenesis) seem to have a particularly strong association with diabetes. In the IDM there is an increase in the rate of anencephaly, meningomyelocele, holoprosencephalia[61] and congenital cardiac defects compared with the general population.[62]

Maintaining normal glycemic levels during organogenesis is accompanied by a significant reduction, but not total elimination, of congenital malformations in IDMs,[63,64] especially those in White's classes D, E and F with greater genetic predisposition to congenital defects. On the other hand, it is possible that in addition to sugars other metabolic fuels, from ketones to deranged lipid peroxidation, may be responsible for the path mechanisms of congenital malformations and the whole metabolic disturbance of the IDM and it is quite conceivable that besides the classical approach to strict glucose control, other dietary measures with supplementation or replacement of deficient substrates (arachidonic acid, myoinositol, antioxidants) may prove beneficial.[65]

Other neonatal complications in infants of diabetic mothers

Perinatal mortality in IDM diminished from 197 to 20 per 1000 NBs between 1967 and 1984,[29] but in our series neonatal mortality continued to be greater in infants of diabetic mothers (pre- or gestational) compared with the overall NB population (Tables 127.3 and 127.4). The rate of neonatal morbidity depends on the severity of the diabetes of the pregnant mother more than other factors. Taking morbidity as a reference for the IDMs in our environment (Table 127.3) and also the reported findings of other authors,[40,41] we may affirm that some of the clinical problems still affecting IDMs are fetal growth disorders (30–40%), hypoglycemia (20–30%), prematurity (10–15%), perinatal asphyxia (15–16%), respiratory distress syndrome (10–15%) and congenital malformations (4–8%).

These complications are seen especially in infants of uncontrolled diabetic mothers, although some of these morbidities are still more common in IDMs than the general population, in spite of good metabolic control, and, in general, these neonates still require a higher rate of admission to neonatal intensive care units.

Respiratory distress syndrome

Clinical investigations into the effects of gestation on the maturation of the fetal lung have generated contrasting data. In one series of 805 IDMs[66] the corrected risk of hyaline membrane disease was six times greater than in those of offspring of non-diabetic mothers, which was in relation to the premature birth and retarded maturation of the pulmonary surfactant. Coinciding with the best obstetric care during diabetic pregnancy, the incidence of hyaline membrane disease has decreased,[67] possibly because the child was born with greater gestational age, more commonly by vaginal route and with a lower degree of hyperinsulinism.

Insulin interferes with the maturation process of the lungs of the fetus, induced by glucocorticoids.[68] In a study of the components of pulmonary surfactant in the amniotic fluid of the diabetic pregnancy woman, a reduced concentration of some of its proteins has been detected (SP-A).[69]

IDMs may have a respiratory distress syndrome (RDS) even with a mature ratio of lecithin/sphingomyelin (L/S) in amniotic fluid (8% of the IDMs), with varying data regarding well-controlled diabetic pregnancies.[70]

Phosphatidylglycerol in amniotic fluid indicates that pulmonary maturation has been completed (is a marker of complete pulmonary maturation) and many obstetricians prefer to verify its presence before undertaking the planned delivery in diabetic women.[45,70]

Strict control of the diabetes, amniotic fluid analysis to evaluate pulmonary maturity, predelivery control of the biophysical parameters and avoiding of cesarean section or premature births should result in no more than 5% of hyaline membrane disease due to tensioactive deficiency and 5–10% additional cases of respiratory disorders from other causes (neonatal transitory tachypnea, hypertrophic cardiomyopathy, meconial aspiration and polycythemia).[45]

Hypertrophic myocardiopathy

In approximately 10–20% of IDMs, hypertrophic myocardiopathy is diagnosed by echocardiography showing asymmetrical septum hypertrophy, so that the hypertrophied septal muscles may bulge into the left ventricle, thereby narrowing the left ventricular outflow tract. The anterior wall of the right ventricle and the posterior of the left ventricle appear, at times, hypertrophied, though to a smaller degree than the interventricular septum.

The presence of this myocardial hypertrophy in some other patients with hyperinsulinemia, as in nesidioblastosis or in rhesus fetuses with primary fetal hyperinsulinemia, supports the hypothesis that high levels of insulin and an altered level in the uterus metabolic environment are responsible for an increase in the number of receptors and in the affinity for insulin.[71]

Approximately a third of these infants with hypertrophic myocardiopathy are asymptomatic. The clinical findings may be cardiomegalia, ejecting systolic breath, congestive cardiac insufficiency signs or low cardiac output. The resolution of the symptoms tends to occur between 2 and 4 weeks and echocardiography normalization in 2–12 months.[72] The use of digoxin is not recommended or any other inotropic that could increase obstruction of the exit tract of the left ventricle. The treatment of the most serious cases has been carried out with propranolol (0.01 mg/kg i.v. every 6 h in 10-min bolus, which may be increased to a maximum dose of 0.15 mg/kg every 6 h).

Hypocalcemia and hypomagnesemia

Approximately 25–50% of the infants of insulin-dependent diabetic mothers develop hypocalcemia (total calcium less than 7 mg/dl or ionic calcium less than 1 mmol/l).[73] The rate and severity of the hypocalcemia is directly related to the severity of the maternal diabetes. The incidence of hypocalcemia in the infants of mothers with gestational diabetes is not higher than in the control group.

Hypocalcemia generally manifests itself in the second or third day of postnatal life. It may present as convulsions, jitteriness, hyperexcitability, hyperreflex, hypertonia, apneas, cyanotic episodes, etc.

Among the factors involved in its etiology, the most accepted is the slowness in the elevation of parathyroid harmone (PTH) levels after birth, when the maternal supply of calcium disappears.[74] Some authors point out that sustained fetal hypomagnesemia, secondary to maternal hypomagnesemia (increased urinary loss of magnesium in serious diabetes) is responsible for the slow postnatal response of the PTH in IDMs to the low levels of calcium, as PTH secretion reduces, because magnesium is critical to normal PTH secretion. Other proposed mechanisms for explaining hypocalcemic episodes are the hyperphosphatemia produced by postnatal tissular catabolism, the abnormal metabolism of vitamin D (intestinal antagonism of raised levels of cortisol) and hypercalcitoninemia.

Generally, in apparently normal IDMs, hypocalcemia is resolved spontaneously without need of treatment. If there are symptoms suggestive of hypocalcemia or if the infant has disease and does not tolerate enteral feeding, 10% calcium gluconate by parenteral route should be administered (5 ml/kg/day). When symptomatic hypocalcemia does not respond to calcium therapy, the presence of associated hypomagnesemia should be investigated (levels less than 1.5 mg/dl), and corrected with magnesium sulfate at 50% (0.1–0.2 ml/kg i.m. or slow i.v.).

Hematological disorders. Polycythemia (venous hematocrit ≥65% or hemoglobin ≥20 g/100 ml) is detected in 20–40% of IDMs.[73]

Abundant nutrient supply and fetal hyperinsulinism produce an increase in metabolic rate and consumption of oxygen, which means oxygen demand may exceed availability. The final result of this sequence is relative fetal hypoxemia, which causes an increase in erythropoietin, erythropoiesis and polycythemia and, in general, hyperviscosity.[75] Also, it may contribute to the raised maternal levels of glycosylated hemoglobin, which involves a deviation to the left of the hemoglobin dissociation curve, eliminating less oxygen at the tissular level.

The risk for polycythemia is correlated with control of maternal diabetes and with the maternal total glycosylated hemoglobin level at delivery.[76]

In general, these NBs are plethoric, often with intense acrocyanosis and occasionally with central cyanosis. They may present cardiorespiratory symptoms, hyperexcitability or lethargy, priapism, testicular infarction, etc. Other complications of polycythemia, especially renal vein thrombosis, should be watched for in these infants. The time of cord clamping at delivery may significantly influence blood volume and the hematocrit value. Immediate clamping of the cord (within 20 s of delivery) should therefore be encouraged.[77]

Treatment of polycythemia involves an adequate supply of liquid and, at times (a partial exanguinotransfusion), an isovolemic exchange transfusion with albumin or saline to decrease the hematocrit value to the desired range.

With the hyperinsulinemia-induced expansion of the erythrocyte mass, an increase in fetal iron utilization occurs and the severely affected infants of diabetic mothers have reduced liver, heart and brain iron concentrations. The role of tissue iron deficiency in the genesis of the abnormal clinical findings in these infants deserves further consideration.[78]

There are higher percentages of total lymphocytes and lower percentages of activated T cells in children of diabetic mothers compared to children of the reference population between the age of 1–6 years. No significant differences in lymphocyte subpopulations between children of mothers with insulin-dependent diabetes mellitus (IDDM) and gestational diabetes have been detected. This may reflect a cellular immune reaction to the particular maternal environment, characterized by both an abnormal metabolic state and persisting autoimmunity in the affected mother.[79]

Hyperbilirubinemia

The incidence of hyperbilirubinemia (bilirubin ≥13 mg/dl) is greater in IDMs that in normal control groups of the same gestational age (Table 127.3). In well-controlled IDMs, with a longer pregnancy, hyperbilirubinemia is less frequent and significant.

A series of variables, frequent in IDMs, contributes to a greater or lesser degree of hyperbilirubinemia, that is, polycythemia (probably the most significant factor in absolute terms); turnover of increased hem (increased production of carboxyhemoglobin) due to the greater hemolysis of the red cells of the IDMs whose cellular membranes are less deformable because of their glycosylation; resorption of blood of cephalohematomas, equimosis or other hematic extravasations brought on by obstetric trauma; the postnatal fast that impedes the conjugation of bilirubin and increases enterohepatic circulation of the non-conjugated bilirubin and the functional immaturity of the required hepatic enzymes for the conjugation of the bilirubin.[8,9]

The treatment of hyperbilirubinemia involves phototherapy, proper hydration and exanguinotransfusion in exceptional cases.

Thrombosis

The incidence of thrombosis, particularly of the renal veins (which may develop intrauteral or postdelivery) in IDMs is higher than in the general population. In its development, hyperviscosity plays a significant role, along with low cardiac output (hypertrophic myocardiopathy, perinatal asphyxia, etc.) and coagulator disorders. Aortic thrombosis may be facilitated in IDMs with aortic catheters, introduced through the umbilical cord.

The postnatal presentation may be with hematuria, hypochondrial mass, signs of acute renal failure or embolic episodes. The diagnosis (also in the fetus) may be carried out by ultrasound. Most patients may be treated conservatively, which allows preservation of the renal tissue.

Long-term complications

High birth weight leads to greater adult obesity and chronic disease, and also increases the risk of cancer. In view of these observations, some authors suggest that adipose tissue may play a role in linking events in fetal growth to the subsequent development of adult disease.[80,81]

Neurodevelopment

Mild to moderate psychomotor and psychological disturbance has been reported in the offspring of diabetic mothers. Less optimal intellectual development is associated with reduced head circumference.

Different authors have found that ketonuria and glycohemoglobin of the pregnant woman bear a subsequent relation with low intellectual level of the IDMs.[82,83] In diabetic pregnancies with adequate metabolic control, these data were not detected.[2] Other authors have reported notably different results and it is not known for certain if the diabetic state causes subtle dysfunction of development.[84]

The presence of major congenital malformations has been associated with worse psychomotor development at 2 years.[85] The risk of malformations of the central nervous system (microcephalia, disorders of neuronal proliferation and migration) as well as sacral agenesia is well known, and there is evidence to suggest abnormal functional development of the nervous system.[86,87]

Cancer

Infants with macrosomia had increased risk of acute lymphocytic leukemia, Wilms tumor and neuroblastoma. A number of authors have postulated that a deregulation of growth factors may have a role in the development of soma childhood cancers. The association of Wilms tumor and Beckwith–Wiedemann syndrome suggests that overexpression of IGF-2 may have some role in both processes.

A questionnaire survey identified a possibly increased risk of malignancy for patients with Sotos syndrome.[88] The possible role of mutations at 3p21 in the etiology of Sotos syndrome and tumor development had been described.[89]

Obesity

In recent years, there has been accumulating evidence, from both animal studies and epidemiological data, to suggest that fetal β-cell hyperplasia and hyperinsulinism found in IDMs may induce irreversible changes leading to obesity and glucose intolerance.

At birth almost 50% of IDMs have corporal weight above the 90th percentile of the control, but at the end of the first year this difference is no longer noteworthy. Acceleration of the ponderal increase reappears at 5–8 years of life. By this time, half of the IDMs again exceed the 90th percentile of corporal weight and there is a higher probability of becoming obese adolescents than for those born with a normal birth weight,[90] but other authors have not confirmed these findings.

There is evidence that the offspring of insulin-dependent diabetic women are exposed to a greater risk of subsequently suffering diabetes (20 times more than children of non-diabetic mothers) and in a lower proportion than those of mothers with gestational diabetes.[45]

Care of the infants of the diabetic mothers should start well before conception, with preconceptional planning and strict glycemic control (HbA_{1c}=5–8%) throughout pregnancy to reduce the incidence of miscarriage, congenital malformations, macrosomia at birth and long-term complications.

Several studies have demonstrated that increased neonatal adiposity in LGA children born of non-diabetic mothers is also associated with obesity in later life. It has been suggested that there are three critical time periods for the development of adiposity during childhood: gestation and early infancy, a rebound period at 5–7 years and adolescence. Nutritional alterations that occur during these key ages may cause permanent physiologic alterations, placing the child at increased risk of adult obesity. Children born LGA, of diabetic and non-diabetic mothers, may be at risk for accumulating excess fat in early childhood and may be more likely to have an early adiposity rebound, increasing the risk for overweight in adulthood.[91]

The results of various studies[92,93] suggest that the positive association between high birth weight and later fatness is largely explained by prepregnancy maternal weight, which may be a more important risk factor for later obesity than birth weight.

A recent study on exclusively breast-fed infants demonstrates a slower growth rate from birth to 5 months of life in fatter NBs (larger arm fat area and higher weight-to-length ratio) than in thinner NBs. The authors hypothesize that the postuterine environment, particularly breast feeding, decelerates postnatal weight gain in fatter infants. Others factors, such as an increase in insulin sensitivity after birth or a higher free fatty acid (FFA) turnover due to higher fat mass may help explain this finding.[94]

Given all these considerations, the macrosomic infant requires specific follow-up to detect any possible complications. If the infant is of a diabetic mother, these risks may be increased and thus strict surveillance is necessary.

SECTION XIV

Preterm delivery

Section Editors: **G. C. di Renzo and R. Romero**

128 Mechanisms of the initiation of human parturition

L. F. Gonçalves, R. Romero, J. P. Kusanovic, E. Soto and J. Espinoza

Introduction

Parturition is the act of giving birth.[1] It is a complex process that includes the anatomical, physiological, biochemical and immunological events taking place in the maternal, placental and fetal compartments. These events are responsible for: (1) the preparation of the uterus for labor; (2) labor *per se*, leading to the delivery of the fetus and placenta; and (3) postpartum uterine involution, lactation and adaptation of maternal behavior.

The mechanisms responsible for labor resemble those involved in implantation. Both have been linked to carefully regulated inflammatory processes and, indeed, many of the molecular events associated with parturition have also been implicated in the process of implantation.

Abnormal parturition is a major cause of maternal and perinatal morbidity and mortality. The failure to initiate labor or prolonged pregnancy is associated with an increased risk of fetal death.[2] Preterm labor and delivery is the leading cause of perinatal morbidity and mortality worldwide.[3] Mothers also pay a price for labor abnormalities. For example, failure to progress in labor at term (often referred to as dystocia) is the most frequent indication for cesarean section.[4] Intrapartum infection (clinical chorioamnionitis) is a common complication that may result in maternal sepsis.[5] Inadequate hemostasis after delivery of the placenta (i.e., postpartum hemorrhage) is a leading cause of maternal death worldwide.[6] Hence, the importance of labor as a clinical entity. Yet, fundamental questions about the physiology and pathology of human parturition, a process that has played a key role in shaping the evolution of our species, remain unanswered at the beginning of the 21st century. In this chapter, we will review the mechanisms of parturition in normal pregnancies. Chapter 129 will address the mechanisms implicated in spontaneous preterm labor and preterm prelabor rupture of the membranes (PROM).

Normal duration of pregnancy

The mean duration of human pregnancy is 280 postmenstrual days or 40 weeks in women with a regular 28-day menstrual cycle (adjustments must be made for shorter or longer menstrual cycles). Studying 4000 women with reliable dates and regular menstrual cycles, Kloosterman[7] found that 4.5% of patients delivered on the expected date of confinement (also known as EDC, which corresponds to the expected date of delivery calculated from the Nägele rule), 29% at 40 weeks ± 3 days, and 80% between 38 and 42 weeks of gestation. Preterm delivery is defined as birth before 37 completed weeks. Post-term pregnancy is one in which the gestation extends beyond 42 weeks.

The duration of gestation varies remarkably among animal species.[8] A combination of fetal genetic and environmental factors appears to play a role in this variation, although the precise mechanisms are unknown. Conceptually, the duration of pregnancy should be linked to the time required for the birth of a developmentally mature fetus capable of surviving extrauterine life, and for the adaptations to be in place to react to changes in environmental conditions. Thus, mechanisms must exist to synchronize fetal growth and maturation with the maternal process of parturition. Evidence of a gene-environment interaction to determine the length of gestation derives from cross-breeding experiments. Allen *et al.*[9] transferred Thoroughbred embryos to the uteri of smaller Pony mares and Pony embryos to Thoroughbred mares in order to determine the effect of maternal size on placental and fetal size. These experiments also afforded an opportunity to examine the role of gene-environment interactions on the duration of gestation. A Thoroughbred in Thoroughbred group and a Pony in Pony group, established by artificial insemination, served as the control groups. The mean duration of gestation of the Thoroughbred in Thoroughbred pregnancy was 339 ± 3 days, while the Pony in Pony pregnancy was 325 ± 3 days. The duration of gestation in

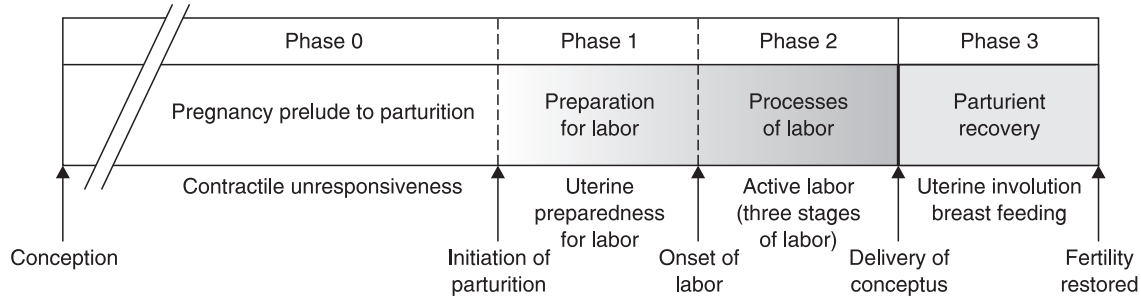

Figure 128.1 The initiation of parturition and the onset of labor. From: Cunningham *et al.*,[10] with permission

the experimental groups fell between these two. The Thoroughbred in Pony (also called 'deprived *in utero* environment') lasted 332 days ±2.8 days, while the Pony in Thoroughbred (also called 'luxurious *in utero* environment') lasted 331 days ±2.7 days. The authors concluded that the fetal and maternal genome, therefore, had an effect on the duration of pregnancy. A longer gestation was associated with a Thoroughbred genome, whether it was a mare or a foal. The longer gestation in the 'luxurious *in utero* environment' provided by the Thoroughbred mother gestating a Pony suggests that environmental factors operate to determine the duration of pregnancy. Otherwise, the fetus could have been born at the expected gestational age of the Pony. In contrast, the effect of the fetal genome is demonstrated in the Thoroughbred in Pony group in which gestational length was longer than that expected from the maternal genome alone in spite of a 'deprived *in utero* environment'. In conclusion, gestational length is likely a function of both genetic and environmental factors.

An overview of parturition and labor

The terms labor and parturition are often used interchangeably, although they are not synonymous. Labor is the acute process by which the fetus is expelled from the uterus, usually within 24 hours. Clinically, labor is defined as a state in which there is increased frequency and intensity of uterine contractions leading to progressive cervical effacement, dilatation and delivery. In contrast, parturition describes the changes that occur in preparation for, during and after labor. The process of parturition goes on for weeks, while labor lasts hours.

An integrated view of the relationship among implantation, pregnancy, labor and parturition was proposed by Paul MacDonald.[10] He suggested that this relationship could be represented to include four stages, which are described below (Figure 128.1).[10] We have slightly modified this insightful conceptual framework to take into account evidence gathered after MacDonald's initial proposal.

Phase 0 is characterized by myometrial tranquility, a state of cervical unripeness and intact membranes. A key feature of this phase of gestation is that the inherent propensity of the myometrium to contract is harnessed so that the uterine smooth muscle is refractory to natural stimulants such as oxytocin.[10] The chorioamniotic membranes remain intact. MacDonald proposed that this physiologic state lasts through 95% of pregnancy.[10]

Phase 1 of parturition is also called 'preparation for labor' and is characterized by the suspension of uterine tranquility and the development of myometrial responsiveness to agents that stimulate contractility (uterotonic agents). The initiation of parturition (not labor), considered as the switch from Phase 0 to Phase 1, is subclinical in nature. There is no current test that can identify this hypothetical switch with certainty. The traditional view has been that there is a progressive nature to the transition from Phase 0 to Phase 1, but this needs to be reconsidered based on clinical and experimental observations, including those demonstrating that parturition could have both a reversible and irreversible course. The irreversible course takes place when the switch from Phase 0 to Phase 1 is followed by Phase 2. For example, some maternal insults, such as pyelonephritis, can lead to increased uterine contractility and induce cervical changes.[11,12] Yet, early treatment of pyelonephritis can prevent preterm delivery.[12] Similarly, the administration of antiprogestins can induce a switch from Phase 0 to Phase 1 of parturition; although this is not always followed by progression to delivery (Phase 2).[13,14] Moreover, the administration of 17-α-hydroxyprogesterone or progesterone may prevent the transition from Phase 0 to Phase 1.[15–17]

Phase 2 corresponds to the process of labor and is clinically characterized by a dramatic increase in the intensity and frequency of uterine contractions (which become painful), progressive cervical effacement and dilatation, and membrane rupture. The term 'onset of labor' specifically refers to the transition from Phase 1 to Phase 2. Challis and Lye introduced the concept of 'activation' to refer to the changes in uterine function that take place between Phase 1 and Phase 2 of parturition.[18] From a clinical point of view,

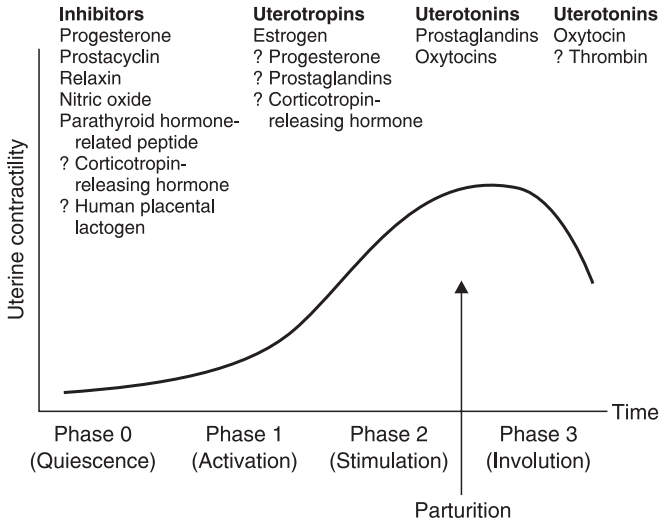

Figure 128.2 Biochemical mediators involved in the four phases of parturition. From: Norwitz *et al.*,[20] with permission.

some of the changes in Phase 2 can be objectively described with partograms, which display the relationship between cervical dilatation and the station of the presenting part as a function of time. The end of Phase 2 occurs at delivery of the conceptus. Clinicians often refer to the first stage of labor as the events taking place between the onset of clinical labor and complete dilatation of the cervix. The second stage is the period between full dilatation and delivery of the fetus. The third stage is the interval between delivery of the fetus and expulsion of the placenta. The first stage is clinically important because this is when most labor disorders are diagnosed (i.e., dysfunctional labor, dystocia, failure to progress in labor, etc.).

Phase 3 refers to the events that occur after delivery and are aimed at maternal recovery from childbirth, maternal contribution to survival of the infant (i.e., breast feeding) and restoration of the non-gestational state.

Challis and Lye proposed that a different set of biochemical mediators are involved in the four phases of parturition.[19] Candidate molecules are displayed in Figure 128.2.[20] For example, Phase 0 may be mediated by inhibitors of uterine contractility such as progesterone, prostacyclin, relaxin, and parathyroid hormone-related peptide (PTHrP).[19] Phase 1 is considered an active process involving fetal development and maturation. Specifically, the fetal hypothalamic–pituitary–adrenal (HPA) axis is hypothesized to increase the output of cortisol, which ultimately leads to upregulation of a group of genes that encode for contraction-associated proteins, including connexin-43 (the major protein of myometrial gap junctions) and oxytocin receptors, among others.[19] The role of the fetus and placenta in changing the concentrations of estrogen (uterotropin) and progesterone are considered central to this phase. Phase 2 of parturition refers to stimulation of a 'prepared' uterus by uterotonic agents, such as prostaglandins and oxytocin.[19] The latter hormone is also involved in uterine contractility after delivery of the placenta, breast milk ejection and maternal–fetal bonding.

The current descriptions of the mediators involved represent the contribution of many investigators using hypothesis-driven research strategies. The utilization of discovery techniques, such as genomics, proteomics and metabolomics (which allow a comprehensive description of the global changes in the transcriptome, proteome, and metabolome), are likely to yield new insights into the processes of normal and abnormal parturition, and allow integration of much of the research conducted to date.[21]

In broad terms, labor may begin because of: (1) removal of inhibitory actions of factors that promote uterine tranquility and a state of cervical unripeness during most of gestation; (2) the effect of stimulatory agents on the same target organs; or (3) a combination of both.

The common pathway of parturition: components

The common pathway of human parturition has been defined as the anatomic, biochemical, physiologic and clinical events that occur in the mother and/or fetus in both term and preterm labor. The intrauterine components of this pathway include increased uterine contractility, cervical ripening (dilatation and effacement) and decidual/fetal membrane activation (Figure 128.3). In addition, systemic processes (endocrinological, metabolic, etc.) are also part of the pathway. For example, term and preterm parturition are associated with an increase in the fetal and maternal plasma levels of corticotrophin-releasing hormone (CRH) and cortisol, as well as an increase in caloric metabolic expenditures.[22–31]

Increased uterine contractility

Although myometrial activity occurs throughout pregnancy, labor is characterized by a dramatic change in the pattern of uterine contractility that evolves from 'contractures' to 'contractions'. Nathanielsz and colleagues[32,33] defined contractures as epochs of myometrial activity that last several minutes and are associated with a modest increase in intrauterine pressure and very fragmented bursts of electrical activity on the electromyogram. In contrast, contractions are epochs of myometrial activity of short duration, associated with dramatic increases in intrauterine pressure and electromyographic activity. The switch from a contracture to a contraction pattern occurs during normal labor,[34] or can be induced by pathological events such as food withdrawal, infection or maternal intra-abdominal

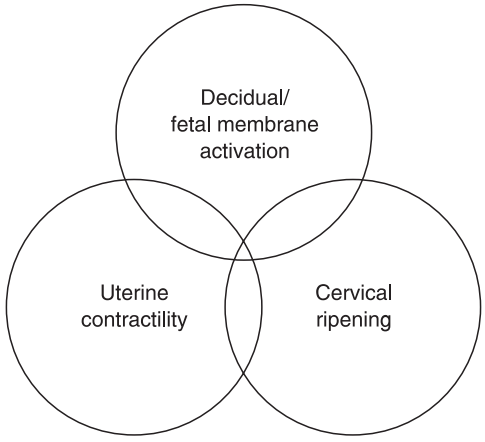

Figure 128.3 The common pathway of preterm and term parturition.

surgery.[35–37] The switch from a contracture to a contraction pattern is a potentially reversible phenomenon.[35,38–40] The increased birth rate observed immediately after a period of fasting suggests that a fasting-induced switch operates in humans.[39,40]

This change in pattern (from contracture to contraction) begins at night and labor is preceded by a progressive nocturnal increase in uterine activity of the contraction pattern.[41,42] The circadian nature of this rhythm suggests that uterine activity is under neural control. Plasma concentrations of oxytocin follow a circadian pattern similar to that of uterine contractility.[41] Oxytocin antagonists blunt the nocturnal increase in uterine activity that precedes the onset of parturition in monkeys,[41–45] suggesting that oxytocin may mediate the circadian rhythm in uterine contractility. Oxytocin is produced by human decidua and the paraventricular nuclei of the hypothalamus, while oxytocin receptors are present in myometrial cells and decidua.[46–52] This hormone, therefore, may play both an endocrine and a paracrine role in the control of parturition.[47,53–60]

Labor is characterized by a coordinated and effective generation of mechanical forces by the myometrium, which eventually lead to the expulsion of the conceptus. Increased cell-to-cell communication is thought to be responsible for the effectiveness of myometrial contractility during labor. Gap junctions develop in the myometrium just prior to labor and disappear shortly after delivery.[61–65] Gap junction formation and the expression of the gap junction protein connexin-43 in human myometrium is similar in term and preterm labor.[66–70] These findings suggest that the appearance of gap junctions and increased expression of connexin-43 may be part of the underlying molecular and cellular events responsible for the switch from contractures to contractions prior to the onset of parturition. Estrogen, progesterone and prostaglandins have been implicated in the regulation of gap junction formation, as well as in influencing the expression of connexin-43.[71–73] Lye *et al.*, for example, have referred to a set of distinct proteins called 'contraction-associated proteins' that are characteristic of this phase of parturition.[70,74,75]

Recently, Lye *et al.*[76] reported that the myometrium undergoes sequential phenotypic remodeling during pregnancy, specifically, that rat myometrium undergoes changes in the extracellular matrix (ECM). They also proposed that contractile proteins can be grouped into three phenotypes, including: (1) *Proliferative*, when the number of myocytes increase, as demonstrated by a higher proliferation cell nuclear antigen labelling and protein expression in early pregnancy. This phenotype coincides with a higher myometrial expression of anti-apoptotic proteins (BCl-2 and BCl-xL); (2) *Synthetic*, when the myometrial cells undergo hypertrophy, as demonstrated by a higher protein/DNA ratio in the second half of pregnancy and coincides with a higher secretion of ECM from the myocytes, in particular collagen I and collagen III, as well as with a high concentration of caldesmon (a marker of synthetic phenotype); and (3) *Contractile*, which occurs at the end of pregnancy and coincides with a low myometrial expression of interstitial matrix and high expression of components of the basement membrane (laminin and collagen IV). In addition, the authors reported a high protein expression of alpha actin in the myometrium in early pregnancy and a high protein expression in gamma actin associated with the contractile phenotype. The authors proposed that the switch from a proliferative to a synthetic phenotype may be regulated by caspase 3 and the switch from the synthetic to the contractile phenotype by a decrease in progesterone.[76] A concept of emerging importance is that mechanical factors, such as uterine stretch, can modify the uterine[76,77] and membrane[78] phenotype and play an important role in parturition.

Cervical ripening

The ability of the cervix to retain the conceptus during pregnancy is unlikely to depend on a traditional muscular sphincteric mechanism.[79,80] The normal function of the cervix during pregnancy depends on the regulation of the ECM. The major macromolecular components of the ECM are collagen, proteoaminoglycans, elastin and various glycoproteins such as fibronectins. Collagen is the most important component of the ECM and determines the tensile strength of fibrous connective tissue.[81] Changes in cervical characteristics during pregnancy have been attributed to modifications in collagen content and metabolism. Proteoaminoglycans have also been implicated in cervical physiology. The proteoaminogylcan decorin (PG-S2) has a high affinity for collagen and can cover the surface of the collagen fibrils, stabilize them, and promote the formation of thicker bundles of collagen fibers. In contrast, PG-S1 (biglycan) has no affinity for collagen and can therefore disorganize collagen fibrils. The predominant dermatan sulfate proteoglycan in the non-pregnant state is PG-S2 and in the term-pregnant state, PG-S1.[82]

The biochemical events that have been implicated in cervical ripening are: (1) a decrease in total collagen content; (2) an increase in collagen solubility (probably indicating degradation or newly synthesized weaker collagen); and (3) an increase in collagenolytic activity (both collagenase and leukocyte elastase).

Contrary to what is generally believed, ECM turnover in the cervix is high and, thus, the mechanical properties of the cervix can change rapidly. Uldbjerg *et al.*[81] demonstrated the importance of collagen content in cervical dilatation, reporting a strong correlation between the collagen content (measured by hydroxyproline determination) of cervical biopsies obtained after delivery and the time required for the cervix to dilate from 2 to 10 cm.

The changes in ECM components during cervical ripening have been likened to an inflammatory response.[83] Indeed, during cervical ripening there is an influx of inflammatory cells (macrophages, neutrophils, mast cell, eosinophyls, etc.) into the cervical stroma. It has been proposed that these cells produce cytokines (e.g., interleukin (IL)-8, IL-8) and other mediators (e.g., prostaglandins), both of which have an effect on ECM metabolism.[84–88]

The chain of events leading to physiological cervical ripening has not been defined. However, strong evidence supports a role for sex steroid hormones including: (1) intravenous administration of 17β-estradiol induces cervical ripening;[89] (2) estrogen stimulates collagen degradation *in vitro*;[90] (3) progesterone blocks estrogen-induced collagenolysis *in vitro*;[90] (4) administration of progesterone receptor (PR) antagonist induces cervical ripening in the first trimester of pregnancy;[91] and (5) IL-8 production by the uterine cervix is downregulated by progesterone.[92] A detailed review of the mechanisms responsible for the changes in cervical physiology during parturition has been recently published by Norman *et al.*[93] The reader is referred to this outstanding review for further details.

Prostaglandins have been widely used to ripen the cervix prior to the induction of labor or abortion. Within hours of administration, prostaglandin E_2 (PGE_2) produces clinical and histological cervical changes resembling physiological ripening that normally develops over several weeks of gestation. The mechanism of action of PGE_2 is thought to involve stimulation of collagenolytic activity and synthesis of PG-S1 by cervical tissue.[82]

Another mediator implicated in the mechanisms of cervical ripening is nitric oxide (NO),[94] which accumulates at sites of inflammation and can act as an inflammatory mediator at high concentration.[95–97] The expression of the inducible form of nitric oxide synthase (iNOS) and NO production in the cervix increase during labor in animals.[98] Moreover, the administration of L-nitro-arginine methylester (a non-specific inhibitor of iNOS) blocks cervical ripening,[98] whereas direct application of sodium nitroprusside (an NO donor) to the cervix can induce cervical ripening.[99] Similar results have been obtained in human clinical trials.[100–103]

Gene expression profiling has recently been used to identify molecular markers of physiological cervical ripening. Microarray analysis was used to compare the gene expression profile of cervical biopsy specimens obtained from 10 women undergoing spontaneous vaginal delivery and 10 women undergoing primary cesarean delivery at term. Messenger RNA expression of 40 genes increased more than 2.5-fold in patients with a ripe cervix. These genes mostly encoded cytokines, chemokines, growth factors, transcription factors and cell-matrix-associated proteins. Messenger RNA expression of 6 genes decreased to less than 0.5-fold in patients with a ripe cervix, including iNOS, FasL receptor, apoptosis regulator bclw, caspase-9 precursor and nucleobinding precursor. For a complete list of genes found to be differentially regulated in patients with a ripe cervix, the reader is referred to the original publication.[104]

Cervical changes precede the onset of labor, are gradual, and develop over several weeks.[105] Wood *et al.*[106] were the first to report that a short cervix was a risk factor for preterm labor and delivery. This observation has been subsequently confirmed by several investigators using both manual and sonographic examinations.[107–117]

Although cervical shortening is traditionally considered an irreversible change, anecdotal clinical observations indicate that some women can have a short cervix, remain pregnant for a long time, and even deliver at term. Reversibility of cervical ripening has been demonstrated with pharmacological intervention in the pregnant ewe. Dexamethasone administration induces cervical ripening and increases uterine contractility. These effects can be reversed with large doses of progesterone.[118]

Decidual/fetal membrane activation

The term 'decidual/fetal membrane activation' refers to a complex set of anatomical and biochemical events that result in the separation of the lower pole of the membranes from the decidua of the lower uterine segment, and eventually in spontaneous rupture of membranes. Untimely activation of this mechanism leads to preterm PROM, which accounts for 40% of all preterm deliveries. For a detailed description of the mechanisms involved in spontaneous rupture of the membranes in preterm PROM, the reader is referred to Chapter 129 (*Mechanisms of preterm labor and preterm premature rupture of the membranes*).

The role of progesterone

Estrogen and progesterone play a central role in the endocrinology and paracrinology of pregnancy.[119] Progesterone is thought to maintain myometrial quiescence, downregulate gap junction formation, and inhibit cervical ripening.[120–122] Estrogens have been

Table 128.1 Source of steroids and mechanism for progesterone withdrawal before parturition in several species (modified from Bernal,[123] with permission)

Species	Source of steroids in late pregnancy	Fall in maternal progesterone concentration	Mechanism
Mouse	Corpus luteum	Yes	Luteolysis
Rat	Corpus luteum	Yes	Luteolysis
Rabbit	Corpus luteum	Yes	Luteolysis
Goat	Corpus luteum	Yes	P450 c17/luteolysis
Cow	Placenta	Yes	P450 c17
Sheep	Placenta	Yes	P450 c17
Guinea pig	Placenta	No	?
Primates	Fetoplacental unit	No	?

P450 c17 enzymes (17-α-hydroxylase and C17-20 lyase activities) are induced in the placenta by an increase in fetal cortisol concentration. Luteolysis is provoked by prostaglandin F2α acting on FP receptor

implicated in increasing myometrial contractility and excitability, as well as in the induction of cervical ripening prior to the onset of labor.[121,122] However, the changes in sex steroid serum concentrations before spontaneous parturition are different among species (see Table 128.1).[123] In many species, a decrease in maternal serum progesterone concentration occurs prior to spontaneous parturition, but the mechanism for this 'progesterone withdrawal' depends, to a large extent, on whether or not the placenta or the corpus luteum is the major source of progesterone.[123]

Luteolysis is a crucial component of the mechanism for parturition in the rat, mouse and rabbit. In the sheep and goat, an increase in fetal plasma cortisol induces the placental production of P450 C17 enzymes (17-α-hydroxylase and C17-20 lyase) and these enzymes catalyze the conversion of progesterone to androstenedione (resulting in reduction of progesterone). Androstenedione would then be transformed by action of aromatases to estrogen.[123] The net effect is that parturition is preceded by a decrease in progesterone and an increase in estrogen concentration. In goats, however, the corpus luteum is responsible for most maternal progesterone production and luteal regression is still required before parturition. In contrast, in primates (including humans) and guinea pigs, there is no apparent change in circulating maternal progesterone concentration before parturition. The human placenta, contrary to the sheep's, lacks P450 C17 enzymes and, therefore, cannot synthesize estrogen and androstenedione (C-19 androgen) from C21-progestins. Consequently, progesterone is the final product of the human placenta. The principal precursor for estrogen synthesis in the human placenta is dehydroepiandrosterone sulfate (DHEA-S) from the fetal and maternal adrenal glands (for estradiol and estrone), as well as 16-OH-DHEA-S from the fetal liver (for estriol).[119] The reader is referred to an excellent review by Young for a comparative physiology of parturition in mammals.[124]

In both human and guinea pig pregnancies, a 'serum progesterone withdrawal' has not been demonstrated. Yet, this hormone is considered important in pregnancy maintenance because inhibition of progesterone action could result in parturition in these two species. For example, administration of antiprogestins [e.g., RU 486 (mifepristone) or ZK 98299 (onapristone)] to pregnant women,[125] primates[126] or guinea pigs[120] during pregnancy can induce abortion and/or labor.[119] Several investigators have proposed alternative mechanisms to explain a suspension of progesterone action without a serum progesterone withdrawal. These alternatives have included: (1) binding of progesterone to a high affinity protein and, thus, a reduced functional active form;[127,128] (2) increasing cortisol concentration in late pregnancy that can compete with progesterone for binding to the glucocorticoid receptors, resulting in functional progesterone withdrawal;[129] and (3) converting progesterone to an inactive form within the target cell before interacting with its receptor. Human amnion and chorion can convert progesterone to the inactive 20-α-dihydroxyprogesterone.[130,131] This metabolite has been observed to increase with advancing gestational age and around the time of parturition.[131] None of these hypotheses, however, have been proven.[132] Therefore, many investigators have shifted their attention to the abundance and modulation of estrogen–progesterone receptor expression, as well as progesterone binding capability to its nuclear response element.

Conflicting results have been reported for the role of the progesterone receptor (PR) in myometrium during human parturition. These discrepancies are probably due to the methods used to assess PR concentration (and binding) and the sampling site. Rezapour *et al.*[133] concluded that there was no

relationship between human parturition and PRs in myometrium.[133] In contrast, How *et al.* examined estradiol and PR expression in the myometrium (lower uterine segment), from women undergoing cesarean deliveries at term in labor ($n=10$), term not in labor ($n=10$), preterm in labor ($n=9$) and preterm not in labor ($n=11$), by immunohistochemistry and Western immunoblot analysis.[134] The intensity of the immunostaining for PR was lower in patients in labor compared to those without labor (preterm and term gestations), indicating that a functional progesterone withdrawal might occur in human labor through a reduction in PR expression. Moreover, among patients without labor, the intensity of the immunostaining for PR was lower in patients at term compared to those of preterm pregnancies, suggesting that the preterm gestation may be more resistant to the effects of progesterone withdrawal than term pregnancies. In contrast, there was no obvious difference in estradiol receptor immunostaining among the four study groups.[134] In conclusion, this study supports the concept that functional progesterone withdrawal occurs in human pregnancy at both term and preterm parturition by reducing PRs in the myometrium.

Henderson and Wilson[135] measured the binding of PR to its nuclear response element in decidual tissue using gel shift assays, which measure progesterone receptor–progesterone responsive element binding, an essential step in progesterone transactivation.[135] The binding of the ligand causes the activation of the receptor through changes that include dimerization and shedding of a heat shock protein. The activated receptor then initiates transcription by binding to its specific DNA response element. A nine-fold decrease in PR binding to its response element was observed in tissues obtained after labor (in both term and preterm gestation) as compared to tissues obtained from women not in labor.[135] However, there was no significant difference in the binding of PR between preterm and term tissues.[135]

Progesterone receptor subtypes

The human PR exists as two major subtypes, PR-A (94 kDa) and PR-B (116 kDa), both encoded by a single gene independently regulated by separate promoters. PR-A is a truncated form of PR-B that lacks the first 164 N-terminal amino acids. In most human cells, type PR-B is the principal ligand-dependent transcriptional *activator* of progesterone-responsive genes, whereas PR-A is a ligand-activated *repressor* of the transcriptional activity mediated by PR-B. The human estrogen receptor (ER) also exists as two major subtypes: ERα and ERβ. Both are derived from separate genes, each having different ligand binding affinities and tissue distribution.[136] The selective actions of estrogens and various estrogen agonists and antagonists are thought to be to the result of differential expressions of ERα and ERβ.[137]

Using Western blot analysis, Pieber *et al.*[132] reported that PR-A protein was expressed in two out of three myometrial samples obtained from women at term after labor (delivered because of fetal distress). In contrast, PR-B protein was equally expressed in the myometrium of both women in labor and women not in labor.[132] Mesiano *et al.*, using quantitative RT-PCR, measured mRNAs encoding PR-A, PR-B, ERα, and ERβ expressions in myometrium from lower uterine segments of women at term with ($n=12$) and without labor ($n=12$).[138] The mRNA expression of PR-A, PR-B, PR-A/PR-B ratio, and ERα were significantly higher in the myometrium of women in labor than in those not in labor. ERβ mRNA expression was unchanged. The PR-A/PR-B ratio correlated with ERα mRNA expression in the myometrium of women not in labor. Furthermore, there was a relationship between ERα mRNA expression and the expression of cyclooxygenase type 2 (COX-2), as well as oxytocin receptor mRNA expression in non-laboring myometrium, indicating that the increase in ERα expression was directly associated with the activation of contraction-associated genes and estrogen responsiveness. These data suggest that in term human myometrium, a significant increase in the expression of PR-A relative to PR-B might be responsible for a functional progesterone withdrawal. Functional estrogen activation would occur because of an increased expression of ERα, resulting in a coordinated expression of a specific ER subtype and a functional progesterone withdrawal. Mesiano *et al.* suggested that the interaction between the PR and ER systems in the human myometrium may be critical for the control of parturition.[119,138]

In support of the interaction of the two isoforms of the PR, Pieber *et al.*[132] conducted a series of experiments in which myometrial cells obtained prior to the onset of labor were transiently transfected with expression vector for either the PR-A or PR-B. Only cells expressing the PR-B could significantly increase the expression of progesterone reporter activity when exposed to progesterone. When both isoforms (PR-A and PR-B) were co-transfected, PR-A exhibited a marked inhibitory effect on PR-B-mediated transcription. This repression was not simply due to an excess of PR-A, because significant repression of transcription was achieved even when a 5:1 ratio of PR-B and PR-A was used for transfection. The authors concluded that PR-A is, therefore, a dominant repressor of PR-B transactivation in myometrial and amnion cells and its increased expression at the onset of labor might cause a 'functional progesterone withdrawal'.[132,139]

An alternative mechanism explaining a 'functional progesterone withdrawal' has been advanced by Professor Phillip Bennett's laboratory.[140,141] The concept is that the activation of nuclear factor (NF)-kappa B in the amnion represses PR function. NF-kappa B, a transcription factor in the cytoplasm, is bound by the inhibitor kappa B (IkB). NF-kappa B (activated by IL-1β and other cytokines) leads to phosphorylation

and degradation of IkB protein, allowing NF-kappa B translocation to the nucleus, where it can bind to specific sites within the promoter sequence of target genes. Indeed, Belt *et al.*[142] demonstrated that stimulation of human myometrial cells with IL-1 could lead to rapid activation of NF-kappa B, inducing the increased expression of COX-2 mRNA, protein, and prostaglandin synthesis. The mutual negative interaction in which NF-kappa B represses PR function has been described in detail elsewhere.[143]

Using transient transfection followed by assays for transcriptional activation and promoter binding, Allport *et al.*[141] demonstrated constitutive activity of NF-kappa B in human amnion cells at the time of labor. The activation of NF-kappa B also induced COX-2 mRNA expression. In cells obtained before labor, when NF-kappa B was low, an increased progesterone concentration repressed NF-kappa B-dependent transcription, while the stimulation with IL-1β increased NF-kappa B activity and repressed progesterone activity. The investigators concluded that human labor is associated with the increased constitutive NF-kappa-B activity within the amnion, whose function is to increase mRNA expression of COX-2, while contributing to a 'functional progesterone withdrawal'.[141]

Collectively, there is substantial evidence supporting the view that a 'functional progesterone withdrawal' is present locally in intrauterine tissues during human parturition in both term and preterm gestation. The changes in estrogen and progesterone ratio activity could activate the three components of the common pathway of parturition, including myometrium, cervix and membranes, directly or indirectly through prostaglandins, or oxytocin and its receptor systems.[46] However, the signal eliciting the onset of these hormonal functional changes in human parturition remains to be determined.

The role of prostaglandins

Prostaglandins have been considered the key mediators for the onset of labor[144–159] since they can induce myometrial contractility,[146–159] changes in ECM metabolism associated with cervical ripening,[144,145,150–152] and decidual/membrane activation.[160]

The evidence traditionally invoked to support a role for prostaglandins in the initiation of human labor includes: (1) administration of prostaglandins can induce early or late termination of pregnancy (abortion or labor);[153,161–171] (2) treatment with indomethacin or aspirin can delay spontaneous onset of parturition in animals;[172–175] (3) concentrations of prostaglandins in plasma and amniotic fluid increase during labor;[14,176–185] (4) intra-amniotic injection of arachidonic acid, the precursor for prostaglandins, induces abortion;[155] (5) prostaglandin concentrations in amniotic fluid increase early during spontaneous labor at term.[184] These observations are consistent with those reported in PROM at term, and[185] similar findings have been described in longitudinal studies performed in non-human primates;[14] and (6) amniotic fluid prostaglandin concentrations increase before the onset of spontaneous labor in humans.[186] Therefore, most of the available evidence in humans, as well as in animals, suggests that prostaglandin concentrations increase prior to the onset of labor or during early labor.[14,184–191] Moreover, in all species examined thus far, including marsupials, prostaglandin secretion increases during labor.[8,192]

Prostaglandins are produced by intrauterine tissues including amnion,[193–195] chorion,[194] decidua,[196,197] myometrium,[198–201] and placenta.[191,194] Although there are many stimulants of prostaglandin biosynthesis, the precise signals responsible for their increase during the course of labor have not been determined. Candidates include cytokines (IL-1, tumor necrosis factor-α),[193,197,202] growth factors (i.e., epidermal growth factor),[203] cortisol,[204,205] and others.

Prostaglandin synthase (PGHS), also known as cyclo-oxygenase, is the enzyme responsible for the initial step in the production of prostaglandins. PGHS has two isozymes: PGHS1 and PGHS2. Recent reports indicate that there is a topographic variation in the distribution of PGHS2 during labor. Indeed, in pregnant baboons the mRNA expression of PGHS2 is higher in the lower uterine segment than in the fundus of the uterus. In contrast, the mRNA expression of 15-OH prostaglandin dehydrogenase (PGDH), the enzyme responsible for the prostaglandins' degradation, is reduced in the lower uterine segment compared to the expression in the fundus. It is possible that such topographic differences in the distribution of these enzymes may play a role in the physiologic control of parturition (see below).[206]

Prostaglandin receptors are classified based on the responses to various agonists and antagonists (IP, TP, DP, EP and FP).[192] The EP receptors are classified into four distinct subtypes, two of which stimulate contraction responses (EP_1 and EP_3) and two that induce a relaxation response (EP_2 and EP_4).[207] Recent studies have examined the expression of prostaglandin receptors in non-pregnant and pregnant human myometrium, as well as in several animal species.[206,208] Topographic differences in the expression of receptors that stimulate uterine contractility and those that inhibit uterine contractility have been found.[209–211] For example, Smith *et al.* reported an increased expression of the EP_2 receptor in the lower uterine segment (which induces relaxation) and increased expression of the EP_3 receptor mRNA in the uterine fundus, while both areas express FP and EP_4 in similar quantities.[212,213] These observations are important because PGE_2 elicits different contractile responses in myometrium, depending on the source of the myometrium. PGE_2 generally stimulates the fundus, but not the lower uterine segment. Collectively, these findings suggest that there may be functional regionalization of the uterus. On the other

hand, a recent study examining *in vitro* contractile responses of the upper and lower segment has not produced findings consistent with those described by Smith *et al.*[212–214]

A role for the fetus in the timing of the onset of labor

A role for the fetus in the control of the timing of labor was demonstrated by the classic studies of Liggins *et al.*,[215,216] as well as by the cross-breeding experiments described at the beginning of this chapter (see Normal Duration of Pregnancy). The importance of the fetal brain has been shown, experimentally, because destruction of the paraventricular nucleus of the fetal hypothalamus results in prolongation of pregnancy in sheep.[217,218] The human counterpart to this animal experiment is anencephaly, which is also characterized by a tendency to have a prolonged pregnancy (if women with polyhydramnios are excluded).[219] However, the situation in human anencephaly is considerably more complicated than the one described in animal experiments. The discrepancy can be explained by the wide range of central nervous system and pituitary lesions found in human anencephaly.

Possible routes for the fetus to signal the onset of labor

The effector organs of labor are the myometrium, cervix and membranes. The fetus could signal the onset of parturition/labor by using a set of molecules which could be delivered to the effector organs using the following routes: (1) an endocrine pathway whereby the fetal circulation delivers the molecules to the placenta and reaches the uterus directly or through the maternal circulation; or (2) a paracrine pathway in which molecules produced by fetal organs, such as the lungs or kidneys, reach the amniotic cavity to exert an effect on the fetal membranes that transduce the signal to the myometrium and cervix (Figure 128.4).[220]

The current paradigm is that once maturity has been reached, the fetal brain, specifically the hypothalamus, increases corticotropin-releasing hormone (CRH) secretion, which in turn stimulates adrenocorticotrophic hormone (ACTH) and fetal cortisol production by the adrenals.[221–223] The increase in cortisol in sheep and DHEA-S in primates eventually leads to activation of the common pathway of parturition.[224,225] In the sheep, but not in the human, fetal cortisol induces expression of 17-α-hydroxylase, which catalyzes the conversion of progesterone to estrogen. Increasing concentrations of estrogen lead to the transcription of contraction-associated genes in the myometrium that favor the onset of labor. The experiments of Liggins *et al.*[215,216] demonstrated that damage to the fetal adrenal glands or pituitary glands would prolong pregnancy. The

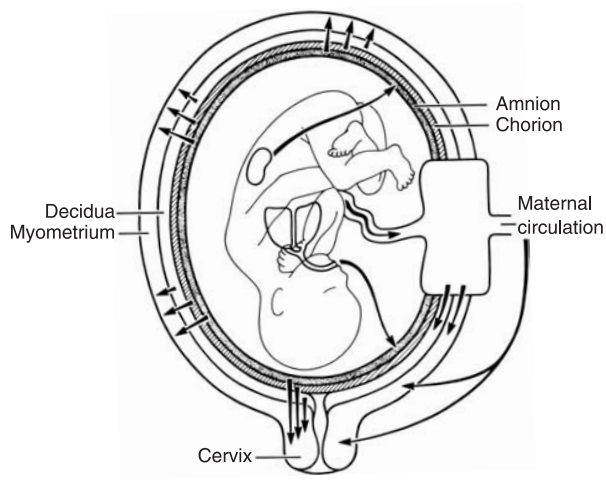

Figure 128.4 Possible routes of transmission of the signal for the initiation of labor from the conceptus to the mother. Note the large area of contact between the chorion and the decidua which makes the paracrine route an effective way of signal transmission from conceptus to mother. From: Schellenberg and Liggins,[220] with permission.

administration of a CRH-antagonist has a similar effect.[226] Nathanielsz has proposed that in non-human primates lacking 17-α-hydroxylase in the placenta, ACTH stimulates the production of androgens, which are converted into estrogens by the placenta and initiate the cascade of events responsible for parturition.[227]

Challis and Lye suggested that the apparent differences in the mechanisms of parturition between the sheep and human can be reconciled.[228] They propose that cortisol in primates has at least three important functions: (1) it increases prostaglandin production by intrauterine tissues directly or indirectly by stimulating the production of PGHS2; (2) it stimulates the production of CRH by the placenta; and (3) it inhibits the enzyme 15-OH prostaglandin dehydrogenase,[229] which catabolizes prostaglandins.[206,230]

CRH is a hormone that is largely produced by the placenta and can stimulate prostaglandin production and induce the fetal adrenal gland to secrete DHEA-S, a source of estrogens that drives the increased expression of oxytocin receptors, gap junctions, and prostaglandins.[231–233] It is important to note that while cortisol suppresses CRH production by the pituitary gland, this hormone stimulates CRH production by the placenta.[229] In support of the importance of cortisol in human parturition, we have reported that fetal plasma cortisol concentrations are elevated in the human fetus before the onset of labor in the context of preterm PROM, and that this elevation is associated with the fetal inflammatory response syndrome.[234]

Parturition as an inflammatory process

Liggins was the first to liken cervical ripening with an inflammatory response.[215] Since then, accumulating

evidence supports that inflammation can be detected in the cervix, myometrium, chorioamniotic membranes, and the amniotic cavity in women in labor. Spontaneous labor at term is associated with infiltration of inflammatory cells in these tissues [235–237] and increased production of a wide range of pro-inflammatory cytokines (IL-1β, IL-6, TNF-α, IL-8)[238–240] and chemokines (GROα, MCP-1, ENA, GCSF, GMCSM, neutrophil attractant/activating peptide-1/IL-8, macrophage inflammatory protein-1α).[240–245] Stjernholm-Vladic *et al.*[245] have recently observed a decrease in glucocorticoid receptors (a mediator of glucocorticoid anti-inflammatory reactions) and a concomitant increase in the expression of NF-kappa-B (a key pro-inflammatory regulator) in cervical tissues obtained at the time of parturition, suggesting that these transcription factors are directly involved in the regulation of the inflammatory response associated with cervical ripening.

Recently, using a genome-wide screen, Haddad *et al.*[247] have been able to demonstrate that genes involved in the control of inflammation are upregulated in the chorioamniotic membranes after labor at term, even in the absence of histologic chorioamnionitis. Of interest is that an inflammatory signature was not observed in the maternal circulation in patients in spontaneous labor at term. This suggests that the inflammatory process is localized to the gestational tissues and specifically to the membranes. These observations are consistent with the findings of Kim *et al.* who reported upregulation of the Toll-like receptor (TLR)-2 and TLR-4 in normal spontaneous parturition.[248] This finding may reflect that spontaneous parturition is associated with increased pro-inflammatory cytokine and chemokine responses in gestational tissues.[240] Indeed, pro-inflammatory cytokines have been shown to upregulate the expression of TLR-2 and TLR-4.[249]

The role of the placenta

Sixty years ago, Van Wagenen and Newton[250] demonstrated that in pregnant primates, surgical removal of the fetus, but not of the placenta, does not affect the timing of labor, suggesting that the onset of labor is independent of the presence of the fetus. Similar results were reported by Albrecht *et al.*[251] However, Lanman *et al.*[252] and, more recently, Nathanielsz *et al.*[253] demonstrated that delivery of the placenta outlasts the normal duration of pregnancy in pregnant rhesus monkeys after fetectomy, indicating that the fetus plays an important role in the timing of delivery in primates, and that in the absence of the fetus, gestational length is significantly longer than in normal pregnancies.

A decade ago, McLean and Smith[22] proposed the existence of a 'placental clock' in human pregnancy, which is active at an early stage and determines the length of gestation and the timing of parturition. This proposal was based on the result of a large, longitudinal study in which women who delivered preterm had a significantly higher plasma concentration of CRH than those who delivered at term. In contrast, women who had prolonged pregnancies had a lower CRH concentration than those who delivered at term. Of note, these differences were already present at 16–18 weeks of gestation.[25] The association between a high maternal plasma concentration of CRH and preterm labor has been confirmed by other studies.[254–256] According to 'the placental clock hypothesis', the rate of increase in the maternal plasma concentration of CRH through pregnancy determines the timing of labor when saturation of the CRH binding protein is achieved and free CRH becomes available and triggers parturition.[22,257] High concentrations of CRH have been described in women with chronic stress and this condition has been associated with a high risk of preterm delivery.[256]

Conclusions

The common pathway of parturition is characterized by increased uterine contractility, cervical ripening and degradation of ECM, which predisposes to membrane rupture. There is growing evidence that parturition occurs over a period of weeks, rather than hours. The mechanisms responsible for the initiation of physiologic labor at term have not been determined in humans. Recent studies implicate the production of fetal or placental signals that would activate the common pathway, such as surfactant protein-A[258] and CRH/cortisol.[259]

This chapter serves as the basis for the understanding of mechanisms implicated in the extemporaneous activation of the common pathway of parturition leading to preterm delivery, which will be discussed in Chapter 129. The expanded utilization of discovery techniques, such as genomics, proteomics and metabolomics, which allow a comprehensive description of the global changes in the transcriptome, proteome, and metabolome, will continue to yield new insights into the processes of normal and abnormal parturition, allowing integration of much of the research conducted to date.[21,104,247]

The concepts described in this chapter, as well as some of the text, were originally published in the book *Preterm Birth*, published by the Royal College of Obstetricians and Gynaecologists in the United Kingdom (Edited by Professor Hilary Critchley, Professor Phillip Bennett and Professor Steven Thornton and published by the RCOG Press). That work, as well as the present work, has been produced by U.S. Government appointees and, therefore, is not subject to copyright. The editors, as well as the publisher, have been informed and agreed with this course of action and their position is gratefully acknowledged.

129 Mechanisms of preterm labor and preterm premature rupture of the membranes

R. Romero, L. F. Gonçalves, T. Chaiworapongsa, J. P. Kusanovic and J. Espinoza

Introduction

Preterm delivery, defined as delivery before 37 completed weeks of gestation, is the leading cause of perinatal morbidity and mortality worldwide.[1] Preterm delivery may result from: (1) spontaneous premature initiation of labor with intact membranes; (2) preterm prelabor rupture of membranes (PROM); or (3) medically indicated preterm delivery to protect the health of the mother and/or the fetus. In this chapter, we will review the mechanisms involved in the initiation of spontaneous preterm labor with or without preterm PROM, with emphasis on the preterm labor syndrome. Preterm birth is the major challenge to modern obstetrics in areas of the world where the problem of maternal mortality has been conquered.[2]

Premature parturition as a syndrome

The current taxonomy of disease in obstetrics is largely based on the clinical presentation of the mother and not the mechanism of disease responsible for the clinical manifestations. The term 'premature labor', for example, does not inform one as to whether the condition is caused by an infection, a vascular insult, uterine overdistension, abnormal allogeneic recognition, stress, or some other pathological process. The same applies to other obstetrical complications, such as pre-eclampsia, small-for-gestational age (SGA) fetal death, etc. The lack of recognition of the syndromic nature of obstetric diseases is responsible for the view that one diagnostic test will detect and one treatment will cure each of these conditions. The key features of obstetrical syndromes[3] are: (1) multiple etiologies; (2) chronicity; (3) fetal involvement; (4) clinical manifestations that are often adaptive in nature; and (5) susceptibility due to a gene–environment interaction.

We will review the available evidence to support the concept that premature labor has '*multiple etiologies*'. Clearly, women with a short cervix in the mid-trimester of pregnancy, with increased concentrations of fetal fibronectin in vaginal fluid, or the presence of bacterial vaginosis are at increased risk for preterm labor or preterm delivery,[4–7] demonstrating that the pathological disorder leading to these conditions is *chronic* in nature. For example, intrauterine infection can be detected at the time of routine mid-trimester amniocentesis for genetic indications and become clinically evident weeks later with either PROM or premature labor.[8–10] '*Fetal involvement*' has been demonstrated in women with microbial invasion of the amniotic cavity. Fetal bacteremia has been detected in 30% of patients with preterm PROM and a positive amniotic fluid culture for microorganisms.[11] Similarly, neonates born after spontaneous preterm labor or preterm PROM are more likely to be SGA, indicating a pre-existing problem with the supply line.[12–18] The *adaptive nature* of labor has been proposed in the context of intrauterine infection in which the onset of labor can be considered a mechanism of host defense against infection that enables the mother to eliminate an infected tissue and allows the fetus to exit from a hostile environment.[19,20] It is possible that other mechanisms of disease in premature labor may also threaten the maternal/fetal pair, and a key question is why some women develop fetal growth restriction

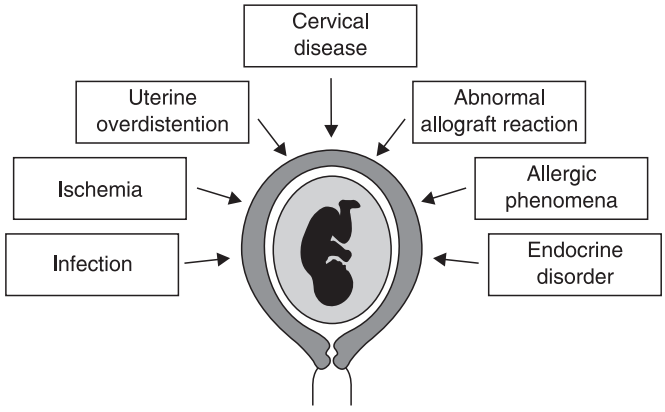

Figure 129.1 The pathological processes implicated in the preterm parturition syndrome From: Romero *et al.*,[21] with permission

and others pre-eclampsia, while yet another group resorts to the onset of preterm labor to deal with the threat. If the clinical manifestations are adaptive, then treatment of the components of the pathway (tocolysis, cerclage, etc.) could be considered symptomatic in nature and not aimed at the specific pathological processes that cause preterm labor. Finally, the predisposition to use a specific mechanism of host defense may be determined by *gene–environment interactions*, as in other disorders such as atherosclerosis and diabetes. However, complexity is added during pregnancy by the presence, and perhaps even the conflicting interests, of two genomes (maternal and fetal).

The pathological processes implicated in the preterm parturition syndrome include intrauterine infection, uterine ischemia, uterine overdistension, abnormal allograft reaction, allergy, cervical insufficiency and endocrine disorders (Figure 129.1). The following sections review the evidence for each of the potential mechanisms of disease.

Intrauterine infection and inflammation

Intrauterine infection has been recognized as a frequent and important mechanism of disease in preterm birth.[22–25] Indeed, it is the only pathological process for which a firm causal link with prematurity has been established with a defined molecular pathophysiology.[26] Moreover, fetal infection/inflammation has been implicated in the genesis of fetal or neonatal injury leading to cerebral palsy[27] and chronic lung disease.[28]

Evidence for a role of infection in the etiology of preterm birth includes: (1) intrauterine infection or systemic administration of microbial products to pregnant animals can result in preterm labor and delivery;[29–34] (2) systemic maternal infections, such as pyelonephritis, typhoid fever, malaria, and pneumonia, are frequently associated with the onset of premature labor in humans;[35–47] (3) subclinical intrauterine infections are associated with preterm birth;[48] (4) antibiotic treatment of ascending intrauterine infections can prevent prematurity in experimental models of chorioamnionitis;[31,49] and (5) treatment of asymptomatic bacteriuria prevents prematurity.[50]

Microbiological and histopathological studies suggest that infection/inflammation may account for 25–40% of cases of preterm delivery.[51] Since infection is frequently difficult to confirm, we often refer to women with histological evidence of acute chorioamnionitis/elevated proinflammatory cytokines in the amniotic fluid and documented microbial invasion of the amniotic cavity as belonging to the 'inflammatory cluster' associated with preterm PROM or preterm labor with intact membranes.

Frequency of intrauterine infection in spontaneous preterm birth

The prevalence of positive amniotic fluid cultures for microorganisms in women with preterm labor and intact membranes is approximately 13%.[52] The earlier the gestational age at preterm birth, the more likely that microbial invasion of the amniotic cavity will be present.[53] In preterm PROM, the prevalence of positive amniotic fluid cultures for microorganisms is approximately 32.4%.[22] Among women presenting with a dilated cervix in the mid-trimester, the prevalence of positive amniotic fluid cultures is 51%.[54] Microbial invasion of the amniotic cavity occurs in 11.9% of twin gestations presenting with preterm labor and delivering a preterm neonate and in 18.8% of patients in spontaneous labor at term.[55,56] The most common microorganisms found in the amniotic cavity are genital *Mycoplasmas*.

A higher prevalence of infection among pregnancies complicated by spontaneous preterm labor or preterm PROM has been identified with the use of molecular techniques.[57–66] Although amniotic fluid specimens were examined in most studies, a recent study examined amniotic fluid, gastric fluid and/or bronchoalveolar lavage fluid for bacterial 16s ribosomal RNA genes in a group of 36 pregnancies (41 neonates) delivered before 33 weeks of gestation.[66] The rationale for this approach is that amniotic fluid can be considered on a continuum with fetal lung and gastric fluids. Bacterial footprints were detected in at least one of the fluid compartments in 70% (7/10) of the pregnancies delivered after preterm PROM and 80% (8/10) of those delivered following spontaneous preterm labor. In contrast, bacterial 16s ribosomal RNA genes were only present in 9% (1/11) of the pregnancies that underwent preterm delivery for maternal or fetal indications and in none of the twin pregnancies delivered before 33 weeks ($n=5$). A strong association was observed between the detection of bacterial 16s ribosomal RNA genes in any fluid and

elevated interleukin (IL)-6 and IL-8 in placental tissues, fetal membranes, and cord blood. Remarkably, only four pregnancies had positive cultures for microorganisms using conventional microbiology techniques.[66]

Intrauterine infection as a chronic process

Evidence in support of the chronicity of intrauterine inflammation/infection is derived from studies of the microbiological state of the amniotic fluid, as well as the concentration of inflammatory mediators at the time of genetic amniocentesis.

Cassell *et al.*[8] were the first to report the recovery of genital *Mycoplasmas* from 6.6% (4/61) of amniotic fluid samples collected by amniocentesis between 16 and 21 weeks of gestation. Two women had positive cultures for *Mycoplasma hominis* and two for *Ureaplasma urealyticum*. Women with *M. hominis* delivered at 34 and 40 weeks without neonatal complications, while those with *U. urealyticum* had premature delivery, neonatal sepsis, and neonatal death at 24 and 29 weeks. Subsequently, Gray *et al.*[9] reported a 0.37% prevalence (9/2461) of positive cultures for *U. urealyticum* in amniotic fluid samples obtained during second-trimester genetic amniocenteses. After exclusion of a therapeutic abortion case, all women (8/8) with positive amniotic fluid cultures had either a fetal loss within 4 weeks of amniocentesis ($n=6$) or preterm delivery ($n=2$). All had histological evidence of chorioamnionitis. These observations suggest that microbial invasion could be clinically silent in the mid-trimester of pregnancy and that pregnancy loss/preterm delivery could take weeks to occur. A similar finding was reported by Horowitz *et al.*,[10] who detected *U. urealyticum* in 2.8% (6/214) of amniotic fluid samples obtained between 16 and 20 weeks of gestation. The rate of adverse pregnancy outcome (fetal loss, preterm delivery and low birth weight) was significantly higher in women with a positive amniotic fluid culture than in those with a negative culture [3/6 (50%) vs. 15/123 (12%); $p=0.035$].

IL-6 concentrations in amniotic fluid are considered to be a marker of intra-amniotic inflammation frequently associated with microbiological infection in the amniotic fluid or the chorioamniotic space.[67–70] Romero *et al.*[71] reported the results of a case–control study in which IL-6 determinations were conducted in stored fluid of women who had a pregnancy loss after a mid-trimester amniocentesis and a control group who delivered at term. Women who had a pregnancy loss had a significantly higher median amniotic fluid IL-6 than those with a normal outcome. Similar findings were reported by Wenstrom *et al.*[72] Of note is that maternal plasma concentrations of IL-6 were not associated with adverse pregnancy outcomes.

The same approach was subsequently used to test the association between markers of inflammation in mid-trimester amniotic fluid of asymptomatic women and preterm delivery. The concentrations of matrix metalloproteinases (MMP)-8,[73] IL-6,[74] tumor necrosis factor-α (TNF-α),[75] and angiogenin[76] in amniotic fluid obtained at the time of mid-trimester amniocentesis were significantly higher in women who subsequently delivered preterm than in women who delivered at term.

Collectively, this evidence suggests that a chronic intra-amniotic inflammatory process may be present in early pregnancy and is associated with both miscarriage and spontaneous preterm delivery. Some indirect evidence suggests that such inflammatory processes may be detectable using maternal blood.[77]

Fetal involvement

The most advanced and serious stage of ascending intrauterine infection is fetal infection. The overall mortality rate of neonates with congenital neonatal sepsis ranges between 25% and 90%.[78–82] The wide range of results reflects the effect of gestational age on the likelihood of survival. One study,[78] which focused on infants born before 33 weeks of gestation, found that the mortality rate was 33% for those infected and 17% for non-infected fetuses. Carroll *et al.*[11] have reported that fetal bacteremia detected by cordocentesis is found in 33% of fetuses with positive amniotic fluid cultures and 4% of those with negative amniotic fluid cultures. Therefore, subclinical fetal infection is far more common than traditionally recognized.

Preterm labor and preterm PROM as 'adaptive responses'

We have proposed that the onset of preterm labor in the context of intrauterine infection is a host defense mechanism with survival value.[19,20] The hosts (mother and/or fetus) would signal the onset of labor for the mother to expel the infected tissue and maintain reproductive fitness. The molecular mediators involved in parturition are similar to those that have evolved to protect the host against infection (cytokines and other inflammatory mediators).

The current view is that during the course of an ascending intrauterine infection, microorganisms may reach the decidua where they can stimulate a local inflammatory reaction, as well as the production of proinflammatory cytokines, chemokines, and inflammatory mediators (platelet activating factor, prostaglandins, leukotrienes, reactive oxygen species, nitric oxide, etc.). If this inflammatory process is not sufficient to signal the onset of labor, microorganisms can then cross intact membranes into the amniotic cavity where they can also stimulate the production of inflammatory mediators by resident macrophages and other host cells within the amniotic cavity. Finally, microorganisms that gain access to the fetus may elicit a systemic inflammatory response syndrome,

characterized by increased fetal plasma concentrations of IL-6[20] and other cytokines,[83–85] as well as cellular evidence of neutrophil and monocyte activation.[86]

Thus far, evidence for the participation of IL-1 and TNF-α in the mechanisms of preterm parturition is persuasive, although the precise role of other pro-inflammatory mediators remains to be elucidated. Evidence supporting a role for IL-1 and TNF-α in preterm parturition includes the following: (1) IL-1β[87–89] and TNF-α[90,91] stimulate prostaglandin production by amnion, decidua and myometrium; (2) human decidua can produce IL-1β and TNF-α in response to bacterial products;[88,89,92] (3) amniotic fluid IL-1β and TNF-α bioactivity and concentrations are elevated in women with preterm labor and intra-amniotic infection;[93–96] (4) in women with preterm PROM and intra-amniotic infection, IL-1β concentrations are higher in the presence of labor;[94,95] (5) IL-1β and TNF-α can induce preterm parturition when administered systemically to pregnant animals;[97,98] (6) fetal plasma IL-1β is dramatically elevated in the context of preterm labor with intrauterine infection;[99] and (7) placental tissue obtained from women in labor, particularly those with chorioamnionitis, produces larger amounts of IL-1β than that obtained from women not in labor.[100]

There is considerable redundancy in the cytokine network and, thus, it is not clear that a particular cytokine is required to signal the onset of labor. Results of knockout animal experiments suggest that infection-induced preterm labor and delivery occur in animals lacking the IL-1 type I receptor.[101] However, a recent observation with a double knockout system indicates that the IL-1 type I and the TNF-α type I receptors are essential mediators for bacterially-induced preterm birth (Hirsch E, personal communication).

Microbial invasion from the amniotic cavity to the fetus can lead to fetal infection and a systemic inflammatory response known as 'the fetal inflammatory response syndrome' (FIRS). FIRS is a subclinical condition originally described in fetuses of mothers presenting with preterm labor and intact membranes or preterm PROM and is operationally defined as a fetal plasma IL-6 concentration above 11 pg/ml.[20] IL-6 is a major mediator of the host response to infection and tissue damage that is capable of eliciting biochemical, physiological and immunological changes in the host, including stimulation of the production of C-reactive protein by liver cells, activation of T and natural killer cells, etc. Fetuses with FIRS have a higher rate of neonatal complications and are frequently born to mothers with subclinical microbial invasion of the amniotic cavity.[20] It is believed that fetal microbial invasion results in a systemic fetal inflammatory response that can progress towards multiple organ dysfunction,[102] septic shock, and death in the absence of timely delivery. Evidence of multisystemic involvement in cases of FIRS includes increased concentrations of fetal plasma MMP-9,[84] neutrophilia, a higher number of circulating nucleated red blood cells, and higher plasma concentrations of G-CSF.[83] The histological hallmark of FIRS is inflammation in the umbilical cord (funisitis) or chorionic vasculitis.[103] Preterm newborns with funisitis are at increased risk for neonatal sepsis[104], as well as long-term handicap, including bronchopulmonary dysplasia[105] and cerebral palsy.[106,107]

An important observation is that the fetuses with preterm PROM and FIRS are at risk for the impending onset of preterm labor regardless of the inflammatory state of the amniotic cavity.[19] This suggests that the human fetus plays a major role in the initiation of preterm labor. Nonetheless, systemic fetal inflammation and even fetal injury may occur in the absence of labor when the inflammatory process does not involve the chorioamniotic membranes and decidua. Examples of this are hematogenous viral infections of the fetus and/or alloimmunization.

Specific mechanisms involved in preterm PROM

Untimely decidua/membrane activation leads to preterm PROM, which accounts for 40% of all preterm deliveries.

Histological studies of the membranes in women with term PROM indicate that membranes ruptured prematurely have a decreased number of collagen fibers, disruption of the normal wavy patterns of these fibers, and a deposit of amorphous materials among them.[108] Similar changes have been observed in the membranes apposed to the cervix in women undergoing elective cesarean section at term with intact membranes.[109] The implication is that although spontaneous rupture of membranes normally occurs at the end of the first stage of labor, the process responsible for this phenomenon begins before the onset of labor.

Histological studies of the site of rupture have demonstrated a 'zone of altered morphology' (ZAM).[109,110] A significant decrease in the amount of collagen type I, III, or V and an increased expression of tenascin have been reported in the ZAM. Tenascin is an extracellular matrix that is characteristically expressed during tissue remodeling and wound healing. Its identification in the membranes thus intimates the presence of injury and a wound healing-like response. Observations by Bell and Mallak[111,112] propose that the changes in the ZAM are more extensive in the setting of preterm PROM. These morphological and biochemical observations are consistent with the results of biophysical studies suggesting that rupture of membranes results from the application of acute or chronic stress on localized areas of the membranes that are weaker.

Structural extracellular matrix proteins, such as collagens, have been implicated in the tensile strength of the membranes, while the viscoelastic properties were attributed to elastin.[113,114] Dissolution of extracellular cements (i.e., fibronectins) is thought to be responsible for the process that allows the membranes to separate from the decidua after the birth of the infant.

Fibronectins are a family of important extracellular cements. Oncofetal fibronectin can be found in the vagina during both term and preterm parturition.[115–118] Therefore, degradation of the extracellular matrix, assessed by the detection of oncofetal fibronectin, is part of the common pathway of parturition.

The precise mechanism of membrane/decidual activation remains to be elucidated. However, roles for matrix-degrading enzymes and apoptosis have been proposed. Several studies have demonstrated increased availability of MMP-1 (interstitial collagenase),[119] MMP-8 (neutrophil collagenase),[120] MMP-9 (gelatinase-B),[121] and neutrophil elastase[122] in the amniotic fluid of women with preterm PROM, compared with that of women in preterm labor with intact membranes. Plasmin has also been implicated in this process,[118] as this enzyme can degrade type III collagen, fibronectin and laminin.[123] Other MMPs are likely to be involved, but systematic studies have not been conducted to date.[124–126] A role for tissue inhibitors of MMPs (TIMPs) has also been postulated.[127]

Accumulating evidence suggests that apoptosis is important in the mechanisms of membrane rupture.[128,129] Rupture of membranes has been associated with overexpression of pro-apoptotic genes and decreased expression of anti-apoptotic genes.[130] Some MMPs, such as MMP-9, may induce apoptosis in amnion.[131–133] Bell and McParland have recently reviewed the subject in detail.[134]

Gene–environment interactions

Gene–environment interactions are important in the understanding of many complex disorders, such as atherosclerosis, obesity, hypertension, etc. A gene–environment interaction is said to be present when the risk of a disease (occurrence or severity) among individuals exposed to both a genotype and an environmental factor is greater or lower than that which is predicted from the presence of either the genotype or the environmental exposure alone.[135,136] There is now considerable evidence that the inflammatory response is under genetic control and, therefore, the interaction between the genotype of the host and microorganisms is important in determining the likelihood and course of some infectious diseases. An example of such an interaction has been reported for bacterial vaginosis, an allele for TNF-α and preterm delivery.[137]

Bacterial vaginosis is a risk factor for spontaneous preterm delivery.[7] However, randomized clinical trials with antibiotic administration to prevent preterm birth have yielded contradictory results.[138–150] Recently, Macones *et al.*[137] reported the results of a case–control study in which cases were defined as women who had a spontaneous preterm delivery and controls as women who delivered at term. The environmental exposure was symptomatic bacterial vaginosis. The allele of interest was TNF-α allele 2, given that its carriage had been demonstrated to be associated with spontaneous preterm birth.[151] The key observations were: (1) clinically diagnosed bacterial vaginosis was associated with an increased risk for preterm delivery [odds ratio (OR) 3.3; 95% CI 1.8–5.9]; (2) women who carried the TNF-α allele 2 were also at increased risk for preterm delivery (OR, 2.7; 95% CI 1.7–4.5); and (3) women with both bacterial vaginosis and the TNF-α allele 2 had an OR of 6.1 (95% CI 1.9–21) for spontaneous preterm delivery, suggesting that a gene–environment interaction predisposes to preterm birth. Other gene–environment interactions may determine the susceptibility to intrauterine infection, microbial invasion of the fetus, and the likelihood of perinatal injury.

Uteroplacental ischemia

Histologic studies of the placentas of patients with preterm labor and preterm PROM indicate that after infection, the most common type of lesions are vascular in nature and can involve the maternal and fetal circulations.[152] Maternal lesions include the failure of physiological transformation of the spiral arteries, atherosis, and thrombosis, while those observed in the fetal circulation include a decreased number of arterioles in the villi and fetal arterial thrombosis. The proposed mechanism linking vascular lesions and preterm labor/delivery is uteroplacental ischemia.

Evidence supporting a role for vascular disorders/uteroplacental ischemia as a mechanism of disease leading to preterm parturition includes the following: (1) experimental uterine ischemia in primates is associated with preterm labor and delivery;[153] (2) vascular lesions in decidual vessels attached to the placenta have been reported by Arias *et al.*[154] in 34% of women with spontaneous preterm labor and intact membranes and in 35% of those with preterm PROM, but only in 12% of women in the control group (term gestation without complications);[154] (3) placental abruption is more frequent in women who deliver preterm with intact membranes or rupture of membranes than in those who deliver at term;[154–159] (4) failure of physiologic transformation in the myometrial segment of the spiral arteries has been found in women with preterm labor and intact membranes and preterm PROM.[160,161] This developmental abnormality had been previously associated with pre-eclampsia and intrauterine growth restriction; (5) women presenting with preterm labor and intact membranes who have an abnormal uterine artery Doppler velocimetry (an index of increased impedance to flow in the uterine circulation) are more likely to deliver preterm than those with normal Doppler velocimetry;[162–165] and (6) the frequency of SGA neonates is increased in women delivering after preterm labor with intact membranes and preterm PROM.[12–18] Vascular lesions leading to compromise of

the uterine supply line could account for both intrauterine growth restriction and preterm labor.

The molecular mechanisms responsible for the onset of preterm parturition in cases of ischemia have not been determined. A role for the renin–angiotensin system has been postulated, as the fetal membranes are endowed with a functional renin–angiotensin system[166] and uterine ischemia increases the production of uterine renin.[167,168] Angiotensin II can induce myometrial contractility either directly[169] or through the release of prostaglandins.[170]

When uteroplacental ischemia is severe enough to lead to decidual necrosis and hemorrhage, thrombin may activate the common pathway of parturition. Evidence in support of this includes: (1) decidua is a rich source of tissue factor, the primary initiator of coagulation and of thrombin activation;[171] (2) intrauterine administration of whole blood to pregnant rats stimulates myometrial contractility,[172] while heparinized blood does not (heparin blocks the generation of thrombin);[172] (3) fresh whole blood stimulates myometrial contractility *in vitro* and this effect is partially blunted by incubation with hirudin, a thrombin inhibitor;[172] (4) thrombin stimulates myometrial contractility in a dose-dependent manner;[172] (5) thrombin stimulates the production of MMP-1,[173] and urokinase type plasminogen activator (uPA), and tissue type plasminogen activator (tPA) by endometrial stromal cells in culture.[174] MMP-1 can digest collagen directly, while uPA and tPA catalyze the transformation of plasminogen into plasmin, that in turn can degrade type III collagen and fibronectin,[175] which are important components of the extracellular matrix in the chorioamniotic membranes;[176] (6) thrombin/antithrombin (TAT) complexes, markers of *in vivo* generation of thrombin, are increased in plasma[177] and amniotic fluid[178] of women with preterm labor and preterm PROM; and (7) an elevation of plasma TAT complex concentration in the second trimester is associated with subsequent preterm PROM.[179]

The recognition that thrombin may play an important role in uterine contractility can explain the clinical observations that retroplacental hematomas in early pregnancy are associated with preterm delivery.[180] Also, vaginal bleeding in the first or second trimester is a risk factor for preterm birth.[181–184]

Although some investigators proposed that fetal hypoxemia is a cause of preterm labor, studies with cordocentesis have indicated that fetal hypoxemia and metabolic acidemia are not more frequent in women with preterm labor and intact membranes who deliver preterm than in those who deliver at term.[185] Similarly, Carroll *et al.*[186] have demonstrated that hypoxemia is not more common in fetuses of women with preterm PROM. Therefore, uterine ischemia should not be equated with fetal hypoxemia, and no evidence currently supports fetal hypoxemia as a cause of preterm parturition.

Uterine overdistension

The mechanisms responsible for the increased frequency of preterm birth in multiple gestations and other disorders associated with uterine overdistension are unknown.[187–191]

The importance of stretch in the initiation of labor is supported by an experiment conducted in humans in which the uteri of pregnant women with a live term fetus or a dead fetus were distended with a balloon inflated with physiologic saline (up to 300 cm^3).[192] Regular uterine contractions occurred in all patients shortly after distension of the balloon, and all delivered within 21 h. This observation indicated that stretch can induce labor at term, regardless of whether the fetus is alive or dead. Moreover, amniotic fluid concentrations of prostaglandin F2α and its stable metabolite in plasma were increased in stretch-induced labor.[192] Recently, it has been reported that in women with twin pregnancies, the presence of polyhydramnios further increases the rate of preterm delivery.[193]

Central questions include how the uterus senses stretch and how these mechanical forces induce biochemical changes that lead to parturition. Lye *et al.* and other investigators have conducted several studies that explore the biochemical consequences of stretch on myometrium.[194–219]

Increased expression of oxytocin receptor,[207] connexin 43,[220] and the *c-fos* mRNA has been consistently demonstrated in the rat myometrium near term.[204–206,208,210] Using a model in which pregnancy was restricted to one of the two uterine horns (by unilateral tubal ligation), the expression of the same genes was substantially lower in the empty horn, but could be corrected by distending the uterus with a 3 mm tube and stretching the horn.[207,220] In another set of studies, progesterone was found to block stretch-induced gene expression in the myometrium.[221] Mitogen-activated protein kinases have been proposed to mediate stretch-induced *c-fos* mRNA expression in myometrial smooth muscle cells.[204–206,208,210]

In addition to the effects of stretch on myometrium, recent studies indicate that stretch can impact the chorioamniotic membranes.[222–236] For example, *in vitro* studies have demonstrated an increase in the production of collagenase, IL-8,[228,237] and prostaglandin E_2,[227] as well as the cytokine pre-B-cell colony-enhancing factor.[231] These observations provide a possible link between the mechanical forces operating in an overdistended uterus and rupture of membranes.

Abnormal allograft reaction

The fetoplacental unit has been considered nature's most successful semi-allograft, and abnormalities in the recognition and adaptation to fetal antigens has been proposed as a mechanism of disease in recurrent pregnancy loss, intrauterine growth restriction and

pre-eclampsia.[238–240] Chronic villitis has been considered a lesion indicative of 'placental rejection' and such lesions have been found in the placentas of a subset of women who delivered after spontaneous preterm labor.[241] We have observed that some women with preterm labor, in the absence of demonstrable infection, have elevated concentrations of the IL-2 soluble receptor.[152] Such elevations are considered an early sign of rejection in non-pregnant patients with renal transplants.[242] Further studies are required to define the frequency and clinical significance of this pathological process in preterm labor. Recently, allorecognition, in which cytotoxicity and rejection reactions are not inevitable consequences of exposure to foreign antigens,[243] has been proposed as a more accurate means of describing the maternal–fetal relationship. This has implications for the concept of allograft rejection as a mechanism of disease in obstetrics. A role for complement and natural killer cells in adverse pregnancy outcome has been proposed,[244–254] but it is unclear whether these systems are disturbed in preterm parturition.

Allergy-induced preterm labor

The concept that an allergic-like mechanism (type I hypersensitivity reaction) may be one of the etiologies of preterm birth was proposed in the early 1990s based upon clinical observations and experimental studies.[255–257] Case reports documented that some women had preterm labor after exposure to an allergen, and that a subgroup of patients with preterm labor had eosinophils as the predominant cell type in amniotic fluid. Since the presence of eosinophils in body fluids is generally considered an indicator of an allergic reaction, patients with preterm labor and eosinophils as a predominant cell type in the amniotic fluid were proposed to represent a form of uterine allergy. Subsequent to this observation, a large body of experimental evidence has accumulated providing biological plausibility to this hypothesis. The key observations have been that mast cells are present in the uterus and their products of degranulation can stimulate uterine contractility. Observations supporting a role for a type I hypersensitivity reaction in preterm labor include the following:[258–269] (1) the human fetus is exposed to common allergens, such as house dust mite. The allergen Der p 1 has been detected in both amniotic fluid and fetal blood. Moreover, the concentrations of the allergen are higher in fetal blood than in maternal blood;[262] (2) allergen-specific reactivity has been demonstrated in umbilical cord blood at birth and as early as 23 weeks of gestation, indicating that the fetus can recognize the allergen and mount an immune response;[263] (3) pregnancy is considered a state in which there is a preponderance of a TH-2 cytokine response that favors the differentiation of naive $CD4^+$ T cells to the TH-2 phenotype and the production of IgE, the key immunoglobulin required for a type I hypersensitivity reaction; (4) the gravid uterus is a rich source of mast cells, the effector cells of allergic responses;[268] (5) several products of mast cell degranulation, such as histamine and prostaglandins, can induce myometrial contractility;[266,267] (6) pharmacological degranulation of mast cells with a compound called '48/80' induces myometrial contractility;[259,261] (7) incubation of myometrial strips from sensitized and non-sensitized animals with an anti-IgE antibody increases myometrial contractility;[261] (8) human myometrial strips obtained from women known to be allergic to ragweed demonstrate increased myometrial contractility when challenged *in vitro* by the allergen (Garfield RE, personal communication). Moreover, sensitivity of the myometrial strips of non-allergic women can be transferred passively by preincubation of the strips with human serum (Garfield RE, personal communication); and (9) premature labor and delivery can be induced by exposure to an allergen in sensitized animals and can be prevented by treatment with a histamine H1 receptor antagonist.[260]

In summary, there is clinical and experimental evidence that a type I hypersensitivity reaction can induce preterm parturition, although the frequency of this phenomenon in humans is still unknown.

Cervical insufficiency

Although cervical insufficiency (formerly known as cervical incompetence) is traditionally considered to be a cause of mid-trimester miscarriage, accumulating evidence suggests it can also be a cause of spontaneous preterm birth.[270] Cervical insufficiency may be the result of a congenital disorder (e.g., hypoplastic cervix or diethylstilboestrol exposure *in utero*), surgical trauma (e.g., conization resulting in substantial loss of connective tissue) or traumatic damage to the structural integrity of the cervix (e.g., repeated cervical dilatation associated with termination of pregnancy).[271] Some cases presenting with the clinical characteristics of cervical insufficiency may be due to infection. Indeed, intrauterine infection has been demonstrated in 50% of women presenting with acute cervical insufficiency.[54] A detailed review of this topic has been recently published by Romero *et al.*[272]

Progesterone deficiency as a potential mechanism of disease in preterm labor

The spectrum of reproductive abnormalities associated with progesterone deficiency is broad. For example, luteal phase deficiency (LPD) is widely believed to be a cause of infertility[273,274] and is commonly listed as a cause of recurrent spontaneous abortion.[275,276] This

disorder has been defined as either a defect of progesterone secretion by the corpus luteum or a defect in the endometrial response to progesterone.[277,278] Thus, in LPD, the reproductive organ could function well enough to ovulate, but the function of corpus luteum and/or endometrium is below a physiologic threshold sufficient for conception or pregnancy maintenance. Since there is no general agreement on the criteria for the diagnosis of LPD,[273,274,279,280] its clinical significance and contribution to adverse pregnancy outcome remains uncertain. However, one retrospective study included 540 infertile patients with a diagnosis of luteal phase defect (endometrial biopsy was out of phase by 2 days in two consecutive cycles) and showed a high rate of preterm delivery [31.2% (169/540)] in patients who had not received progesterone treatment.[281] Interestingly, those patients who were treated with progesterone vaginal suppositories for at least 12 weeks demonstrated a significant reduction in the rate of preterm delivery at less than 32 weeks and less than 37 weeks of gestation [for 32 weeks, no progesterone: 12.5% (4/32) vs. progesterone 1.3% (6/469), $p < 0.01$; and for 37 weeks, no progesterone: 31.2% (10/32) vs. progesterone 13.7% (64/469), $p < 0.01$].[281]

Several pathophysiologic mechanisms have been proposed to explain LPD, though the precise etiology remains unclear.[282] Progesterone supplementation in patients with LPD has been reported to improve pregnancy outcomes (reduction in the rate of recurrent abortion)[283–285] and increase the rate of successful pregnancy[286,287] in some, but not all, studies.[288,289] Recently, the use of gonadotropin releasing hormone (GnRH) agonist to suppress a premature surge of luteinizing hormone during ovarian stimulation in *in vitro* fertilization (IVF) cycles has led to corpus luteum dysfunction and, subsequently, to abnormal progesterone and estrogen concentration/function in several infertile patients. A meta-analysis of randomized trials[290] showed that luteal phase supplementation with intramuscular progesterone injection significantly improved fertility outcomes (clinical pregnancy rates and the rate of pregnancies achieving 24 weeks of gestation). Thus, there is evidence suggesting that progesterone might be important in human pregnancy, especially in early gestation.

Other than a primary progesterone functional deficiency such as LPD, reduction of progesterone function could result from other pathologic mechanisms, such as, intrauterine infection. In animal models of ascending intrauterine infection, bacteria-induced and LPS-induced preterm birth is preceded by a significant fall in serum progesterone concentration,[291] and the mechanisms by which this occurs were attributed to: (1) LPS and pro-inflammatory cytokines induced prostaglandin synthesis and, subsequently, luteolysis; (2) a direct anti-gonadotropic effect of pro-inflammatory cytokines and, thus, the suppression of progesterone production; and (3) pro-inflammatory cytokines up-regulated an inducible form of nitric oxide synthase and, thus, inhibited steroidogenesis, including progesterone production. However, Hirsch and Muhle[292] have argued that the fall in serum progesterone concentration is unlikely to be a primary mechanism by which intrauterine inoculation with bacteria causes preterm parturition in mice, since the mean interval to delivery is shorter in animals with intrauterine infection than ovariectomized animals, despite a higher serum progesterone concentration in the former.[292]

Patients with preterm PROM who went into spontaneous labor and delivered within seven days of cordocentesis had a significantly higher median plasma concentration of fetal cortisol than those who delivered after seven days.[293] Fetal plasma cortisol concentration, but not maternal cortisol concentration, was an independent predictor of the duration of pregnancy after adjusting for gestational age and the results of amniotic fluid culture (hazards ratio 2.9, $p < 0.05$). There was a significant correlation between fetal plasma cortisol and fetal plasma IL-6 concentrations. This evidence suggests that the activation of the fetal hypothalamic–adrenal axis may be present and that it is associated with intrauterine infection.[293,294]

It is well known that intrauterine infection is associated with an increase in pro-inflammatory cytokines[295,296] (i.e., IL-1, TNF-α, etc.) in amniotic fluid,[93–96] fetal membranes,[297,298] decidua[88,89,92] and myometrium.[299–302] In the context of infection-related preterm birth, the increased concentration of IL-1β in gestational tissue could stimulate NF-kappa B.[303–305] The activation of NF-kappa B, other than increasing COX-2 (mRNA and protein expression) and prostaglandin production,[303] could repress progesterone activity, as proposed by Allport *et al.*,[306] resulting in 'functional progesterone withdrawal' and, thus, preterm parturition.

Conclusions

Term and preterm labor share a common pathway characterized by increased uterine contractility, cervical ripening and degradation of extracellular matrix, which predisposes to membrane rupture. The evidence presented in this chapter provides support for the concept that preterm parturition is a complex disorder, which is also syndromic in nature. The predominant clinical presentation of this syndrome (i.e., uterine contractility, preterm cervical ripening without significant clinical contractility, or PROM) will vary depending upon the type and timing of the insult. This conceptual framework has implications for the understanding of the mechanisms responsible for the initiation of preterm parturition, as well as the diagnosis, treatment, and prevention of preterm birth. Since preterm labor is a heterogeneous condition, it is unlikely that one diagnostic modality or one therapeutic intervention will prevent all preterm births. We believe that the way forward requires a systematic examination of the taxonomy of preterm labor, which is now possible using genomic, proteomic and metabolomic techniques.

The concepts described in this chapter, as well as some of the text, were originally published in the book *Preterm Birth*, published by the Royal College of Obstetricians and Gynaecologists in the United Kingdom (Edited by Professor Hilary Critchley, Professor Phillip Bennett and Professor Steven Thornton and published by the RCOG Press). That work, as well as the present work, has been produced by U.S. Government appointees and, therefore, is not subject to copyright. The editors, as well as the publisher, have been informed and agreed with this course of action and their position is gratefully acknowledged.

130 Management of preterm labor: pharmacological and non-pharmacological aspects

G. C. Di Renzo, A. Cutuli, L. Liotta, L. Burnelli and G. Luzi

Introduction

Tocolysis is the first therapeutic tool for treatment of threatened preterm labor allowing timely administration of corticosteroids, to induce lung maturation, and antibiotics when appropriate. However, before starting with tocolysis, careful diagnosis is needed, so as to detect manageable conditions and fetal and/or maternal contraindications. For pregnant woman with threatened preterm labor, bed rest is advisable, as well as monitoring by cardiotocography. If membranes are intact, cervical condition must be evaluated by means of digital and/or preferably sonography examinations. Relative and absolute contraindications related to tocolysis therapy are listed in Table 130.1.

As most contraindications are relative, tocolysis is preferable to the high risk of perinatal mortality or morbidity. Maternal medical conditions, such as diabetes mellitus, could be negatively influenced by administration of tocolytic agents like β-mimetics. Minor vaginal bleeding or spotting is often associated with preterm labor and cervical changes, but could be also due to abruptio placentae. If the cervix is dilated above 4–5 cm, tocolytic treatment can hardly be successful. If the pregnancy is between 22 and 26 weeks, prolongation of pregnancy by 1–2 weeks could positively affect the perinatal outcome, especially in multiple pregnancy.

Pharmacological treatment of preterm labor

The use of mild sedatives is sometimes advisable to reduce anxiety and fear. Bed rest and hydration do not have any significant effect on uterine contractions. Nevertheless, bed rest is usually recommended in the management of a patient with threatened preterm labor.

Tocolytic drugs currently used are:

(1) Magnesium sulfate
(2) Inhibitors of prostaglandin synthesis
(3) Calcium antagonists
(4) β-sympathomimetics
(5) Oxytocins antagonists
(6) Nitric oxide donors.

Magnesium sulfate

Magnesium sulfate has been widely used for the treatment of pre-eclampsia and as a tocolytic agent only over the last 20 years. Its inhibitory activity on the

Table 130.1 Absolute and relative contraindications to tocolysis

Absolute contraindications	Relative contraindications
Pregnancy induced hypertension	Mild chronic hypertension
Severe bleeding	Placenta previa
Chorioamnionitis	Maternal cardiac diseases
Fetal death	Hyperthyroidism
Fetal lethal anomalies	Uncontrolled diabetes mellitus
Severe IUGR	Fetal distress
	Fetal anomalies
	Mild IUGR
	Cervical dilation > 5 cm

smooth muscle is well known, but its mechanisms of action are still unexplored. A high concentration of magnesium has a central inhibitory effect, interfering with acetylcoline release and then with nervous conduction. Magnesium also suppresses the contractile activity of isolated myometrium. Furthermore, magnesium increases cyclic adenosine monophosphate and decreases intracellular calcium.

Myometrial contractility is inhibited by maternal serum levels of magnesium of 5–8 mg/dl. Concentrations of 9–13 mg/dl may provoke deep tendineal reflex and a level above 14 mg/dl may cause respiratory depression. Magnesium is excreted mainly by the kidneys, with at least 75% of the infused dose excreted during infusion and 90% during the subsequent 24 h. In two randomized and controlled studies, there were no advantages in using magnesium sulfate vs. placebo. A recent meta-analysis suggests that magnesium offers the slight advantage of delaying the time of delivery without affecting the newborn.

More than 45% of patients, especially during intravenous treatment, have hot flushes, headaches, nistagmus and lethargy. More than 75% of patients suffer from hypovisus or diplopy. Furthermore, a reduction of memory has been reported. Some cases have been published of transitory ischemia, maternal hypothermy, osteoporosis with spontaneous fractures from therapy over 60 days and neuromuscular block due to association with nifedipine.

In the presence of renal hypofunction, even a mild hypermagnesemia can lead to respiratory and cardiac dysfunction. Magnesium in patients with myasthenia gravis must be carefully administered. After infusion of magnesium, serum calcium decreases and is abundantly excreted by the urine. It also increases serum phosphorus and parathyroid hormone. These changes may involve a decrease of bone density during the first week after delivery, in case of prolonged magnesium therapy.

A study of 1000 patients treated with magnesium and terbutaline showed a relative low incidence of side effects. Other studies have demonstrated an increase in maternal side effects with combined use of ritodrine and magnesium.

In neonates with magnesium concentration ranging between 4 and 11 mg/dl in umbilical cord vessels, motor and respiratory depression has been noticed. In the newborns of mothers who underwent magnesium sulfate therapy with serum levels of 4–7 mg/dl, decrease of muscular tone and lethargy have been reported.

For plasmatic concentrations of 6–8 mg/dl per 24 h, 50% of fetuses show an unreactive cardiotocograph tracing and only 20% of breathing movements interfering with biophysical profile interpretation. The recommended starting dose is 4–6 g, administered intravenously for more than 20 min, followed by a maintenance dose of 1–4 g/h. The endovenous therapy must be continued for about 12 h, until the reduction of uterine contractions below four to six per hour has been reached.

As treatment with magnesium may lead to pulmonary edema, strict observation of intake and out-take is needed, daily decreasing the administration of fluids below 1500–2500 ml. It is recommended that constant examination of tendineal reflex and calcium and magnesium serum levels be done so as to avoid toxic effects. In case of toxic effects caused by hypermagnesemia, calcium gluconate should be promptly administered.

Inhibitors of prostaglandin synthesis

Several drugs such as indometacin, naproxen, ketoprofen and diclofenac interfere with the synthesis of prostaglandins, inhibiting both cyclooxygenases (COX), which catalyze the conversion of arachidonic acid into prostaglandins G, precursors of prostaglandins E and F.

Indometacin is a generic inhibitor of COX, after absorption by oral or rectal administration, which achieves the plasmatic peak in 1–2 h. The half-life is about 5 h. This drug binds largely to plasmatic proteins and is eliminated unmodified. Indometacin crosses the placenta and the concentration in the umbilical artery is similar to the maternal one 5 h after administration. In comparison with aspirin, indometacin binds reversibly to COX, having an inhibiting effect while the drug is in circulation. The half-life in the newborn is about 15 h. In the neonates, 90% of the drug binds to the proteins.

Several studies have shown tocolytic effects of this inhibitor of prostaglandin synthesis comparable to β-sympathomimetics and fewer maternal side effects. Tocolysis by indometacin may double the maternal bleeding time, although it does not influence the prothrombin levels or activate thromboplastin partial time. Prolonged administration may be associated with headache, dizziness and depression.

The inhibition of contractions by prostaglandin inhibitor synthesis can cause closure of the ductus arteriosus, neonatal pulmonary hypertension, ventricular hemorrhage and oligohydramnios, especially if the drug is administered after 30 weeks of pregnancy.

Studies on animals have shown that COX-1 is mainly responsible for patent ductus arteriosus. Indometacin inhibits both enzymes COX-1 and COX-2 and rapidly crosses the placenta. Serial fetal echocardiography has demonstrated that antenatal administration of indometacin may cause a narrowing of the ductus arteriosus, which can resolve within 24 h of drug interruption.

In other studies, of 53 fetuses exposed to indometacin, the narrowing of ductus appeared in 61% at 31–34 weeks, in 43% at 27–30 weeks and in none before 27 weeks. These findings suggest that limiting the use of indometacin to within 32 weeks of gestation and, furthermore, fetal echocardiography could help evaluate the narrowing of the ductus arteriosus in case of indometacin treatment for more than 48–72 h.

The etiology of neonatal primitive pulmonary hypertension could be the prolonged deviation of blood from the ductus arteriosus to the pulmonary

vascular bed, probably with treatment lasting more than 48 h. Furthermore, antenatal exposure to indometacin seems to be associated with postnatal patent ductus arteriosus, and is refractory to medical therapy.

Fetal exposure to indometacin is correlated to a high incidence of intraventricular hemorrhage, when it is used after failure of other therapies or in combination with magnesium sulfate. Some authors did not confirm the increased risk of intraventricular hemorrhage associated with the use of indometacin. Indometacin can increase the risk of necrotizing enterocolitis. Its use in the last 5 weeks of pregnancy is associated with anuria, microcystic kidney lesions and increased neonatal mortality.

Treatment with indometacin is also associated with oligohydramnios due to decreased fetal urinary production. This effect is reversible with the interruption of the drug treatment. For this reason, some cases of polyhydramnios can be treated with indometacin.

Most studies used indometacin 50 or 100 mg suppository; alternatively, they used 50 mg per os, followed by 25–50 mg per os every 6 h, depending on the therapeutic effects. Tocolysis by indometacin must be limited for women before 32 weeks, without intrauterine growth restriction (IUGR) and normal amniotic fluid volume. The duration of administration should not exceed 48–72 h.

Calcium antagonists

Calcium antagonists are considered as tocolytic agents because of their important role in blocking cytoplasmatic free ion calcium into smooth muscular contractility. Nifedipine acts by inhibiting calcium passage through the plasmatic membrane, particularly interfering with voltage-dependent ion channels. Nifedipine reaches a plasmatic peak 30–60 min after oral administration, and more quickly by sublingual administration. The half-time is 1–2 h and it is excreted through the renal and intestinal system. The calcium channel block is reversible with interruption of therapy. Nifedipine crosses the placenta, yet its kinetics are not completely known.

In an observational study, nifedipine has been proved to abolish uterine activity and prevent delivery for 3 days in a significant percentage of cases vs. placebo. Some studies have demonstrated that nifedipine has a similar or better effect than ritodrine in the suppression of contraction and in delaying delivery for at least 48 h.

This substance causes vasodilation. Frequently, hyperemia is associated with headache and nausea, as well as transitory tachycardia and mild reduction of blood pressure. Occasionally, a significant hypotension may occur. The use of nifedipine in combination with magnesium may cause neuromuscular toxicity. In monkeys, after the administration of nifedipine, there may be a severe reduction of oxygen in the fetal circulation and a decrease of pH, probably due to a reduction of uterine blood flow.

Doppler investigations of pregnant women treated with nifedipine have shown changes in uteroplacental fetal circulation, with an increase of fetal cerebral flow, but no alteration in other districts.

The first dose is usually 10 mg of nifedipine per os, to be repeated after 20 min if the contractions persist. Sublingual administration must be avoided in patients at risk of hypotension. Oral therapy is to be carried out for 10–20 mg every 4–6 h. The duration of therapy has not been established.

β-sympathomimetics

Substances like ixosuprine, exoprenaline, fenoterol, ritodrine, salbutamol and terbutaline belong to this family. They have a β2-adrenergic effect at the uterine level. Nevertheless, these drugs have a partial β1-adrenergic activity. Their action is mediated by cyclic adenosine monophosphate, which inhibits the kinase of light chain of myosin, thus avoiding myometrial cell contraction. Most of these drugs are excreted unmodified or conjugated. Ritodrine and terbutaline cross the placenta, but fenoterol and exoprenaline cross the placenta in a lower concentration.

The maternal serum concentration of ritodrine rises with the increasing infusion dose, but it can vary more than 100% among patients at low doses. The half-time of ritodrine is about 2 h and about 3–4 h for terbutaline. Myometrial β-receptors decrease in the pregnant uterus treated with β-sympathomimetics. In sheep, continued exposure to β-adrenergic stimulation leads to a reduction of inhibition of the contractility induced by oxytocin, whereas intermittent administration of ritodrine does not show any changes in β-adrenergic receptor or adenyl cyclase activity, and maintains the inhibition of contractility induced by oxytocin.

There is no strong evidence about the better effect of one drug vs. another; these substances may delay delivery by 3–7 days, but the efficacy in decreasing preterm morbidity and the advantages for the newborn are still a matter of controversy. Oral administration is not useful, both for a long and for a short period, and meta-analysis does not show any advantage regarding the prevention of preterm delivery, the period of time until delivery as well as the recurrence of preterm delivery. Although these substances have a maximum effect on the uterus and a minimal effect at the extrauterine level, they may significantly influence the maternal cardiovascular physiology and metabolic system. Table 130.2 lists the changes in some maternal systems due to β-sympathomimetic administration.

Some effects are slight, but others may be dangerous for maternal life. The most important side effects are hypotension, cardiac arrhythmia, myocardial ischemia and pulmonary edema. The incidence in treated women is about 0.3–5%. Intravenous administration of ritodrine is associated with palpitations in about 30% of patients, hot flushes in 10–15% and

Table 130.2 β-Sympathomimetics responses of different body systems

chest pain in 8%. In 7–10% of patients, the therapy has to be interrupted. Maternal death has been observed in case of heart disease or unknown myocarditis.

The most frequent and severe effect is pulmonary edema. This complication rapidly regresses by interrupting the therapy and administrating diuretics. Predicting factors are twin pregnancies (about 50% of observed cases), persistent heart frequency higher than 130 bpm, anemia below 9 g/dl, maternal infection and iatrogenic fluid overload.

β-sympathomimetics stimulate the renin–aldosterone system, decrease urinary output and colloidal pressure by about 20% after 24 h of infusion. All these factors lead to an increase in fluids, especially if colloidal pressure decreases below 15 mmHg. Most cases of pulmonary edema have been reported 30–60 h after the beginning of treatment.

It has been reported that the incidence of pulmonary edema in patients treated with β-sympathomimetics and corticosteroids is similar to the incidence in patients treated only with corticosteroids. β-sympathomimetics increase glucogenolysis and maternal glycemia for 3–24 h from the beginning of therapy. In patients affected by insulin-dependent diabetes, there is an increased risk of ketoacidosis. Subsequent to hyperglycemia hypokalemia develops, although all parameters return to the normal range in 24–48 h. During treatment, nausea, vomiting, insomnia and agitation have often been reported, and also rarely paralytic ileus and dermatitis.

A low dose of infusion is not related to major changes in the fetal heart rate, whereas a high dose can provoke fetal tachycardia and reduction of variability. In a retrospective study on newborns from mothers delivering within 48 h of treatment with ixosuprine, it has been observed that the newborns may develop hypoglycemia, hypocalcemia, ileus and hypertension.

The incidence of intraventricular and periventricular hemorrhage is increased, according to two studies, in newborns exposed to β-sympathomimetics.

The follow-up of babies exposed to β-sympathomimetics in the uterus shows normal growth and development in the second year, with no alterations in anthropometric measurements, neurological tests and behavior in the sixth year. β-sympathomimetics may be administered intravenously, intramuscularly, subcutaneously or orally. The treatment with ritodrine or terbutaline can be started intravenously, using an infusion pump, intramuscularly with ritodrine or subcutaneously with terbutaline. Before treatment, the fluid balance needs to be recorded and fluid intake between 1500 and 2500 ml is recommended.

Initially, 0.005–0.10 mg/min of ritodrine is administered intravenously, with an increase of 0.05 mg/min every 10–30 min, up to a maximal dose of 0.350 mg/min. Terbutaline can also be administered endovenously, starting with 0.01 mg/min and increasing by 0.01 mg/min every 10–30 min, up to 0.08 mg/min. The infusion dose is adjusted according to the uterine activity or by considering the maternal side effects. However, the infusion must not cause an increase of maternal heart rate over 130 bpm or a decrease of blood pressure below 80–90 mmHg.

Some physicians continue infusion for 6–24 h after tocolysis, while others recommend a slow decrease to the lower tocolytic dose, protracting it for over 12 h.

Oxytocin antagonists

For several years research has been focused on molecules for specific uterine receptors, avoiding the influence on other tissues. Oxytocin antagonists tend to inhibit oxytocin receptors, inducing uterine contraction in human and animal models. Oxytocin antagonists inhibit the double oxytocin effect on myometrium, which activates channels and indirectly stimulates prostaglandin production by decidual and fetal membranes. The only commercially available oxytocin antagonist is atosiban, analog to oxytocin, which is able to block myometrium and decidual receptors of oxytocin competing specifically with the substance. It is a synthetic peptide characterized by fast action and dose-dependent effect. This was the first oxytocin antagonist used in clinical practice.

Atosiban is able to delay preterm delivery. It has a uterus-specific action and it is therefore safer than other tocolytics. Some studies show an affinity of atosiban for vasopressin receptors, but this is not a clinical problem, since during labor the oxytocin uterine receptors are more numerous than vasopressin receptors.

Therapeutic indications are:

(1) Gestational age at 24–33 weeks,
(2) Presence of four or more regular contractions for 30 min, lasting at least 30 s,

(3) Cervical dilation of 1–3 cm (0–3 for nulliparous) and cervical shortening ≥50% and
(4) Normal fetal cardiac activity.

The rare maternal side effects of atosiban are nausea, headache, dizziness, tachycardia, hypertension, hyperglycemia and allergic reactions. The effects on the fetus are not remarkable. The efficacy and safety of atosiban vs. β-sympathomimetics in the treatment of preterm labor have been studied in a randomized, multicentric, controlled, double-blind trial. A total of 742 women have been randomized, with a diagnosis of preterm labor and gestational age between 23 and 33 weeks; 733 underwent tocolytic therapy, 363 with atosiban and the other 379 with β-sympathomimetics, for at least 18 h and within a maximum of 48 h. No statistically significant difference was found between atosiban and β-sympathomimetics in delaying delivery, either for 48 h (88.1% vs. 88.9%) or for 7 days (79.7% vs. 77.6%).

The main gestational age at delivery was similar (35.8 vs. 35.5 weeks), as well as the birth weight. (2491 vs. 2461 g). Tolerability and efficacy were statistically different for pregnant women who delivered over 7 days, without requesting any alternative tocolytic drug (57.7% atosiban vs. 47.4% β-sympathomimetics; $P=0.0003$). There was no statistically relevant difference as far as the feto–neonatal outcome is concerned (bradicardia, tachycardia, fetal distress, neonatal morbidity and hospital stay in the neonatal intensive care unit).

Maternal side effects, especially cardiovascular, were observed more frequently in women treated with β-sympathomimetics than in those treated with atosiban (81.2% vs. 8.3%, respectively, 10 times less frequent), imposing the interruption of therapy in 15.4% vs. 1.1% of the cases, respectively. The modality of atosiban administration is indicated in Table 130.3.

Table 130.3 Modality of administration of atosiban

Stage	Regimen	Dosage	Modality	Time length
1	0.9 ml i.v.	6.75 mg	Bolo	1 min
2	e.v.	18 mg/h	24 ml/h	3 h
3	e.v.	6 mg/h	8 ml/h	Until 45 h

Nitric oxide

Nitric oxide (NO) is a myorelaxant gas that mainly acts on vessels, bowel and uterine muscle. Nitroglycerine is a NO donor. The application of nitroglycerine patches seems to be efficacious for treating preterm delivery, but it has some maternal hypotensive effects. NO is a lipophilic molecule with a low molecular weight, derived from arginine intake by diet. NO binds to cyclic guanosine monophosphate, causing relaxation of smooth muscle of vessels and inhibiting platelet aggregation and endothelial adhesion.

NO is synthesized by the endothelium, epatocytes, macrophages, platelets, human placenta (especially syncitiotrophoblast) and umbilical vessel. It is a vasodilator, neurotransmitter, cytotoxic and cytostatic agent. The maternal side effects are nausea, vomiting, tachycardia, orthostatic hypotension and cutaneous rash.

The fetal adverse effects are determined by variation of feto-placental flow, due to maternal vasodilation. Neonatal hypotension can be observed. The acute treatment of preterm delivery is represented by a transdermic patch of 10 mg, initially applied every 12 h, then every 6 h and finally replaced by another patch every 12 h. Conservative treatment is carried out by means of a transdermic patch of 5 mg, applied daily for 12 h.

Improving NO synthesis by increasing L-arginine synthesis could lead to a reduction of uterine contractility. Nevertheless, the findings from human studies are contradictory. *In vitro* studies show that NO donors do not have any significant effect on myometrial contractions; other studies show a decrease.

In conclusion, there is no evidence to support the routine administration of NO donors in the treatment of preterm delivery. It might be useful to combine them with other tocolytic drugs (atosiban and indometacin) for a synergistic effect, which may prevent the increase of maternal side effects.

Non-pharmacological aspects

Despite the high possibility of identifying the risk cases of preterm delivery, the range of prevention is still limited.

The chances that can currently be taken into consideration are listed:

(1) Identification of a risk subject by cervical sonography screening or by dosage of fetal fibronectin according to demographic factors (low social status), life habits (smoking and drugs use), working conditions (hard work), obstetric anamnesis (previous preterm deliveries, miscarriage due to cervical incompetence), gynecologic anamnesis (uterine malformations or cervical conization) or current pregnancy (multiple pregnancy, polyhydramnios and placenta previa). Some authors have proposed risk scoring systems depending on the presence or absence of the above risk factors. It is very important to detect high-risk subjects among the population, in order to identify the most appropriate diagnostic and therapeutic tool.
(2) Change in life habits. In risk subjects some working conditions need to be changed, and bed rest is advisable, as well as avoiding smoking and use of illicit drugs.
(3) Study of cervico-vaginal microbial flora and its correction. In about 15–20% of pregnant women, the vagina is colonized by microbic agents, such as gardnerella vaginalis and anaerobic bacteria (causing bacterial vaginosis). The association between bacterial vaginosis and preterm delivery

is particularly striking. Antibiotic treatment of bacterial vaginosis reduces the rate of preterm delivery only in high-risk patients, but not in the general population. It is useful to perform the cervico-vaginal culture specimen test in the second trimester, in order to detect and to treat bacterial vaginosis or infections by other microorganisms (chlamydia, ureaplasma or mycoplasma).

(4) Cervical cerclage. In the past it was widely used for all pregnancies considered at risk of preterm delivery. In a recent meta-analysis it has been shown to be efficacious only in cases at high risk. Recent evidence has shown that cervical cerclage on patients with cervical shortening, evaluated by transvaginal ultrasound, reduces the incidence of preterm delivery.

(5) Prophylactic therapies. There is no evidence that in high-risk patients (positive obstetric history, cervical shortening or positive fibronectin test) there is an advantage in the use of prophylactic tocolytic agents.

Role of progesterone

In the field of obstetric and gynecologic pharmacology no other drug has been so extensively studied as progesterone, since its synthesis in 1934. In particular, this hormone has been proposed and used in the treatment of different gynecological pathologies such as endometrial hyperplasia, dysfunctional uterine hemorrhage, amenorrhea, luteal phase deficiency, premenstrual syndrome, as well as being utilized as a contraceptive tool alone or in combination with estrogens and in assisted reproductive technologies and in the maintenance of pregnancy.

The mechanism of action of this hormone is mainly through specific cytoplasmatic receptors that are influenced by the concentrations of estradiol.

Preterm labor

The hypothesis of Csapo, 40 years ago, implicated progesterone in the mechanism of human parturition (at term and preterm) with alternative observation. Adequate progesterone levels in the myometrium have been shown to counteract prostaglandin stimulatory activity as well as oxytocin properties, enhancing the activity of β-mimetic agents. Moreover, progesterone decreases the concentration of myometrial oxytocin receptors, counteracting the effect of estrogens; the same is apparent in the number and properties of gap junctions. Progesterone also inhibits prostaglandin production by amnion–chorion–decidua and it has been shown that the increase in binding of progesterone at the level of fetal membranes at term gestation may justify the predominant effect of estrogen in promoting prostaglandin production and triggering labor.

A high dose of progesterone has been advocated as a possible tocolytic agent; however, its action is slow and its use has been abandoned in acute tocolysis except in conjunction with β-mimetics; in this regard the combination of the two drugs has shown a synergistic effect, reducing the need for high concentrations of β-mimetics with potential dangerous side effects (Tables 130.4 and 130.5).

Recently, the use of prophylactic progesterone in a high dose has been proposed in patients at high risk of preterm labor (one or more previous preterm deliveries before 32 weeks). An NIH randomized controlled trial has clearly shown that the weekly administration of 17-α-hydroxyprogesterone caproate at 300 mg intramuscularly is related to a decrease of almost 50% of the chances of having another preterm delivery before either 32 or 36 weeks, irrespective of the etiology.

This study has been reinforced by similar results obtained by De Fonseca *et al.*[12] with high-dose progesterone given vaginally.

In conclusion, progesterone may be utilized either in acute tocolysis in order to decrease the concentration of potentially harmful tocolytic drugs or as a preventive agent in a population at high risk for preterm delivery.

131 Efficient and simple program including community-based activities for prevention of very early premature birth

E. Saling, J. Lüthje and M. Schreiber*

Introduction

Overview

The rate of prematures (< 37 + 0 gestational weeks) in Germany is increasing, 9.4% in 2004, similar to other European countries and the USA. In the past, it was not possible to substantially reduce this rate.

One of the most urgent tasks for modern obstetrics is to reduce the rate of very early (< 32 + 0 gestational weeks) prematures, and those with a very low birth weight (< 1500 g). These infants form the group of newborns with the highest mortality and morbidity.

Mortality and morbidity

Although in industrial countries, neonatologists have achieved enormous success in keeping extremely premature infants alive, mortality increases rapidly with decreasing birth weight. The immediate and long-term sequelae of prematurity are also alarming – something that is sometimes neglected when just measuring the 'successes' of modern intensive care by mortality rates. Table 131.1 summarizes the complications caused by prematurity or low birth weight.

The psychological and physical burden, which often exists for the families concerned, is another important factor that underlines the urgent necessity for effective prematurity prevention activities.

Costs

The enormously high costs of intensive care and follow-up care should be an urgent inducement to make even

Table 131.1 Specific published complications caused by prematurity or low birth weight (from Berkowitz *et al.*,[1] Hack *et al.*,[2] Edwards *et al.*,[3] Saigal *et al.*,[4] Riegel *et al.*,[5] Monset-Couchard *et al.*[6] and Wolke *et al.*[7])

more efforts to reduce the number of very small prematures if possible.

After a calculation by Künzel,[8] based on the well-organized German perinatal studies, the costs of care of all prematures born at less than 32 gestational weeks (about 8000 per year) were about 300 million EUR, and the costs for those born between 32 and 36 gestational weeks (about 47,000 per year) were about 430 million EUR, amounting to 730 million EUR. Additionally, the costs of clinical management of mothers with threatened prematurity were about 360 million EUR, totalling more than 1 billion EUR per year. These calculations do not even include the costs of long-term care of children and adults who are impaired due to prematurity.

Lewit *et al.*[9] estimated that in the USA each year the costs of medical care, child care and education for 3.5–4 million children aged 0–15 years, who had been born with low birth weight, were between $5.5 billion and $6 billion more than they would have been if those children had been born with normal birth weight.

Causes of late abortions and prematurity

Overview

Late abortions and, in particular, very early prematurity should be considered together, because their etiology is often the same.

A number of reasons are known to cause late abortions and prematurity. Lockwood and Kuczynski[10] divided most of the known causes of prematurity into four pathogenetic processes:

- Activation of the maternal or fetal hypothalamic–pituitary–adrenal (HPA) axis
- Decidual chorioamniotic or systemic inflammation
- Decidual hemorrhage
- Pathological distension of the uterus.

The various pathomechanisms initially follow different pathways, merge later on and cause changes in the cervix, leading to premature contractions and/or premature rupture of the membranes and finally to premature birth.

As far as effective preventive measures are concerned, most of the avoidable causes, particularly before 32 gestational weeks, are to be found among patients with ascending genital infections, and the diagnostic and therapeutic strategies in this direction are of definitive importance.

As far as other less frequent causes are concerned, both the possibility of treatment being available and the chances of success are clearly lower than in the infection group. Furthermore, some problems are directly related to the causes resulting from genital infection.

We want to emphasize that smoking and abuse of other drugs (especially alcohol) are important avoidable causes of prematurity and low birth weight. The physician should inform any pregnant woman about the risks of the above-mentioned and should encourage her to discontinue smoking, consuming alcohol or drug taking.

Ascending infections

The first convincing and direct confirmation of the ascension infection genesis was found at the beginning of the 1980s when the operative early total cervix occlusion (ETCO) was introduced for patients with recurrent late abortions.[11] This creates a complete barrier within the ascension area and leads to remarkably good results.[†]

Profound biochemical studies later performed by Romero *et al.*[12] brought us immensely forward in understanding the mechanisms by which infections lead to premature birth. Another pioneering step that underlines how important it is to improve prevention of infections is the concept of the 'fetal inflammatory response syndrome'.[13] It explains that fetal inflammation is linked to the onset of labor, and that the multisystemic involvement in this condition can lead to fetal injury, such as brain damage, which predisposes the subsequent development of cerebral palsy.

In the meantime, association between infections and prematurity has been proved by many studies. If early diagnosed, infections can often be treated effectively. Besides ascending genital infections, for instance, due to *Chlamydia trachomatis*, other infections must be considered, especially urinary tract infections.

Infections with *Candida* alone do not normally increase the risk of prematurity. *Chlamydia* infections are associated with a risk of prematurity that is as high as the risk associated with bacterial vaginosis. Some authors also report a similarly high risk of infection with *Trichomonas*, but *Trichomonas* is often associated with bacterial vaginosis, although *Chlamydia* and *Trichomonas* infections are not as prevalent as bacterial vaginosis.

Table 131.2 shows several urogenital infections and their impact on pregnancy and morbidity of infants and mothers.

Stress and immune system

Concerning efforts to prevent prematurity, many publications and recommendations have been reviewed in the literature. Most of them, for example, by Papiernik,[15] are based on the fact that socioeconomical factors, such as low social status, psychological and physical stresses, are important reasons and causes for premature birth. Some successes have been achieved with programs based on these aspects, particularly in

[†]For details see our article 'Operative Early Total Cervix Occlusion for Prevention of Late Abortion and Early Prematurity'

Table 131.2 Urogenital infections and associated complications in pregnancy (from Martius *et al.*[14])

Infection	Increased rate of prematurity	Increased morbidity by infection of the mother	Increased morbidity by infection of the newborn
Bacterial vaginosis	Yes	Yes	Unknown
C. trachomatis	Yes	Yes	Yes
Streptococcus Group B	Unknown	Yes	Yes
N. gonorrhea	Yes	Yes	Yes
Trichomonas vaginalis	Unknown	Unknown	Seldom
Mycoplasma hominis	Unknown	Unknown	Unknown
Ureaplasma urealytikum	Unknown	Unknown	Unknown
Urinary tract infection	Yes	Yes	No
Candida species	No	Yes	Yes

model studies. However, the main obstacle preventing a consistent reduction in the number of very low birth weight infants on a broad scale concerns the amount of expense involved. Considerable organizational and personal expenses are necessary to realize such projects, and these resources are hardly available to such an extent in all countries.

Another interesting aspect is that, as far as the cellular and humoral parameters of the immune system are concerned, concrete signs of impairments of the immune status could be found in women with prematurity symptoms.[16] In pregnant women with symptoms of threatened prematurity, significantly lower levels of lymphocytes, T-lymphocytes and T-helper cells were measured than in women who had a normal course of pregnancy. The T_4/T_8 ratio was also clearly reduced in those cases where later preterm birth actually occurred; it was particularly low at 1.1 compared to 1.6 in cases with uncomplicated pregnancies. In the group of pregnant women with premature labor, the rate of those who found their situation 'very stressful' amounted to 65%, and in the group whose course of pregnancy was normal, the rate was 26%. We assume that ascending infections are probably enhanced by such impairments of the immune system. Furthermore, we conclude that those pregnant women living in critical socioeconomical environments and who, therefore, are more likely to have impaired immunity can be helped effectively through exposure to appropriate information and preventive medical measures initiated early in pregnancy.

Early intervention by the prematurity-prevention program (see below) is more realistic and, consequently, more successful in reducing prematurity than the complicated and necessarily expensive intensive measures given by social services or later in pregnancy when prematurity symptoms are evident.

The protective lactobacillus system

Role of lactobacilli

The human vagina possesses a biosystem that under normal conditions provides a balance between physiologic lactobacilli and pathogenic bacterial flora, and so ensures a good protection against the spreading of pathogens, including their ascension to the uterine cavity. The importance of lactobacilli for the normal vaginal milieu was first described by Döderlein.[17]

In an article of particular interest to us, Gregor Reid[18] describes the role of lactobacilli in the urogenital tract infections.

The following main functions of lactobacilli are known (Figure 131.1):

(1) They produce acids, mainly lactic acid.
(2) They produce hydrogene peroxide (H_2O_2), which releases oxygen and has a disinfecting effect. These factors, combined with
(3) Bacteriocines, inhibit the growth of pathogens, which are always present in the vagina.
(4) They produce biosurfactants, which cover the surface of the vaginal wall, thereby inhibiting the adhesion of pathogens.
(5) They produce coaggregation molecules, which block the spread of pathogens.

Not every lactobacillus strain produces all the factors mentioned above. That is the reason why some strains are more effective against specific infections than others. For instance, women with H_2O_2-producing lactobacilli have a lower risk of bacterial vaginosis than women whose lactobacilli do not produce H_2O_2.[19] Unfortunately, there are also some microorganisms, the growth of which is not or only marginally inhibited by lactobacilli (e.g. *Streptococci* and *Candida*).

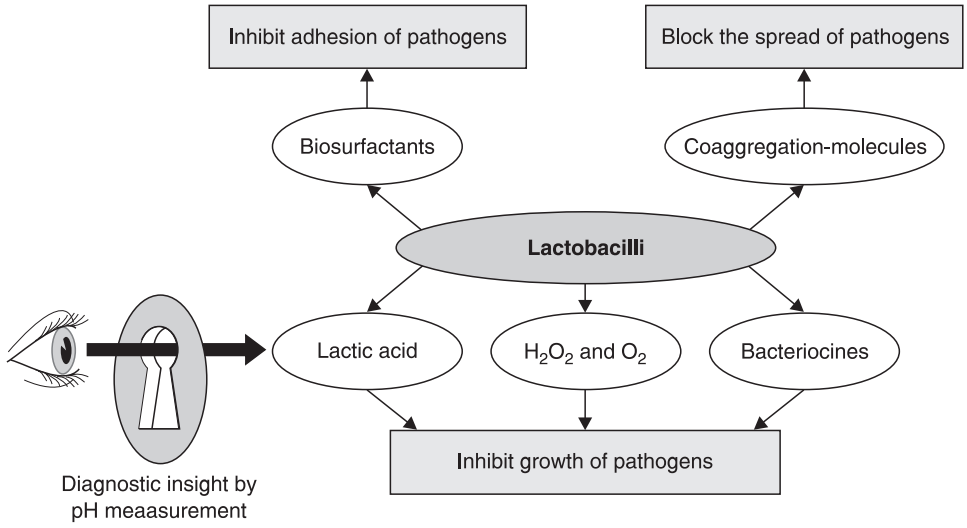

Figure 131.1

However, we can assume that lactobacilli are the main regulating factors of the vaginal milieu. Vaginal pH measurement gives us insight – like peering through a keyhole – into this protective biosystem. Vaginal pH measurement was already used by Döderlein, in order to distinguish pathological from normal vaginal fluid.[17]

Importance of pH measurement

The importance of lactobacilli and measurement of vaginal pH is illustrated, for instance, by the following facts:

Ernest *et al.*[20] found out that the risk of premature rupture of the membranes before 37 + 0 gestational weeks is three times higher when the vaginal pH is repeatedly above 4.5, compared to pregnant patients with pH ≤ 4.5.

A retrospective evaluation carried out by one of our coworkers reveals that: the earlier in pregnancy the examined children were born the more frequently the mothers had an increased vaginal pH when admitted to hospital. All 15 mothers (100%) of children with a gestational age lower than 32 + 0 gestational weeks had increased pH values; as far as prematures between 32 + 0 gestational weeks and 36 + 6 gestational weeks were concerned, the rate was still about 60%; when born mature only 43.5% were affected.[21] It follows, that ascending infections very frequently play a role concerning very early prematurity, and that in many of these cases threatening prematurity can be detected by measurement of increased pH values.

In a prospective study, Hengst[22] was able to show the practical importance of measuring the vaginal pH, which we recommend in routine prenatal care for the prevention of prematurity. In a cohort of pregnant women with a normal course of pregnancy until the study, who had an increased pH > 4.5 and who had received no therapy for acidification, the number of prematures amounted to 15.1%. On the other hand, the number was only 2.0% when an acidifying therapy with *Lactobacillus acidophilus* preparations had been applied.

In another earlier evaluation, we also found results concerning how many pregnant patients had normal vaginal pH values and how many had pathological (≥ 4.7). In 67% of all the 695 evaluated cases, normal pH values were present; in 33%, the values were increased twice or more and 7% of these were permanently increased.[23]

It is of particular interest to examine the success rate in normalizing the pH, in cases with increased vaginal pH values, by using *L. acidophilus* therapy. Success was achieved in 83% of 75 such patients, and this is really an unexpectedly good result. The therapy was carried out for 5 ± 3 days to achieve this success.[23]

Normal flora – disturbed milieu – infection

According to some published data, we assume that the main reason for the good results of our prematurity-prevention program (see below) is not the early detection of existing infections, but the early detection of their precursors, namely disturbances of the vaginal milieu.

- Hillier *et al.*[24] diagnosed an intermediate pattern between normal flora and bacterial vaginosis – see also Schröder[25] – in 16% of the pregnant women examined, while 22% of the women suffered from bacterial vaginosis, and 61% had a normal flora. Of the women with such a transitional stage in the second trimester, in the third trimester in about one-third the findings were the same, in about one-third the findings were normal, and about one-third developed a bacterial vaginosis.

- Hay *et al.* found in a study[26] an increased risk of loss of pregnancy, when just an intermediate pattern was present.
- Viehweg *et al.*[27] reported that an increasing pH value during the course of pregnancy leads to an increased risk of prematurity, even when the pH value stays within the normal range.

In the literature, there are controversial results concerning the success of treatment of bacterial vaginosis, and its effects on pregnancy outcome. However, there may have been little success, when screening, diagnosis and treatment took place rather late in the course of pregnancy, or when the diagnosis was incorrect, and there was probably a so-called 'aerobic vaginitis' (which is associated with aerobic microorganisms, mainly group B *Streptococci* and *Escherichia coli*) rather than bacterial vaginosis.[28]

We assume, that the main reason for those different results is that up to now no studies have been published where vaginal acidity was checked by pH measurement so early in pregnancy and at such short intervals (allowing early treatment), as is the case for the pregnant women who participate in our prenatal-care self-examination (see below).

We have first results that indicate that already disturbances of the vaginal milieu can be detected by pH measurement at regular intervals, before bacterial vaginosis develops.[29] In 24 pregnant patients who visited their doctor because they had themselves measured an increased vaginal pH value, 33 diagnoses were made:

- 46% of the patients were told that they only had a disturbance of the vaginal milieu, and not yet bacterial vaginosis.
- Bacterial vaginosis was diagnosed only in 4%.
- *Candida* were diagnosed in 33%, *Chlamydia* in 8% and other bacteria in 8%.

Although we received these data from the patients, and not directly from their physicians – and thus they should be interpreted with caution – there is no reason to question the results on principle.

Prematurity-prevention program

General aspects

We began our activities to reduce the rate of prematures in 1972,[30,31] but our successes[32] were only transiently satisfying. The program could not be maintained for long periods because it was too expensive for practical use. Fifteen years ago, we changed to another policy and developed a new prematurity-prevention program, which is based on the most frequent cause of prematurity, namely, as already mentioned above, the ascension infection genesis. Some reports on this program have already been published.[33–37] Its practical introduction into our clinical routine and later in general practitioners' offices by colleagues in the area has led to a considerable decrease in the number of very small, low birth weight infants. However, in spite of achieving a reduction rate of about 40% in our department and 50% in cooperation with practitioners, we had to admit that the practical employment of the program and the consequent application of preventive measures started at a relatively late stage in the entire prematurity pathogenetic process. Therefore, in 1993 we developed another supporting new concept, namely active cooperation of the pregnant patient herself.[38] Our present program is the combination of these two important parts. This solution appears to be quite different from conventional measures; it is a relatively simple, economical and more easily achieved way to attain considerable success in reducing the rate of very small and extremely small prematures.

Table 131.3 Risk factors for prematurity

Anamnestic risk factors
One or more premature births or stillbirths
Two or more pregnancy terminations
Prior cervical conization
Prior vaginal infections
After infertility treatment
In the present pregnancy
Low social status
Younger than 18 or older than 35 years
Multiples (twins, triplets, etc)
Polyhydramnios
Certain pressure situations (professional or private, physical or emotional)
Smoking, regular alcohol consumption, or use of other drugs

Diagnostic measures

Risk factors

Risk factors (Table 131.3) can be divided into anamnestic risk factors (mainly previous premature births or stillbirths) and events in the current pregnancy.

Screening for infections

Each time when a pregnant patient consults her physician, attention should also be paid to disturbances of the vaginal milieu or to manifest infections. Besides, medical history and physical examination (vaginal discharge, redness, etc.), especially measurement of the pH value should be performed. An increased pH value normally indicates a so-called

'dysbiosis', a bacterial vaginosis or – less frequently – another infection.

It is also important to note that some vaginal infections are normally not associated with increased pH values. This concerns *Candida* species, *C. trachomatis*, *Neisseria gonorrhoeae* and B-streptococci.

Systemic infections and urinary tract infections can also lead to prematurity. Therefore, we should always look for symptoms and signs of these infections (see also Ascending Infections and Table 131.2).

Measurement of pH value

The most important step during routine diagnosis in our prematurity-prevention program is to measure the pH value in the vagina. A high level of acidity in the vaginal milieu does not guarantee completely secure protection against ascending infections, but it is certainly very effective.

According to our investigations in an undisturbed course of pregnancy the pH-value at the introitus vaginae (at a depth of approximately 2–3 cm) is regarded as normal:

- $\leq$4.2 when measured with pH-meter
- $\leq$4.4 when measured with indicator paper.

In order to achieve uniformity, we recommend that measurements on principle be made in the lower area of the vagina. The higher in the vagina measured, that is, the nearer to the cervical canal, according to our examinations, the higher are the pH values.[39] In the cervical canal itself, for example, when measured in the external os, almost neutral pH conditions at 6.5 are to be found in women with an undisturbed course of pregnancy.

- A simple way of measuring the pH is to use a small portable pH-meter.
- If indicator strips are used, they have to be introduced into the area of the introitus vaginae with the finger either before or after the vaginal examination and compared with the corresponding color scale. We made by far the best measurements, when using Spezialindikator pH 4.0–7.0, art-no. 1.09542 by Merck, Darmstadt (Germany), because the reading is especially easy and reliable.
- In the meantime, special disposable gloves with the indicator paper from Merck fixed on the index finger are available for use by the physician. The gloves are almost identical to the ones that we recommend for the patients (see below). The only difference is that the paper in the version for the physician is attached to the *middle phalanx* of the index finger, so that during vaginal examination the pH value will be measured automatically at the introitus vaginae.

Stages and appropriate measures

The stages of threatened prematurity, prophylactic and therapeutic measures depending on diagnostic findings and/or the presence of symptoms as well as chances of success and efficiency of countermeasures are summarized in Table 131.4.

Stage 1: anamnestic risk

In the first, very early stage, a potentially increased risk is found in cases with poor medical history, such as one or more previous late spontaneous abortions or very premature labor. The best prophylactic countermeasure is to perform an operative ETCO at about 12 gestational weeks to create a barrier against ascension of organisms.‡

Stage 2: disturbance of vaginal milieu

The second early stage of increased risk is a disturbance of the vaginal milieu, which mostly can be detected by simple pH-measurement at the introitus. In such a case of so-called dysbiosis simple substitution with a *L. acidophilus* preparation for about 7 days is recommended. Especially effective are *Lactobacillus* strains that produce H_2O_2. For instance, the German preparation Gynoflor®** contains only H_2O_2-producing lactobacilli. Because *Lactobacillus* therapy normally takes 2–8 days, until the pH values normalize, additional local acidifying therapy might be indicated (e.g. lactic acid in the morning and *Lactobacillus* preparation in the evening). However, currently there is no scientific proof that this additional measure reduces the rate of prematurity.

Both stages 1 and 2 allow the best chances for success in prevention of prematurity.

Stage 3: infection

The third, also relatively early stage of increased risk includes cases without symptoms of premature labor, but in which vaginal infection has been confirmed, such as bacterial vaginosis, *Chlamydia* infection of the cervical canal or urethra, infections of the lower egg-pole (which can be detected by our egg-pole lavage‡) or significant bacteriuria. In such cases, we recommend:

- in case of bacterial vaginosis, local therapy with octenidine hydrochloride, metronidazole or clindamycin;
- when there is evidence of *Chlamydia* in the cervix or urethra, pregnant patients should get systemic therapy with erythromycine succinate;

‡For details see our article 'Operative Early Total Cervix Occlusion for Prevention of Late Abortion and Early Prematurity'
**Organon GmbH, personal communication, 25 August 2004

Table 131.4 Stages of threatened prematurity, prophylactic and therapeutic measures, and prognosis

Stage of endangerment	Symptoms and findings	Prophylactic and therapeutic measures			Chances of success
Anamnestic risk	Mean (one miscarriage or very small premature)	Small ETCO			
	High (≥two miscarriages or very small prematures)	Extensive ETCO			
Disturbance of vaginal milieu	pH ↑ and/or dysbiosis in native preparation, but No evidence of bacterial vaginosis No ascension of bacteria No increased contractions Normal cervical state	Only here treatment with *L. acidophilus* alone is recommended (maybe combined with acidifying therapy)			Best prognosis
Infection	Microscopically or culturally proved vaginal infection (such as bacterial vaginosis, *trichomoniasis, candidiasis*)	Local therapy Antiseptics Antibiotics Other chemotherapeutics (such as metronidazole)	Recommendation of rest and relaxing measures (among others, for improving immunological conditions)	After treatment with *lactobacillus* preparation in case pH ↑ (may be combined with acidifying therapy)	Still good prognosis
	Evidence of *Chlamydia* in cervix or urethra Evidence of bacteria at lower egg-pole Significant bacteriuria	Systemic antibiotic therapy + local acidifying therapy			
Symptoms of prematurity	Preterm labor and/or critical cervical state, and local infection in vagina, cervix or at lower egg-pole or signs of inflammation (e.g. CRP↑, leucocytosis)				Increasingly unsuccessful

- for other infections (including significant bacteriuria >100,000/ml), specific systemic antibiotic therapy.

In some countries, some colleagues are hesitant to apply antibiotics in pregnancy. Therefore, we want to stress that pregnancy is not an obstacle for a necessary local or systemic therapy against microorganisms.

The patients should have the recommended amount of physical rest, as well as use of psychological relaxing measures to try to improve their immunological status. The chances of success are still acceptable.

Stage 4: symptoms of threatened prematurity

This most advanced stage is found when symptoms of prematurity, such as apparent premature uterine contractions and/or critical cervical findings, are present. If organisms can be identified, or laboratory parameters, such as C-reactive protein (CRP), are positive, systemic antibiotic therapy (e.g. with clindamycin, or better according to the antibiogram, if available) is the method of choice. In most of these cases, admittance to hospital is recommended. In the last stage, the therapeutic measures are increasingly unsuccessful.

In both stages, an additional 'after treatment' with *L. acidophilus* preparations may be indicated because most of the therapeutic measures concerned also disturb the vaginal milieu, which can be confirmed by increased vaginal pH values.

In this context, it should be emphasized that our prematurity-prevention program contains, above all, measures most suitable for the prevention of premature rupture of the membranes, as ascending infection is the most frequent cause of this event.

Prenatal-care self-examination

The other, more important, part of our prevention program, is the so-called prenatal-care self-examination of the pregnant patient. The main points are given below.

pH self-measurement

Every pregnant woman is advised to measure the pH value in her vagina twice a week herself, by using a special indicator (see above). It can be used in the form of a test paper by itself, but in cooperation with us special disposable gloves with a piece of test paper fixed on the tip of the index finger have been developed (CarePlan VpH, made by Unipath). The majority

Table 131.5 Warning signs of a threatened premature birth (part of the patients brochure)

The patients are advised to get in touch with their doctor as soon as possible if any of these signs are present
Repeated measurement (with the test glove) of a vaginal pH value of 4.7 or higher. *Attention*: Particularly high values may be due to the loss of amniotic fluid (premature rupture of the membranes)
Vaginal bleeding or spotting
Bad smelling or highly increased discharge (a slight increase is normal during pregnancy)
Abnormally frequent urination (a slight increase is also normal) or a burning sensation when urinating
Itching or burning in the intimate region
Fever and/or diarrhea (these conditions are often associated with an increase in uterine activities)
Premature contractions:
Considerable pain similar to menstruation
Aching in the groin or in the sacral region
Temporary, repeated hardening of the uterus
Premature contractions should be regarded as critical to threatening, if they occur more than twice per hour, or more than 10 times during the whole day

of the women whom we consulted reported that it is much more comfortable to use the gloves, rather than the test paper alone.

The woman simply introduces the index finger into her vagina, withdraws it shortly afterward, and compares the color of the indicator paper with the enclosed special color scale, in order to read the pH value. When pH values are increased to 4.7 or higher, the patient should see her practitioner at once.

If her doctor confirms the reduced acidification, additional examinations should be performed, in order to find the cause of the acidity disturbance. The further procedure depends on the stage of threatened prematurity (see prematurity-prevention program above).

Self-observation of warning signs

Independent of the vaginal pH self-measurement, all expectant mothers should be made aware of the most important warning signs. They are listed in the information brochure (see Table 131.5). If anything unusual occurs, the patient should see her doctor.

Benefits of the self-care program

As the program is fundamentally based on a screening-principle, as many patients as possible should be motivated to take part, at best, every pregnant woman without exception. The reason for a recommendation such as this is that, during the course of even supposedly normal pregnancies, late abortions and preterm delivery can occur. It is very probable that a large number of these patients will have early symptoms that could have been detected but remained concealed.

The self-examination should be started very early on, to detect the threat of irregularities in good time, that is, at the earliest possible moment in the pregnancy. It would be even better, in cases with a poor history, to choose a preconceptional moment, that is, weeks or months before a planned pregnancy. For some women, it could be really important to detect potential risks themselves at such an early stage and to inform their practitioner even before the pregnancy has started or at least very early on in the pregnancy.

Recently, Hübner confirmed the importance of early onset of pH self-measurement in pregnancy. She evaluated questionnaires from 607 pregnant women, who participated in the Thuringia Prematurity Prevention Campaign 2000' (see below) (Hübner, in preparation).

Among women who started measurement before 15 + 0 gestational weeks, the total rate of prematures was 4.8%, and the rate of very early prematures was 0%. In contrast, when women started pH-measurement at 15 + 0 gestational weeks or later, there were 6.1% prematures and 0.9% very early prematures.

The main advantage achieved by the patient's active participation is that increases in vaginal pH or the manifestation of any other risk factors are identified very early and this leads to the detection of a considerable number of disturbances connected with spontaneous abortions and prematurity. This enables the practitioner to avoid longer, critical latency periods, sometimes of several weeks. In particular, without these new facilities, some symptoms remain concealed, although they are, in fact, easily recognizable. Furthermore, there is also a possibility of controlling the behavior of

vaginal acidity at short intervals, for instance, to follow effects of therapeutic measures.

Hübner also confirmed that it is important to measure regularly at short intervals. Among patients who did not only start pH-measurement early in pregnancy, but also – according to our recommendations – measured twice a week, the total rate of prematures was 4.2%, and the rate of very early prematures was 0%. In contrast, in the group of women who started pH-measurement at 15 + 0 gestational weeks or later, or measured less frequently than twice a week, there were 7.3% prematures, and 0.8% very early prematures. However, the differences between these rates are not statistically significant (Hübner, in preparation).

Now and then, some colleagues argue that self-measurement of vaginal pH would have no other effect than confusing the pregnant women. The opposite is true. In an inquiry, we asked the women who participated in our prenatal-care self-examination program regarding this point. The vast majority answered that they found it 'very good', 'reassuring' and had 'a good feeling' about it, etc. because they 'were able to do something themselves'. Although it might seem surprising, because of these simple regular self-examinations, most of the users have the feeling of not being a 'treated object' during pregnancy anymore but an 'active subject'.

Results of self-examination

The results evaluated up to now appear to justify the pH self-measurement by pregnant patients and demonstrate the efficiency of the prenatal-care self-examination program.

In a study by our department[39] of 100 women who had measured their vaginal pH themselves using indicator paper, 91% of the measurements corresponded with the results later measured by a physician with a pH-meter. In 9% of cases, the results were false-positive; this means that with the indicator paper an increased pH value was measured, but the value controlled by the pH-meter was normal. This is not a grave error, as there were no false-negative results, i.e. no pathological findings were overlooked.

Furthermore, we found that in about 70% of the patients who had increased pH values measured both by indicator paper and by the pH-meter, evidence of pathogenous organisms was found in the vagina and/or the cervix, whereas when the pH values were normal, the figure was only 8%.

The full prenatal-care self-examination program was started in September 1993. The program was advertised in publications that are frequently read by pregnant women.

To date, about 10,000 pregnant patients have participated or are still participating, and about 3000 returned the questionnaire to us. Of the 1715 women whose data have been evaluated so far, 595 were pregnant for the first time and 1120 had been pregnant before. The anamnestic information given by the group of women with previous pregnancies was particularly interesting. A high number of these women, namely 46.4%, had had miscarriages and about 18.3% had had underweight infants during the immediate previous pregnancies. To date, we are able to draw the conclusion that the participating women belong to a higher-risk group rather than to a lower-risk group. According to the returned records, 60.8% of the patients reported 'disturbed courses' in their present pregnancy.

Our evaluations have shown that the rate of underweight infants, in particular the very small ones (birth weight < 1500 g) in all pregnant patients who took part in this program is clearly lower at 1.3% than in previous pregnancies, when the rate was 7.8%. The rate of extremely small infants (< 1000 g) is 0.9% when the women participated in our program, compared with 3.9% in previous pregnancies.

Another evaluation shows comparisons between the results of the immediate previous pregnancies and the present pregnancies only of those women who had suffered a premature birth in the immediate previous pregnancy. Of the 111 women, only 20 (18%) again gave birth to a premature baby ($< 37 + 0$ weeks of gestation). Of the 38 women who had given birth to a very early premature ($< 32 + 0$ weeks' gestation) in the immediate previous pregnancy, only 3 (8%) suffered the same misfortune again, and, of the 22 who had given birth to an extremely early premature ($< 28 + 0$ weeks of gestation), no recurrence occurred.

The effectiveness of our self-care program was also proved by two prospective campaigns.[40] The first was carried out in Erfurt (the capital of Thuringia, Germany), where pregnant women have been offered to perform self-measurements of their vaginal pH by means of test gloves. Patients who were not interested in participating served as a control group. In this study, the prematurity rate was 8.1% in the self-measurement/intervention group vs. 12.3% in the control group. Of the neonates 0.3% vs. 3.3% belonged to the group of very early prematures with a gestational age of $< 32 + 0$. Premature rupture of membranes was registered in 22.8% vs. 30.8%, respectively.

Encouraged by these results, in 2000, a similar pH screening campaign was initiated in the whole state of Thuringia, in order to reduce prematurity. A significant reduction of early prematurity from 1.58% to 0.99%, and regarding low birth weights a significant reduction of cases in all groups, was achieved.

After this campaign had been finished, the prematurity rates monitored in 2002 were as high as they had been prior to the introduction of the activities.

That is why the new Thuringia prematurity prevention campaign 2004/2005 was started on September 1 2004.

Also, four major German health insurance companies currently offer our prenatal-care self-examination program as a pilot project to their pregnant members at no charge. This is especially important, because prematurity is most frequent in women with low social status. The companies started this project in December 2003, and after first internal evaluations, they have already saved a high amount of expenses.

Conclusion

Currently, our prematurity-prevention program, particularly with its self-care activities – as has been confirmed by our evaluation and afterward by two campaigns by Hoyme and coworkers – seems to be the most efficient, easily applicable and inexpensive program for prevention of very early prematurity. Thus, it has high importance in the field of health and social care, and has considerable value within our social community.

132 Operative early total cervix occlusion for prevention of late abortion and early prematurity

E. Saling, M. Schreiber and J. Lüthje

Introduction

Recurrent late abortions and early prematurity continue to be two of the inadequately solved problems in modern obstetrics and perinatal medicine. The patients concerned often feel heavily burdened: On the one hand, they yearn for a child and on the other hand, they experience recurring losses, which are often accompanied by increasing psychological problems. To achieve a surviving infant is in such cases a particularly important medical and psychological task.

Several causes of late abortions and prematurity are known. Lockwood and Kuczinski[1] divided most of the known causes of prematurity into four pathogenetic processes. However, as far as the avoidable causes are concerned, infection, particularly ascending genital infection, is known to be the most common.*

The most efficient measure for preventing ascending genital infections in cases of recurrent late abortions and early prematurity is to establish a total barrier within the cervical canal by early total cervix occlusion (ETCO). We introduced this measure in 1981.[2,3]

Before that, there were only very few reports in the literature about operative cervix occlusion for treatment of imminent abortion, mainly in advanced stages. For instance, 40 years ago, Szendy published two articles on the topic 'Measures to Prevent the Birth of the Infant in Advanced Premature Labor' (translated from the German).[4,5] Thus, it was thought of as an emergency measure, to be taken mostly when prolapse of membranes had occurred.

We introduced the ETCO as an original early preventive measure for use when the cervix is still in an anatomically normal state and that should be performed early in pregnancy at about 12 gestational weeks (gw), and only in women with previous critical history. It is important to note that the ETCO is quite different from a cerclage (and in principle, also from the occasionally used pessary). The ETCO actually closes the cervical canal, thus preventing ascension of organisms, whereas the cerclage only tightens the canal (Figure 132.1) and has much poorer results (see below).

Definition

With regard to total cervix occlusion (TCO), we differentiate between 'early' and 'late' and between 'small' and 'extensive'.

- *ETCO* is performed at $< 16+0$ gw and with an almost normal state of the portio (sonographically measured† cervix length ≥ 30 mm or modified[6] Bishop score of ≤ 4).
- *Late TCO* is performed at $\geq 16+0$ gw or when the portio is in a critical state (cervix length < 30 mm or modified Bishop score of > 4).

Because the results (of preventing premature birth) are much better (see below), we recommend ETCO rather than late TCO.

- *Extensive TCO*: After removing both the glandular epithelium in the cervical canal and the epithelium of the portio surface, the cervix is closed by two to three circular internal sutures, followed by

*More details can be found in our article 'Efficient and Simple Program Including Community-Based Activities for Prevention of Very Early Premature Birth', Chapter 131.

†The sonographic measurement of the cervical length is more reliable than the assessment using the Bishop score and should therefore be preferred.

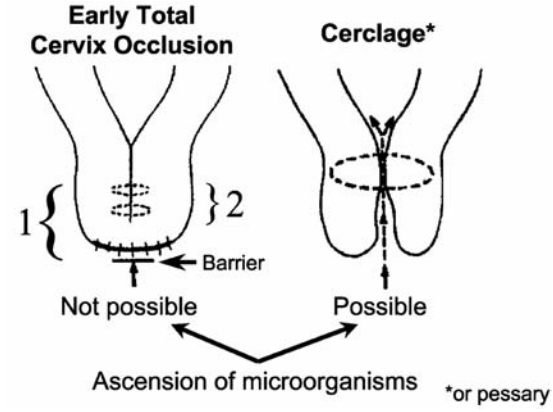

Figure 132.1 ETCO vs. cerclage or pessary: (1) 'extensive' ETCO and (2) 'small' ETCO.

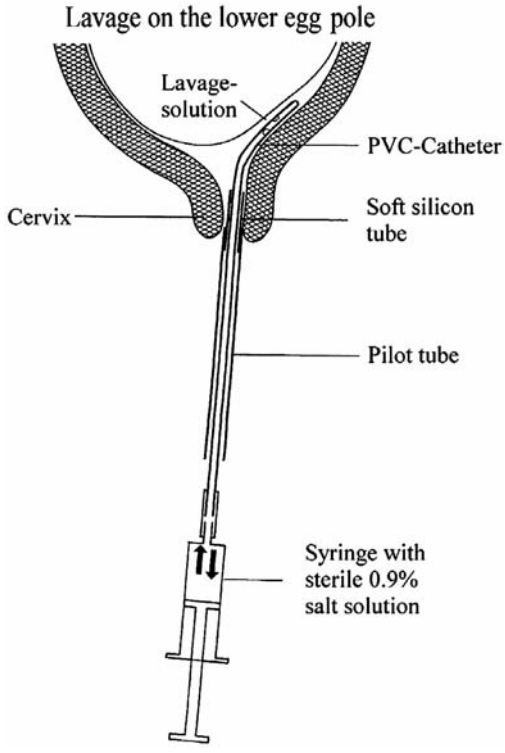

Figure 132.2 Lavage on the lower egg pole.

two transverse rows of knotted stitches to close the surface of the portio. See Figures 132.1(1) and 132.5(2)–(5). For most cases we recommend extensive TCO, preferably ETCO.

- *Small TCO*: Only the cervix canal is closed by two to three circular sutures after removing the glandular epithelium. See Figure 132.1(2).

Indications and contraindications

(1) *Indication* for ETCO is two or more

- late abortions ($\geq 12+0$ gw) or
- early premature births ($< 32+0$ gw) in the patient's history either
- with infection as the cause of these events or
- (in the absence of any other cause) when, for instance, premature rupture of the membrane (PROM) has occurred. Please note that the main reason for PROM is ascending vaginal infection.

(2) Up to now no study is available on whether in cases with only one previous late abortion or premature birth a consequent screening for vaginal infection (see Chapter 131, 'Efficient and Simple Program Including Community-Based Activities for Prevention of Very Early Premature Birth', in this section) will lead to similar good results as with ETCO. Therefore, one might consider an ETCO even after only *one* abortion or premature birth, particularly when additional risks exist, for instance, when the patient is older or when there have been problems with fertility. In these cases, a small occlusion of the cervix may be sufficient.

A *contraindication* is dilatation of the cervix with apparent signs of infection and labor activity, which cannot be inhibited.

Preoperative diagnostics and measures

Examinations for infections are compulsory, for example, vaginal and cervical smears with microscopic and/or bacteriologic examinations. Further, should pathological findings be present – such as bacterial vaginosis, candida, *Trichomonas* or *Chlamydia* infection – the patient should be given an appropriate local or systemic therapy.

After an ETCO has been performed, there is no further opportunity to examine whether organisms have already ascended to the intrauterine space. Therefore, we recommend performing a so-called egg-pole lavage (which we introduced in 1992) directly before the operative occlusion of the cervix.

Egg-pole lavage (Istmical lavage)

The use of this method is still not sufficiently widespread. In the beginning of the 1990s, we started to achieve direct access to the area of the lower uterine segment, namely, the egg pole, and have tried to obtain bacteriological information from this region.[7,8]

A pilot tube, the front part of which is made of silicone, is inserted into the cervical canal (see Figure 132.2). In this pilot tube a flexible 1.5-mm-diameter plastic (polyvinyl chloride) catheter is introduced and pushed further 2–6 cm forward, according to the state of separation of the membranes from the uterine wall. In this way, we can be sure that we have reached the area of the lower egg pole, and that the front end of the inner plastic catheter is in the uterus.

Figure 132.3 Ligature with the loop instrument:[9] There is a ratchet on the traction stick with a blocking spring. This allows the stainless steel plaited wire loop to be attached in a circle around the portio and to be fixed in a tightened state. We always try to clamp the loop so tight that there is minimal bleeding remaining. This is a sign that the tissue circulation is not completely interrupted. When the hemostasis has to be suspended at the end of the operation, the traction stick is turned about 90°. The blocking spring slides out of the traction and the loop is set free.

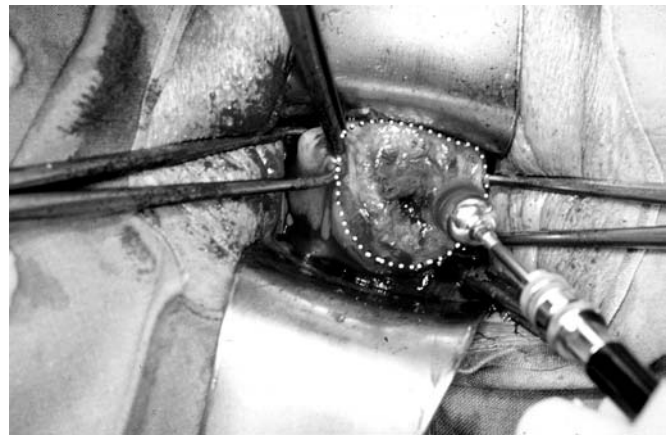

Figure 132.4 Removal of the portio epithelium with rotating wire brush. White points indicate the position of circular incision.

Then, using a syringe attached to the outer end of the catheter, 2 ml of sterile 0.9% physiological saline solution is slowly injected and, shortly afterwards, as much as possible of this solution is aspirated back. When we have reaspirated more than 0.3 ml (the dead space of the catheter), we can be certain that we have collected fluid that was in contact with the membranes or intrauterine wall at the lower egg pole.

The aspirated fluid undergoes bacteriological examination. If the laboratory is close enough, the syringe with the fluid at body temperature can be brought directly to the laboratory for all examinations. Otherwise, the fluid should be instilled into two blood culture bottles (one for aerobe and one for anaerobe examination). Additionally, special transport media provided by the laboratory should be used for other examinations, such as for *Chlamydia* and *Neisseria gonorrhoea*.

A disadvantage of the lavage method is that it is not yet possible to be certain of preventing some organisms from being carried up to the cervical canal. On the other hand, it must be assumed that organisms that have already reached the cervical canal will probably ascend further to the lower egg pole and can certainly develop pathogenicity there. Organisms from the vagina very probably are not transported, as the outer os uteri is treated with disinfectant before catheterization and the device is inserted under visual control directly into the cervical canal.

Operation technique

Before starting the actual operation, we recommend using a procedure and a device that we specially introduced to avoid considerable bleeding. This involves a tight circular ligation of the portio as high as possible, so that the circulation is almost cut off. This measure has two particular advantages: first, the blood loss, which can be considerable on account of the hypervascularization in pregnancy, is reduced to a minimum, and second, it is much easier to see and control the operation area. For a simple and successful ligature we have developed a special loop instrument[9] (see Figure 132.3).

In order to allow the os uteri to grow completely together, the upper surface of the portio has to be dissected, that is, the epithelium has to be almost completely removed. So as to clearly mark the surface to be removed, and also to find the exact positioning of the wounded area later for the row of stitches adapting the upper surface of the portio, we make a circular incision 1 mm deep with a radius of 10–15 mm around the external os uteri with a scalpel. Then, we remove the portio epithelium with a quick rotating wire brush or a special metal rasp in a similar way as is used in dermatology to smooth out scars (Figure 132.4). This method of removing the tissue is more effective and preserves the tissue better than the method we had previously used, when we removed the epithelium by sharp dissection using a scalpel.

Later, the glandular epithelium of the cervical canal is also removed, as far as possible to a depth of about 1–2 cm using the same rotating device, while the os uteri is spread out using mosquito clamps. Then, two to three circular inner stitches are made to close the cervical canal. Consequently, two rows of knotted stitches are made, which close the outer os uteri completely (Figure 132.5). For all the stitching we use synthetic monofile thread like PDS or braided thread, such as Vicryl. These threads, when compared to catgut, are much better for the healing process and are reabsorbed much more slowly.

Measures at the end of pregnancy

The scar should be opened:

- when labor starts spontaneously,
- when an induction of labor is planned or
- when 37 gw are completed.

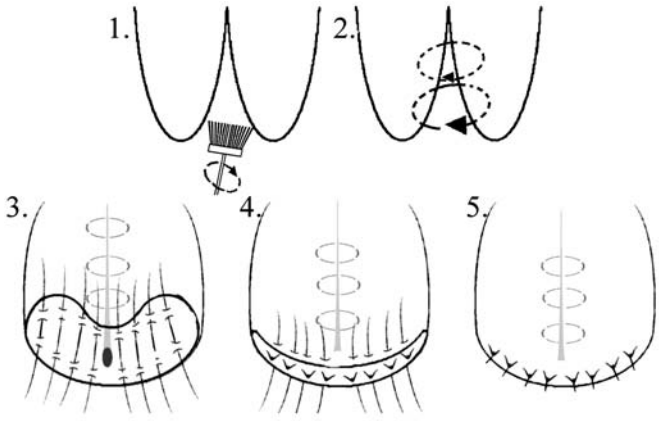

Figure 132.5 Operation technique of ETCO with the different sutures: (1) removal of the glandular epithelium, (2) two to three circular cervical sutures, (3) transverse stitching of the whole dissected area for deep adaptation, (4) second row of knotted stitches adapting the surface tissue and (5) situation after the operation.

We generally cut the portio scar with scissors under local anesthesia. Then, we penetrate with the finger to a depth of about 1–2 cm into the loose cervical tissue in the assumed direction of the cervical canal. If the patient wants to leave the hospital after the scar has been opened, to wait until labor starts spontaneously, we see no reason why she should not do so, provided there are no signs of any risk.

We do not think that a primary cesarean section is necessary at all. Quite the contrary: when recanalization of the cervix takes place during a vaginal delivery, it is in fact a good prerequisite for the reestablishment of normal anatomic conditions.

Results

To assess the results of ETCO, particularly in comparison with cerclage, one should look only at high-risk groups which match the above-mentioned indications for an ETCO (two or more late abortions or premature births). We have no knowledge of any randomized study on ETCO. On the basis of the results published so far we do not think that the operation can be withheld from any woman with such a critical history. A randomized study would not receive the approval of any ethic council – at least not in Germany – and no woman is likely to agree to being integrated into a control group anyway. Therefore, an acceptable solution is to compare the outcome of pregnancies after performing an ETCO with the outcome of former pregnancies of these patients.[3,6,10] We should also consider that the chances of giving birth to a surviving infant are reduced the more late abortions or premature births the woman has previously had.[11]

In 1990[12] we evaluated retrospectively the data from a group of 113 patients with previous recurrent abortions. From a total of 389 wanted pregnancies only 101 infants were born alive (26%). However, 35 of these infants died in the neonatal period. In total, 66 survived, which means that only 17% of all these pregnancies resulted in a surviving infant. Through the introduction of TCO (either early or late) the same patients achieved 132 pregnancies with 94 live and surviving infants (71%!). We could also show that the results in cases with an early TCO are twice as good as with a late TCO (80% vs. 40%).[12]

Similarly, good results have been obtained by other clinicians performing the TCO. In 1996 we reported the results of a multicenter evaluation, in which 11 German hospitals took part,[6] and the outcome of a total of 819 pregnancies with TCO was assessed. It emerged that the rate of surviving infants in the pregnancies before TCO had been performed was 21% compared to 74% in the pregnancies with TCO. Hormel and Künzel[10] reported similar good results.

As far as the mode of delivery is concerned, 71% of the patients with a cervical occlusion had a spontaneous delivery and 15% had an operative vaginal delivery. The rate of cesareans was 14% in comparison to 9% for the whole department at that time.[12]

In 1997 we reported the results of a follow-up examination carried out on 52 women who had previously had a TCO.[13] On the basis of these results, we can generally conclude that up to now no remarkable negative effects have been proven in connection with the operative TCO.

ETCO vs. cerclage

The cerclage is a widely used measure and there are numerous publications on it. Some authors report good results – but one should look at these reports very closely and verify whether or not cerclage had been performed on women at similar high risk (see above). But cerclage is hardly capable of preventing ascending infections because this method only tightens the cervical canal and does not close it (Figure 132.1). In our sample of women treated with ETCO, we found that in 51 previous pregnancies in which cerclage was performed, only 13 infants survived. This is a survival rate of only 26% (as compared to a survival rate of 80% with ETCO). These results underline how advisable it is to give the ETCO preference over cerclage in cases with such a critical history.

Conclusion

On the basis of previous experiences and available results, the TCO – in particular the early occlusion – is a convincingly efficient operative measure for the prevention of late abortions and early prematurity, particularly in cases where such events had previously occurred recurrently.

133 Assessment of risk for preterm birth in asymptomatic patients and those with preterm labor

J. Espinoza, R. Romero, L. F. Gonçalves, J. P. Kusanovic and J. K. Nien

Introduction

Preterm delivery is the leading cause of neonatal mortality worldwide.[1] Several biochemical and biophysical markers have been proposed for the identification of patients at risk for preterm delivery, in both patients with threatened preterm labor and asymptomatic ones, with the hope that interventions could prevent preterm delivery. However, current interventions such as tocolysis, cerclage and antibiotic therapy have been ineffective in this regard. This may be due to the nature of these interventions, which are aimed at treating the symptoms, rather than the causes, of preterm labor or at modulating the mechanisms of disease involved in preterm parturition. Mechanisms of disease implicated in preterm labor include infection, vascular insults, stress, uterine overdistension, allergy, cervical insufficiency, hormonal disturbances and others (see Chapter 129). The clinical presentation of preterm labor may depend on (1) the intensity of the insult (i.e., microbial load or virulence), (2) the timing and duration of the insult (i.e. infection may cause abortion in the first trimester and preterm birth in the second or third trimester), and (3) the evolving nature of the host response.

This chapter will review the biophysical and biochemical markers that have been used to determine the risk of preterm birth among symptomatic and asymptomatic pregnant women.

Cervical ultrasonography to assess the risk for preterm delivery

Several investigators have examined the utility of cervical ultrasound to identify patients at risk for preterm delivery. In the early 1990s, Andersen *et al.*[2] examined the risk of preterm delivery by transabdominal and transvaginal ultrasonography, along with manual assessment of the cervix, in a group of 113 patients with singleton gestations and no cervical incompetence. Patients were examined once before 30 weeks of gestation. The patient population, with an overall prematurity rate of 15%, was not separated into low-risk and high-risk categories. Twenty-five percent of the patients with a cervical length < 39 mm (50th percentile for gestational age) delivered preterm, compared to 6.7% of those with a cervical length ≥ 39 mm ($P = 0.01$). When the cervical length was below 34 mm (25th percentile), 34.8% of the patients delivered prematurely, compared to 10.1% of those with a cervical length ≥ 34 mm ($P = 0.003$). Using 34 mm as a cutoff point, the sensitivity and specificity of cervical length measurement by transvaginal ultrasound to identify patients at risk for preterm delivery were 47% and 84%, respectively, compared to 36% and 76% with manual assessment of the cervix.

Several studies have confirmed and extended the observations of Andersen *et al.* Details of studies performed on patients presenting with preterm labor,[3–12] asymptomatic patients at low risk for preterm delivery[2,13–17] and asymptomatic patients at high risk for preterm delivery[18–22] are presented in Tables 133.1–133.3. Only studies with adequate information to allow calculation of diagnostic indices and predictive values are included. Collectively, the information provided by these studies shows that cervical sonography is a powerful method to assess the risk of preterm delivery in patients presenting with preterm labor, low-risk asymptomatic patients, and patients at high risk for preterm delivery. Furthermore, in patients with a long cervical length, the likelihood of preterm delivery is low and, therefore,

avoiding aggressive intervention in the setting of premature labor may be justified.[23]

Some of the studies presented in Tables 133.1–133.3 represent significant contributions to understand the value of cervical sonography in screening for spontaneous preterm birth. These are described in greater detail below.

Cervical sonography in asymptomatic patients at low risk for preterm delivery

The Maternal–Fetal Medicine Units Network of the National Institute of Child Health and Human Development conducted a prospective cohort study entitled 'The Preterm Prediction Study'. This study evaluated the value of clinical, demographic, microbiological, biochemical and sonographic parameters in the prediction of preterm birth. Iams *et al.*[14] reported the cardinal observations of cervical sonography for the assessment of risk for preterm delivery. A total of 2915 low-risk asymptomatic patients were examined at 24 and 28 weeks of gestation by transvaginal sonography to evaluate the cervical length and calculate the risk of preterm birth. An exponential increase in the relative risk of delivering before 35 weeks was described. This large study confirmed the results of

Andersen *et al.*,[2] which indicate that a short cervix increases the risk for preterm delivery, while a long cervix decreases such a risk. The study also extended the observations by allowing discernment of the comparative value of cervical length with other predictors of preterm delivery (i.e. demographic, biochemical, microbiological and clinical variables).[14]

An important series of studies reported by Heath *et al.*[16] and conducted at King's College Hospital in London examined the value of cervical sonography in screening for preterm birth. Cervical length was measured by transvaginal sonography in a low-risk population of 2702 patients. Patients with a history of preterm birth, of African-Caribbean origin, of low maternal age (< 20 years) and with a low body mass index had a shorter cervix than those without such risk factors. However, when logistic regression analysis was used to examine the contribution of all these parameters to the prediction of preterm birth (< 32 weeks), a short cervix was the only significant predictor.[24] These findings suggest that clinical and demographic risk factors associated with preterm birth operate through inducing cervical ripening. In this study, a cervix of 15 mm or less at 23 weeks of gestation in 1.7% of the population identified 60% of patients who subsequently had spontaneous preterm birth at less than 32 weeks and 80% of those who had spontaneous preterm birth at less than 28 weeks.

Hassan *et al.*[17] conducted a retrospective cohort study of 6877 women who had cervical sonography performed between 14 and 24 weeks. Examinations were conducted transabdominally and in cases of cervical length < 30 mm or suboptimal visualization, transvaginally. A cervical length of ≤15 mm had a positive predictive value of 48%, a negative predictive value of 97%, a sensitivity of 8% and a specificity of 99.7% for spontaneous preterm delivery at ≤32 weeks. A history of preterm delivery and African-American ethnicity were also associated with the occurrence of spontaneous preterm birth, although the odds ratio (OR) was considerably lower than that of a short cervix. The low sensitivity of a short cervix in this study is similar to that reported by Taipale *et al.*[15] in a large study conducted in Finland. The apparent discrepancy among the studies can be explained by the different gestational ages at which ultrasound examination was conducted. There is evidence that later scans are more predictive of preterm delivery than earlier ones. The study of Heath *et al.*[16] included exams conducted at 23 weeks, while the exams by both Hassan *et al.* and Taipale *et al.*[15] were performed at earlier gestational ages.

Cervical sonography in patients at high risk for preterm delivery

Cook *et al.*[18] conducted a prospective cohort study in 120 women considered to be at risk for preterm delivery. The patients at risk included those with a history of recurrent first-trimester loss, second-trimester loss, previous preterm delivery (< 34 weeks), previous cervical surgery and uterine anomalies. Initial cervical assessment was made between 9 and 29 weeks of gestation. Further assessments varied on weekly to monthly schedules, according to cervical findings and obstetric history. The parameters measured were cervical length, diameter and internal os dilatation. Twenty-four patients (20%) delivered before 34 weeks of gestation. Cervical length was the only significant factor found for the prediction of preterm delivery. A cervical length ≤ 20 mm before 20 weeks was associated with delivery before 34 weeks in 95% of the women studied.

Owen *et al.*[20] performed an observational study of 183 patients who had a history of spontaneous preterm birth before 32 weeks of gestation. The patients were

enrolled between 16 and 19 weeks of gestation and were followed every 2 weeks until 24 weeks. Forty-eight (26%) women delivered before 35 weeks of gestation. A short cervix (< 25 mm) at the first scan was associated with a relative risk of 3.3 (95% CI: 2.1–5.0) for spontaneous preterm birth (< 35 weeks). The sensitivity, specificity and positive predictive values were 19%, 9% and 75%, respectively. After controlling for cervical length, neither funneling nor dynamic shortening was an independent contributor of spontaneous preterm birth. However, using the shortest cervical length on serial evaluations, after any dynamic shortening, the relative risk of a cervical length of less than 25 mm increased to 4.5 (95% CI: 2.7–7.6) with a sensitivity, specificity and positive predictive value of 69%, 80% and 55%, respectively. Therefore, based on these findings, a serial measurement through 24 weeks significantly improves the sensitivity but lowers the positive predictive value of the test.

Guzman *et al.*[25] enrolled 469 high-risk patients between 15 and 24 weeks of gestation. High risk was defined as the presence of a history of spontaneous preterm birth before 37 weeks of gestation, prior mid-trimester loss, more than two terminations of pregnancy, cone biopsy, uterine malformation, previous cerclage or diethylstilbestrol exposure. Transvaginal cervical sonography was performed and transfundal pressure was applied, and the shortest cervical length, funnel width, funnel length and cervical index were recorded serially. A cervical length of 25 mm or less had a sensitivity, specificity, positive predictive value and negative predictive value of 76%, 68%, 20% and 96%, respectively, to identify preterm birth at less than 34 weeks of gestation. Cervical length was the best parameter for the prediction of preterm birth in women with prior mid-trimester losses. The authors proposed that a cervical length of ≤ 15 mm had a sensitivity, specificity, positive predictive value and negative predictive value of 81%, 72%, 29% and 96%, respectively, in predicting spontaneous preterm delivery at less than 34 weeks. Cervical length was better at predicting earlier forms of prematurity (< 28 or < 30 weeks) than later forms (< 32 or < 34 weeks).

Odibo *et al.*[22] demonstrated the relationship between a short cervix and preterm premature rupture of membranes (PROM) leading to preterm birth in a high-risk population. They studied 69 women at high risk for preterm birth (by obstetric history and transvaginal cervical length < 25 mm) between 14 and 24 weeks of gestation. The incidence of preterm PROM was 39% (27/69). Cervical length of less than 10 mm had a sensitivity, specificity, positive predictive value and negative predictive value of 33%, 90%, 69% and 68%, respectively, in predicting preterm PROM at less than 35 weeks of gestation.

The evidence provided by these studies suggests that to prevent preterm delivery, patients with a previous history of preterm birth or mid-trimester pregnancy loss require a longer cervix than those without such a history.[23]

Cervical sonography in patients presenting with threatened preterm labor

There is now compelling evidence that examination of the cervix with ultrasound in patients presenting with preterm labor can assist in determining the risk for preterm delivery. Table 133.1 summarizes the results of some of the studies published to date. In general, the shorter the cervix, the higher the risk for preterm delivery and vice versa. Recently, Tsoi *et al.* analyzed the value of cervical length measurement for the prediction of preterm delivery at < 35 weeks among 510 pregnant women with singleton pregnancies who were admitted with symptoms of preterm labor between 24 and 34 completed weeks.[12] The authors reported that cervical length and vaginal bleeding were independent explanatory variables for the prediction of preterm delivery at < 35 weeks. However, among patients with threatened preterm labor, the inclusion of vaginal bleeding did not improve the performance of cervical length for the prediction of preterm delivery.[12]

In summary, cervical sonography is a powerful method to assess the risk of preterm delivery in asymptomatic patients and those presenting with preterm labor. In the latter group, avoiding aggressive intervention in patients who have a long cervix would probably be beneficial. In contrast, patients who have a short cervix would have a higher rate of preterm delivery and may benefit from targeted interventions (i.e. steroid administration and transfer to a center with a newborn special care unit).

Fetal fibronectin in vaginal fluid and preterm delivery

Fetal fibronectin in patients with preterm labor

Fetal fibronectin is a glycoprotein considered to be a major component of the extracellular matrix of the choriodecidual junction.[27] It has been proposed that a positive fetal fibronectin test in the second and third trimesters represents the separation of the chorion from the decidual layer of the uterus, with the release of intact or degraded chorionic components of the extracellular matrix into the cervical and vaginal secretions.[28] A growing body of evidence indicates that a positive fetal fibronectin test in cervical and/or vaginal fluid is associated with preterm delivery both in patients with threatened preterm labor[29–34] and in asymptomatic patients.[35–43] The conventional view is that the presence of fetal fibronectin in cervical and vaginal fluid before 20 weeks is due to the absence of complete fusion between the fetal membranes and the decidua.[27] However, it has recently been reported that a high concentration of fetal fibronectin in vaginal fluid between 13 and 20 weeks is also a risk factor for preterm delivery.[44] Honest *et al.* performed a systematic review that included 28 studies in asymptomatic pregnant women and 40 studies in women with threatened

preterm labor, and concluded that a positive fetal fibronectin test is a risk factor for delivery at < 34 weeks in both symptomatic and asymptomatic patients (Tables 133.4 and 133.5) and for delivery within 7–10 days in women with threatened preterm labor.[45] A negative fetal fibronectin test identifies patients at low risk for preterm delivery; however, a positive test has a limited positive predictive value.[27,45]

Table 133.6 Pooled estimates of likelihood ratios for bacterial vaginosis according to different diagnostic criteria in the prediction of spontaneous preterm birth in asymptomatic pregnant women and in those with threatened preterm labor (adapted from Honest *et al.*,[84] with permission)

Bacterial vaginosis and the risk of preterm delivery

Bacterial vaginosis, a condition characterized by a change in the microbial ecosystem of the vagina,[51,52] is present in up to 15–20% of pregnant women[53–57] and is a risk factor for spontaneous preterm delivery[36,53,57–72] (Table 133.6), preterm PROM[73–76] and postpartum endometritis.[53,77] The change in the bacterial ecosystem is characterized by a decrease in the number of lactobacilli and an overgrowth of several anaerobic or facultative bacteria (such as *Mobiluncus* species, *Prevotella* species, *Gardnerella vaginalis* and genital Mycoplasmas – *Mycoplasma hominis* and *Ureaplasma urealyticum*).[52,78] Yet, despite the substantial microbial overgrowth, the conventional view has been that bacterial vaginosis is not associated with signs of inflammation (i.e. vaginal fluid leukocytes).[79–81] Hence, the condition is called vaginosis rather than vaginitis.[78,79] The reason for the absence of a local inflammatory response in most women with bacterial vaginosis, in spite of increased microbial load in the vaginal fluid, is yet to be determined. Clearly, the vaginal mucosa is capable of mounting an inflammatory response, as infections with *Trichomonas vaginalis* and *Candida* species can cause an intense inflammation that is clinically manifested as vaginitis.[82,83] Thus, it is noteworthy that bacterial vaginosis is asymptomatic in approximately 50% of patients.[51,83]

Although the cause of bacterial vaginosis is unknown, the condition can be considered as a microbial/mucosal immunity disorder. The clinical criteria for the diagnosis of bacterial vaginosis (Amsel's criteria) is based on the presence of at least three of the following findings: (1) a thin homogenous vaginal discharge; (2) vaginal pH >4.5; (3) positive 'whiff' test (release of the amine odor with the addition of a base); and (4) clue cells on a saline wet mount.[85] However, the standard method for the diagnosis of bacterial vaginosis is a Gram stain examination of vaginal fluid.[86] Nugent *et al.* developed standardized criteria for the interpretation of the Gram stain based on the examination of four bacterial morphotypes.[87] A score of 7–10 is considered diagnostic of bacterial vaginosis. This method, both highly reproducible and reliable,[87–89] has been very helpful in advancing the state of knowledge of bacterial vaginosis. However, about 20% of women with bacterial vaginosis by Amsel's criteria have a Nugent score of 5 or 6.[90] Thus, it has been proposed that a score of 4–10, according to Nugent's criteria, should be considered to indicate 'abnormal vaginal flora'.[90]

Screening and treatment of bacterial vaginosis have been used to test whether antimicrobial agents can prevent preterm birth. The rationale behind this approach to prevent preterm parturition is that bacterial vaginosis is associated with intra-amniotic infection[57,58,70,71,91] and is a clear risk factor for preterm delivery[59,63,65,67,92,93] (Table 133.6). However, the results of randomized clinical trials have yielded conflicting results[94–107] (Table 133.7). The reader is referred to the original trials and systematic reviews for details of this controversy.[108–110]

The Centers for Disease Control, as well as some of the leaders in the field of infectious diseases in obstetrics and gynecology, have recommended that patients at high risk for preterm delivery (those with a previous history of a spontaneous preterm birth) should be screened and treated with prophylactic metronidazole or clindamycin.[108,110–116] However, a recent systematic review reported that antibiotic treatment of patients with a previous preterm birth and bacterial vaginosis in the index pregnancy does not reduce the rate of preterm birth regardless of the type of antibiotic used[116] (see Table 133.8).

Bacterial vaginosis, tumor necrosis factor alpha (TNF-α) allele 2 and the risk of preterm birth

Macones *et al.*[117] reported the results of a case–control study in which cases were defined as patients who had a spontaneous preterm delivery (defined as < 37 weeks) and controls as women who delivered after 37 weeks. The environmental exposure was clinically diagnosed bacterial vaginosis (symptomatic vaginal discharge, a positive whiff test and clue cells on a wet preparation). The genotype of interest was TNF-α allele 2, given that carriage of this genotype had been demonstrated by the author to be associated with spontaneous preterm birth in previous studies.[118] The key observations were: (1) clinically diagnosed bacterial vaginosis associated with an increased risk for preterm delivery (OR: 3.3; 95% CI 1.8–5.9); (2) women who carried the TNF-α allele 2 were also at increased risk for preterm birth (OR: 2.7; 95% CI 1.7–4.5); and (3) patients with both bacterial vaginosis and the TNF-α allele 2 had an OR of 6.1 (95% CI 1.9–21) for spontaneous preterm delivery, suggesting that a gene–environmental interaction predisposes to preterm birth. These estimates were derived from logistic regression and are referred to Table 133.9.

The significance of this observation is that bacterial vaginosis, in a host defined by genotype analysis, substantially increases the risk for spontaneous preterm delivery. However, it is noteworthy that these patients had clinical symptoms requiring treatment with metronidazole and, thus, were different from those included in a large randomized clinical trial of bacterial vaginosis that included patients with an abnormal Gram stain of vaginal fluid, but excluded symptomatic women. It is possible that symptomatic women could have not only a change in the vaginal microflora (bacterial vaginosis), but also inflammatory changes and, hence, symptoms.

Table 133.8 Treatment of bacterial vaginosis to prevent preterm birth in women with a previous preterm birth (adapted from Riggs and Klebanoff,[116] with permission)

Study	Antibiotic	Odds ratio (95% CI)
Morales *et al.*[94]	Metronidazole	0.28 (0.10–0.76)
Hauth *et al.*[96]	Metronidazole + erythromycin	0.48 (0.25–0.91)
McDonald *et al.*[105]	Metronidazole	0.11 (0.01–1.09)
Carey *et al.*[98]	Metronidazole	1.35 (0.73–2.49)
Odendaal *et al.*[102]	Metronidazole	2.44 (1.09–5.43)
Ugwumadu *et al.*[104]	Clindamycin	0.33 (0.12–0.95)
Overall (95% CI)		0.61 (0.28–1.34)

Macones *et al.*[117] have called for additional studies that would allow confirmation of these findings. Such investigations are necessary in light of the recent history of conflicting results of genetic association studies.[117–122] However, if these observations are confirmed there may be substantial implications. For example, serious consideration would need to be given to the incorporation of genotype assessment in the design of clinical studies to reduce the rate of preterm birth. Assessment of the local host response (vaginal inflammation) and determination of the genotype may be required to identify patients who might benefit from intervention. Clearly, relying on the Gram stain for the diagnosis of bacterial vaginosis has not been sufficient.

Table 133.9 Contingency table to estimate genetic, environmental and gene–environment effects (adapted from Romero *et al.*,[122] with permission)

Environmental	Genotype	Cases	Controls	Odds ratio (95% CI)	Type
BV	TNF-α2				
−	−	57	171	1	
−	+	29	49	1.8 (1.0–3.1)	Genetic
+	−	12	22	1.6 (0.8–3.5)	Environmental
+	+	27	8	10.1 (4.4–23.5)	Interaction

BV = vacterial vaginosis; TNF-α 2 = tumor necrosis factor-alpha allele 2. Raw data provided by Macones *et al.*

Home uterine monitoring and the risk for preterm delivery

The assessment of the frequency of uterine contractions has been proposed to identify those at risk for preterm delivery in both asymptomatic[123,124] and symptomatic pregnant patients.[125] The rationale for this is that increased frequency of uterine contractions leads to preterm delivery. Thus, early detection and suppression of uterine contractions could potentially reduce the rate of preterm delivery. However, the results of randomized clinical trials have indicated that ambulatory uterine monitoring has not reduced the rate of preterm delivery.[126–130] For example, in 1995, the Collaborative Home Uterine Monitoring Study (CHUMS) group reported the results of a multicenter randomized controlled trial of home uterine monitoring.[126] The authors randomized 1292 pregnant women between 24 and 36 weeks of gestation at high risk of preterm labor or birth into home uterine activity monitoring with either active (data revealed) or sham (data concealed) devices. Seventy-two percent of these patients ($n = 842$) completed the study. The data analysis was performed according to the intent to treat. The results of the study indicated that there were no differences in the rate of preterm birth, referral rates to the hospital, unscheduled emergency visits or antepartum admissions between the two arms of the study. Recently, Iams *et al.* demonstrated that the limited use of ambulatory uterine monitoring is due to its low sensitivity and a low positive predictive value of preterm delivery in both low- and high-risk patients[131] (Table 133.10).

Garfield *et al.*[132] proposed that more sensitive methods to measure uterine activity, such as uterine electromyography (a non-invasive assessment of uterine electrical signals) may allow for a more objective evaluation of uterine activity. The authors reported that the power spectrum peak frequency within the uterine electrical burst remained relatively low in patients with preterm labor, but increased dramatically 4 days prior to delivery. The authors proposed that uterine electromyography may predict preterm birth within 4 days of the evaluation.[133] The value of this technique to evaluate the risk of preterm delivery has not yet been determined.

Table 133.10 Diagnostic indices of ambulatory uterine monitoring for the prediction of delivery at < 35 weeks (adapted from Iams *et al.*,[131] with permission)

Test	Weeks of gestation at time of testing		
	22–24	27–28	31–32
Maximum nighttime contraction frequency ≥ 4/h			
Sensitivity	8.6	28.1	27.3
Specificity	96.4	88.7	82.0
Positive predictive value	25.0	23.1	11.3
Negative predictive value	88.3	91.1	93.0
Maximum daytime contraction frequency ≥ 4/h			
Sensitivity	0	12.9	13.6
Specificity	98.4	93.9	84.9
Positive predictive value	0	20.0	7.1
Negative predictive value	87.0	90.2	92.1

Values expressed as percentage

Corticotropin releasing hormone (CRH) and the risk of preterm delivery

A decade ago, McLean *et al.* proposed the existence of a 'placental clock' (which is active from an early stage in human pregnancy) that determines the length of gestation and the timing of parturition.[134] This

proposal was based on the result of a large longitudinal study in which women who delivered preterm had a significantly higher plasma concentration of CRH than those who delivered at term. In contrast, women who had prolonged pregnancies had a lower CRH concentration than those who delivered at term. Of note, these differences were already present at 16–18 weeks of gestation.[134] The association between a high maternal plasma concentration of CRH and preterm labor has been confirmed by other studies.[135–137] Moreover, high plasma concentrations of CRH have been described in women with chronic stress, and this condition has been associated with a high risk for preterm delivery.[137] According to 'the placental clock hypothesis', the rate of increase in the maternal plasma CRH through pregnancy determines the timing of labor when saturation of the CRH binding protein is achieved and free CRH becomes available and triggers parturition.[134,138] However, Inder *et al.*[139] reported that a plasma concentration of CRH at 26 weeks of gestation of >90 pmol/l had a sensitivity of 45%, specificity of 94%, and positive predictive value of 46.7% for the prediction of preterm delivery. Based on these results, the authors suggested that maternal plasma CRH may identify patients at risk for preterm delivery, but it may not be a good screening method for preterm delivery.[139]

Salivary estriol and the risk of preterm delivery

McGregor *et al.*[140] performed a longitudinal study that included 241 singleton pregnancies with women at low [30% (72/241)] and high risk [70% (169/241)] for preterm labor. The authors measured salivary estriol concentration at least once a week from 22 weeks onward, and reported that patients who delivered at <37 weeks of gestation had a higher salivary estriol concentration than those who delivered at term. Moreover, a cutoff of 2.3 ng/ml had a sensitivity, specificity and false-positive rate of 71%, 77% and 23%, respectively, for the prediction of preterm delivery. The authors proposed that determination of salivary estriol concentration would be more accurate than clinical risk assessment in the prediction of preterm birth.[140] In a larger, more recent study, the same group of investigators reported that a cutoff of 2.1 ng/ml had a sensitivity, specificity, and positive and negative predictive values of 57%, 78%, 9% and 98%, respectively, for the prediction of preterm delivery.[141] Furthermore, the authors reported that the risk of preterm delivery was higher if a second salivary sample, collected within a week of the first sample, was also positive.[141,142] Collectively, this evidence indicates that a high concentration of salivary estriol is a risk factor for preterm birth, but it is unlikely to become a useful screening index because of the low positive predictive value.

Evidence of thrombin generation and the risk of preterm delivery

Thrombin is a multifunctional serine protease that results from the proteolysis of the prothrombin molecule into thrombin and prothrombin fragments 1 and 2. This protease plays a central role in the coagulation cascade by catalyzing the conversion of fibrinogen into fibrin and activating clotting factors (factors V and VIII).[143] Natural anticoagulant mechanisms limit thrombin action by binding antithrombin III to form a stable stoichiometric complex with thrombin, also known as the thrombin-antithrombin (TAT) complex.[144] TAT concentrations in plasma are widely considered to be an index of *in vivo* thrombin generation and, therefore, of activation of the coagulation cascade.

Normal pregnancy is a state in which there is excessive thrombin generation, as indicated by an increased concentration of fibrinopeptide A, prothrombin fragments 1 and 2, and TAT complexes.[144–146] Elovitz *et al.*[147] performed a case–control study of patients with preterm labor ($n=19$) and controls ($n=24$) between 24 and 32 completed weeks of gestation. The authors reported that the mean plasma TAT concentration was significantly higher in patients who delivered within 3 weeks (7.8 ± 2.86 ng/ml) of blood sampling than in those who delivered after 3 weeks (5.57 ± 1.69 ng/ml; $P<0.05$) and those in the control group (5.77 ± 1.43; $P<0.05$). A maternal plasma TAT cutoff of 6.8 ng/ml as determined by a receiver operating curve analysis, had a sensitivity of 80%, specificity of 71%, positive predictive value of 50%, and negative predictive value of 91% for the prediction of preterm delivery within 7 days. Similarly, a maternal plasma TAT concentration greater than 6.3 ng/ml had a sensitivity of 75%, specificity of 73%, positive predictive value of 67%, and negative predictive value of 73% for the prediction of preterm delivery within 3 weeks.[147] These observations are consistent with our previous report that women with preterm labor and intact membranes and preterm PROM had significantly higher median plasma TAT complex concentrations than normal pregnant women.[148] Collectively, these results indicate that preterm parturition is associated with an excess of thrombin generation, which may precede the clinical presentation of preterm labor.

Value of combining cervical ultrasonographic data and other biological markers of preterm delivery

Preterm delivery is a multifactorial condition and, therefore, individual screening tests are inherently limited in predicting all preterm births.[149] It has been recently suggested that to improve the sensitivity of cervical length assessment by ultrasound, new studies

should focus on the development of scoring systems that combine ultrasound data with biochemical, hormonal and molecular diagnostic methods (e.g. fetal DNA assessment in maternal blood).[149,150]

Biomarkers in cervicovaginal secretions, cervical ultrasonography and the risk of preterm delivery

A positive fetal fibronectin test[6,7,10,26,46,93,151] or increased cytokine concentrations in cervicovaginal fluid[152] increase the predictive value of cervical ultrasonography to identify patients at risk for preterm delivery. Rizzo *et al.*[6] studied 180 patients with preterm labor and intact membranes and found that the combination of a cervical index ≥0.5 and a positive fibronectin test (≥60 ng/mL) was more efficient than each test alone in the prediction of the admission-to-delivery interval. Similar findings were reported by Hincz *et al.*,[10] who proposed a two-step approach to the examination of patients with preterm labor. In their study, a positive fetal fibronectin test in patients with a cervical length between 21 and 30 mm was associated with a shorter admission-to-delivery interval (38.6 days, 95% CI: 26.7–50.4 vs. 109.2 days, 95% CI: 97.8–120.7; $P < 0.001$). More recently, Gomez *et al.*[26] measured cervical length and fibronectin concentrations in the vaginal fluid of 215 patients with preterm uterine contractions, intact membranes and cervical dilation ≤3 cm by digital examination. Although both tests had a comparable performance for the prediction of spontaneous preterm delivery, significant improvement was observed when fetal fibronectin results were added to those of cervical length.

Rizzo *et al.*[152] have also demonstrated that increased interleukin-8 concentrations in cervicovaginal fluid and a short cervix by ultrasonographic examination were independently associated with positive amniotic fluid cultures and histological chorioamnionitis. More recently, Kurkinen-Raty *et al.*,[153] using logistic regression analysis, proposed that a combination of interleukin-6 > 61 ng/l, interleukin-8 > 3739 ng/l and a cervical index > 0.36 improved the prediction of preterm delivery over that achieved with the use of each of these tests alone.

Collectively, the evidence reviewed in this chapter indicates that biophysical markers, biochemical markers, or a combination of both may identify patients at risk for preterm delivery. However, interventions aimed at modifying some of these markers have failed to prevent preterm delivery. This lack of effectiveness may be due to: (1) the limitations of the current tests, (2) inadequate interventions, (3) the timing of the interventions, and (4) an incorrect conceptual framework. We have proposed that preterm labor is one of the great obstetrical syndromes[154,155] together with SGA, preeclampsia, preterm PROM and fetal death. Thus, preterm labor has multiple etiologies, is chronic in nature and is frequently associated with fetal disease, and the clinical manifestations in both the mother and the fetus may be adaptive in nature (Chapter 129). Moreover, these manifestations may depend on the maternal and fetal gene–environment interaction. Therefore, it is not surprising that symptomatic treatment of preterm labor has been ineffective thus far.

Two main strategies have been used in the search for biomarkers for preterm delivery. The hypothesis-driven technique is a deductive scientific method used in most of the studies reviewed in this chapter. However, an alternative approach is provided by 'discovery science', an inductive scientific method that includes the so-called 'omics' sciences (genomics, transcriptomics, proteomics and metabolomics). These discovery techniques have been used to improve the taxonomy of the preterm labor syndrome.[156,157] Our group has recently reported that patients with preterm labor who delivered at term, those with infection/inflammation who delivered preterm and, more importantly, those without infection/inflammation who delivered preterm have a stereotypical metabolic profile. Indeed, unsupervised metabolomics analysis was able to discriminate these groups with 88.5% accuracy.[158] Discovery sciences hold the promise of accelerating the understanding of the mechanisms of disease of the great obstetrical syndromes, which may potentially provide better tools to identify women at risk for preterm delivery and guide the design of interventions aimed not at the symptoms but at the underlying causes of the disease or at modulating the mechanisms of disease (i.e. interleukin-10 or dexamethasone for modulation of intra-amniotic inflammation[159]). An intervention tailored to the mechanisms of disease and the genetic makeup of the mother/fetus is likely to be more effective in preventing preterm delivery than traditional interventions.

134 Prevention of fetal and neonatal lung immaturity

M. M. Anceschi, L. Maranghi and E. V. Cosmi

Fetal lung immaturity is the principal contributor to neonatal mortality of preterm neonates; therefore, the lung has been the primary focus of strategies to improve the survival of newborn infants. If the lungs are immature, the infant will develop neonatal respiratory distress syndrome (NRDS), which still remains a leading cause of morbidity and death in preterm neonates. Untreated, around 25% of babies with NRDS born before 28 weeks of gestation will die within 28 days of birth, and another 25% will develop chronic lung disease, e.g. bronchopulmonary dysplasia (BPD), rendering affected babies dependent upon extra oxygen for long periods of time.

A deficit of pulmonary surfactant is known to be involved in the pathophysiology of NRDS; nevertheless, other factors may play an additional role, e.g. the immaturity of lung structure. Fetal lung maturity (FLM) is mainly the result of the enhancement (either quantitative or qualitative) of the synthesis and secretion of pulmonary surfactant and of structural changes of the lung parenchyma.[1] Factors that are known to be associated with increased or decreased risk of NRDS are summarized in Table 134.1.

The serendipitous findings by Liggins in 1969[2] that antenatal administration of glucocorticoids (GCs) prevented the development of NRDS in premature newborn lambs have stimulated a formidable deal of interest in the possibility of pharmacological enhancement of FLM. The effect of GCs on many parameters of FLM have been analyzed *in vitro* and *in vivo* in several mammalian species.[3]

Many clinical studies have confirmed the findings of the first trial by Liggins (1972)[4] that antenatal administration of GCs to the mother is associated with a statistically significant reduction in the incidence of NRDS. Over the past two decades, the strategy for the prevention and causal treatment of NRDS has been directed toward the acceleration of FLM *in utero* mainly by administering antenatal GCs (ANCs) to the mother and by intratracheal supplementation of surfactant to neonates for treatment of NRDS or to those at high risk for the disease.

Glucocorticoids

Betamethasone and dexamethasone are the preferred hormones used for antenatal corticosteroid therapy: both cross the placenta and are scarcely inactivated by placental enzymes, i.e. 11β-ol-dehydrogenase (11β-HSD), which convert active steroids into inactive 11-ketosteroids. Betamethasone crosses the placenta to the extent that fetal concentration is about 33% of those in maternal circulation.[5] Betamethasone and dexamethasone have a fluoride substituted in the steroid, greatly increasing GC potency and giving negligible mineralocorticoid effect. Both drugs are given intramuscularly (i.m.); this route is the most suited for clinical use, because of the rapid absorption of the drug, depending on its hydrosolubility. The most common hydrosoluble esters are 21-phosphate (dexamethasone and betamethasone) and 21-acetate. The use of 'Celestone Cronodose' (21-phosphate/21-acetate betamethasone) allows a continuous release with a prolonged therapeutic effect. Both drugs have a prolonged plasma half-life and a longer duration of biological action than cortisol and prednisolone.

Table 134.1 Risk factors for neonatal respiratory distress syndrome (NRDS)

Increased risk	Decreased risk
Low Apgar score	Labor before delivery
Male sex	Severe IUGR (< fifth percentile associated with ARED)
Genetic factors (SP)	Female sex
PIH	Smoking in pregnancy
Cesarean section	

SP, surfactant associated proteins; PIH, pregnancy-induced hypertension; IUGR, intrauterine growth retardation; ARED, absent/reverse end-diastolic flow

Cytoplasmatic receptors for GC are present in all fetal tissues, particularly in lung, liver, bowel, pancreas, stomach, skin, retina, brain, placenta, adrenal cortex and medulla and breast. In the fetal lung, the presence of these specific receptors and their progressive increase during gestation indicate that the maturing lung is a physiological target tissue for endogenous GCs.

The biological action of GCs depends on tissue distribution, metabolism, delivery to target cells and receptor affinity. The cellular mechanism underlying GC stimulation of pulmonary surfactant production and lung maturation is not completely understood. GCs are known to modulate the expression of several genes, by a mechanism that involves the binding of the activated receptor to specific DNA sequences. As a result, the transcription of specific messenger RNAs is then promoted and the synthesis of certain proteins activated. Because the receptors are saturated by physiological levels of GCs, their effect on FLM can be obtained with small doses. However, the ability of a particular tissue to respond to the hormone and the type of response depend on the degree of its cellular and biochemical differentiation and also upon the stage of fetal development.[6]

Aminophylline

Several studies indicate that aminophylline can stimulate fetal lung surfactant secretion, although it seems to exert only minor beneficial effects on FLM. Aminophylline is able to cross the human placenta (Cosmi and Condorelli, unpublished data) in significant amounts during late gestation and, through inhibition of phosphodiesterase, increases the levels of cyclic adenosine monophosphate (cAMP) in fetal lung tissue. Increased cAMP produces glycogen breakdown, contributing to surfactant synthesis and, above all, secretion. Studies on the efficacy of this drug to prevent NRDS are conflicting. Animal studies have shown that aminophylline administered to pregnant rabbits fails to accelerate the biochemical maturation of the fetal lung, but stimulates the synthesis and secretion of lung phospholipids that normally takes place at term. Animals treated with aminophylline had improved pressure–volume diagrams and increased amount of surface active phospholipids in lung lavage fluid; however, studies have shown that repeated antenatal administration of aminophylline to pregnant rabbits increases the survival rate and the respiratory frequency of preterm offspring, but other parameters of neonatal lung mechanics were unaffected.[7]

Among the proposed mechanisms of action in the perinatal lung adaptation, aminophylline may act as a central respiratory stimulant and also a smooth muscle relaxant (uterus, bronchi, vessels), promoting bronchodilatation in the premature lung. Aminophylline increases fetal breathing movements (FBM) in the human fetus and, therefore, may be useful in the prevention of fetal lung hypoplasia and in promoting the entry of supplementary surfactant following *in utero* administration, as it was recently shown by Ilia *et al.* in fetal rabbit[8] and for treatment of apnea of prematurity. Aminophylline remains a promising approach, but its use alone or in combination with other agents for the prevention of NRDS and other complications of prematurity needs further study.

Inositol

Inositol, a sugar alcohol, is a vitamin-like factor that is involved in growth and differentiation and is a precursor of cell membrane components responsible for signal transduction. Because of the effects of GCs on lung growth and body weight indexes, inositol has been given in association with GCs to pregnant animals counteracting their effects on growth parameters. Animal studies have shown that addition of inositol to the feeds of GC-treated pregnant rabbits increased surfactant in alveolar lavage from fetal lung. In rabbit fetuses prematurely delivered on day 28, inositol added to betamethasone on days 26 and 27 of gestation caused an increase in lung–thorax compliance and a decreased interstitium/air space, suggesting homogenous expansion of alveoli, not only with respect to controls, but also and, most importantly, with respect to animals treated with betamethasone alone. This finding was associated with an increase in lung weight, protein and DNA content. Furthermore, the association seemed to reverse the so-called male disadvantage in fetal lung maturation and the reported refractoriness to steroid treatment. Male neonates treated with betamethasone plus inositol had a mean lung–thorax compliance significantly higher than the corresponding males from the betamethasone-alone treated group.[9] These studies demonstrate that dietary inositol modifies the physiological and biochemical response of the immature lung to pharmacological doses of exogenous GCs.

A placebo-controlled randomized trial of inositol administration to preterm neonates with respiratory distress syndrome, who were receiving parenteral nutrition during the first week of life, showed that inositol supplementation was associated with increased survival without brochopulmonary dysplasia (BPD) and with a decreased incidence of retinopathy of prematurity.[10]

Betamimetics

Several studies have examined the outcome of premature infants delivered by mothers who received tocolytic therapy, and a positive effect on lung maturation in double-blind placebo-controlled studies has been observed. A decreased incidence of NRDS in babies born to mothers treated antenatally with ritrodine or isoxsuprine has been found by several authors, although others have reported no effect of the long-term administration of betamimetics on FLM.[11]

Currently beta-adrenergic agents are used as tocolytic drugs to prolong pregnancy in order to allow the administration of GCs.

Thyroid hormones

At least five trials on the effects of the combined use of antenatal thyrotropin releasing hormone (TRH) and GCs have shown a significant reduction in the risk of respiratory distress syndrome (RDS), the severity of RDS and the incidence of chronic lung disease, defined as dependency on oxygen at 28 days of life and/or oxygen dependency at 36 weeks post conception. The largest of such trials is by Ballard *et al.* published in 1992.[12] In humans, TRH associated with betamethasone at a dose of 400 μg intravenously every 8 h for 48 h determines a significant elevation in free and total thyroxine (T_4) and a depression of the TRH levels. Neonatal outcome showed that the combined use of GCs and TRH was more beneficial in preventing and ameliorating NRDS and its consequences than the use of GCs alone. Regarding fetal–neonatal side effects, transient elevations of fetal thyroid hormone levels have been found when TRH stimulation was performed during crucial periods of brain development. However, the results of the combination were challenged by a large Australian trial in 1234 women at 24–31 weeks' gestation, in which it was shown that the incidence of RDS and the need for assisted ventilation was not reduced following combined treatment involving up to four doses of 200 μg. In addition, the incidence of maternal symptoms (such as nausea, vomiting, lightheadedness) and hypertension (>140/90 mmHg) was significantly higher. Nonetheless, the results of the study have raised important questions that need to be clarified, e.g. the increased frequency of depressed 5-min Apgar scores and apparent protection against pulmonary hemorrhage.[13]

A recent meta-analysis including 13 trials on 4600 women at risk of very preterm birth who had received prenatal TRHs in addition to corticosteroids showed that the combination did not improve infant outcomes and could cause maternal side effects.[14]

Clinical studies

Among the hormones tested for the accelerating FLM, ANCs have proven effective in reducing the incidence of NRDS and of other complications, such as intraventricular hemorrhage (IVH), periventricular leukomalacia (PVL), retinopathy of prematurity (ROP), necrotizing enterocolitis (NEC), patent ductus arteriosus (PDA). A meta-analysis[15] comprising 18 trials including data on over 3700 babies showed that antenatal GC administration was associated with a 50% reduction of NRDS and that its effectiveness was more evident when delivery occurred after 24 h and within 7 days of drug administration (Table 134.2). For every 11 fetuses treated with ANC there will be one less case of NRDS and a similar reduced need for postnatal surfactant treatment. There will be also one less death in the neonatal period for every 23 treated fetuses and a similar reduction in IVH.[16] Since it is unlikely that further prospective controlled placebo trials on antenatal corticosteroids will ever be performed, the results of the meta-analysis by Crowley represent the definitive evidence-based proof of the effects of ANCs.

Table 134.2 The effects of antenatal glucocorticoid administration on neonatal outcome (from Crowley[15])

Effect on	Pooled odds ratio (95% CI)	*P*
NRDS (total)	0.55 (0.44–0.63)	0.001
NRDS (< 34 weeks)	0.36 (0.27–0.48)	0.001
NRDS (< 32 weeks)	0.33 (0.21–0.50)	0.001
NRDS (< 30 weeks)	0.48 (0.30–0.77)	0.001
NRDS (< 28 weeks)	0.64 (0.16–2.50)	NS
NRDS (< 48 h < 7 days after first dose)	0.38 (0.25–0.57)	0.001
NRDS (> 7 days after first dose)	0.41 (0.18–0.90)	0.04
NRDS (> 34 week)	0.65 (0.33–1.29)	0.20
Neonatal death	0.60 (0.48–0.75)	0.001
Intraventricular hemorrhage	0.29 (0.14–0.51)	0.001
NEC	0.59 (0.15–0.68)	0.09
Surfactant use at birth	0.41 (0.18–0.89)	0.02
Fetal and neonatal infection	0.82 (0.57–1.19)	0.30
Chronic lung disease	1.57 (0.87–2.84)	0.14

NRDS, neonatal respiratory distress syndrome, NS, not significant; NEC, necrotizing enterocolitis

There are, however, aspects that need to be further investigated. One relates to the type of GC to be administered to warrant optimal results. Kari *et al.*[17] in a randomized multicenter study on dexamethasone vs. placebo treatment in preterm pregnancies (< 32 weeks' gestation) showed that treated neonates had higher mean blood pressure during the first 3 days after birth. In the treated group, there was also a decreased incidence of IVH and PVL. The cerebral protection conferred by dexamethasone occurred in neonates born < 24 h after administration of GC, raising the possibility that prenatal steroids are beneficial even when delivery is imminent. These findings are suggestive of the fact that the protective effect of dexamethasone against cerebral complications is independent from the induction of FLM, possibly affecting

the maturation of germinal matrix vessels and of the cardiovascular system, thus preventing neonatal hypotension that predisposes in turn to cerebral ischemia and hemorrhage.

To evaluate the effect on the occurrence of cystic PVL, a major cause of cerebral palsy, a cohort of 883 live-born infants, with gestational ages ranging from 24 to 31 weeks was retrospectively analyzed. The rate of cystic PVL was 4.4% among the infants whose mother received betamethasone, 11.0% among the infants whose mother received dexamethasone and 8.4% among the infants whose mother did not receive a GC. Antenatal exposure to betamethasone, but not dexamethasone, was associated with a decreased risk of cystic PVL among very premature infants.[18] In another retrospective cohort study including 1161 neonates with gestational age of 24–34 weeks and birth weights of 500–1750 g, ANCs were associated with significantly less PVL or IVH (23% vs. 31%), PVL with IVH (5% vs. 11%) and isolated PVL (3% vs. 7%). ANC treatment was associated with over 50% reduction in the incidence of PVL.[19] However, a recent study has challenged the conclusion, demonstrating that there are no advantages to maternal antenatal treatment with betamethasone compared with dexamethasone in reducing the risk of PVL in low birth weight ($\leq$1750 g) infants.[20]

In a recent review, Jobe and Soll have concluded that although these synthetic corticosteroids have almost identical structures, betamethasone is superior in preventing three major morbidities, i.e. NRDS, IVH and neonatal death.[21] The US National Institutes of Health Consensus Conference[22] has stated a general recommendation on the use of GC for the induction of FLM in fetuses at risk of preterm delivery. The optimal dose to administer has been fixed in two doses of 12 mg of betamethasone given i.m. 24 h apart or four doses of 6 mg of dexamethasone i.m. given every 12 h. These therapeutic regimens result in about 75% of corticosteroid receptor occupancy, providing a near maximal induction of antenatal corticosteroid receptor-mediated response in fetal tissues.

For infants born at 29–34 weeks' gestation, treatment with antenatal GC clearly reduces the incidence of NRDS and of overall mortality. While antenatal GCs do not clearly decrease the incidence of NRDS in infants born at 24–28 weeks' gestation, they reduce its severity. More important, antenatal GCs clearly reduce mortality and the incidence of IVH in this group.

All fetuses between 24 and 34 weeks' gestation should be considered candidates for this treatment, unless immediate delivery is imminent ($<$ 24 h) or GC may have an adverse effect on the mother. The only absolute contraindications to the use of GC are: chorioamnionitis, peptic ulcer and tuberculosis. In infants born beyond 34 weeks' gestation the risk of neonatal mortality, NRDS and IVH is low. The use of GC in mothers expected to deliver at more than 34 weeks is therefore not recommended, unless there is evidence of pulmonary immaturity as assessed by amniotic fluid FLM tests.

Maternal side effects

Among maternal complications, pulmonary edema has been reported when GCs are used in combination with tocolytic agents. Since the mineralocorticoid action of beta- and dexamethasone is rather small, a potential role of GCs in sodium and water retention resulting in volume overload is considered rather negligible. Therefore, edema may develop as the consequence of the effects of betamimetic drugs, including: (1) increased electrolyte and water retention in the lung; (2) an increase in mean pulmonary arterial pressure; (3) a disturbance of membrane properties and (4) decreased blood vessel resistance. The potential of pulmonary edema seems to be particularly relevant in multifetal pregnancy or in severely infected women, or in any other circumstance in which fluids are administered injudiciously to the mother. Sporadic cases of maternal death have been reported in the 1980s following the combined treatment of betamimetics, especially fenoterol, with GCs. Overall, however, there is little evidence that one course of steroids alone causes major maternal side effects in healthy pregnant women. However, obstetricians should be cautious when steroids are administered to women with poorly compensated diabetes.

Fetal effects

GCs result in a variety of fetal effects that are unrelated to the process of acceleration of FLM. They affect fetal behavior; it is known that GC treatment abolishes diurnal rhythms in fetal hormones. Betamethasone produces a reduction of FBM, body movements and fetal heart rate (FHR) variability. Such effects are transient and return to normality occurs at discontinuation of therapy. Conversely, dexamethasone causes an increase in FHR variation.[23]

That these effects are gestational-age-dependent is shown by a study by Mulder *et al.* in fetuses exposed to betamethasone at 29–34 weeks' gestation, where a decrease in FHR on day 1 (indicative of baroreceptor reflex), and reduced breathing activity and prolonged episodes of quiescence with a concomitant decrease in body movements on days 1 and 2, was elicited. However, these changes were not observed if betamethasone administration occurred at 26–28 weeks' gestation. Betamethasone-induced reductions in FHR variability were similar in young and older fetuses. Age-related differential responsiveness to betamethasone was found for all the fetal processes studied (body and breathing movements, FHR and quiescence), except FHR variability, suggesting ontogenic changes in the mechanisms presumed to underlie these processes [GC receptor (GR) maturation, cardiovascular and neuroendocrine development].[24]

Table 134.3 Effects of corticosteroids on arterial Dopplers (from Visser[23])

Author	Population	Beta/Dex	Ut.art.	UA	MCA
Cohlen *et al.*[26]	High risk	B	—	—	—
Fallace *et al.*[27]	IUGR	B	—	↓	—
Wijnberger *et al.*[28,29]	IUGR	B	—	—	—
Rotmensch *et al.*[30]	High risk	B	—	—	—
Senat *et al.*[31]	IUGR	B/D	—	—	—
Chitrit *et al.*[32]	High risk	D	—	—	↓
Piazze *et al.*[33]	High risk	B	—	—	↓
Simchen[34]	IUGR/ARED	B	—	↓	—
Barkehall-Thomas[35]	High-risk twin	B	—	↓	—
Muller *et al.*[36]	High risk	B	—	—	↓

Ut.art., uterine artery; UA, umbilical artery; MCA, middle cerebral artery; B, betamethasone; D, dexamethasone; —, no change in waveform pattern; ↓, decrease in pulsatility index

The observed reductions in FHR variation and in body and breathing movements following betamethasone treatment might be interpreted as a sign of fetal hypoxemia. However, there are no striking changes in Doppler waveform patterns in uterine artery, umbilical artery or in various other fetal blood vessels in normally grown fetuses. Therefore, delivery on the basis of changes in biophysical variables 2 or 3 days after betamethasone administration should be considered with caution. If not, advantages of improved maturation might be offset by the risks of iatrogenic preterm delivery. It must be feared that in the past a number of fetuses has been unduly delivered as a result of suspected fetal distress following administration of betamethasone, which was given with the view to prevent the hazards of preterm delivery. In case of uncertainty about fetal condition, one may record Doppler waveform patterns of fetal vessels or monitor FHR with special emphasis to the occurrence of FHR decelerations.[23]

GCs exert a direct and potent vasodilatory effect on human umbilical artery resistance *in vitro*, thus providing an explanation for the previously unexplained vascular effects associated with antenatal administration of corticosteroids.[25] The effects of ANCs on the fetal vasculature and uterine vessels are summarized in Table 134.3. These effects are of considerable interest, especially in IUGR fetuses. As shown, these agents are known to have a vasodilatory effect on the human umbilical artery *in vitro* and to improve umbilical vascular dynamics transiently in many fetuses with absent end-diastolic flow.

Wallace and Baker[27] first found a temporary reduction in placental vascular resistance after betamethasone in fetuses with absent end-diastolic velocities in the umbilical artery. Simchen *et al.*[34] have recently identified a small subset of fetuses with intrauterine growth restriction who, rather than responding to steroids with a decrease in vascular resistance, actually increase resistance. This led to poor outcomes, presumably the result of an increase in systemic mean arterial pressure leading to an incremental increase in the after-load of very sick fetuses with impending cardiac failure.

Preterm premature rupture of the membranes

The use of antenatal GC to reduce infant morbidity in the presence of preterm premature rupture of membranes (pPROM) has been matter of controversy, particularly for the possible maternal and fetal adverse effects. According to the Crowley's meta-analysis,[15] it does not seem to be a significant increase in neonatal infection after GC treatment in pregnancies with pPROM. In pPROM at < 32 weeks, repeated administration of courses of steroids is not associated with an increase in the prevalence of clinical or histologic evidence in infectious outcome. However, Garite *et al.*[37] presenting combined data from seven randomized trials concerning GC and PROM, found that the risk of maternal infection after treatment with GC was increased by 70% over those women with pPROM who did not receive steroids.

In a recent meta-analysis, Harding *et al.*[38] combined data from 15 controlled trials involving more than 1400 women with pPROM and showed that GC reduces the risk of NRDS, IVH and NEC. Antenatal GC may also reduce the risk of neonatal death; they do not appear to increase the risk of infection in either mother or newborn infant. The duration of pPROM

Table 134.4 The effect of ANCs on neonatal outcomes in the setting of pPROM[38]

Effect on	Pooled odds ratio (95% CI)
NRDS	0.59 (0.48–0.71)
Intraventricular hemorrhage	0.47 (0.31–0.70)
NEC	0.21 (0.05–0.82)
Maternal infection	1.95 (0.83–4.59)
Fetal and neonatal infection	1.26 (0.55–2.86)
Neonatal death	0.68 (0.43–1.07)

NRDS, neonatal respiratory distress syndrome

did not alter these outcomes. The available data indicate that ANCs is beneficial in the setting of pPROM. In the opinion of the authors, further trials to address this question cannot be justified (Table 134.4).

The issue whether ANCs may affect the outcome of pregnancies complicated by chorioamnionitis was addressed by Elimian *et al.*[39] Among neonates exposed to antenatal steroids who had histologic chorioamnionitis, there was a significantly less incidence of low Apgar scores (18% vs. 33.5%), NRDS (39.6% vs. 55.9%), IVH and PVL (21.9% vs. 36.9%), major brain lesions (7.7% vs. 18.4%), PDA (14.8% vs. 23.7%) and neonatal death (8.3% vs. 16.2%), with no increase in rate of proven neonatal sepsis (18.3% vs. 14%). In the presence of histologic chorioamnionitis, antenatal steroids significantly decreased the incidence of RDS, IVH and PVL, major brain lesions and neonatal mortality, without increasing neonatal sepsis.

In a non-concurrent prospective analysis of women with singleton pregnancies who delivered between 24 and 32 weeks' gestation after pPROM, a single course of betamethasone administered antenatally to the mother with pPROM was associated with a decrease in the incidence of both NRDS and advanced grades of IVH without any increase in perinatal infections.[40]

Pregnancy-induced hypertension

A number of clinical evidences suggest that the administration of GC to induce FLM in patients with severe pregnancy-induced hypertension (PIH), who are carefully monitored, does not appear to be contraindicated.[41]

Contrary to the common perception of a decreased risk of NRDS as a result of increased fetal stress thereby resulting in acceleration of FLM, the risk of NRDS in fetuses < 32 weeks' gestational age born from pre-eclamptic patients is in fact increased (OR 1.35; 95% CI, 1.03–1.78).[42] As to the effect on FLM amniotic indexes, Piazze *et al.*[43] observed decreased FLM indexes in PIH, particularly evident between 24 and 33 weeks' gestation. GC treatment significantly improved FLM as judged from AF tests performed in the same gestational age, showing the greatest effectiveness between 29 and 33 weeks. No significant effect was observed in the period between 34 and 38 weeks, apart from increased lamellar bodies count.

The efficacy and side effects of corticosteroid therapy in pregnant women with severe pre-eclampsia at a gestational age between 26 and 34 weeks for the prevention of NRDS was studied in a prospective double-blind randomized trial. The incidence of the disease was significantly reduced in the corticosteroid group (23%) compared to the placebo group (43%). The relative risk of IVH, PDA and perinatal infection was also significantly decreased in the corticosteroid group: 0.35 (95% CI 0.15–0.86), 0.27 (95% CI 0.08–0.95) and 0.39 (95% CI 0.39–0.97), respectively. The study suggests that ANCs are a safe and efficient treatment in patients with severe preeclampsia at between 26 and 34 weeks' gestation.[44] ANCs also improve significantly the hematologic abnormalities associated with hemolysis, elevated liver enzymes and low platelet count (HELLP) syndrome. Two doses of betamethasone given 12 h apart was the most effective corticosteroid regimen.[45]

Twin pregnancy

The benefits of ANC on twin pregnancy are debated. Spinillo *et al.*,[46] in a retrospective study, showed a significant reduction in the incidence of NRDS in 21 pairs of twins treated with antenatal GC therapy. However, the reduction in NRDS may have been due to the significantly greater gestational age and birth weight, noted in the treated group compared to the non-treated group. Ardila *et al.*[47] reviewed 134 pairs of twins between 24 and 34 weeks' gestation and found a significant reduction in NRDS only at a gestational age of 28 and 32 weeks; no significant differences were found for the other gestational age group. Conversely, Turrentine *et al.*[48] did not find any difference in the incidence of NRDS in 21 pairs of twins, delivered between 24 and 34 weeks' gestation, compared to the controls. Interestingly, it has been suggested recently that administration of GC to enhance FLM in women with multiple pregnancy might predispose to earlier delivery.

The assumption that the maternal levels achieved with the current regimen of ANCs might not be high enough to reach both siblings resulting either from increased body mass of the pregnant women or from the increased mass of the placentas with their capacity for inactivating GC (*vide supra*) has prompted clinical studies. Mulder *et al.*[49] performed a prospective study to determine whether the effects of betamethasone on FHR and behavior in preterm twin pregnancy are similar to those observed in singleton pregnancies and whether the effects occur similarly in both twin

members, in a group of 18 twin pregnancies receiving optimal corticosteroid treatment. Betamethasone administration was associated with significant transient decreases in basal FHR (day 1), FHR variability (days 2 and 3) and body and breathing movements (day 2). The overall changes in twins were similar to those previously found in singleton pregnancies. There was a high degree of association of response to betamethasone among individual members of twin pairs suggesting that the current regimen of antenatal corticosteroids used in preterm twin pregnancies results in achieving betamethasone levels high enough to reach the compartment of either twin member.

Repeated courses

Whether repeat doses should be given if delivery does not occur shortly after the initial course of GC is a matter of controversy. In women who remain undelivered but at continued risk of preterm birth, it is common practice to administer repeated doses of corticosteroids every 7–10 days. The practice has arisen because the evidence from randomized trials suggested that infants delivered after 7 days of maternal corticosteroid treatment did not have a lower incidence of NRDS, implying that the effect of treatment is short lived.

There exist some controversies about the disappearance of the beneficial effect of ANCs beyond 7 days from the initial administration. Animal experiments have shown that the induction of surfactant synthesis in the fetal lung is reversible and that betamethasone is cleared from the fetal circulation 48 h after maternal administration. More recent observations of preterm infants delivered over 7 days after maternal corticosteroid treatment showed that the efficacy of therapy was maintained,[50] though the effect of increasing gestational age is confounding. The finding does not seem to be operating in small fetuses. In infants who weighed 500–1500 g, the time interval between exposure to antenatal corticosteroids and delivery does not appear to affect neonatal outcome.[51]

A review on the effects of repeated doses of antenatal corticosteroids on lung and brain function and on growth restriction in animals has been recently published. Nineteen studies were included: the animals that were studied included sheep, monkeys, rabbits and mice. There were eight studies that assessed the effects of repeated doses of antenatal corticosteroids on lung function. All the studies reported improvement in lung function after repeated doses of antenatal corticosteroids. Seven studies investigated the effects of repeated doses of antenatal corticosteroids on brain or nervous system function or growth; all the studies found adverse effects with repeated doses of antenatal corticosteroids. Eleven studies looked at the effect of repeated doses of antenatal corticosteroids on fetal growth. Nine studies found evidence of fetal growth restriction with repeated doses of antenatal corticosteroids. One study assessed long-term behavioral outcomes in mice and found no effect. By reviewing all animal studies that these authors have collected, it is evident that repeated doses of antenatal corticosteroids may have beneficial effects in terms of lung function but may have adverse effects on brain function, i.e. delayed myelination and fetal growth. However, because of the differences between animals and humans, it is difficult to extrapolate directly the results of these studies to humans.[52]

The results of retrospective studies on repeated courses of ANCs are conflicting. In a study performed for 609 mothers and their 713 infants who were treated with 1–12 courses of ANCs, the incidence of NRDS was 45% for single-course and 35% for multiple-course groups ($P=0.005$; OR 0.44; 95% CI 0.25 – 0.79). The multiple-course group also had significantly less PDA (20% vs. 13%; $P=0.016$). The multiple-course group had a reduction of 0.46 ± 0.19 cm in head circumference at birth ($P=0.013$) when adjusted for gestational age and pre-eclampsia. The authors concluded that the exposure to multiple courses of ANCs compared with a single course resulted in a significant reduction in the incidence of NRDS in singleton preterm infants delivered within a week of the last corticosteroid dose. This was associated with a reduction in the head circumference at birth and an increased incidence of maternal endometritis.[53]

In another study, Elimian *et al.*[54] have studied the effectiveness between single and multiple courses of ANCs in preterm infants who weighed 1750 g or less at birth. Infants exposed *in utero* to multiple courses had a significantly lower rate of NRDS (18% compared with 41%; $P \leq 0.001$) and surfactant use (43% vs. 57%; $P=0.02$) with no apparent increase in neonatal sepsis or disturbances in fetal growth.

In another study, the outcome for premature neonates after multiple courses of ANCs was examined through a *post hoc* non-randomized analysis on 710 neonates of 25–32 weeks' gestation and who received one, two, or three or more courses of ANCs. No detectable clinical difference in the incidence of NRDS, chronic lung disease and IVH related to courses of ANCs was observed, and outcome was similar for infants delivered at 7–13 days compared with those delivered at 1–6 days after receiving antenatal GC. Compared with those who received a single course, neonates who received two or more courses had significantly lower birth weights (−39 g), and those receiving three or more courses had increased risk of death (adjusted OR 2.8; 95% CI 1.3–5.9; $P=0.01$) and had lower levels of plasma cortisol at age 2 h. In this retrospective analysis, multiple courses of ANCs did not improve outcome and were associated with increased mortality, decreased fetal growth and prolonged adrenal suppression.[55]

When birth size, growth and development in preterm infants after repeated antenatal corticosteroids were analyzed, birth weight ratio decreased with increasing number of corticosteroid courses

($P=0.001$), and multivariate analyses confirmed a reduction in birth weight of as much as 9% ($P=0.014$) and a reduction in head circumference of as much as 4% ($P=0.0024$). There were no additional benefits in mortality or respiratory outcomes, and there was a trend toward more severe chronic lung disease. Repeated corticosteroids were associated with adverse effects on size at birth without apparent benefits. These changes have the potential to affect later development.[56]

A recent study on the effects of repetitive doses on lung mechanics at birth has shown that respiratory compliance was higher in the multiple-course group than in the remote single-course or untreated group; functional residual capacity (FRC) was higher in the multiple-course group than in the untreated group and similar to that of a single-course group, reflecting a maturation of the lung architecture independent of surfactant production.[57]

A National Institutes of Health (NIH) consensus conference[58] reaffirmed the practice of giving a single course of corticosteroids to pregnant women between 24 and 34 weeks' gestation who are at risk for preterm delivery, but underlined that there were insufficient evidence for giving repeat courses of the drugs.

The most important study addressing this issue has been published in 2001. This randomized, double-blind, placebo-controlled intention-to-treat trial was conducted in 13 academic centers in the USA from February 1996 through April 2000 on 502 pregnant women between 24 and 32 completed weeks' gestation at high risk of preterm delivery. All patients received a complete single course of antenatal corticosteroids (either betamethasone, 12 mg i.m. repeated once in 24 h for two doses, or dexamethasone, 6 mg i.m. repeated every 12 h for four doses). Participants who had not delivered 1 week after receipt of the single course were randomly assigned to receive either betamethasone, 12 mg i.m. repeated once in 24 h for 2 doses every week until 34 weeks' gestation or delivery, whichever came first ($n=256$), or a similarly administered placebo ($n=246$). Composite neonatal morbidity (including severe RDS, bronchopulmonary dysplasia, severe IVH, PVL, proven sepsis, NEC or perinatal death) occurred in 22.5% of the weekly-course group vs. 28.0% of the single-course group (unadjusted relative risk 0.80; 95% CI 0.59–1.10). Weekly courses of antenatal corticosteroids did not reduce composite neonatal morbidity compared with a single course of treatment. However, it must be noted that the incidence of severe RDS was significantly reduced in the repeated course group with respect to single course treatment.[59]

In order to evaluate the impact of repeated courses on neonatal lung function, pregnant women of 25–33 weeks' gestation, who remained undelivered 1 week after their first course of antenatal corticosteroids (two 12-mg doses of betamethasone) were randomized to weekly courses of corticosteroids vs. weekly placebo until delivery or 34 weeks' gestation. FRC was measured within 48 h of life. There was no significant difference in FRC (28.5 vs. 27.5 ml/kg) or respiratory compliance between the infants who received a single remote course of antenatal corticosteroids and those who received weekly courses of corticosteroids until delivery. There was no significant difference in admission head circumference or birth weights between the groups, demonstrating that weekly repetitive courses of AS do not significantly increase FRC or respiratory compliance in preterm infants when compared with a single remote course of steroids given at a mean gestational age of 29 weeks.[60]

To ascertain whether a repeated course may be of benefit in the setting of pPROM, the study by Yang *et al.* found that multiple courses of antenatal corticosteroid therapy were associated with an increased risk of clinical chorioamnionitis and seemed not to reduce the incidence of RDS and other neonatal morbidities in patients with pPROM.[61] In a companion prospective study on a group of 161 women with pPROM, half received weekly courses of steroids and half remained untreated following a single course. No significant differences in composite morbidity between the groups (34.2% vs. 41.8%; $P=0.41$) were observed. Chorioamnionitis was higher in patients who received weekly courses of antenatal steroids 49.4% vs. 31.7% ($P=0.04$). Repeated courses of ANCs in pPROM did not improve neonatal outcomes beyond that achieved with single-course therapy suggesting that ANCs should not repeated weekly in patients with pPROM.[62]

Incomplete courses

In everyday clinical practice, it is not uncommon that delivery occurs before the completion of the course of GC, i.e. two doses of 12 mg of betametasone 24 h apart. To find out whether beneficial effects may still ensue, an incomplete course of antenatal corticosteroids was associated with reduction in the need for vasopressors, the rate of IVH and neonatal death in preterm neonates in one study.[63] One dose of antenatal steroids given 4–24 h before delivery was clinically comparable in terms of reduction of IVH and mortality to the recommended schedule of the NIH in surfactant-treated preterm infants.[64]

Policies of administering antenatal GCs

In spite of guidelines on the use of ANCs issued twice by NIH over the last 10 years (1994 and 2000) and adopted by most of the National Societies of Maternal–Fetal Medicine and Perinatal Medicine, the policies of antenatal administration of corticosteroids may vary according to country, institutions and individuals. Several reports have addressed the issue.

A Canadian network study including 11,440 infants < 38 weeks' gestation admitted to the neonatal intensive care unit (NICU) from 1996 to October 1997 showed that the incidence of antenatal corticosteroid treatment was 42% for infants < 24 weeks' gestation, 59% for infants 24–34 weeks' gestation and 10% for infants > 34 weeks' gestation with wide institutional differences in the incidence of antenatal corticosteroid treatment for women. The authors concluded that increasing the use of antenatal corticosteroids for preterm deliveries could reduce neonatal mortality in Canada by up to 10%.[65]

The Europe Against Immature Lung (EURAIL) study group have investigated the practice of ANC administration in a survey of obstetric departments of 14 European countries: 11% of the respondents started ANCs from 23 to 24 weeks' gestation, 82% from 24 to 28 weeks and 7% from 28 to 36 weeks. The use of multiple ANC courses was observed in 85% of the units. After adjustment for country, number of infants delivered at 24–32 weeks' gestation annually in the NICU and maternal hypertension, maternal hypertension doubled the odds of using multiple courses of ANCs (OR 1.97; 95% CI 0.75–5.17), although the association was not significant ($P = 0.17$). The survey's conclusion were that the high proportion of departments that initiated ANCs between 24 and 28 weeks of gestation is consistent with the high incidence of neonatal morbidity and mortality in that age range. Multiple courses are overwhelmingly prescribed in Europe; the practice appeared to be associated, albeit slightly, with maternal hypertension; this points out the importance of closely monitoring women at risk of premature delivery.[66] In a companion survey carried out in 1998 on all Fellows, Members and trainees of the Royal Australian College of Obstetricians and Gynaecologists, it was observed that 97% of obstetricians prescribe antenatal corticosteroids in the classical setting of uncomplicated early preterm labor and 85% prescribe repeated courses in those cases in which the risk of preterm birth persists or recurs; 50% of obstetricians prescribe this agent weekly in cases with persisting risk of preterm birth.[67]

In the UK, 98% of the obstetricians prescribed repeated courses, which shows that repeating courses is a common practice; the indications most commonly cited by units that prescribed steroids were prelabor spontaneous rupture of membranes (84.2%) and suspected preterm labor (81.8%).[68]

Follow-up studies

Concerns have been expressed for the potential short- and long-term adverse side effects on the fetus and the neonate of GC treatment. Follow-up studies of children exposed *in utero* to GC up to 12 years have shown that ANC treatment does not adversely affect physical growth or psychomotor development.[69] In order to study the late side effects of ANC on health and sexual development in subjects 20–22 years old, a follow-up study was conducted by Dessens *et al.*[70] No differences were found between corticosteroid-treated and placebo groups as to medical or psychological variables. In general, the subjects were healthy and had normal intellectual capacities. The 20-year follow-up study indicates that one course of ANC to prevent NRDS does not have adverse effects up to adulthood.

Higher blood pressure in adulthood has been described in several animal species after exposure to antenatal corticosteroids; however, reports in humans are scant. In a cohort study of 210 preterm survivors with birth weights of < 1500 g exposed to ANCs, blood pressure was measured at 14 years of age with a standard mercury sphygmomanometer. Children exposed to antenatal corticosteroids had higher systolic and diastolic blood pressures than those not exposed to corticosteroids. However, few had blood pressure in the hypertensive range.[71]

In animals, a dose-dependent decrease in birth weight after prenatal exposure to steroids has been found in rabbits[72] and in sheep.[73,74] Three courses of steroids given 1 week apart resulted in a 20–25% reduction in birth weight in sheep.[74]

In humans, a study of singleton preterm infants found an association between repeated antenatal administration of corticosteroids and reduced body weight and head circumference at birth;[75] reduction in growth of the head circumference in very low birth weight infants is known to be associated with poor neurodevelopmental outcome.[76] However, two out of four observational studies on repeated antenatal steroid courses report a decrease in birth weight.[77,78]

One recent study suggests that birth weight may already be reduced following one course of dexamethasone.[79] We have found a significant reduction of birth weight in pregnancies exposed to ANCs that eventually delivered at term (A. Ruozi, J. J. Piazze, M. M. Anceschi, unpublished).

In a follow-up study by Kumar *et al.*[80] of infants born between 24 and 34 weeks' gestational age exposed *in utero* to multiple courses of antenatal corticosteroids, it was found that treatment was not associated with increased incidence of abnormalities on subsequent neurodevelopmental outcome measures at 30 months of age.

To determine the effects of repeated courses of antenatal corticosteroids on childhood behavior and disabilities, including cognitive delay and cerebral palsy, French *et al.* have analyzed the physical, cognitive, and psychological assessments up to 6 years in infants who were exposed *in utero* to repeated courses of antenatal corticosteroids. Increasing numbers of antenatal corticosteroid courses were associated with a reduction in the rate of cerebral palsy. Three or more courses were also associated with increased rates of aggressive/destructive, distractible and hyperkinetic

behavior and these effects were present at both ages 3 and 6 years. Measures of internalizing behavior and intelligence quotient were unaffected by antenatal corticosteroid use, suggesting that repeated antenatal courses of corticosteroids may protect against cerebral palsy but are associated with hyperactivity later in childhood.[81] Similarly, no difference was found with regard to head circumference, length of body and birth weight and at 4 years of age, as was the age at which the ability to sit and walk without assistance was attained in another follow-up study.[82]

In an elegant prospective observational study of 201 preterm singleton infants who received one or more courses of corticosteroids and were delivered between 24 and 34 weeks' gestation neurodevelopmental outcome was evaluated at 2 years corrected age. Two-thirds of infants were treated with betamethasone whereas the remaining third with dexamethasone. The prevalence of infant leukomalacia, including both prolonged echogenicity and cystic leukomalacia, was 25.9% after a complete corticosteroid course, 40% after one course, 42.3% after two courses and 44.4% after more than two additional courses, respectively (adjusted P for trend = 0.011). In the same categories of steroid exposure, the corresponding prevalence of 2-year infant neurodevelopmental abnormalities were 18% (20/111), 21.4% (3/14), 29.2% (7/24) and 34.8% (8/23), respectively (adjusted P for trend = 0.038). Compared with betamethasone, exposure to multiple doses of dexamethasone was associated with an increased risk of leukomalacia (OR = 3.21, 95% CI = 1.07–9.77) and overall 2-year infant neurodevelopmental abnormalities (OR = 3.63, 95% CI = 1.03–13.58).[83]

Future developments

Some questions still remain on the clinical use of antenatal GCs, i.e. the mode of administration, the minimum dose required, the minimum interval between their administration and delivery of the fetus, although the basic question revolves around the need to repeat courses in the circumstances under which the risk factors for preterm birth persist.

Regarding the mode of administration, animal studies has shown the feasibility of a direct fetal therapy (by intravascular or intramuscular injection of betamethasone). The minimum interval from fetal exposure to GCs to delivery for improving lung function was between 8 and 15 h, with an effect on pulmonary edema and blood pressure that was occurring within 8 h. Small observational series on direct intramuscular injection of betamethasone to the human fetus has been published showing effectiveness in prevention of RDS and no procedure-related complications, although no definitive conclusion can be drawn at the moment.[84,85]

The administration of supplementary surfactant directly to the fetus *in utero* via the amniotic fluid has been demonstrated either in the animal model,[86,87] and in humans either by intra-amniotic injection in the mouth area by Cosmi *et al.*[88,89] or directly into the mouth via endoscope through the vagina in the second stage of labor.[90] In the fetuses supplemented with surfactant *in utero* a decrease in the incidence of NRDS has been constantly observed, although the studies were observational or quasi-randomized.

This elegant approach may represent the true prophylactic antenatal treatment of NRDS. However, to the intriguing question whether the surfactant supplement injected into the amniotic fluid enters the trachea and eventually reaches the peripheral airways and lung tissue thereby altering the clinical course of lung development, no evidence is yet available in the human fetus. Although Hallman[91] has demonstrated in rabbit fetuses that only 6% of intra-amniotically injected surfactant was detected in the fetal lungs, with the majority entering into the gastrointestinal tract, in the same model Galan *et al.*[92] have shown that iron dextran (a substance mimicking the chemical–physical properties of surfactant) does enter the peripheral airways in unparalyzed rabbit fetuses and that is normal fetal breathing, not acute asphyxial gasping, that results in the movement of intra-amniotic iron dextran into the fetal lungs; further, the amount of substances that moves into the fetal lungs accumulated with time;[93] analogous conclusions have been reached by Illia *et al.* following intra-amniotic injection of natural bovine surfactant labelled with

Table 134.5 Summary of recommendations on the use of antenatal corticosteroids for the women at risk of preterm delivery (NIH and modified by EURAIL Study Group, from Visser and Anceschi[94])

- All pregnant women from 24 to 34 weeks' gestation who are at risk of preterm delivery within 7 days should be considered candidates for antenatal treatment with a single course of corticosteroids; pregnant women between 34 and 37 years of age are candidates as well in the presence of immature FLM tests
- Repeat courses of corticosteroids (i.e. more than one completed course), cannot be recommended at this time
- In IUGR fetuses, determination of fetal lung maturation may precede the use of corticosteroids
- Betamethasone seems to be a more effective drug than dexamethasone with respect to perinatal mortality and morbidity and might, therefore, be considered as the drug of choice, but be aware of the temporary effects that this drug has on FHR variation and on fetal movements

Tc-99 and with FBM stimulated by maternal injection of aminiphylline.[8]

At present one can only speculate that in the human fetus intra-amniotically administered surfactant may effectively achieve intrapulmonary distribution; reasons include: (1) injection in the mouth area; (2) FBM induced by administration of aminophylline to the mother and (3) possible bronchial smooth muscle relaxation induced by aminophylline facilitating entry.

Conclusions

Among the several methods proposed to accelerate FLM and to enhance lung adaptation in preterm neonates antenatal GC therapy remains one of the most striking successes in perinatal management of complicated pregnancies leading to premature birth. Despite this and the possibility of treatment with supplementary surfactant to neonates, NRDS still remains a major health problem, also as a result of the fact that not all fetuses delivered preterm have been exposed to therapeutic doses of GC and that NRDS is not solely the consequence of lack of surfactant. A summary of current recommendations on the use of antenatal GC is outlined in Table 134.5.

More recently, the possibility of surfactant administration directly to the fetus *in utero* may underscore a significant improvement in neonatal outcome, particularly for those fetuses necessitating immediate delivery.

135 Route of delivering and monitoring of the preterm fetus

R. Luzietti and G. C. Di Renzo

Introduction

The mode of delivery for the preterm fetus remains controversial, as incontrovertible data supporting either vaginal or abdominal delivery are not readily available. The mode of delivery for the preterm fetus is determined to some extent by the presentation (breech vs. cephalic), fetal weight and gestational age. The use of elective cesarean delivery has increased markedly over the last 20 years. The proportion of first-born singleton infants delivered by elective cesarean delivery between 20 and 27 weeks has increased from 5% in 1983–1985 to 13% in 1995–1997. For infants born between 28 and 31 weeks the increase has been from 21% to 36%; however, at 32–36 weeks the change was 12–16%, which is comparable to the 4–6% increase seen in term infants. The meta-analysis of the trials assessing the value of a policy of elective cesarean section vs. selective cesarean section for women in preterm labor at risk of delivering immature babies does not allow definitive conclusions. Controversy, therefore, still persists about the merits of vaginal vs. cesarean delivery, especially if the fetus is in a breech presentation. Controversy also exists as to whether forceps should be used to protect the more fragile preterm fetal head. Moreover, although it has long been thought that a use of generous episiotomy could reduce resistance to the preterm fetal head and minimize the risk of injury, data to support this theory have not been fully appreciated. As Stewart *et al.*[1] first showed a better prognosis for selected very low birth infants after cesarean section, subsequent investigators have also shown an improved long-term fetal outcome for preterm infants delivered by cesarean section. These reports turned attitudes in favor of abdominal delivery for selected preterm fetuses. Numerous authors subsequently reported on improved survival, reduction of hypoxia, and less intracranial trauma and intraventricular hemorrhage (IVH) after cesarean birth in subgroups of low birth weight neonates. During the last decade, however, many investigators have questioned the value of cesarean delivery for preterm fetuses. The reason for this shift is that many of the early investigations were retrospective, not well controlled, and biased in favor of heavier fetuses (> 1000 g). In many respects, obstetricians were biased against performing a cesarean unless the doctor reasonably believed that the fetus had a substantial chance of survival. In fact, more carefully controlled studies with adequate numbers have not found a neonatal benefit for routine cesarean birth. Thus, available information regarding the route of delivery of low birth weight infants is based primarily on retrospective investigations. Whether a randomized prospective study will be performed in the future to answer this important question is not known. In clinical practice preterm deliveries continue to increase, and survival rates of preterm infants have improved over the years. Elective delivery due to fetal and maternal complications have also increased among preterm deliveries. Most of these patients deliver abdominally because of an unfavorable cervix. In those cases, preterm infants may do better following abdominal delivery, although comparison of elective cesarean delivery to induction with careful fetal monitoring has not been adequately done. Moreover, studies on the application of prostaglandin E2 for cervical ripening in the preterm patients are limited and require further investigation. Regardless of the route of delivery, the goal is the avoidance of asphyxia and trauma to the preterm infant. This will necessarily include someone capable of neonatal resuscitation at the time of delivery.

It has also to be remembered that a cesarean section does not assure one of an easier delivery. Cesarean section in the preterm pregnancy can be complicated by an undeveloped lower uterine segment or an inadequate uterine incision. In the preterm pregnancy, the

lower uterine segment is only 1.0 cm wide at 28 weeks and 4.0 cm at 34 weeks. With such a poorly developed and narrow lower uterine segment, a low transverse uterine incision may not be technically feasible. Moreover, an inadequate incision could lead to birth trauma or to lateral extension of the lower uterine segment incision, resulting in broad ligament lacerations and significant maternal morbidity. As a result, a higher rate of low vertical and classical uterine incisions is found in the preterm patient. The long-term impact of the classical incision will be less in patients available for a vaginal birth after cesarean in a subsequent pregnancy.

This does not mean a low transverse uterine incision cannot be made. Regardless of the type of incision, intraoperative complications including bladder injury, broad ligament lacerations and uterine artery laceration are more common at the time of preterm cesarean section than with delivery of term infants.

Preterm cephalic presentation

There is even less consensus for the optimal route of delivery in the preterm vertex presentation compared with the preterm breech. Cesarean section significantly improved the neonatal survival of the very low birth weight infants, but vaginal delivery also has advantages, such as the fetal chest compression facilitating lung expansion and the more complete placental transfusion to the fetus. Thus, it is evident that cesarean section should be more liberally used in the delivery of the preterm vertex. Nevertheless, cesarean section is probably more indicated in those below 30 weeks of gestation, while those infants greater than 32 weeks' gestation who carry a lower risk of immaturity may be delivered vaginally.

Although some reports have shown that cesarean delivery of the low birth weight fetus with a cephalic presentation may decrease trauma and the incidence of IVH, most investigations do not show a fetal or neonatal advantage or protective effect from cesarean delivery. Thus, cesarean delivery may not be the preferred route of delivery for a low birth weight infant presenting as a vertex over vaginal birth. Moreover, the incidence of germinal matrix bleeding that may extend to an IVH is probably unaffected by the route of delivery. Studies failed to show a difference in perinatal outcome between infants delivered by cesarean and those delivered vaginally. If, however, the case was complicated, cesarean appeared to improve perinatal outcome, but the use of cesarean delivery after the onset of labor does not prevent central nervous system (CNS) bleeding. According to some studies, cesarean delivery of very low birth weight infants reduces the incidence of IVH; however, Bejar and associates, using cranial ultrasound in the first 24 h of life, concluded that it was not the route of delivery but the presence of labor that was the critical factor in the development of IVH. Most studies, when corrected for gestational age, presentation and labor complications, fail to support these findings. Thus, we can identify situations requiring delivery in the face of a long-closed cervix that may tilt the analysis in these preterm fetuses away from a long and potentially morbid induction of labor toward elective cesarean birth; however, the studies to date have not provided sufficient evidence to recommend one route of delivery over another to prevent IVH. For example, there are many recognized conditions associated with IVH. These include prematurity, perinatal asphyxia, respiratory distress syndrome, neonatal trauma and the use of hyperosmolar solutions. It is unclear whether the route of delivery carries sufficient significance to be a factor when compared with these other known causes of IVH. Others have emphasized the complex basis for germinal matrix hemorrhage. Although immaturity does play a major role, additional factors also possibly play a role. Those suggested include intrapartum fetal distress and acidosis at birth, umbilical cord pH < 7.20, heparinization to avoid catheter-related thromboembolic events and vascular fluctuation in the velocity of cerebral blood flow. Attention to intrapartum events could help decrease the incidence of neonatal acidosis and may lessen the risk of IVH. There is, however, no evidence that routine cesarean delivery for the premature fetus presenting as a vertex will decrease the incidence of periventricular hemorrhage.

Notwithstanding, neonatal management of the preterm fetus can play a role in the subsequent development of IVH. In addition to the problems related to mechanical ventilation, medications such as muscle relaxants, phenobarbital, vitamin K and vitamin E appear to reduce the severity of IVH. Indometacin did not affect the incidence of hemorrhage.

Thus, there is no convincing evidence to support the concept that vaginal delivery should not be the mode of delivery when the fetus is in a vertex presentation, when the labor is progressing normally and when the fetal heart rate (FHR) pattern is within normal limits. While cesarean section may be indicated if there are reasons for urgent delivery on maternal or fetal grounds and/or vaginal birth is contraindicated, there is no good evidence to support its general use. The lower uterine segment may be poorly formed very early in pregnancy, making delivery difficult and the procedure poses significant risks to the woman, as well as consequences for her in any future pregnancies.

Until further information becomes available, use of cesarean section for preterm birth should only be undertaken if there is considerable clear benefit to the woman or her infant(s). The options should be discussed with her, including the need to extend the incision into the upper segment and the implications of that for future reproductive health.

Some other aspects should be considered like the routine use of forceps delivery and episiotomy. There are similarly few data to support these practices in

preterm vertex births. Significant maternal morbidity occurs with both these procedures.

Episiotomy

A liberal episiotomy has been suggested for the vaginal delivery of the low birth weight infant to reduce resistance and shorten the second stage of labor. The theoretical basis for this recommendation is to protect the soft fetal head from injury; however, these forces are less than those generated by the cervix and muscles of the vagina through which the fetus has already passed. Thus, there are insufficient data to suggest that a liberal episiotomy will improve perinatal outcome in the low birth weight infant.

'Prophylactic' forceps

The National Collaborative Perinatal Project data found that premature infants (< 2500 g) delivered by low forceps had the best outcome. Recent studies, however, have not shown a benefit from the use of forceps. Moreover, there are studies that have suggested that the use of forceps in this circumstance may in fact be harmful to the fetus as several fetuses in their study had intracranial hemorrhages. Therefore, prophylactic use of forceps appears unnecessary when more than minimal traction is going to be required. The forceps are designed for infants weighing 1500–1900 g and appear to be too large for a fetus under 1000 g. Unlike the term fetus, midforceps should be avoided, where possible, because of the force required to pull the fetus through a resistant and unprepared vagina and firm perineum.

Preterm Breech

Breech presentation is more frequent in preterm labor with an incidence of 25% at 28 weeks' gestation compared with 2–3% at term. The optimum mode of delivery of women in preterm labor with a fetus presenting by the breech is controversial. Most of the published data are observational and retrospective and are prone to serious biases.

There is one study available that has tried to determine the optimum mode of delivery – vaginal vs. cesarean section – of the early preterm fetus in breech presentation. Four retrospective cohort studies, one incomplete randomized control trial and one comparative study indicated that the risk of neonatal death for infants with breech presentation born vaginally was significantly greater than for those born by cesarean section. Two retrospective cohort studies from Northern Nigeria and Jordan did not advocate the routine use of cesarean section for delivering preterm breech fetuses. Three retrospective cohort studies showed no difference in neonatal mortality between those born vaginally and those born by cesarean section. Nine of the 11 studies shared a similar outcome – neonatal mortality and morbidity. Of the remaining two studies, survival rates were examined at 2- and 5-year intervals.

Three of the studies detailed neonatal mortality according to weight and disease, two according to disease and weight alone, one by delivery and one by weight and gestational age. Seven of the studies obtained their data from the clinical environment while the remaining four studies extracted data from detailed births and deaths registries.

Retrospective cohort studies have yielded conflicting results regarding the appropriate delivery of the preterm breech infant. Jain *et al.*[2] and Sun Lee *et al.*[3] found that when comparing vaginal births with cesarean births, cesarean births had a lower neonatal (less than 28 days) mortality rate when ranked according to a birth weight group. In all birth weight groups, the difference in mortality between the vaginal births and the cesarean births was greater in the first hour of life. The difference decreased progressively throughout the day but remained significant in the first day of life. The least difference was noted in the period of 1–27 days. Gravenhorst *et al.*[4] and Kiely[5] also found a significantly lower neonatal mortality rate for breech presenting infants born by cesarean section compared with those delivered vaginally. They concede, however, that, because of the observational design and the fact that statistical analysis described only a trend, they were unable to conclusively state the appropriate mode of delivery. Supplementing the equivocal argument of Gravenhorst *et al.*[4] about the appropriateness of delivery were the studies undertaken by Gilady *et al.*[6], Kaplan *et al.*[7], Ziadeh *et al.*[8] and Wolf *et al.*[9] Both Gilady *et al.*[6] and Ziadeh *et al.*[8] reported no significant difference in the rate of neonatal mortality in the breech infants delivered by cesarean section and those delivered vaginally when compared by birth weight. Likewise, with Kaplan *et al.*[7] and Wolf *et al.*[9], a similar scenario was demonstrated only with a comparison made to the neonatal disease state. It was interesting to note, however, that Gilady *et al.*[6] proffered cautiously that breech infants weighing 1001–1600 g would benefit from a prophylactic cesarean section. This ran counter to the arguments put forward by Emembolu,[10] who claimed that a cesarean section would be an important morbidity consideration in his sample population. However, Gilady *et al.*[6] concedes that because of the potential limitations of such a study – problems of validity and reliability of medical record information, the duration of the study and its impact on treatment regimen and the challenges of the intention to treat analysis – only a mode of delivery trend has been identified. Thus, a prospective, randomized control trial would be essential.

Unfortunately, there was a paucity of prospective, randomized control data regarding the premature breech fetus and the appropriate mode of delivery. The incomplete study undertaken by Zlatnik[11] in the United States was able to recruit only 38 patients between 28 and 36 weeks' gestation from 1978 to 1983.

As a result of low patient recruitment, the authors terminated the study and lamented in their report the difficulties faced with randomization and the mode of delivery. In the second large non-randomized prospective evaluation, Malloy *et al.*[12] collected data on 437 very low birth weight breech infants admitted to seven intensive care units. After several neonatal variables were adjusted for by logistic regression, no significant difference was found in the rate of neonatal mortality in the breech infants delivered by cesarean section and those delivered vaginally, when compared by birth weight. However, Penn *et al.*,[13] like Zlatnik,[11] reported their experience in attempting to initiate a randomized controlled trial to compare elective cesarean delivery vs. a trial of vaginal delivery in the preterm breech infant. They surveyed 26 English hospitals to determine their willingness to participate. Unfortunately, only six hospitals were actively recruiting participants resulting in its termination by a governing body. They cite difficulty with obtaining consent, concern over the availability of skilled personnel, medicolegal issues and disagreement about the desirability of the trial as the cause of its demise.

In spite of the lack of clear scientific evidence that the mode of delivery of the breech presentation affects neonatal outcomes, the cesarean section rate for breech presentation continues to rise. In Australia, the cesarean section rate – as the preferred mode of delivery – has increased from 19.7% in 1996 to 21% in 1998.[14] In light of the medico-ethical dilemmas that may affect the clinician, it will be extremely difficult to launch any appropriately designed randomized controlled trial to answer this eluding question. We must therefore deal with non-selected and retrospective data to determine the course of clinical action.

Furthermore, bias existed in many of the studies available related to matching for gestational age and infant condition. Matching for gestational age at delivery may bias results against vaginal birth because a cesarean section will generally be performed earlier than a vaginal delivery. The difference in gestational age may be large, depending on the pressure to prevent vaginal delivery. This possible disadvantage of cesarean section might explain the increased need for artificial ventilation in those delivered by this method.

Regarding fetal condition it may be argued that for extremely low birth weight fetuses – 700 to 1000 g – the choice of the route of the delivery may in part reflect judgments on their viability. Specifically, it is possible that fetuses presumed to be less viable were selectively relegated to the vaginal mode of delivery. If true, such selection of high-risk patients for vaginal delivery may account for the survival advantage of the extremely low birth weight infants with breech presentation delivered by cesarean section.[16–25]

In conclusion the findings can be summarized as follows. Although the majority of obstetricians will use cesarean section for the uncomplicated preterm breech, only a minority believe that there is sufficient evidence to justify this policy. There is general acknowledgment that the numerous retrospective studies that suggest that cesarean section confers a better outcome in this situation have been subject to bias. This is acknowledged in some reports. The poor outcome for very low birth weight infants is mainly related to complications of prematurity and not the mode of delivery. Grant[15] has reviewed the controlled trials assessing the value of elective vs. selective cesarean delivery of the small baby. He felt that the data 'are not sufficient to justify a policy of elective caesarean section'. In the absence of good evidence that a preterm baby needs to be delivered by cesarean section, the decision about the mode of delivery should be made after close consultation with the laboring woman and her partner (Evidence Level III).[27–30]

Regarding twins, there is insufficient evidence to support cesarean section for the delivery of the first or second twin. The plan for delivery will need careful consideration and full discussion with the parents. Although many clinicians choose cesarean section when the first twin presents as a breech, because of concern about 'interlocking', this complication is extremely rare. Cohen *et al.* reported 'interlocking' occurring only once in 817 twin pregnancies. Oettinger *et al.* compared the outcome of breech presenting twins over two time periods where the cesarean section rate increased from 21% to almost 95%, and found no change in neonatal morbidity or mortality. They did, however, find an increase in maternal mortality in association with a cesarean section delivery. If the second twin is non-vertex (which occurs in about 40% of twins), vaginal delivery is considered safe. Rabinovici *et al.* carried out a randomized study of twin deliveries where the second twin presentation was non-vertex. Although the study included only 60 twins, the results showed no difference in 5-min Apgar scores or in any other indices in neonatal morbidity between the two groups.

There are other non-randomized reports on the safety of vaginal delivery for the non-vertex second twin. Laros had no fetal losses in either group of second twins with 74 being delivered by cesarean and 76 delivered vaginally.

Monitoring of the preterm fetus

During labor, the preterm fetus should be monitored with continuous fetal heart recording. It is noteworthy that the heart rate present in the preterm fetus has characteristics that are specific and different from that of the term fetus.[26] Cesarean section should be performed if there is any evidence of impending fetal hypoxia, which can contribute to the development of respiratory distress syndrome.

Cardiotocography (CTG) is the most widely used method for fetal monitoring. This technique provides

Table 135.1 Fetal development and cardiovascular response during 20–30 weeks' gestation

Immature parasympathetic system not fully developed (average baseline heart rate 150–155 bpm); variability within normal range of amplitude but with poorly defined cycles
Baroreceptor response present with frequent small baroreceptor response with movements (cord not protected by Wharton's jelly)
Peripheral chemoreceptors present and activated by decreased PO_2 and increased CO_2
Cerebral cortex immature, resulting in FHR accelerations, but with majority of them of less than 15-s duration
Constantly changing fetal state; REM state observed from 23 weeks

Table 135.2 Fetal development and cardiovascular response during 30–36 weeks' gestation

Maturing parasympathetic nervous system with decreased FHR baseline and increased cycles of variability
Baroreceptor response unexpected as cord is protected well (increased Wharton's jelly formation);
Chemoreceptors response: peripheral chemoreceptors present
Cerebral cortex maturing, resulting in FHR accelerations greater than 15 bpm lasting longer than 15 s
Quiet sleep (non-REM) emerging; longer time spent in specific states

Table 135.3 Fetal development and cardiovascular response during 36–40 weeks' gestation

Mature parasympathetic nervous system results in decreased baseline FHR with variability cycles well defined
Baroreceptor response unexpected (Wharton's jelly and amniotic fluid provide cushion)
Chemoreceptors response with both peripheral and central chemoreceptors able to function
FHR accelerations greater than 20 bpm lasting longer than 15–20 s, 90% correlated with fetal movements
Well-differentiated and extended behavioral states

useful information on fetal conditions but also presents well-recognized limitations. These limitations, in the term fetus, are mainly linked to the difficulty of interpretation of abnormal FHR patterns and to the poor specificity of the technique in identifying threatening hypoxia.

The normal FHR pattern is characterized by a baseline frequency between 110 and 150 bpm, the presence of periodic accelerations, a normal heart rate variability with a bandwidth between 5 and 25 bpm and the absence of decelerations.

The FHR pattern is abnormal when one or more of the following features are observed: a baseline frequency below 110 or above 150 bpm, the absence of accelerations for more than 45 min, decreased or absent FHR variability and the existence of repeated variable or late decelerations. Assessment of fetal well-being in the preterm fetus by analysis of FHR presents specific difficulties.

The antepartum non-stress test of recognized value in the term fetuses is of less well-defined value in the preterm, due to more uncertainty in the relationship between baseline heart rate, reactivity and fetal conditions. During preterm labor the incidence of abnormal findings from intrapartum monitoring is higher as compared to term labor, when the same set of criteria for interpretation are used for both groups and, therefore, in preterm fetuses specific interpretative criteria considering the peculiar physiological aspects of the maturing fetus should be used. Together with 'extrinsic factors' (such as baseline maternal oxygen tension, maternal oxygen-carrying capacity, adequate blood flow to the uterus, uterine contractions, placental surface area and placental blood flow and umbilical cord occlusion or compression), the FHR is also influenced by 'intrinsic factors' such as the balance between the sympathetic and parasympathetic portions of the autonomic nervous system (constant interplay between the 'slowdown' influence of the parasympathetic system and the 'speed-up' influence of the sympathetic system), the CNS: medulla oblongata (integrative center for central and peripheral neural control of the cardiovascular system) and higher brain centers (responsible for variations in FHR in response to FBS); baroreceptors (homeostatic mechanism): pressure receptors located within the vessel walls of the aortic arch and carotid body; chemoreceptors (peripheral: aortic arch and carotid body, central: medulla): responsive to changes in the concentration of oxygen and CO_2 and hormonal influences, like, for example, catecholamine.

In the preterm fetus, the maturational process of the above-mentioned structures, influences the patterns of FHR, which results, with advancing gestation, in a progressive decrease in basal FHR, in a progressive increase in the amplitude of FHR accelerations and in a progressive increase in long-term FHR variability with advancing gestation (Tables 135.1–135.3).

The interpretation of FHR patterns of the preterm is not only more difficult because of the age of the fetus but also complicated by the impact on FHR of specific drugs, more frequently used in women with threatened or actual preterm labor (betamimetics, magnesium

sulfate and steroids) or for other concomitant pathological conditions, for example, antihypertensives, that can influence FHR.

It is known, for example, that betamimetics increase the baseline FHR and are associated with a decrease in FHR variability, magnesium sulfate causes a decrease in FHR variability and antihypertensives may cause tachycardia, bradycardia, flattening of the accelerations or a decrease in variability. Betamethasone, contrary to dexamethasone, leads to a decrease in the incidence of fetal body and breathing movements and concomitantly a decrease in the number of accelerations and diminished variability.

Finally, the situation is also complicated by the fact that complementary techniques, like fetal electrocardiogram analysis, useful to improve the specificity of intrapartum fetal surveillance in the term fetuses, cannot be utilized in fetuses below 36 weeks of gestation.

In conclusion, interpretation of FHR changes in the preterm fetus presents specific difficulties in adjunction to the well-recognized limitation of CTG interpretation in term fetuses even if FHR nevertheless provide useful information about neurodevelopmental integration and the cardiovascular response to stress and hypoxia. FHR changes are the result of numerous intrinsic and extrinsic influences: interpretative criteria should consider the specific physiological aspects of the maturing fetus and in the interpretation of FHR patterns it is necessary to make adjustments for gestational age. It is important to underline that interpretation of FHR should not be separated by consideration of the complete clinical picture. Further studies are required to develop specific interpretative criteria considering the specific physiological aspects of the maturing fetus and to devise appropriate interpretative criteria for FHR monitoring of preterm fetuses.

136 Resuscitation of newborn infants

O. D. Saugstad

Introduction

It has been estimated that, of the 130 million infants born worldwide every year, approximately 3–5% (4–7 million) of newborns need some kind of resuscitation at birth, of these 4 million suffer from birth asphyxia. In turn 1 million of these will die and an equal number develop sequel. Further, approximately 1.6 million stillbirths occur annually due to intrauterine asphyxia. In low-income countries, it has been estimated that 30% of perinatal deaths are due to perinatal asphyxia. In the USA, it has been reported that 5% of all newborn infants require basic life support in the delivery room or nursery, constituting 200,000 newborn infants in the USA alone. In Western Europe there are similar figures, and in industrialized countries 2–6 per 1000 live births develop acute clinical sequel of intrauterine asphyxia, the so-called hypoxic-ischemic encephalopathy or neonatal encephalopathy. Of those who survive, 25% of moderate and 75–100% of severe cases seem to develop neurodevelopmental sequelae later. In low-income countries neonatal encephalopathy is more frequent, for instance, in Nepal it was observed in 6 per 1000 live births with birth weight > 2000 g, with a higher proportion of severe cases than, for instance, in Australia. Mortality of these children was three times higher in Nepal than in Australia. Due to the high mortality, few babies with neurodevelopmental handicap survive in such a low-income setting.

Some bodies do not recommend the term 'birth asphyxia' anymore. The American College of Obstetricians and Gynecologists, for instance, has abandoned both the terms 'fetal distress' and 'asphyxia'. 'Non-reassuring fetal status' is suggested instead of 'fetal distress'. In spite of this and different and sometimes rather vague definitions of birth asphyxia, the term is still in use and there is no doubt that a large number of newborn infants require resuscitation at birth both in industrialized and in low-income countries. It is very important, therefore, that existing resuscitation routines are based on scientific evidence. Furthermore, trained personnel and adequate equipment should be available at every delivery. As most deliveries throughout the world still occur at home, far away from a hospital and without authorized health personnel present, it is also important to develop simple resuscitation routines that can be handled by traditional birth attendants.

Birth asphyxia

As mentioned above, there is no uniform and clear definition of birth asphyxia. The term itself is Greek and means 'loss of pulse', but is often used synonymously with a condition where a combined respiratory and metabolic acidosis is found in the newborn infant. Today, the diagnosis of perinatal asphyxia is mainly based on its consequences and there is general agreement that the existence of multiple signs and symptoms are needed. Both intrapartum and neonatal distress combined with neurological symptoms in the newborn infant are usually required.

Intrapartum distress implies fetal bradycardia and hypoxemia resulting in a mixed acidosis. Intrapartum asphyxia can be diagnosed by measuring the heart rate and analyzing the heart-rate pattern by cardiotochography, as well as measuring pH in the scalp blood during delivery. Heart-rate abnormalities such as tachycardia and bradycardia are signs of intrapartum distress as in the so-called silent pattern, i.e. loss of heart-rate variability, and late or variable decelerations. Changes in the fetal QRS complex from the electrocardiogram (ECG) signal analyzed by computer-assisted electronic fetal monitoring have been recently obtained, and it seems to be an even more sensitive measure of *in utero* asphyxia. A clinical sign of fetal distress still in use is passage of meconium. A low cord blood pH is also a sign of intrapartum distress. A pH of < 7.05 or 7.00 and a base deficit (BD) > 12 mmol/l by many are held as evidence for intrauterine asphyxia.

Neonatal distress is most often diagnosed by using the Apgar scoring system. Low Apgar score, for

instance < 4 for more than 5 or 10 min after birth, is often used as an indication of neonatal distress. Biochemical variables such as acid–base status, lactate, plasma and urinary hypoxanthine, erythropoietin, the number of nucleated erythrocytes in peripheral blood, brain-type creatine kinase isoenzyme, neuron-specific enolase and excitatory amino acid, as well as a number of other markers have been suggested and used to diagnose this condition. More sophisticated means such as magnetic resonance spectroscopy and positron emission tomography, as well as physiological indicators such as the electroencephalogram, evoked potential, cerebral blood flow, and oxygenation evaluated by near-infrared spectroscopy have also been used.

Apgar score is not a measure of asphyxia itself, but a low score still indicates the presence of neonatal distress. In a study from the USA, Apgar scores < 4 were found in 4.5% of newborn infants at 1 min and in 0.9% at 5 min of age. In Sweden, the incidence of infants with Apgar scores < 4 at 5 min was found to be 0.26%. In a Norwegian population with birth weight > 2500 g and no birth defects, a low Apgar score < 4 was found in only 0.7% at 1 min and 0.1% at 5 min.

Neurological symptoms and signs in the newborn following asphyxia vary depending also on when in the postpartum period the child is observed and include muscular hypotonia, feeding difficulties, and seizures. The term hypoxic-ischemic encephalopathy has been designed, a condition seen in term or near-term infants with onset within the first 24 h of life. Clinical scoring systems of this condition have been developed, classifying the condition according to its severity. Stage 1 usually has an excellent prognosis and stage 2 invariably results in sequelae, whereas stage 3, in most cases, leads to death or a severe injury of the child. In a recent survey of approximately 600 newly born infants mainly from low-income countries needing resuscitation, 30% developed hypoxic-ischemic encephalopathy; of these 45% had stage 3, 35% had stage 2 and 20% had stage 1 hypoxic-ischemic encephalopathy.

The term hypoxic-ischemic encephalopathy has by many authors been substituted by neonatal encephalopathy. This indicates that there are a number of other causes of newborn encephalopathy than asphyxia. In fact, one study from Australia indicates that the majority of newborn encephalopathy cases are due to factors other than asphyxia.

A practical definition of perinatal asphyxia given by the American College of Obstetricians and Gynecologist, where all four conditions must be fulfilled is:

(1) pH in umbilical cord blood < 7.0 and BD ≥ 12 mmol/l;
(2) Apgar scores < 4 more than 5 min;
(3) Multiple organ affection (brain, lung, myocardium, kidney, liver, and intestine);
(4) Evidence of neonatal neurologic sequelae.

From this definition it can also be appreciated that birth asphyxia is a retrospective diagnosis, which can be set not until some time has passed from birth. Resuscitation, which has to be initiated promptly, therefore, has to be carried out before a diagnosis of birth asphyxia is confirmed. In fact, BD > 12 mmol/l in umbilical arterial blood seems to represent a threshold value where cerebral and other organ injury may occur.

Guidelines for resuscitation of the newly born

There are several sets of international guidelines for newborn resuscitation. The World Health Organization published their guidelines for basic newborn resuscitation in 1998 applicable for most children around the world. The ILCOR guidelines from 1999 and the guidelines of the American Heart Association/American Academy of Pediatrics (AHA/AAP) from 2000 and 2005 are widely used internationally. A number of countries also have their own national guidelines. AHA/AAP has published an extensive textbook with CD-ROM demonstrations. These guidelines emphasize a practical approach and especially AHA/AAP has strived to be as evidence-based as possible.

Practical management

Selection of risk cases

It is important to anticipate those infants at risk: the antepartum and intrapartum history can often be of help in predicting which infants will need resuscitation. Some risk factors are listed in Table 136.1.

Fetal-movement counting, non-stress testing, fetal biophysical profile, electronic fetal monitoring, and scalp pH measurement all contribute to an identification of infants at risk for low Apgar scores and need for resuscitation. Electronic fetal-heart monitoring combined with scalp pH determinations improves the specificity; however, sensitivity is low. In spite of these measures, the need for resuscitation often cannot be foreseen and 20–50% of the infants requiring resuscitation have no identifiable risk factors; therefore, at every delivery, the caregiver should be prepared for a possible need of intervention.

Preparation for birth, personnel, and equipment

Most deliveries are uneventful and the adaptation to extrauterine life occurs smoothly. Only in some infants should more vigorous resuscitation procedures be carried out. Most of these can be performed with a bag and a face mask, but in some newborn infants, endotracheal intubation and more sophisticated treatment and observation are needed.

Resuscitation is team work, and at least one person skilled in resuscitation and one assistant should attend to the delivery. Optimally, two trained persons

Table 136.1 Factors indicating increased risk of need for resuscitation of newborn infants

Abnormal presentations
Congenital malformations
Decreased fetal activity
Fetal bradycardia or distress
Maternal age >35 years
Maternal illness
Anemia or isoimmunization
Cardiovascular disease
Chronic or pregnancy-induced hypertension
Diabetes mellitus
Drug therapy
Hemorrhage
Infection
Renal failure
Substance abuse
Maternal sedation
Meconium-stained amniotic fluid
Multifetal gestation
No prenatal care
Premature rupture of membranes
Preterm
Previous fetal or perinatal death
Prolapsed cord
Prolonged labor
Post-term
Small fetus for maternal dates

Table 136.2 Equipment needed for newborn resuscitation

Adhesive tape
Bulb syringe
Clock
Disinfectant
ECG monitoring if available
Endotracheal tubes and connectors (2.5, 3.0, 3.5, and 4.0 mm internal diameter)
Endotracheal tube introducers
Face masks, newborn, and premature sizes
Feeding tube 8F
Gloves, sterile
Laryngoscopes (at least two), straight bladed Nos. 0 (preterm) and 1 (term)
Magill forceps for nasal endotracheal intubation
Meconium aspirator
Medications
Epinephrine (1:10,000)
Naloxone hydrochloride (1 or 0.4 mg/ml)
Sodium bicarbonate (0.5 mmol/ml)
Volume expander (normal saline or Ringer's lactate)
Mucus extractor
Nasogastric tubes
Neonatal resuscitation bags
Oropharyngeal airways 0, 00, and 000 sizes or 30, 40, and 50 mm lengths)
Pulse oximeter if available
Radiant warmer
Scalpel
Scissors
Stethoscope
Suction catheters 5F or 6F, 8F, 10F, and 12F
Suction with manometers
Syringes 1, 3, 5, 10, 20, and 50 ml, needles (25, 21, and 18 gauge), intravenous cannulae and specimen bottles
Three-way stopcock
Umbilical catheters 3.5F and 5F
Umbilical vessel catheterization tray
Warmed linens

should actually perform the resuscitation and one should assist. All equipment should be at hand and functioning. Table 136.2 lists equipment needed for optimal resuscitation, which should be available in the delivery room. It is important to have specific daily routines, checking that the necessary equipment and drugs are present and that the equipment is functioning. The care provider should check, before the infant is born, the oxygen supply and equipment for intubation and that the bag, mask, and suction are functioning. Each team member should identify himself/herself, and it should be clear who the team leader is. Each order should be stated clearly and repeated by the recipient.

Most deliveries worldwide occur in the community outside hospitals and, if any, only basic equipment is at hand, such as a warm and clean bed, stethoscope, bag and face mask, and suction apparatus. A sterile scalpel to cut the cord should be used at every delivery.

Indication for resuscitation

The decision to resuscitate or not is a purely clinical one. The most important indication of the need for resuscitation is failure to breathe after birth. If the

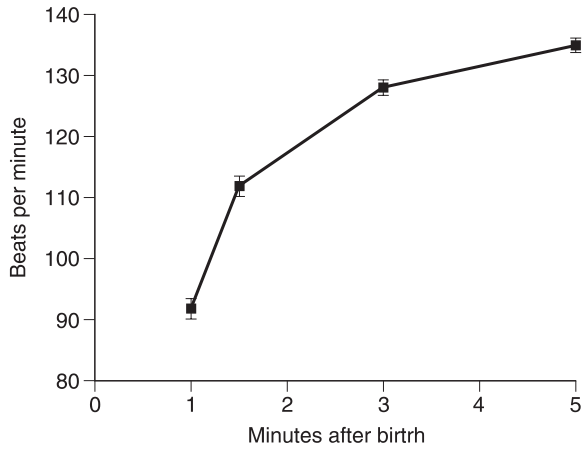

Figure 136.1 Heart rate in the first 5 min of life of approximately 600 newborn infants from the Resair 2 study resuscitated due to bradycardia (heart rate < 80 bpm) and or apnea or insufficient respirations. Values are expressed as mean and SEM.

newborn does not cry or breathe, or is only gasping after the initial quick suctioning, drying, and tactile stimulation, resuscitation should be started. Apneic infants with heart rate > 100 per minute probably represent those with primary apnea, and the infants often require tactile stimulation and a few inflations with a bag and mask only. Apnea and heart rate < 100 per minute may represent secondary apnea, and ventilation should be initiated. In most of these cases, the heart rate improves and spontaneous ventilation quickly develops (Figure 136.1).

Resuscitation, when needed, should start as soon as possible, not later than 30 s after birth. By observing breathing movements, tone, color, and, not the least, heart rate indications, it may be decided whether the infant is in need of resuscitation or not. According to AHA/AAP, every time a child is delivered, the following four questions should be answered:

- Is amniotic fluid clear of meconium?
- Is the baby breathing or crying?
- Is there a good muscle tone?
- Was the baby born at term?

If the answer is 'no' to any of these questions, resuscitation should be considered. Clinical judgment should be based on heart rate, breathing, color, and tone. If the child has apnea or insufficient breathing movements and/or heart rate < 100 bpm, and is blue or pale, resuscitation should be started.

ABC of resuscitation

The ABC of resuscitation is the same whatever the size of the patient: A, airways should be cleared and the infant positioned correctly; B, breathing should be stimulated or performed; and C, circulation should be assessed by heart rate and skin color.

The AHA/AAP guidelines have divided resuscitation into five major steps:

(1) Assess babies' response to birth.
(2) Keep the baby warm and position the baby correctly and keep airways clear. Stimulate to breathe by drying or giving oxygen (if necessary), suctioning.
(3) Establish effective ventilation by bag and mask or in some intubate endotracheally.
(4) Provide chest compression.
(5) Administer medications.

Every newborn goes through the first two; however, only a few go through the last steps. A few – approximately 5% – need the third: bag and mask resuscitation. The fourth step, chest compression, is needed in approximately 1–3% of those needing bag and mask, that is, 1–2 per 1000 deliveries. The fifth and final stage, medication, is very rare.

Evaluation

The sequence of events following asphyxia has been studied in animals. Immediately after asphyxia, there is a period of regular small-volume breaths followed by a fall in heart rate and cessation of breathing. This is the so-called primary apnea. This might last for a minute or so, and is followed by spontaneous gasping for 4–5 min before the secondary apnea develops. If resuscitation is not carried out at this stage, the infant will die.

As soon as the infant is delivered, a clock is started and, during the transport to the resuscitation table, the personnel should form a preliminary opinion regarding the seriousness of the situation, do an evaluation that is performed continuously during the resuscitation process. For instance, a completely lifeless and pale infant probably needs a more aggressive approach than a blue infant with some movements and perhaps also a feeble cry.

During the short period of the initial stabilization, the respiratory efforts are assessed, the heart rate recorded, and color noticed. Heart rate should, after the short initial stabilization, be monitored more precisely. Bradycardia combined with no respiratory efforts or gasping are warnings of immediate intervention. Central cyanosis indicates insufficient oxygenation, whereas acrocyanosis is common even in vigorous newborn infants. Pallor may be sign of reduced cardiac output, anemia, hypovolemi, hypothermia, or acidosis. Apgar scoring in itself should never be used as a criterion for resuscitation because Apgar scoring is not performed before 1 min of life and, in addition, it takes some time. It requires experience to determine Apgar scores correctly, and they are dependent on a number of factors other than the severity of asphyxia, such as drugs given to the mother and the degree of prematurity. It is clinical judgment, therefore, that should be

used in deciding when and what kind of resuscitation should be initiated.

Step 1: assess babies' response

Most infants require only to be delivered into a warm room where they can be dried immediately. Their cord should be cut with sterile equipment and their breathing pattern should be observed. The mother herself is most often the best caregiver and provider of warmth, food, and protection from infections. Occasionally, the heart rate of the infant should be monitored preferably by auscultation of the left side of the thorax or alternatively by palpating the pulse for instance at the base of the umbilical cord.

Step 2: warmth, position, and suctioning

Newborn infants and especially asphyxiated ones have an unstable thermoregulation. Hypothermia is an important risk factor, possibly inducing hypotension and delaying the recovery from acidosis. Also, a healthy newborn infant, when exposed to a relatively cold delivery room, may experience a significant decrease in body temperature. Heat loss should be prevented and this is one important reason why deliveries should be performed in a warm delivery room. The newborn should be quickly dried with towels, with particular attention to the drying of the head, and swept into preferably prewarmed towels or other linens. It is recommended that the infant be placed under a prewarmed radiant heater on a table designed for resuscitation.

Some recommend that the nose and mouth should be suctioned with a bulb syringe after delivery of the shoulders but before the thorax has been delivered. However, as this may delay initiation of the resuscitation, this should be considered carefully in each individual case. The infant should be carried to the resuscitation table and placed in a supine position with the head toward the care provider. The neck should be in a neutral position, as both overextension and flexion may cause obstruction of the airways.

At the resuscitation table, the heart rate is quickly recorded by auscultation. An experienced person needs to listen for only a few seconds to obtain an impression of the degree of bradycardia. Count ten s and multiply by six. The nose and mouth should then be suctioned thoroughly but quickly, and for not more than 5–15 s. A bulb syringe or a mechanical suction apparatus attached to an 8F or 10F suction catheter should be used, and the negative pressure should not exceed 136 cmH_2O (100 mmHg). Suction can induce bradycardia and even heart arrest via vagal reflexes, especially when deep suctioning in the oropharynx is performed. Laryngospasm and pulmonary artery vasospasm have also been reported after suctioning. Suction bulb is less likely than suction catheters to induce cardiac arrhythmias but they are probably not as efficient. There is no justification for the practice of routine gastric suctioning not even after cesarean section and such suctioning might even be harmful.

Simultaneously, the other member(s) of the resuscitation team should continue drying the infant with warm and clean towels and changing the initial linens, which are usually wet. This also provides tactile stimulation. which may help initiate breathing in mildly depressed infants. No further stimulation is appropriate. This initial stabilization should be finished within 30 s.

Step 3: establish effective ventilation

After initial correct stabilization, positioning, suctioning, and drying, the infants who fulfill the criteria for further resuscitation, that is those having apnea or heart rate < 100 bpm, should be given ventilatory support. In the majority of these, a bag and face mask is adequate. Various bags and masks are available, but a bag with a reservoir and a 'pop-off' valve that automatically opens if the inflation pressure exceeds a certain figure, usually between 30 and 40 cmH_2O, is recommended, especially in preterm infants. A self-inflating bag is often preferable, as it is independent of gas supply, and ambient air can be used. Bags used for newborns should have a volume of 200–750 ml. Only a soft mask provides a tight seal where the mask is applied to the newborn's face to achieve adequate pressures. A soft-rimmed mask with a small dead space gives the best face seal.

The first breath of the newborn often generates a negative pressure, sometimes of the magnitude of 70 cmH_2O and even more, although in most infants the negative pressure generated by the first breath is < 10 cmH_2O. The first artificial breath given to the infant, therefore, requires a high pressure for term infants, perhaps in the range of 30–40 cmH_2O or even greater, but lower in preterm infants. The succeeding inflations usually require less pressure, around 15–20 cmH_2O. It is preferable to have a manometer coupled to the bag, so that peak inflation pressures can be recorded. The recommended rate of ventilation according to the AHA/AAP is 40–60 breaths per minute. The best way to monitor successful ventilation is to observe movements of the chest wall and follow the heart rate. The pulse picks up very quickly during a successful resuscitation procedure (Figure 136.1). At least three-quarters of asphyxiated infants have spontaneous breathing after establishing these initial steps.

The effects of bag and mask ventilation has been investigated in some studies. In unexpanded lungs, a satisfactory tidal volume is not achieved, and bag and mask ventilation on apneic newborn infants is probably futile. It has been suggested that the most important contribution by using bag and mask ventilation is that the Head's paradoxical reflex is elicited. This means that newborn infants in primary apnea often respond to rapid lung inflation by gasping instead of apnea. This makes the child inflate the lungs. The effect of bag and mask ventilation is therefore less efficient in babies in secondary apnea, since reflexes are not released in such babies. In aerated lungs, correct

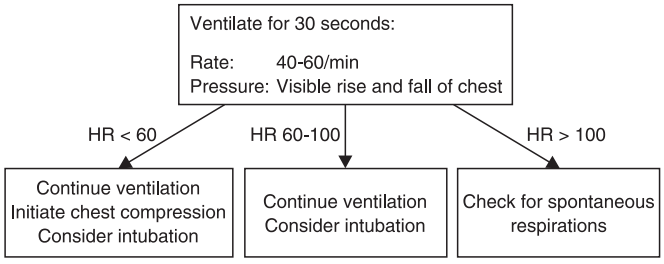

Figure 136.2 Flow chart for ventilation, chest compression and/or endotracheal intubation.

bag and mask ventilation provides tidal volumes of 5–15 ml.

After adequate ventilation has been established for 15–30 s, the heart rate should be recorded for 10 s. If the heart rate is at least 100 per minute and spontaneous respirations are established, positive pressure ventilation may be discontinued. If the heart rate is between 60 and 100 per minute and improving, ventilation should continue. If the heart rate is less than 60 per minute and not improving, assisted ventilation is continued and external heart massage is started (Figure 136.2).

Endotracheal intubation. Endotracheal intubation is necessary when bag–mask ventilation is not efficient enough to normalize the heart rate and establish spontaneous respiration. If chest compression does not quickly improve heart rate or prolonged assisted ventilation is anticipated, endotracheal intubation should also be carried out. A newborn infant without any heart beat or respiratory movement should also be promptly intubated, as bag and mask ventilation probably is not very efficient (see above).

Endotracheal intubation is rare in term infants. The indications are mainly tracheal plugging, for instance, by meconium. Some infants in secondary apnea need intubation and also the most immature infants who often do not have enough muscle strength for their respiratory drive to be sufficient. It has been estimated that 5–6% of all newborn infants need bag and mask ventilation. Of these, 4–20% according to different authors would need endotracheal intubation, approximately 2–10 per 1000. Recent studies indicate that the need for endotracheal intubation is even lower both in term and preterm infants.

The equipment for endotracheal intubation should be ready at hand. Equipment needed in addition to suction devices includes a laryngoscope(s) and blades, straight No. 01; a Magill forceps for nasal endotracheal tubes; endotracheal tubes of 2.5-, 3.0-, 3.5- and 4.0-mm inner diameter; and endotracheal tube stylets. Illumination of the laryngoscopes should be checked before the infant is born. Extra batteries and bulbs should be available. The length of the tube can be calculated in several ways. When nasal intubation is used, the length of the tube can be estimated to be 1.5 times the distance from the anterior part of the tragus to the lateral and caudal part of the ipsilateral ala nasi. The length of the tube from the tube tip to the lips, when oral intubation is performed, can be estimated in centimeters to be (6 + the weight in kg). An infant weighing 3 kg, therefore, needs an oral tube of $6+3=9$ cm. Whether one should intubate orally or nasally is a matter of experience. If the tube is cut remember to add 1–2 cm for taping the tube.

After intubation, the position of the tube should be checked by listening to equal breath sounds, especially in the axillae, and for absence of breath sound in the stomach. Symmetrical movements of the chest wall are also an indication of proper placement of the tip of the tube. However, primarily, improvement in heart rate and color and activity of the infant are indications of adequate ventilation and oxygenation. An infant with open eyes and adequate movements is not a severely depressed infant. The position of the tube can also be checked by repeated visualization of the larynx and in the case of a prolonged intubation by chest x-ray. Some centers are using pneumotachographs or color methods to detect CO_2 in the expired air to assure the tube is correctly placed.

Oxygen supplementation. A high concentration of supplemental oxygen (80–100%) has usually been recommended in most textbooks and guidelines dealing with newborn resuscitation. There is, however, no scientific basis for such recommendations. The Resair 2 study has shown that most newborn infants can be resuscitated as efficiently with room air as with 100% oxygen. Even the most depressed newborn infants seem to be adequately resuscitated with room air when assessed by response in the neonatal period. A meta-analysis of five studies including more than 1700 newly born infants in need of resuscitation has shown that early recovery is faster if resuscitation is carried out with ambient air instead of 100% O_2. Time to first breath was registered earlier, heart rate at 90 s, and 5-min Apgar scores were higher. More importantly perhaps, the neonatal mortality is significantly reduced in room-air resuscitated babies. For this reason 100% oxygen should be avoided as a routine for newborn resuscitation. New recommendations seem to favor the use of room air to start out with having oxygen available as back up. The reasons for the toxic effects of oxygen are not fully understood. However, it has been shown in animal studies that resuscitation with oxygen triggers inflammation in the lung, heart, and brain and also seems to exaggerate brain injury. In humans it has been demonstrated that an increased oxidative stress lasting at least 4 weeks is triggered by resuscitation with pure oxygen. The use of oxygen consumes antioxidants and it may take a long time till these are restored, hence a long-lasting increased oxidative stress is induced, although the exposure to oxygen in most cases is very brief, a few minutes.

If room-air resuscitation is not successful within 90 s, we have supplemented it with oxygen. In such a case, it is probably optimal to monitor the arterial oxygen saturation by pulse oximetry. The oxygen supply in all delivery units should have a blender, so that the oxygen concentration can be adjusted to the requirement. If giving supplemental oxygen is justified, for instance, if central cyanosis or bradycardia persists for more than 90 s, it is recommended to start with 40–60% oxygen and adjust according to the clinical response and, if possible, oxygen saturation measured by pulse oximetry.

Step 4: chest compression

Chest compression is rarely needed and not recommended for basic newborn resuscitation. If bradycardia persists with a heart rate of less than 60 per minute and no signs of improvement after 30 s, adequate ventilation and chest compressions should be carried out. In the Resair 2 study, only 1.7% had a heart rate of 60 or less after 180 s and 1.2% after 300 s. Still almost 20% received chest compression.

AHA/APA recommends that chest compression should be performed by placing the two thumbs on the middle third of the sternum with the fingers encircling the chest and supporting the back. The thumbs should be placed side by side on the sternum just below an imaginary line drawn between the nipples. In small, premature infants the two thumbs may have to be superimposed instead of being placed side by side. The tips of the middle finger and either the index or ring finger of one hand positioned directly above the chest can also be used for chest compression. The sternum is compressed to a depth of 1/3 of its anterior–posterior diameter with a somewhat longer time for the relaxation phase. Chest compression should always be carried out simultaneously with adequate ventilation. A synchronized chest compression and ventilatory rate of 3:1 giving 90 compressions and 30 breaths per minute is recommended. An adequately performed resuscitation with chest compressions obviously requires at least two trained persons.

Heart rate should be assessed after 30 s of well-coordinated chest compressions and ventilation. When the spontaneous pulse rate has reached 60 per minute, chest compression should be discontinued and positive pressure ventilation is continued at a rate of 40–60 breaths per minute (Figure 136.2).

Step 5: medications

When oxygenation is established through adequate ventilation of the asphyxiated infant, it is extremely rare that drugs are needed. Epinephrine (Adrenalin) is indicated in asystole or in sustained bradycardia (heart rate < 60 bpm) in spite of a minimum of 30 s of adequate ventilation and oxygenation and another 30 s of coordinated chest compressions and ventilations. Epinephrine (1:10,000 solution – 0.1 mg/ml) is given as a bolus as rapidly as possible intravenously or intratracheally in a dose of 0.01–0.03 mg/kg (0.1–0.3 ml/kg) – a higher range of dose if endotracheal administration is chosen. The dose may be repeated every 3–5 min if needed. Bradycardia due to insufficient ventilation technique should be corrected by adequate ventilation before administration of epinephrine. Higher doses to premature infants should be avoided.

Naloxone hydrochloride is a narcotic antagonist; however, few studies have documented any benefit of this drug given during resuscitation. The potential negative effects are of concern, as it increases metabolic requirements and redistributes blood flow. Naloxone administration should be restricted, therefore, only to infants who are considered depressed from narcotics administrated to the mother during labor, within 4 h of the delivery, and who require active resuscitation in the immediate postnatal period. Adequate positive pressure ventilation that restores normal heart rate and color should always be established before administration of Naloxone. The appropriate dose is debated, but AHA/AAP recommends an initial dose, given intravenously or intratracheally, of 0.1 mg/kg of a 1- or 0.4-mg/ml solution, which can be repeated every 2–3 min as needed. Naloxone should not be given to newly born infants whose mothers are suspected of having recently abused narcotic drugs, because it may precipitate abrupt withdrawal signs.

The optimal treatment of hypovolemia and shock seems to be unclear; however, shock may be treated with repeated transfusions of volume expanders, usually 10 ml/kg. As volume expanders, normal saline or Ringer's lactate are recommended. The volume expander may be given over 5–10 min and repeated. Albumin or other plasma substitutes are not recommended. Blood volume expanders during acute resuscitation are only indicated when there are unmistakable signs of shock with evidence of acute blood loss, including feto-maternal hemorrhage. In case of blood loss, O-negative blood cross-matched with the mother's blood is given.

Sodium bicarbonate or Tribonat has no routine place in newborn resuscitation. No randomized studies have shown beneficial effects of these drugs. In fact, sodium bicarbonate may be counterproductive by decreasing intracellular pH. Only in prolonged cardiac arrest not responding to other therapy, administration of sodium bicarbonate, in a dose of 2 mmol/kg infused slowly, could be used. Sodium bicarbonate should be given only after all other steps of resuscitation described above have been taken and if ventilation is established. This drug is very caustic and if given should not be given endotracheally but in a large vein.

There is no evidence that atropine or calcium has any beneficial effect during the acute phase of resuscitation of the newborn infant.

In the Resair 2 study, a large trial comprising approximately 600 infants in need of resuscitation, 15% were given one or more drugs. Seven percent were given epinephrine, 6% were given sodium bicarbonate, 1% received Naloxone, and only 0.6% was infused with albumin or underwent blood transfusion.

Meconium aspiration

Meconium aspiration syndrome significantly increases morbidity and mortality. Meconium in the amniotic fluid is present in 10–12% of deliveries. However, only approximately 5% of these develop the meconium aspiration syndrome. In the Resair 2 study, approximately 40% had meconium-stained amniotic fluid.

If the amniotic fluid is meconium-stained, there is no evidence that suctioning the oropharynx before the thorax is delivered has any beneficial effects. As this is not harmful, this procedure is still often recommended. There are, today, no indications that an infant with thick meconium-stained amniotic fluid benefits from routine intubation and suctioning. It is therefore not recommended any more that suctioning of the nose, mouth, and posterior pharynx should be carried out thoroughly before delivery of the shoulder and thorax. A bulb syringe may also be adequate. Routine endotracheal intubation and suctioning of every infant born with meconium-stained amniotic fluid is not justified. However, it is recommended to intubate and suction, through the endotracheal tube with a bore suction catheter larger than 10F, all meconium-stained infants who are not vigorous. It has also been recommended previously to intubate and suction the infant if the meconium is thick or particulate. However, any positive effects of this procedure have not been demonstrated.

Preterm infants

Recent studies have shown that cardiorespiratory resuscitation of extremely low birth weight infants in the delivery room is not futile and a more active approach therefore seems to be established. In fact, studies show that intact survival of delivery room cardiopulmonary resuscitation of infants with birth weight < 750 g is identical to age and gender-matched controls not in need of resuscitation. Advanced cardiopulmonary resuscitation, therefore, is justified also in extremely low birth weight infants.

There are no or very few studies on optimal resuscitation of premature infants. This means that even the extremely low gestational age newborn infants are mainly resuscitated according to the guidelines and principles established for term and near-term infants. Obviously there is an urgent need for separate guidelines for the most immature ones. The following is, however, especially important for the preterm and is more important, the more immature the infant is:

- These infants have a relatively large surface area and a thin skin, therefore losing heat quickly.
- They have low tidal volume, for instance, only 5–10 ml or even lower. Just a few blows with large tidal volumes may ruin their lungs. On the other hand their lungs may be stiffer due to surfactant deficiency. Those with gestational age < 28 weeks are, therefore, often intubated by giving surfactant and in some centers they are immediately extubated.
- Premature infants have a fragile germinal matrix in their brain. Rapid changes in blood pressure or vascular volume in addition to hypoxia may be associated with germinal matrix hemorrhage. These infants should be handled as gently as possible. Rapid boluses of fluid and quick changes in body positions should be avoided.

According to one study, premature infants also have higher neonatal mortality if resuscitated with 100% oxygen compared with room air. There are no data for infants with birth weight < 1000 g but there are reasons to believe these are even more vulnerable to high oxygen exposures.

Response to resuscitation

In the Resair 2 study, the heart rate rose from a mean of 92 per minute at 1 min of age to 112 per minute at 90 s, and 128 at 3 min (Figure 136.1); only 8% and 5% of the infants had a heart rate of < 100 per minute at 3 and 5 min of age, respectively. Apgar scores were (median) 4 at 1 min and increased to 7 at 5 min, and 8 at 10 min of age. The median duration of ventilation was 2 min; 3/4 required less than 4 min, 1/10 required 10 min or more, with approximately 1/20 being ventilated for more than 30 min. Mean BD and pH in umbilical cord were 14.3 mmol/l and 7.11, respectively. After 10 min, arterial values did not show much difference with a BD of 14.1 mmol/l and a pH of 7.16, respectively. However, at 30 min of age, BD was (mean) 11.7 mmol/l and pH was 7.26. This means that heart rate is a much more sensitive indicator of the success of resuscitation than acid–base status, which normalizes very slowly. BD seems to fall 6–7 mmol/l/h during adequate ventilation and oxygenation.

To withdraw or withhold resuscitation

From the large Collaborative Perinatal Project of the National Institute of Neurological and Communicative Disorders and Stroke in the USA, it is known that very low Apgar scores for 15 min or more substantially increase the risk for severe sequel. In this study, in surviving infants with birth weight more than 2500 g, an Apgar score < 4 after 15 min or more substantially increased the risk of cerebral palsy. If the

duration of very low Apgar scores was 5 min, the rate of cerebral palsy was found to be approximately 1%; however, after 20 min, the rate had increased to 57%. As it is often problematic to estimate the duration of prenatal asphyxia, resuscitation should consequently always be carried out for a minimum of 15–20 min without response, before withdrawal. Animal studies have shown, however, that the more immature the fetus, the longer is the period of hypoxia tolerated. A preterm infant, therefore, probably tolerates a substantially longer period of hypoxia than a term infant before severe hypoxic-ischemic encephalopathy develops. On the other hand, the preterm infant has an increased risk of developing intracranial hemorrhage.

In some cases, resuscitation should be withheld. Infants with malformations incompatible with life should not be resuscitated. Many centers do not resuscitate newborn infants with gestational age of less than 23 weeks. According to the author's opinion, the following conditions represent contraindications to newborn resuscitation: anencephaly, bilateral renal agenesis, spinal muscular atrophy type I (Werdnig–Hoffmann disease) with neonatal onset, trisomy 13, trisomy 18, and other diseases/conditions not compatible with survival beyond the neonatal period or infancy. The author resuscitates and tries to stabilize all infants with a gestational age of 23 weeks or more. Often, neither the exact diagnosis nor the gestational age is known at birth. A liberal policy of resuscitation is recommended whenever doubt about the care of the individual infant exists. This allows the doctor to collect more information about the clinical status and prognosis of the child. This also allows one to inform the parents, so that they can be prepared and perhaps participate in the discussion and decisions about subsequent therapy. How much the parents should participate in the decision is debatable. Active participation in the decision process requires a thorough understanding of the prognosis of the individual child. The final formal decision, therefore, belongs to the doctor. However, each institution needs a clear policy and guidelines in these matters, so that these difficult decisions are not left to individuals.

Postresuscitation care

After a successful resuscitation, heat loss should be prevented by drying the child with dry towels. The child should be labeled and frequently checked with regard to breathing efforts, respiratory rate, color, heart rate, signs of birth injury, or malformations. If the resuscitation was brief and the situation was not too dramatic, the newborn could be monitored in the nursery, provided an adequate respiration is established. The child could be placed with the mother so that skin-to-skin contact with the mother is obtained. However, this depends on the local conditions and the possibilities for adequate observation by a trained observer.

Even if the infant is not in need of artificial ventilation following resuscitation, the child is often brought to the intensive care unit for further close follow-up, which includes monitoring of the heart rate, ventilation, and determination of arterial pH, blood gases, and electrolytes. Any hypotension should be treated with volume expanders or pressors, appropriate fluid therapy, and seizures treated according to standard guidelines. During the first hours following the resuscitation, the newborn infant should be regularly screened for any hypoglycemia or hypocalcemia. Breast-feeding should be encouraged, if possible, as soon as 1 h after birth. If the resuscitation was unsuccessful and the child died, the parents need a close follow-up.

Documentation

It is useful if only one attending person observes and immediately writes down the procedures followed. A thorough documentation in the medical record of all observations and actions is required before the resuscitation is complete. Each institution should keep records documenting the condition and procedures carried out at birth. The important details of resuscitation to be recorded are identification of the newborn, the condition at birth (Apgar scores, etc.), procedures undertaken to initiate respiration (suctioning, stimulation, bag–mask ventilation, intubation, chest compression, oxygen, drugs, etc.), clinical observations during and after resuscitation, and identification of the resuscitation team.

Training programs in neonatal resuscitation

Birth asphyxia requires immediate availability and recognition of qualified personnel. A training program is necessary, at least at the local level. Some countries have implemented national training programs as, for instance, the successful program in India: 'Give a breath, save a life'. In the USA, AHA/AAP, through the National Resuscitation Program (NRP), provides teaching programs and courses and it is recommended that renewal take place every second year. This means continuous education for doctors, nurses, and midwives should be organized in each region/country.

Every institution that provides deliveries must develop its own standards for newborn resuscitation, and a plan of action should exist. The personnel should gain and maintain skills in newborn resuscitation by training using manikins, and an evaluation of the training is necessary.

Summary of practice and guidelines

- Approximately 3–5% of all newborn infants require resuscitation immediately after birth, which represents 4–7 million newborns worldwide every year. Resuscitation of the newly born infant, therefore, is one of the most frequent procedures carried out in medicine. Simple and clear guidelines for this procedure should exist. Training programs, identification of risk cases, and preparation for the resuscitation procedures should be part of the routine. The resuscitation itself can be divided into five steps. Not all infants requiring resuscitation go through all these steps, but the different steps of resuscitation should be clearly identified and be based on scientific evidence. Today, this is not the case, and there is obviously a need for more research in this field.
- Optimal resuscitation is a team effort. Every birth should be prepared so that adequate personnel skilled in resuscitation are present and adequate equipment is at hand. It is important that newborn infants in need of resuscitation are immediately identified and that trained personnel perform the procedures adequately.
- The asphyxiated newborn infant should be quickly evaluated and initially stabilized by drying and stimulation, proper suctioning, and positioning. Ventilation with a soft face mask and a self-inflating bag, in most cases, establishes spontaneous breathing. A small fraction of resuscitated infants only need endotracheal intubation, and data indicate that ambient air is at least as efficient as 100% oxygen for newborn resuscitation. If supplementary oxygen is used, it should be given with care and preferably simultaneously with continuous recording of arterial oxygen saturation by pulse oximetry. External heart massage and drugs are rarely needed. If there is no adequate response to the resuscitation procedure, ventilation is stopped after approximately 20 min.
- A liberal policy for initiation of newborn resuscitation is recommended. Preterm babies and those with meconium aspiration need specific guidelines. Resuscitation should be withheld in newborn infants with conditions incompatible with life; however, each institution should have its own guidelines concerning when resuscitation should be withheld or withdrawn.
- Postresuscitation care includes both the care of the newborn and the communication with the parents. Documentation of all observations and actions, as well as an adequate training program, is required in a proper resuscitation program for newborn infants.

137 Intrapartum fetal asphyxia: prediction and diagnosis

J. A. Low

Controversy is currently centered on the benefits, risks and costs of intrapartum fetal surveillance. This is appropriate, recognizing the effort that has been committed to the development and application of methods for this purpose.

These questions will not be answered until the objectives of intrapartum fetal surveillance are clearly defined. Epidemiological studies indicate that a small component of long-term morbidity, such as cerebral palsy, can be attributed to intrapartum fetal asphyxia.[1,2] It is not realistic to anticipate that intrapartum fetal surveillance and management will have a major effect on long-term morbidity.

A realistic goal of intrapartum fetal surveillance is the diagnosis of fetal exposure to asphyxia and the prevention of morbidity and mortality due to this process. Thus the outcome measure for intrapartum fetal surveillance should be metabolic acidosis in the fetus and related morbidity in the newborn in the neonatal period.

This review will discuss outcome criteria and define the magnitude of the problem in the intrapartum period. The status of technology used in clinical practice or under development to predict this outcome will be examined.

Significance of fetal asphyxia

Exposure of the fetus to asphyxia has been a concern since the first report of an association between perinatal events and the mental and physical condition of the child.[3] The need for an animal model to systematically examine the effect of asphyxia and ischemia on the fetus was recognized in the late 1940s.[4] Since that time, research studies in the fetal monkey and lamb have advanced our understanding of the significance of asphyxia to the fetus.

Fetal asphyxia of a particular degree and duration may cause brain damage. Studies of the association between fetal asphyxia and brain damage in the fetal monkey and lamb have examined the effect of anoxia,[5,6] hypoxia[7–10] and ischemia.[11] Brain damage may occur in each model. However, in every instance, brain damage did not occur until the asphyxia was severe and hypotension with cerebral ischemia was present.

The studies of hypoxia in particular have demonstrated that the majority of fetuses who experience an asphyxial exposure do not have evidence of brain damage. This is due in part to the cardiovascular response of the fetus. The concept of fetal compensation has been established on the basis of studies in the fetal lamb. The effect of fetal asphyxia due to maternal hypoxemia,[12,13] reduced uteroplacental blood flow[14,15] and cord occlusion[16,17] on fetal cardiovascular function have been examined. There is a centralization of the fetal circulation with increased blood flow to the brain, heart and adrenal glands.

This cardiovascular response with increased cerebral blood flow is important to the integrity of the central nervous system during the compensatory phase. Cerebral oxygen metabolism is maintained because of the combination of increased cerebral blood flow and oxygen extraction and decreased oxygen requirements.[18] However, if the asphyxial exposure continues, decompensation with a progressive metabolic acidosis and a fall in arterial pressure will occur. The combination of hypoxemia and cerebral ischemia due to hypotension results in a marked reduction of cerebral oxygen metabolism, leading to cerebral dysfunction and brain damage.

This pathophysiological sequence of events is summarized in Figure 137.1. The important feature of anoxia is the short duration of the sequence of events with limited compensation prior to the threshold of brain damage. On the contrary with hypoxia, compensation may continue for variable periods (hours) before the threshold of decompensation leading to brain damage is reached.

Diagnosis of fetal asphyxia

A Task Force set up by the World Federation of Neurology Group defined asphyxia as a condition of

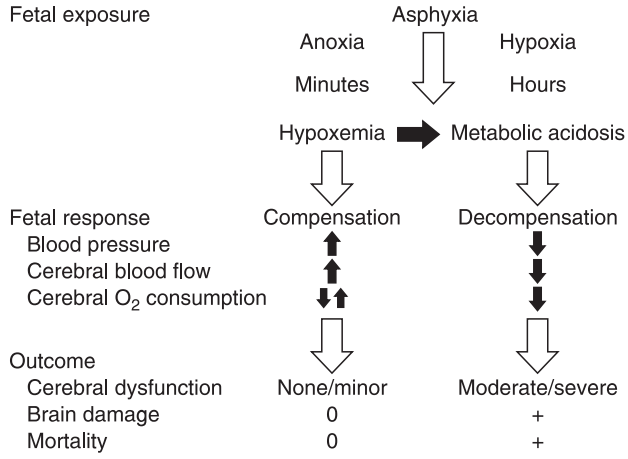

Figure 137.1 The pathophysiological sequence of events after exposure to asphyxia.

impaired blood gas exchange, leading, if it persists, to progressive hypoxemia and hypercapnia.[19] This is a good definition of asphyxia as it may affect the fetus and newborn. However, this may occur in a transient fashion which, although of physiological interest, has no pathological significance. Additionally, hypercapnia and respiratory acidosis alone do not account for organ system dysfunction or damage.[20] Significant fetal asphyxial exposure, leading to tissue oxygen debt with accumulation of fixed acids, results in a metabolic acidosis. Thus, for intrapartum fetal asphyxia, the following addition is proposed for this definition:

> Fetal asphyxia is a condition of impaired blood gas exchange leading to progressive hypoxemia and hypercapnia with a significant metabolic acidosis.

The diagnosis of intrapartum fetal asphyxia requires a blood gas and acid–base assessment. The important question is the threshold of a metabolic acidosis beyond which fetal morbidity or mortality may occur.

Umbilical vein and artery blood gas and acid–base measures at delivery represent valuable reference points of asphyxial exposure during labor. The umbilical vein reflects the effectiveness of maternal fetal blood gas exchange while the umbilical artery reflects the acid–base status of the fetus. The introduction of microelectrode blood gas systems has provided the opportunity to examine these measures in all pregnancies at delivery without risk to the fetus and newborn. Reference data for these measures in the umbilical vein and artery for 21,744 deliveries in our center are presented in Table 137.1.

Umbilical vein and artery acid–base status, and in particular the assessment of umbilical artery metabolic acidosis, is the most valuable indicator of fetal exposure to asphyxia during labor. Recognizing the importance of this measure, the Plymouth group was the first to emphasize the need for quality data to provide the basis for interpretation.[21] Several procedural and technical errors may occur during umbilical cord blood sampling and subsequent blood gas analysis.

Table 137.1 Mean blood gas and acid–base measures for 21,744 deliveries

	Umbilical vein		Umbilical artery	
	Mean	SD	Mean	SD
pH	7.340	0.07	7.248	0.069
pco_2	40.4	7.7	54.5	9.7
po_2	27.2	6.1	15.1	5.1
Base deficit	3.0	2.7	6.8	3.2

Table 137.2 Quality assessment of umbilical cord blood gas and acid–base data

	n	%
Single umbilical vein sample		
Single sample	1671	7.7
Two samples, single vessel	290	1.3
Paired samples, pco_2 error		
pco_2 outside physiological range	32	0.1
Artery–vein $pco_2 \leq 0$ mmHg	165	0.7
Artery–vein pco_2 1–3 mmHg	255	1.2
Paired samples, satisfactory criteria	19,931	89

Optimal interpretation requires a paired sample from both umbilical vein and artery. A single sample from the umbilical vein will define venous metabolic state but cannot rule out an arterial metabolic acidosis. During sampling, two aliquots may be drawn from the umbilical vein. Such a procedural error is implied when the vein–artery pH difference is less than 0.02. The accuracy of the calculated measures of metabolic acidosis is dependent upon the quality of the pH and pco_2 estimations. The accuracy of the pco_2 estimation should be questioned when the pco_2 value is outside the physiological range or the pco_2 artery–vein difference is a negative value or less than 4 mgHg. In these circumstances, the interpretation should be limited to pH alone. A review of our data in Table 137.1 indicated possible procedural or technical errors in 11% of the samples examined (Table 137.2).

Because of the lability of pco_2, pH is not a satisfactory proxy for metabolic acidosis.[22] Thus, an umbilical artery blood measure of metabolic acidosis is the best indicator of tissue oxygen debt experienced by the fetus. Lactate is the principal fixed acid contributing to this metabolic acidosis. However, an increase of lactate may be due to an increase of pyruvate as well as hypoxia.[23] We established an umbilical artery base deficit > 12 mmol/l as a criterion of fetal asphyxia. This represented 2 standard deviations below the mean adjusted for the component attributable to tissue oxygen debt. Whether this criterion reflects the threshold for

Table 137.3 Prevalence of significant intrapartum fetal asphyxia

UABD, umbilical artery base deficit

morbidity in the fetus and newborn has been examined in recent studies.

Fifty-nine term fetuses with a metabolic acidosis, i.e. an umbilical artery base deficit > 16 mmol/l, were matched with 59 fetuses with normal blood gas measures at delivery. Forty percent of the newborns with an umbilical artery base deficit > 16 mmol/l had moderate or severe complications in one or more of the central nervous system, cardiovascular system, respiratory system or kidney.[20] A similar association was demonstrated in a matched case–control study of preterm newborns between 32 and 36 weeks of gestational age.[24]

In view of these findings, a study was conducted to determine the threshold of metabolic acidosis. This was a matched case–control study of three groups of term fetuses based on umbilical artery base deficit at birth. The three groups were umbilical artery base deficit 12–16 mmol/l ($n = 58$), umbilical artery base deficit 8–12 mmol/l ($n = 58$) and umbilical artery base deficit 4–8 mmol/l ($n = 58$). Moderate and severe newborn complications occurred only in the fetuses with an umbilical artery base deficit > 12 mmol/l. The incidence of moderate and severe complications with an umbilical artery base deficit 12–16 mmol/l was 10%.[25] There is a progression of frequency of such complications with increasing metabolic acidosis, as noted in the study reported above, with a 40% incidence of moderate and severe complications when the umbilical artery base deficit was > 16 mmol/l.

These studies would support the contention that the threshold of fetal metabolic acidosis beyond which moderate or severe newborn complications *may* occur is an umbilical artery base deficit > 12 mmol/l.

The magnitude of the clinical problem is determined by the prevalence of a significant metabolic acidosis (Table 137.3). Approximately 20 fetuses per 1000 births will have a metabolic acidosis at delivery which exceeds the threshold for morbidity. The probability is greater in five fetuses per 1000 deliveries who have a metabolic acidosis with a base deficit > 16 mmol/l. The best measure of morbidity after intrapartum fetal asphyxial exposure is newborn cerebral dysfunction, expressed by moderate or severe newborn encephalopathy. Based upon our experience, the prevalence of intrapartum fetal asphyxia with a significant metabolic acidosis and moderate or severe newborn encephalopathy is of the order of three per 1000 births. Cerebral dysfunction does not necessarily imply brain damage with subsequent major handicap. A meta-analysis of the best available studies indicates that deficits due to brain damage occur in 20% after moderate newborn encephalopathy and 80% after severe newborn encephalopathy.[26] This implies a prevalence of intrapartum fetal asphyxia with brain damage in approximately one to two per 1000 births.

Prediction of intrapartum fetal asphyxia

The clinical paradigm which has been widely used combines clinical risk scoring with fetal heart rate surveillance to identify the fetus at risk of asphyxial exposure. The diagnosis can be confirmed or ruled out by a caput sample with a fetal blood gas and acid–base assessment. This has not resolved the problem due to shortfalls of each element of the paradigm which have become evident with increasing clinical experience.

Clinical risk scoring

The limitations of clinical risk scoring have been demonstrated in two studies. The predictive value of selected clinical risk factors was examined in 1909 consecutive pregnancies (Table 137.4) and in a second population of 100 consecutive pregnancies with biochemically determined intrapartum fetal asphyxia.[27] A second study examined the association between clinical risk factors and pregnancies resulting in a perinatal death with evidence of brain damage due to fetal asphyxia on postmortem examination.[28] These studies highlighted two points.

Fetal exposure to asphyxia occurs in pregnancies with no clinical risk factors. This occurred in 23% of the pregnancies studied to assess the predictive value of risk factors and in 35 of the 100 consecutive pregnancies with biochemically determined intrapartum fetal asphyxia. In the review of the perinatal mortality with postmortem evidence of brain damage due to antepartum or intrapartum fetal asphyxia, approximately 40% of the pregnancies had no clinical risk factors.

In those cases in which clinical risk factors were present, risk was determined by a wide range of clinical complications, with no single risk factor demonstrating a strong association with intrapartum fetal asphyxia. The positive predictive value for both antepartum and intrapartum risk factors for intrapartum fetal asphyxia was 3%. This low predictive value was true for all risk factors. Thus clinical risk scoring has a major problem with false-positive prediction of intrapartum fetal asphyxia.

Thus, the first step in the fetal assessment paradigm has not been validated. All pregnancies are at risk for this complication. The term 'low risk' based on clinical markers cannot be applied in regard to fetal exposure to asphyxia during labor. A number of clinical markers, such as antepartum hemorrhage, pregnancy-induced hypertension, fetal growth retardation and meconium in the amniotic fluid, are associated with a modest increased risk. However, in each case, the positive predictive value is low.

Fetal heart rate surveillance

Fetal heart rate observations began early in the 19th century with intermittent auscultation. Subsequently, continuous electronic fetal heart rate monitoring has been developed during the 20th century.[29] It has been difficult to determine if this surveillance has contributed to a decrease of fetal mortality or morbidity due to asphyxia.

Evidence has been presented to indicate that the introduction of electronic fetal heart rate monitoring has been associated with a reduction in the number of intrapartum fetal deaths.[30,31] However, mortality has not been resolved. Intrapartum fetal deaths continue to be reported in randomized clinical trials and in studies of perinatal mortality of stillbirths and early neonatal deaths after fetal asphyxia. In the last UK Confidential Enquiry into stillbirths and death in infancy, 9% of all deaths between 20 and 44 weeks of gestation were related to labor and, of the normally formed babies weighing at least 2500 g, 4.3% could be linked to intrapartum events.[32]

There is no evidence that fetal heart rate surveillance has been associated with a decrease in long-term morbidity as expressed by brain damage and cerebral palsy. The evidence of an association between abnormal fetal heart rate patterns and subsequent neurological abnormality has been limited.[33,34] A matched case–control study in our center examined the heart rate of fetuses with no metabolic acidosis at delivery who had a motor and cognitive assessment at 1 year. There was no difference in the fetal heart rate characteristics during the last 2–4 h of labor between the children with and without motor and cognitive disability at 1 year (unpublished data). Rosen and Dickinson[35] failed to find consistent fetal heart rate patterns that would predict brain injury. The authors concluded that these findings should not be surprising because the majority of brain damage occurs outside the intrapartum period.

A role for fetal heart rate surveillance to predict fetal metabolic acidosis holds greater promise. Laboratory studies in the fetal lamb and monkey have demonstrated a relationship between fetal heart rate behavior and fetal hypoxemia and metabolic acidosis. Late decelerations have been shown to occur when fetal oxygen tension decreases below a critical level. The interval between the onset of the contraction and the onset of the deceleration reflects the time necessary for fetal oxygen tension to fall below this threshold.[36–38] Late decelerations due to fetal hypoxemia in a previously normoxic fetus are due to chemoreceptor initiated reflex bradycardia which can be blocked by atropine, while in previously hypoxic fetuses the bradycardia is presumably due to a direct effect upon the myocardium.[39,40] The interpretation of heart rate variability by studies in the fetal lamb has been confounded by an apparent species difference. The late gestation sheep fetus consistently and reliably experiences an increase of heart rate variability with acute hypoxemia with or without acidosis.[41] In contrast, the hypoxemic human fetus generally exhibits a decrease of fetal heart rate variability.[42,43]

Two clinical studies have demonstrated an association between decreased baseline variability and late and prolonged decelerations and fetal metabolic acidosis at delivery.[44,45] An algorithm of three fetal heart rate patterns were defined on the basis of the presence of these fetal heart rate variables in six 10-min cycles in 1 h (Table 137.5). The sensitivity of this algorithm was good identifying 75% of fetal asphyxia and 96% of moderate and severe fetal asphyxia. The positive predictive value of the predictive fetal heart rate pattern was 90%. However, the positive predictive value of potentially predictive patterns ranged from 5% to 10%. The striking number of false positives for potentially predictive patterns represents the outstanding problem in the use of fetal heart rate surveillance as a screening test for intrapartum fetal asphyxia.

Well-designed, randomized, controlled trials are proposed as a means of minimizing selection bias and providing a measure of the true risks and benefits of a medical intervention. There have been no randomized clinical trials to compare fetal heart rate surveillance with intermittent fetal heart rate auscultation. The randomized clinical trials comparing intermittent auscultation and continuous electronic fetal heart rate

Table 137.5 Predictive and potentially predictive fetal heart rate patterns for intrapartum fetal asphyxia

	Baseline variability (cycles/h)		Decelerations late/prolonged (cycles/h)
Predictive	Absent ≥1	+	≥2
Potentially predictive	Minimal ≥2	+	≥2
	Minimal ≥2	or	≥2

monitoring have not demonstrated that continuous electronic fetal heart rate monitoring was associated with a decrease of fetal and newborn morbidity. Two factors have confounded these studies. The prevalence of intrapartum fetal asphyxia with cerebral dysfunction or brain damage is low. The magnitude of the randomized trials to date has not been sufficient to discriminate this infrequent outcome. The largest trial reported a decrease of newborn encephalopathy but not cerebral palsy.[46] The study protocols in these trials have modified clinical management by providing one-to-one support of care, assuring continuous surveillance during labor, a circumstance which, although widely advocated, is rarely achieved in clinical practice.

The randomized clinical trials have made an important contribution, confirming the occurrence of false-positive interpretation of electronic fetal heart rate recording, with unnecessary interventions. Nine randomized clinical trials, three with electronic fetal monitoring alone and six with electronic fetal monitoring with scalp sampling, have been analyzed in the Cochrane Pregnancy and Child Birth Database.[47,48] These studies have demonstrated that electronic fetal heart rate monitoring in relation to intermittent auscultation has been associated with increased incidence of cesarean section for fetal distress and dystocia, increased operative delivery and general anesthesia. It must be recognized that these outcomes are not due to the method of fetal heart rate surveillance but are a result of inappropriate interpretation of the fetal heart rate data.

The continuing use of fetal heart rate surveillance must recognize these limitations, i.e. some cases of asphyxial exposure will be missed and a large number of false positives must be clarified in order to avoid unnecessary intervention. Additionally, it is important that the quality of the fetal heart rate data be adequate for interpretation. This requires an optimal signal, recognition of interpretation problems and a satisfactory assessment protocol.

The data provided for interpretation by continuously recorded electronic fetal heart rate are superior to intermittent auscultation.[49] Interpretation of baseline variability can only be achieved from continuously recorded data interpreted either visually or by computer. The quality of the data must be adequate for interpretation. The ultrasound fetal heart rate signal and the tocodynometer have provided an attractive non-invasive option. These methods provide a good signal but not necessarily consistently. This is particularly true for the tocodynometer. A scalp electrode and an intrauterine catheter should be used in such circumstances.

Differences of classification criteria, decelerations in particular, remain. Classifications of late decelerations have, on the one hand, given first priority to the timing of the nadir of the deceleration, while others have emphasized the waveform. Interpretation of the waveform has focused on the onset to the nadir[50] or examined the residual component of the waveform.[51,52] Efforts to quantify decelerations are continuing.[53,54] Until a consensus is developed, criteria used in clinical practice should be clearly defined and consistently applied.

Encouraging progress has been made on computer-based programs for the interpretation of fetal heart rate patterns. However, the vast majority of clinical records are read visually. The limited interobserver reliability for the visual interpretation of fetal heart rate patterns has been well documented.[55] A study has been recently completed in our program. The interobserver reliability *k* values were: baseline fetal heart rate 0.70, baseline variability 0.55, accelerations 0.56, variable decelerations 0.46 and late decelerations 0.57. However, the interobserver reliability for an abnormal fetal heart pattern over 1 h of recording, based upon the presence of decreased baseline variability and/or late decelerations, was good. This experience supports the practice of defining patterns rather than assessing individual fetal heart rate variables.

There is no consensus in regard to the protocol for fetal heart rate assessment. Since low-risk and high-risk pregnancies for fetal asphyxia cannot be defined, fetal heart rate screening must be available for all patients. Since the objective of fetal heart rate screening is the prediction of asphyxial exposure, surveillance should begin early in labor with continuous recording of reasonable duration to permit interpretation. Visual interpretation requires that the fetal heart rate be carefully scored to establish the presence of abnormal patterns over a period of time.

Two clinical interventions have been advocated as options to improve the specificity of abnormal fetal heart rate patterns. Vibroacoustic stimulation with an acceleration response has been proposed as a sign of fetal reactivity and as a means of ruling out fetal acidosis in the presence of fetal heart rate patterns with decreased baseline variability and late decelerations with no accelerations.[56] However, subsequent reports of the predictive value of vibroacoustic stimulation have been equivocal.[57–59] A number of trials of amnio-infusion, particularly in the presence of oligohydramnios, have demonstrated a beneficial effect, relieving variable decelerations and reducing the rate of cesarean section for fetal distress.[60–64] These clinical interventions require further investigation.

Complementary technologies

The assessment of the fetal electrocardiographic (ECG) waveform is an attractive option since the signal can be obtained from the same fetal scalp electrode used for recording the fetal heart rate. It is possible to study the waveform in detail with appropriate filter characteristics and signal processing.[65] The time segments of ECG waveforms studied have included the ST segment and the PR interval.

Laboratory studies have examined the effect of hypoxemia and acidosis on the ST segment. In studies of acute hypoxemia, the ratio of the T-wave height to QRS height increased.[66–69] However, the results have not been consistent. ST segment depression with negative T-waves has been observed in experimentally growth-retarded guinea-pigs.[70] Slowly developed acidemia in fetal lambs was not detected by ST waveform analysis.[71]

Preliminary clinical observations suggested caution in the interpretation of ST waveforms.[72] Newborns with acidosis have had T/QRS ratios in the normal range.[73] Weak relationships have been reported between T/QRS ratios and fetal academia.[74,75] The recent development of higher-order FHR analysis has provided monitoring systems that can add automated fetal ECG ST segment analysis to the standard FHR and uterine contraction information which have been applied in a number of clinical trials. The result of the first trial was a 46% reduction of operative deliveries for fetal distress without change in newborn outcome.[76] Meta-analysis of two large randomized clinical trials of fetal heart rate assessment with the support of ST waveform analysis have shown that the number of babies born with metabolic acidosis at delivery could be reduced in conjunction with a reduction of operative deliveries for fetal distress.[77]

Laboratory studies of acute hypoxemia and fetal acidemia have demonstrated a conversion from negative relationships between the PR interval and the fetal heart rate to a positive relationship.[69,78] Preliminary observational studies and a randomized clinical trial suggest that this observation may be of value in the assessment of the human fetus during labor.[79,80]

Pulse oximetry provides a non-invasive measure of oxygen saturation which has proven of great value in patient surveillance in anesthesia and critical care. Fetal pulse oximetry is being developed for intrapartum assessment.[81,82]

Fetal pulse oximetry must have an acceptable level of precision and accuracy in measuring oxygen saturation. There have been technical problems unique to the fetus. The fetal signal is much smaller. The light-emitting diodes are placed in reflective rather than transmission mode. The sensor contact with the skin must be a good site free of hair. Progress has been made and the precision of newer prototypes has been encouraging.[83] The validation of the accuracy of pulsatile oxygen saturation measures in the human fetus is difficult. An encouraging correlation has been reported between pulse oximetry oxygen saturation and scalp blood oxygen saturation with cord vein oxygen saturation.[84,85]

Prospective clinical trials of pulse oximetry require a critical threshold of oxygen saturation. Chronic hypoxemia studies in fetal lambs have demonstrated that normal acid–base status in terms of pH and base deficit is maintained until oxygen saturation approaches 30%.[86,87] Data from the human fetus are limited. There is a decrease of fetal oxygen saturation during labor.[82,88] An examination of the relationship of a 30% threshold with pH in umbilical cord blood reported an encouraging sensitivity but poor specificity.[89] Carefully controlled clinical trials are required before this promising technology can be used as an adjunct to electronic fetal heart rate monitoring in intrapartum fetal assessment.

Near infrared spectroscopy has been used to provide quantitative data of cerebral oxygenation and hemodynamics in the newborn infant.[90] Near infrared spectroscopy is being developed as a means of continuous, non-invasive real-time measurement of change in fetal cerebral oxygenation and hemodynamics during labor. Preliminary reports of the application of this technology for fetal assessment during labor have been published.[91,92] There is some evidence of a correlation with pulse oximetry oxygen saturation during labor[91] and with acid–base status at delivery.[93] However, much research remains to be done before this technology can be considered for intrapartum fetal assessment. The outstanding issues have been reviewed recently.[94] These include the satisfactory maintenance of fetal contact of the sensor, confounding factors affecting the measurements and normative data during labor.

Fetal blood gas and acid–base assessment

The diagnosis of fetal asphyxia requires a blood gas and an acid–base assessment with evidence of a significant metabolic acidosis. An assessment can be carried out on fetal capillary blood obtained by scalp sampling during labor or in umbilical vein and artery blood at delivery. Such an assessment can confirm or rule out a metabolic acidosis.

The limitations of fetal sampling and blood gas and acid–base assessment are well known. This assessment provides a measure at one point in the continuum of labor and delivery. Continuous rather than intermittent assessment of acid–base status would be an optimal method of fetal surveillance. However, pH electrodes tested in recent years have had to contend with technical difficulties and artifacts.[95,96] Thus, this

option is not available for clinical practice at the present time. The second problem is that fetal scalp sampling may not be technically feasible in early labor, while later in labor the procedure is invasive with a small but significant risk. This is a constraint in regard to repeated sampling in a fetus with a developing metabolic acidosis during labor and the frequent sampling required to clarify false-positive abnormal fetal heart rate patterns.

Discussion

Intrapartum fetal asphyxia is important to the fetus and newborn. Laboratory studies in the fetal monkey and lamb have established that a single severe episode of asphyxia accompanied by cardiovascular decompensation with cerebral ischemia can cause brain damage.

The responsibility of the obstetrician is early recognition to prevent morbidity and mortality. Clinical studies have established that asphyxial exposure with a significant metabolic acidosis occurs in approximately 20 per 1000 births. The key to understanding the significance of an asphyxial exposure is expressed by the equation:

Fetal asphyxial exposure + fetal response = outcome

The majority of fetuses are not compromised because of the fetal compensatory response to the asphyxial exposure. This fact provides the window of opportunity for the obstetrician to make a precise diagnosis of fetal exposure with a developing metabolic acidosis and to intervene before fetal compromise has occurred. Based on the animal studies, this window ranges from minutes to hours subject to the severity and nature of the asphyxial exposure. There is reason to speculate that, during labor, in most cases the asphyxial exposure is relative in degree and intermittent in nature. Thus, the window of opportunity to predict and diagnose asphyxial exposure tends to be longer rather than shorter.

Fetal exposure with fetal decompensation does occur. Clinical studies indicate that morbidity after fetal asphyxia is uncommon with cerebral dysfunction in three per 1000 births and brain damage in one to two per 1000 births. The responsibility of the neonatologist is early diagnosis, continuing assessment, and management of the newborns to minimize morbidity. Within the foreseeable future, medical interventions may be available to interrupt the cascade of biochemical events leading to neuronal death in order to minimize brain damage.

An appropriate objective for intrapartum fetal asphyxia would be to reduce the incidence of fetal exposure from 20 to 10 per 1000 births and prevent asphyxial exposure with cerebral dysfunction and brain damage. There is little evidence that intrapartum fetal surveillance has achieved such a goal, while the modest specificity of current methods has led to an increase of unnecessary interventions. This can be attributed to the limitations of current assessment protocols and technology.

Clinical risk scoring of pregnancies for intrapartum asphyxia has not proven to be of benefit. Asphyxial exposure occurs in pregnancies without clinical risk factors, while relevant risk factors have limited predictive value. Thus fetal heart rate assessment has become the primary method of screening for intrapartum asphyxia. Fetal heart rate patterns of decreased baseline variability and late decelerations have predictive value. However, the sensitivity is modest with 25% of fetal exposures not identified, while specificity is poor with a large number of false-positive fetal heart rate patterns requiring clarification. Fetal acid–base assessment will provide a definitive diagnosis. However, these measures provide a measure at one point in the continuum of labor and delivery.

The significance of fetal asphyxia justifies continuing efforts to improve the predictive sensitivity and specificity of intrapartum fetal surveillance protocols. Fetal heart rate surveillance has predictive value and should continue. However, the limitations must be recognized. In order to be a useful predictor, quality data beginning early in labor and of sufficient duration to permit interpretation are required. Satisfactory interpretation requires standardized criteria with well designed assessment protocols which can serve as a basis of ongoing evaluation of this method. It is widely acknowledged that fetal heart rate surveillance will require supplementary assessment methods to improve sensitivity and specificity of prediction. The role of fetal ECG waveform analysis and pulse oximetry is being examined. Near infrared spectroscopy is at a much earlier stage in development. These complementary measures are not yet ready for use in clinical practice.

The liberal use of fetal blood gas and acid–base assessment must be entertained until the predictive characteristics of current screening modalities have improved. Routine umbilical vein and artery blood gas assessments at delivery ensure that all asphyxial exposures during labor are identified. This is a valuable outcome measure for intrapartum fetal assessment and ensures that the neonatologist is forewarned of all newborns that have experienced an asphyxial exposure during labor. Periodic fetal scalp sampling and acid–base assessment during labor represent the only definitive methods to confirm that a suspected fetal exposure is occurring or to establish that an abnormal fetal heart rate pattern represents a false-positive prediction.

138 Cardiotocography

H. P. van Geijn

Introduction

Until the second half of the 20th century, assessment of the fetal condition depended on very limited information: the growth of the uterus and its contents, the movements of the fetus perceived by the mother and listening to the fetal heart beat with a mono- or biauricular stethoscope.[1] Sudden absence of fetal movements in the second half of pregnancy was, at that time, not only a very emotional but also a serious diagnostic problem. Usually one had to wait for some weeks in order to observe any growth of the uterus before the decision could be reached to induce labor. The Spalding's sign at x-ray examination, showing overlapping of the fetal skull bones like roof tiles as a result of advanced maceration of the fetal tissues, was one of the few helpful objective diagnostic signs of fetal demise.

This recurrent dilemma of whether or not the fetus had died *in utero* formed the major impulse for the development of cardiotocography.[2] Initially, fetal abdominal electrocardiography and phonocardiotocography were experimented with, but failed, primarily due to technical problems.

It was only when the fetal heart beat was found to be detected easily by means of ultrasound (the Doppler-shift) or through the application of direct electrocardiography that cardiotocography became popular as the method for monitoring the condition of the fetus. Currently, the majority of obstetric decisions to assist delivery of the baby by artificial means (cesarean section, forceps or vacuum extraction) for reasons of suspected fetal distress rely on information gathered through the application of cardiotocography.

It is the confirmation that the fetal heart rate (FHR) pattern is normal and, therefore, the near 100% certainty that the fetus is in a good condition, which have made cardiotocography so attractive and have encouraged its widespread use. This development is very understandable considering the dependence on indirect signals from the fetus and the problems mentioned above concerning the very limited means of monitoring the condition of the fetus prior to the introduction of cardiotocography. However, now cardiotocography has been in use for some decades, criticism of the method itself and objections to its widespread application are increasing (Table 138.1). These criticisms and objections will be discussed in more detail and an attempt made to reach a more meaningful conclusion.

The normal and abnormal fetal heart rate pattern

The normal FHR pattern is characterized by a baseline frequency of between 110 and 150 beats/min, presence of periodic accelerations, a normal heart rate variability with a bandwidth of between 5 and 25 beats/min and the absence of decelerations.[3] In this regard, the importance placed on the 120 and 160 frequencies is misleading. It originates from the second half of the 19th century when the normal frequencies were stated by Von Winckel to be between 120 and 160 beats/min.

The FHR pattern is abnormal when one or more of the following features are observed: a baseline

Table 138.1 Criticisms of cardiotocography

Insufficient understanding of the (patho)physiological background
Too indirect a signal of the fetal condition
Number of technical pitfalls
Differences in recording techniques
Primarily qualitative information (pattern recognition)
Lack of uniform classification systems
Confusion due to the many influences on the fetal heart rhythm
Substantial intra- and interobserver variation regarding the interpretation
Low validity, high incidence of false-positive findings
Primarily screening method, too often applied as a diagnostic
Leads to an increase in artificial deliveries
Lack of agreement on how, when and whom to monitor
Contributes to medico-legal vulnerability

frequency of below 110 or above 150 beats/min, absence of accelerations for more than 45 min, decreased or absent FHR variability and the existence of repeated variable or late decelerations. A baseline frequency between 100 and 110 can be considered as normal when the duration of pregnancy has exceeded 41 weeks.

Are the criticisms of cardiotocography justified?

In recent years cardiotocography has been criticized for a number of reasons. A far from complete summary is given in Table 138.1. The criticisms have a very diverging character. Each of them will be commented on in the following sections.

The FHR pattern is too indirect as a signal of the fetal condition

The (patho)physiological background of the fetal heart rhythm is extremely complex.[4] Blood pressure, cardiovascular regulation, the condition of the autonomic and voluntary central and peripheral nervous system, respiration, temperature regulation, the renin–angiotensin system, the functioning of the adrenals, endocrine mechanisms, the cardiac conduction systems, the condition of the vessel walls and cellular processes all contribute to the shape of the heart rate pattern recorded on paper or a visual screen. Under normal circumstances the FHR pattern primarily represents the state of the central nervous system, i.e. the 24-h (circadian) rhythms and the cycling of behavioral states (ultradian rhythms). When the condition of the fetus is being threatened there is a shift to a more likely representation of disturbances in the regulation of the blood pressure and the cardiac performance, and ultimately a direct influence on the fetal heart.

Artificial occlusions of the umbilical cord circulation and the uterine circulation in animal experiments have contributed to a better understanding of the various aspects of the FHR pattern under pathological circumstances. The human situation is far more complex however: successive uterine contractions vary in duration and intensity; the position of the human fetus may change; the amount of amniotic fluid varies from fetus to fetus; occlusions of the uterine circulation, umbilical vessels and/or placental circulation can be absent, be partial or even be total; and the circulation in the umbilical vein and/or one or both umbilical arteries can be affected. These are just a few of the many combinations on the circulatory level that may occur when the fetal condition is threatened. Next there are the many complex variations regarding the biochemical status of the fetus, in particular the state of the acid–base balance. It should be remembered that depth, duration and shape of variable decelerations have no direct relation to the acid–base balance of the fetus at a particular moment.[5]

Differences in technique

For a correct understanding of the FHR pattern as recorded on paper or a screen, it is essential to understand the technical procedures involved with the acquisition and processing of the heart beat signal obtained through ultrasound or direct electrocardiography.[6] The cardiotocographic equipment has been improved markedly since the introduction of cardiotocography. Nevertheless, some technical problems have never been fully resolved: some artificial FHR variability, halving and doubling of heart rate frequencies, no recording made of cardiac arrhythmias with Doppler ultrasound and recording of the maternal instead of the FHR frequency. The major problems, however, occur in clinical practice. There is no uniform opinion regarding the preferred paper speed. Recording speeds vary from 1 to 2 to 3 cm/min, depending on the obstetric unit. A low paper speed facilitates the overview of a recording but has definite disadvantages: 'long-term' FHR variability is artificially accentuated, 'short-term' variability is hardly recognizable and the time-relation between uterine contractions and decelerations is more difficult to assess.

The many influences of the FHR pattern

The healthy near-term fetus demonstrates a characteristic FHR pattern with continuous cycling of a 'reactive' and a 'non-reactive' FHR pattern representing the cycling of the sleep states 2F [rapid eye movement (REM)-sleep, active sleep] and 1F (non-REM-sleep, quiet sleep).[7] This cycling is interspersed, in particular around midnight, with periods of fetal activity (jogging) accompanied by recurrent accelerations sometimes mimicking fetal tachycardia. The maximum duration of a 1F state is 45 min in a healthy fetus.

When pregnancy advances, accelerations increase in number, duration and amplitude. Variability increases during the 2F states, but is nearly constant after 26 weeks of gestational age in 1F states.[8] The variability in the 1F states primarily relates to the absence or presence of clusters of regular mouthing movements (associated with oscillations!) or breathing movements (associated with short-term variability!).[9] FHR variability may vary from day to day and week to week in the individual fetus.[8]

Interpretation of a cardiotographic tracing is particularly difficult early preterm. In general, the decision to start cardiotocography is determined by a serious obstetric problem such as the presence of intrauterine growth restriction, rupture of membranes, vaginal blood loss or pregnancy-induced hypertension.

Interpretation then is not only more difficult because of the age of the fetus and the presenting obstetric problem, but also because of the use of maternally administered medication. Betamimetics increase the baseline FHR and are associated with a decrease in FHR variability. Magnesium sulfate causes a decrease in FHR variability. Antihypertensives may cause tachycardia, bradycardia, flattening of the accelerations or a decrease in variability. Bethamethasone, contrary to dexamethasone, leads to a decrease in the incidence of fetal body and breathing movements and concomitantly a decrease in the number of accelerations and diminished variability.[10]

High intra- and interobserver variability

Reading, classification and interpretation should be the successive steps in the assessment of cardiotocographic tracings. Often, too easily a conclusion is reached in (vague) terms of a suspicious, pathological, ominous or terminal FHR pattern.

The high intra- and interobserver variability concerning the classification and interpretation of FHR patterns has been substantiated in a large number of publications. Assessment of the baseline frequency and the presence or absence of accelerations and decelerations is rather uniform, but lacks any uniformity when FHR variability and deceleration types are concerned.[11] Easy, exact guidelines as to how to determine and interpret FHR variability are lacking. It appears that in daily obstetric practice variable decelerations far too often are classified as early or late decelerations, merely on the basis of the time-relation between the associated uterine contraction and the deceleration. The typical characteristics of the variable decelerations are that they vary in shape, duration and depth and, on this basis, nearly all decelerations occurring during labor should be classified as being of the variable type.[12] The 'shouldering', i.e. the increase in FHR prior to and following a variable deceleration, can incorrectly be interpreted as an acceleration. Their monotonous and recurrent character is, however, very different from the irregularly spaced accelerations occurring in association with fetal body movements. Recurrent increases in the FHR during uterine contractions should raise suspicion that the (umbilical) venous circulation is being obstructed.

The low validity, high false-positive rate

The low validity of cardiotocography has been concluded from a very limited number of earlier performed randomized studies, in which cardiotocography was compared with intermittent auscultation. These studies suffer from a number of serious drawbacks and inadequacies concerning patient selection, sample size, randomization procedures, in- and exclusion criteria, the knowledge of the responsible obstetricians as to how to classify and interpret cardiotocographic tracings and the comparability of the applied intermittent auscultation with daily obstetric practice (dedicated nurses participated in the auscultation groups).

A major problem with these and other studies aiming to assess the validity of cardiotocography and related procedures is the lack of solid endpoints concerning the fetal condition. One of the few hard endpoints is the status of the acid–base balance in arterial and venous cord blood, often applied to assess justification of artificial deliveries for reasons of suspected fetal distress. The primary aim of obstetric interventions in this regard is, however, to prevent fetal distress and as such these measures are not very helpful in assessing the adequacy of obstetric management in individual cases.

Cardiotocography increases medico-legal vulnerability

Ultrasonography and cardiotocography have been named as the 'minefields of obstetrics'. In contrast to antepartum monitoring, it is the intrapartum application of cardiotocography which may lead to litigation. The knowledge that their baby was in a good condition at the start of the birthing process is for parents an unbearable thought when the baby suffers from handicaps in later life which may possibly relate to the occurrence of fetal distress during the process of labor and delivery. The consumers, supported by legal experts, expect from the obstetrician not so much that she/he diagnoses fetal distress, but that a serious threat to the fetal condition is being avoided, certainly if it concerns a child with full potential for later life. The layman wonders why obstetricians do not all apply the same monitoring techniques and cannot understand why FHR patterns cannot be classified and interpreted uniformly.

The medico-legal vulnerability associated with the application of cardiotocography and other monitoring techniques is a very complex area.[13] Many aspects are involved, such as the time path followed, the standard of care at a certain moment, the preceding training experienced, the chain of command at a certain moment, the limitations of indirect information, uncertainty when damage to the infant occurred, the confusing nomenclature in use and the lack of exact definitions and guidelines. Nearly all cases are discussed 'in retrospect' knowing the fatal result of a particular case. Laymen have little understanding of peak loads in clinical care, the time span necessary before conclusions can reasonably be reached and the intensity of communication prior to a secondary cesarean section. The consumers demand optimal care at each moment in order to maximize future potentials for their child. They exert more and more pressure on decision making and easily push for a cesarean section when the condition of their child might be endangered.

Cardiotocography leads to an increase in obstetric interventions

One of the objections toward electronic fetal monitoring is that the widespread application has induced an increase in the number of obstetric interventions, in particular the incidence of cesarean sections. Randomized studies in the 1970s and early 1980s have demonstrated a higher incidence of artificial deliveries when cardiotocography was compared with (dedicated) intermittent auscultation. This was especially apparent when FHR monitoring was applied in low-risk pregnancies. The adding of microblood sampling as a second mode of fetal surveillance, to assess the fetal acid–base status in case of suspicious or abnormal FHR patterns, clearly reduces the number of obstetric interventions if compared with the application of cardiotocography alone.

Following the introduction of cardiotocography, however, obstetrics and maternal–fetal medicine have developed in different directions. Certain changes in attitudes of the profession and the public have favored obstetric intervention: a shift toward a far lower gestational age at which all is done to increase chances for fetal survival and diminished neonatal morbidity, another approach toward the fetus in breech position both preterm and term, an increase in the maternal age for the first pregnancy, an increase in the number of twins and triplets, another look at the pain experienced by the mother during labor and delivery, other criteria for the duration of the birthing process, etc. The main line in obstetric policies has moved toward prevention of serious maternal and fetal risks in whatever circumstances. Large randomized studies in high-risk populations and a recent meta-analysis provide evidence of an approximate 60% reduction in perinatal mortality due to fetal distress when electronic fetal monitoring is applied as a routine in high-risk groups.[14] These and other studies support earlier recommendations to apply cardiotocography in risk groups. Risks with a potential impact on the condition of the fetus may be identified before pregnancy (hypertension, diabetes), may show up during the course of pregnancy (vaginal blood loss, early preterm rupture of membranes) or may occur during the process of labor and delivery (meconium staining, FHR decelerations). An anticipative attitude by the obstetrician taking care of the pregnant mother should always be warranted.

The future of cardiotocography

Cardiotocography was initially introduced merely on an empirical basis. At the start little was understood of the (patho)physiology at the basis of the FHR pattern, the many factors influencing the shape of the FHR pattern and the clinical implications to be drawn from ‘abnormal’ FHR patterns. A classic example is the pseudosinusoidal pattern related to fetal sucking which for a long time was not distinguished from the truly sinusoidal pattern associated with serious fetal anemia or severe fetal acidosis. The simultaneous introduction of guidelines for classifying and interpreting FHR patterns by outstanding obstetricians living on different continents (Caldeyro-Barcia, Hammacher, Hon, Maeda, Wood) has further contributed to the confusion in nomenclature and definitions, a problem which has not been resolved in mondial terms until today.

In spite of many efforts, improvements in the quality of the instrumentation, better understanding of the FHR patterns and improved recognition of the position of cardiotocography among the full arsenal of fetal surveillance techniques, the current status of cardiotocography is still at the awkward age. It certainly has not reached full maturity yet. Major weaknesses are found in its application. Differences in paper speed, lack of uniform and exact definitions, uncertainties regarding how, when and whom to monitor, problems with storage of cardiotocographic tracings, uncertainty if and when fetal microblood sampling should be applied, the generally very limited training of those who are directly involved with fetal monitoring and the lack of guidelines on how to handle the great variety of (often complex) clinical circumstances are just a few of the problems which have weakened the position of cardiotocography as a monitoring technique. Another aspect is the department’s organization regarding responsibilities at various locations, i.e. the outpatient clinics, the antenatal clinics and the labor and delivery unit. Are

Table 138.2 Improvements in cardiotocography

Further understanding of (patho)physiology
Knowledge of technical pitfalls
Uniform paper speed, vertical scaling
Knowledge of the many factors influencing fetal heart rate (FHR) patterns
Knowledge of all relevant clinical data
Discipline in reading, classification and interpretation of FHR patterns
Recognition that cardiotocography is an indirect parameter of fetal condition
Recognition that cardiotocography is only one parameter of fetal condition
Recognition that cardiotocography is only a screening technique
Disposition of maximal possible information (microblood sampling)
Availability of protocols how, when and whom to monitor
Availability of quantitative, objective FHR analyses
Digital storage of fetal heart rate data
Systematic pre- and postgraduate training

there solid and uniform arrangements and can one trust that they are continuously followed by each and every member of the department? Ways in which cardiotocography could be improved are shown in Table 138.2.

A computerized system permitting digital processing and storage of all FHR data has a number of potential advantages: the availability of quantitative information including analysis of trends, easy retrieval of relevant cardiotocographic traces for education purposes, decreased medico-legal vulnerability concerning lost cardiocographic traces, etc. The currently available integration of a number of fetal (heart rhythm, oxygen saturation) and maternal (heart rhythm, electrocardiogram, oxygen saturation, blood pressure) variables in one monitor offers more possibilities for fetal monitoring in future, in particular studies of the effects of changes in the maternal cardiovascular status on the condition of the fetus. There have been some initial experiences with management supporting systems in which clinical, biophysical and biochemical data of the mother and the fetus are integrated. These systems still have a long way to go, but certainly deserve further study.

Cardiotocography in itself is a useful and indispensable adjunct for monitoring the condition of the (endangered) fetus. In this regard, the continuous debate concerning its usefulness compared with intermittent auscultation is meaningless. Both methods, in principle, provide similar information. However, cardiotocography in comparison with intermittent auscultation results in continuous vs. spot-like, and objective vs. subjective, data.

139 Intrapartum fetal heart rate monitoring

T. Ikeda, H. Sameshima, M. Kaneko, Y. Kodama and T. Ikenoue

Introduction

In developed countries, fetal heart rate (FHR) monitoring is widely used to survey fetal well-being in the intrapartum period. In the early stage of introduction of FHR monitoring by Hon,[1] Caldeyro-Barcia *et al.*,[2] and Hammacher and Werners,[3] it seemed that FHR monitoring could contribute to a decrease in perinatal mortality and morbidity and to a decrease in incidence of perinatal brain damage, including cerebral palsy and mental retardation.[4] Despite early enthusiasm, subsequent randomized controlled trials comparing FHR monitoring with intermittent auscultation did not support the efficacy of FHR monitoring in preventing adverse fetal outcomes.[5–7] These trials unexpectedly showed higher rates of cesarean section and operative delivery in FHR monitoring groups than in auscultation groups, without exception. A meta-analysis of 58,855 pregnant women from 12 studies confirmed these observations.[8] Low specificity of FHR monitoring to detect fetal asphyxia is a partial explanation for increased cesarean section and operative delivery rates.

Concurrently, epidemiologists used advanced statistical techniques to analyze the real origin of cerebral palsy in large cohort[9] and population-based studies,[10] and concluded that intrapartum asphyxia causes no more than 10% of cerebral palsy cases, significantly less than had previously been thought. Intrapartum FHR monitoring seemed to lose its role in preventing the majority of cerebral palsy and major mental retardation cases, playing a preventive role in just 10% of cerebral palsy and minor mental retardation cases.

However, there is a discrepancy between the statistical evidence against intrapartum FHR monitoring and good clinical acceptance by caregivers.[11] There was a need to reevaluate the effectiveness and safety of FHR monitoring, following agreement on definitions and nomenclature of FHR patterns, and the establishment of management algorisms in hospitals. Guidelines published in 1997 for interpreting electronic FHR monitoring[12] fitted the first need exactly.

Here, we first explain FHR patterns of classification according to the National Institute of Child Health and Human Development (NICHD) guidelines, and physiological and pathological meanings underlying these FHR patterns. Secondly, we discuss several issues important to the successful application of this new research guideline to clinical practice. Finally, we emphasize the need to urgently establish a standard clinical management algorism and discuss the clinical endpoints we should reach.

NICHD Research Planning Workshops and research guidelines for interpreting electronic FHR

NICHD research planning workshops were held between May 1995 and November 1996 in Bethesda, MD, and Chicago, IL. Eighteen specialists in the field attended, mainly from North America, with various educational and research backgrounds. The guidelines developed at the workshops only include definitions and classifications of FHR patterns that most members agreed on. Therefore, it is important to note that these guidelines constitute an inadequate basis for decision making by caregivers; other classifications and nomenclatures are needed, as we discuss later. There are four basic components of FHR to read and understand: (1) baseline rate, (2) baseline FHR variability, (3) acceleration, and (4) deceleration.

Baseline rate

The baseline FHR is the approximate mean FHR rounded to 5 beats/min during a 10-min segment, excluding (Figure 139.1):

- Periodic or episodic changes
- Periods of marked FHR variability
- Segments of the baseline which differ by more than 25 beats/min.

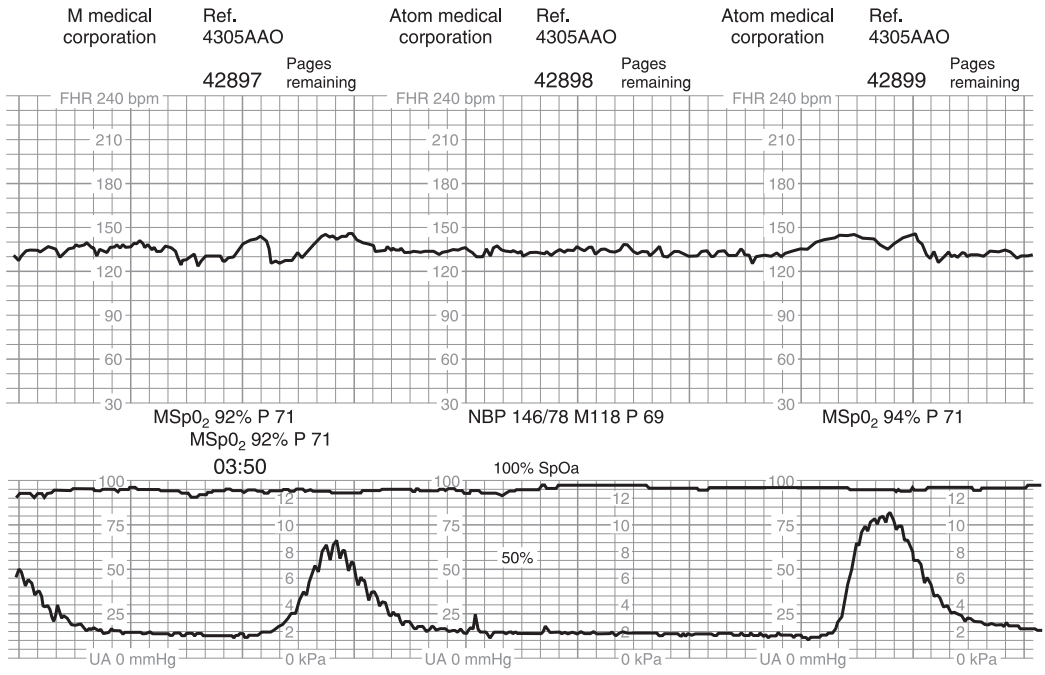

Figure 139.1 The baseline fetal heart rate (FHR) is the approximate mean FHR rounded to 5 beats/min during a 10-min segment. The baseline FHR in this case is 135 beats/min.

In any 10-min window, the minimum baseline duration must be at least 2 min, otherwise the baseline for that period is indeterminate, in which case one may need to refer to the previous 10-min segment(s) for determination of the baseline. The normal baseline FHR is regarded as between 110 and 160 beats/min. Values below 110 beats/min are regarded as bradycardia and those above 160 beats/min are regarded as tachycardia.

The baseline rate is determined by two autonomic nervous systems, sympathetic and parasympathetic, with the latter system being the more important contributor.

Baseline FHR variability

Baseline FHR variability is deemed as fluctuations in the baseline FHR of 2 cycles/min or greater. These fluctuations are irregular in amplitude and frequency and are visually quantified as the amplitude of the peak-to-trough in beats per minute as follows:

- Amplitude range undetectable = *absent* FHR variability
- Amplitude range detectable but $\leqq 5$ beats/min = *minimal* FHR variability
- Amplitude range 6–25 beats/min = *moderate* FHR variability
- Amplitude range > 25 beats/min = *marked* FHR variability

These grades of fluctuation are illustrated in Figure 139.2, together with a sinusoidal pattern. The sinusoidal pattern differs from variability in that it has a smooth, sine wave-like pattern of regular frequency and amplitude and is excluded in the definition of FHR variability.

Baseline variability has been thought to be a product of a 'push-and-pull' relationship between sympathetic and parasympathetic systems. However, the degree of each contribution is not the same; the parasympathetic system is more dominant than the sympathetic system. This is evidenced by the fact that atropine, a parasympathetic blocker, completely diminishes variability, whereas propranorol, a beta-sympathetic blocker, does not.[13] The presence of normal variability guarantees that perfusion and oxygenation to the cerebral cortex, mid-brain, heart and connections between these organs is well maintained.[14] Therefore, baseline variability is the most important parameter to ensure fetal well-being.

Baseline variability can be evaluated by eye, because it is well correlated with computer-calculated values.[15] In clinical practice, the observer does not need to differentiate short-term and long-term variability, as they almost always change concurrently and separate evaluation of the two kinds of variability is not helpful in clinical decision making.

Accelerations

An acceleration is a visually apparent abrupt increase (defined as onset of acceleration to peak in less than 30 s) in FHR above the baseline. The increase is calculated from the most recently determined portion of the baseline. The acme is more than 15 beats/min

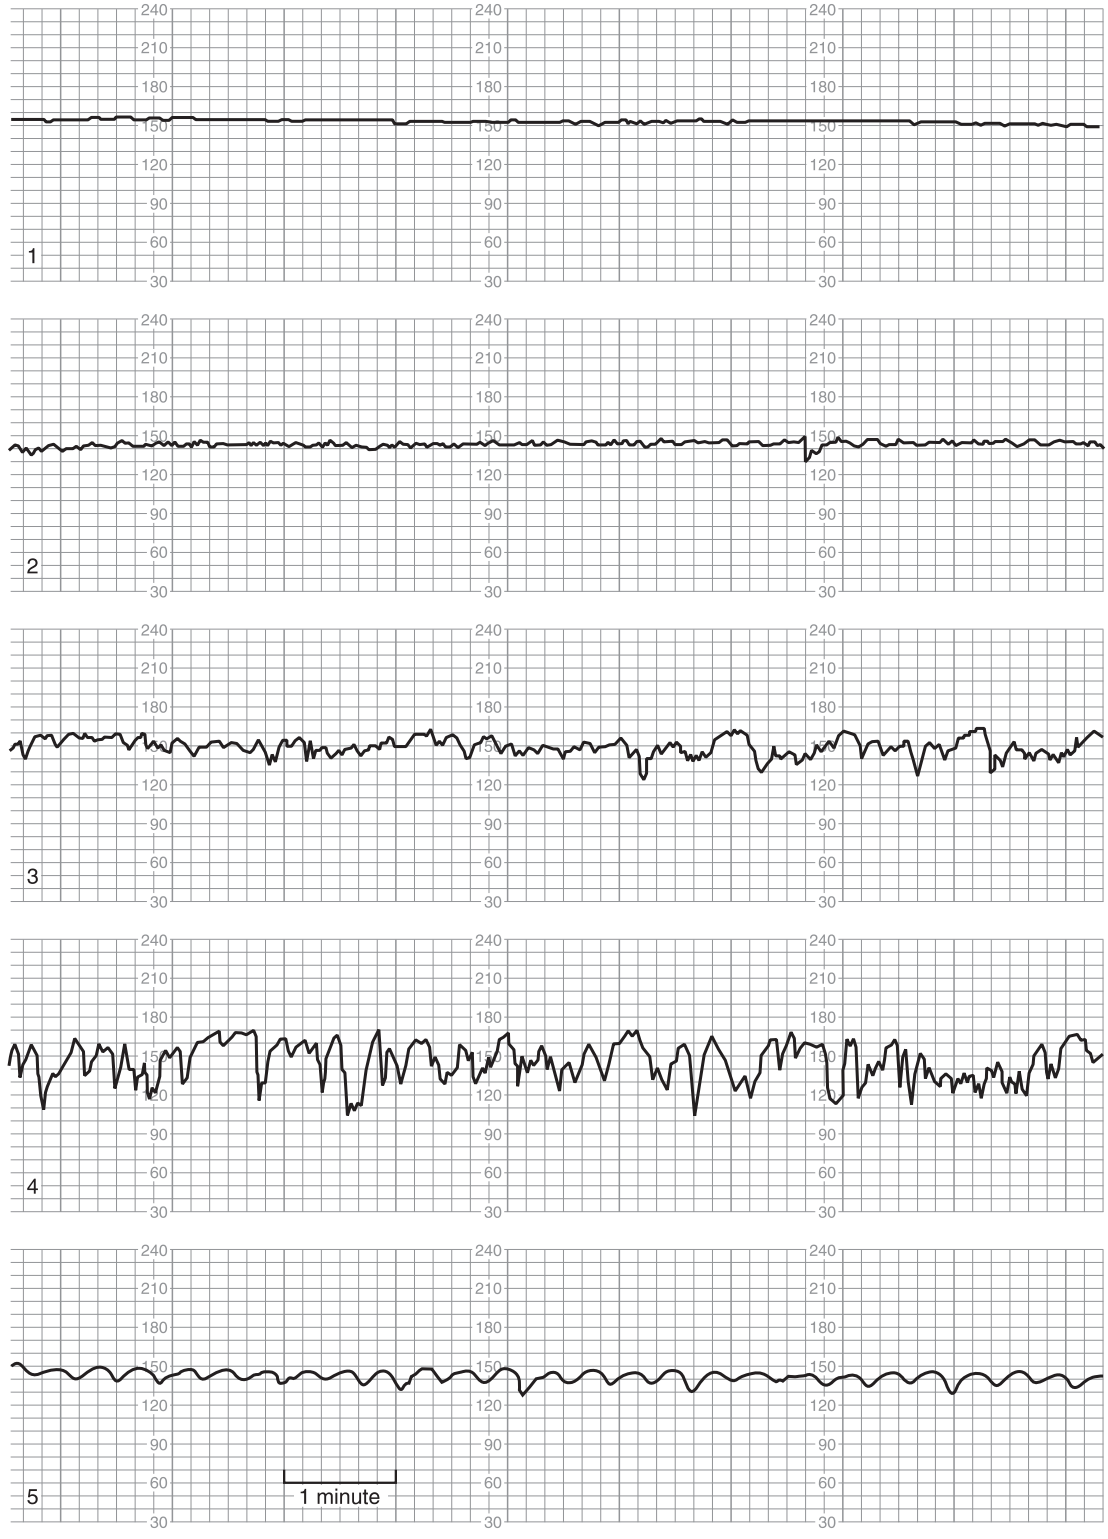

Figure 139.2 Varying degrees of FHR variability. 1, Undetectable; 2, minimal; 3, moderate; 4, marked; 5, sinusoidal pattern. Original scaling, 30 beats/min per centimeter vertical axis, and paper speed 3 cm/min horizontal axis. From National Institute of Child Health and Human Development Research Planning Workshop.[12]

above the baseline, and the acceleration lasts more than 15 s but less than 2 min from the onset to return to baseline. Before 32 weeks of gestation, accelerations are defined as having an acme of more than 10 beats/min above the baseline and duration of more than 10 s. A prolonged acceleration is between 2 and 10 min in duration. There is a close association between the presence of accelerations and normal FHR variability, and both accelerations and normal variability have the same positive prognostic

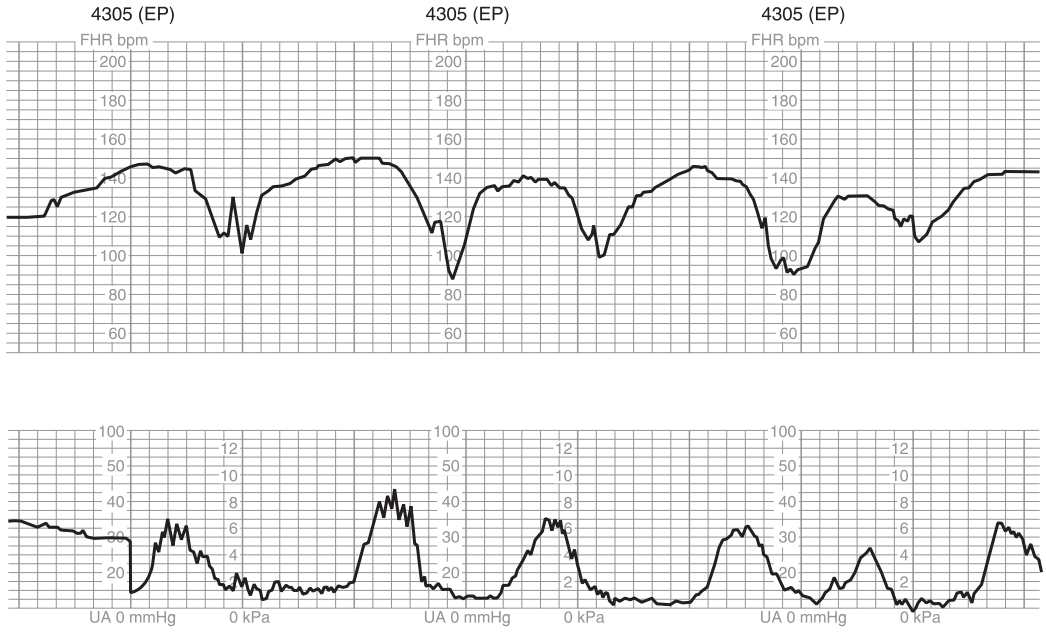

Figure 139.3 'Non-reflex late deceleration'. Primiparous 31-year-old woman was received cesarean section for fetal asphyxia and placental abruption was confirmed. The gas analysis of umbilical arterial blood showed severe metabolic acidosis: pH, 6.982; pco_2, 43.0 mmHg; po_2, 19.2 mmHg; base excess −21 mEq/l. Apgar score is 5 and 6 at 1 and 5 min after birth, respectively. Newborn elicited convulsion at her first day.

significance of normal fetal oxygenation.[14] In the dying monkey fetus, loss of acceleration is always preceded by the appearance of late deceleration.[16]

Decelerations

Periodic patterns are the alterations in FHR associated with uterine contractions. The three characteristic periodic patterns seen are late decelerations, early decelerations, and variable decelerations. Prolonged decelerations are a subcategory of variable or late decelerations. Episodic decelerations are similar to periodic patterns, but do not have the same constant association with contractions.

Late deceleration of the FHR is a visually apparent gradual decrease (defined as onset of deceleration to nadir more than 30 s) and return to baseline FHR associated with a uterine contraction. In most cases, the onset, nadir, and recovery are all late in relation to the beginning, peak, and ending of the contraction, respectively.

There are two types of late deceleration in terms of mechanisms to appear. One type is related to chemoreceptor and baroreceptor reflex to fetal hypoxemia,[17] and is sometimes called 'reflex late deceleration'. The other type is related to myocardial depression and is called 'non-reflex late deceleration' (Figure 139.3). Reflex late deceleration usually accompanies baseline variability and normal acid–base status, but with non-reflex late deceleration, baseline variability shows a minimal or undetectable fall in fetus acidosis. It is clinically important to differentiate these two types of late deceleration.

Early deceleration of the FHR is a visually apparent gradual decrease (defined as onset of deceleration to nadir longer than 30 s) and return to baseline FHR associated with a uterine contraction. The nadir of the deceleration coincides with the peak of the contraction. In most cases, the onset, nadir, and recovery all coincide with the beginning, peak, and ending of the contraction, respectively.

Variable decelerations are visually apparent abrupt decreases (defined as onset of deceleration to beginning of nadir less than 30 s) in FHR from the baseline. The decrease in FHR below the baseline is at least 15 beats/min, lasting (from baseline to baseline) at least 15 s, but less than 2 min. When variable decelerations are associated with uterine contractions, their onset, depth, and duration commonly vary with successive contractions (Figure 139.4).

Until now, two mechanisms have been thought to produce variable deceleration: umbilical cord compression and head compression. Both mechanisms require the presence of vagal reflex. It is important to note that a severe degree of variable deceleration with deep and long heart rate can cause a fetus to decompensate and suffer acidosis.[14] Therefore, to rule out acidosis in clinical practice, it is critical to keep track of the presence of baseline variability.

Prolonged deceleration is a subcategory of variable deceleration. The decrease in FHR below the baseline is at least 15 beats/min, lasting between 2 and 10 min. The definition changes to a change in baseline rate (e.g. bradycardia) if the prolonged deceleration is longer than 10 min.

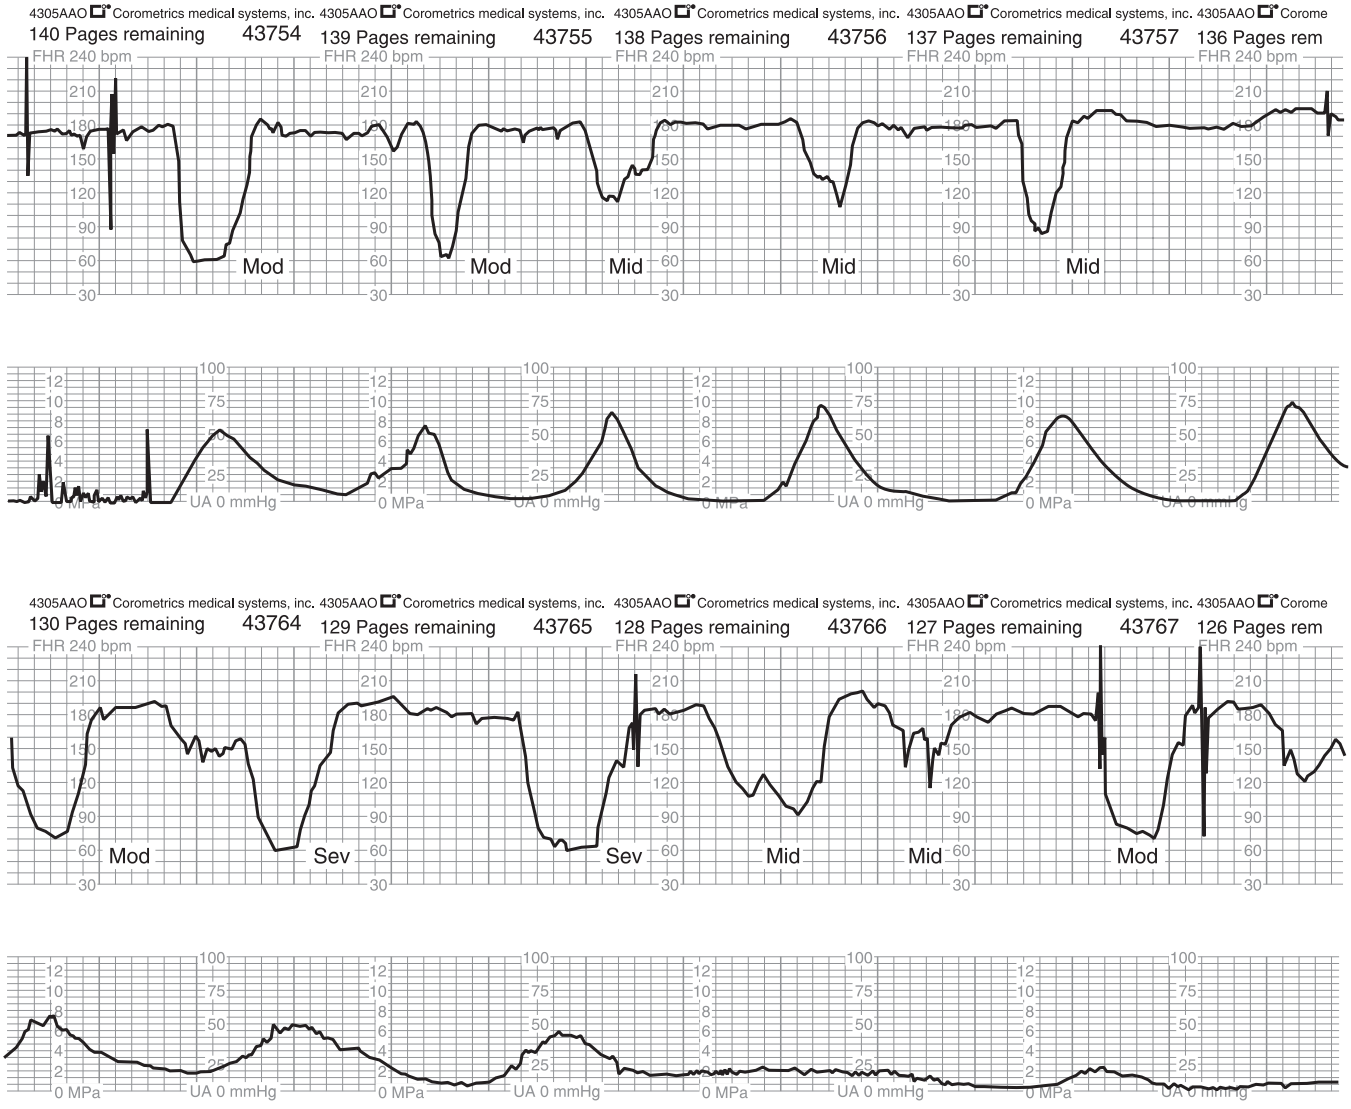

Figure 139.4 Variable decelerations. According to Kubli *et al.*'s classification, mild (Mid), moderate (Mod), and severe (Sev) variable decelerations are classified based on the nadir and duration of the deceleration.

Application of NICHD guidelines to intrapartum clinical management

As stated earlier, because the NICHD guidelines derive from the consensus of only 18 experts, other considerations about FHR patterns are needed in clinical decision making.

Consideration of clinical background

It is important to consider the clinical background, because different fetuses with different characteristic backgrounds show the same FHR pattern, and such patterns have a different clinical effect on each fetus. With intrapartum FHR decelerations, intrauterine growth restriction fetuses had a significantly higher lactate level than that appropriate for gestational age fetuses.[18] When an FHR pattern signifying hypoxia or asphyxia is observed in fetuses suspected antenatally to have intrauterine growth restriction, intervention should be considered earlier than appropriate-for-gestational-age fetuses.

Gestational age should be taken into account whenever FHR patterns are assessed. Premature fetuses have a propensity to higher basal FHR rates, lower amplitude of acceleration, and lower baseline variability compared with mature fetuses. In addition, the higher variability (active) phase and the lower variability (resting) phase can be differentiated after 28 weeks of gestational age in human fetuses.[19]

Maternal medication is another important factor affecting FHR patterns. Drugs known to decrease baseline variability include narcotics (e.g. morphine, meperidine), tranquilizers (e.g. diazepam), magnesium sulfate, and vagal blockade drugs (e.g. atropine, scopolamine). There have been few studies on causal

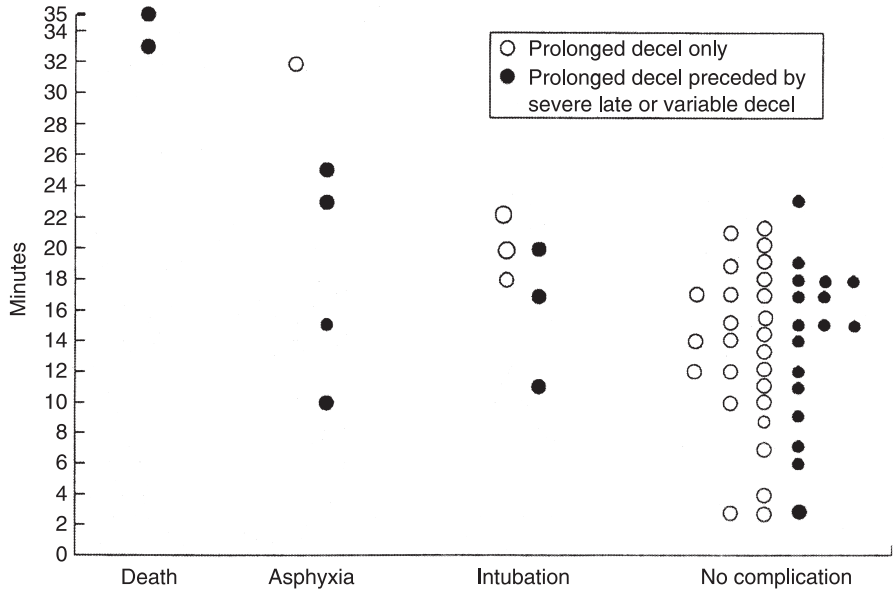

Figure 139.5 Prenatal outcome as related to time of delivery from onset of prolonged decelerations. From Leung *et al.*[20] When the prolonged deceleration or bradycardia followed the normal FHR pattern, no newborns showed umbilical cord artery pH < 7.0 and/or organ damage if they were born in less than 17 min of prolonged deceleration or bradycardia. In contrast, when prolonged deceleration or bradycardia was preceded by severe late or variable deceleration, no newborn showed asphyxic status in less than 9 min of prolonged deceleration or bradycardia.

relationships between given FHR patterns and outcomes in patients with disorders such as intrauterine infection, pre-eclampsia, diabetes mellitus, overterm, and congenital malformation.

Considering evolution of FHR patterns

Leung *et al.*[20] correlated the duration from onset of prolonged deceleration or bradycardia to delivery in 56 women with uterine rupture. When the prolonged deceleration or bradycardia followed the normal FHR pattern, no newborns showed umbilical cord artery pH < 7.0 and/or organ damage if they were born in less than 17 min of prolonged deceleration or bradycardia (Figure 139.5). In contrast, when prolonged deceleration or bradycardia was preceded by severe late or variable deceleration, no newborn showed asphyxic status in less than 9 min of prolonged deceleration or bradycardia. It is very important for the observer to take into consideration the evolution of FHR patterns.

It is important to understand the worsening pattern of deceleration. Late deceleration changes to have greater depth, with lower baseline rate or with higher baseline rate than normal range, and baseline variability becoming minimal or undetectable. Variable deceleration changes to an atypical variable pattern as described by Krebs *et al.*,[21] in addition to the changing pattern of late deceleration.

In a study by Fleischer *et al.*,[22] the average time duration from appearance of late decelerations to the time umbilical arterial pH reached 7.25 was 115 min; for variable decelerations, 145 min, and for flat line tracings, 185 min.

Baseline variability, the most important parameter indicating acidosis

Loss of variability, especially in the presence of other periodic patterns during labor, is the most sensitive indicator of metabolic acidemia in a fetus.[14] The factors of minimal or undetectable baseline variability are divided into asphyxic and non-asphyxic causes. Non-asphyxic causes include prematurity, tachycardia, drugs (such as narcotics, anesthetics, and parasympathomimetics), non-rapid eye movement sleep, and cardiac arrhythmia (such as atrioventricular block). Clinically, it is important to differentiate asphyxia-induced decreased variability from non-asphyxia-induced variability. One indication is that if the decreased variability is not accompanied by decelerations, it is likely to be non-asphyxial.[14] As reported by Samueloff *et al.*,[23] decreased baseline variability does not correctly predict umbilical arterial acidosis (defined as pH < 2.0) or a low Apgar score (< 7 at 5 min of life), if not accompanied by decelerations.

On the contrary, when decreased variability was accompanied by decelerations, predictability for acidosis (umbilical arterial blood pH < 7.1) was higher than when we did not take the presence of deceleration into account. In our recent study of 5522 low-risk pregnancies, the positive predictive value of umbilical artery pH < 7.1 increased exponentially from 0% in no deceleration, to 1% in occasional late decelerations, and 6–12% in recurrent late decelerations with moderate variability regardless acceleration present or not. In comparison, the positive predictive value was 54% in recurrent late

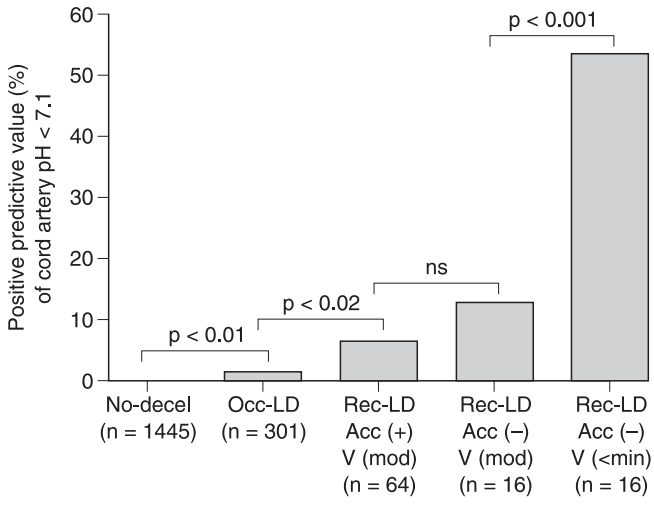

Figure 139.6 Predictive value of umbilical artery pH < 7.1 was increased as the FHR patterns were deteriorated from no-decel (no decelerations), occ-LD (occasional late decelerations), rec-LD (recurrent late decelerations) with accelerations present [Acc(+)] and variability moderate [V(mod)], to rec-LD with accelerations absent [Acc(−)] and variability minimal/absent [V(min)]. From Sameshima and Iknenoue.[24]

decelerations with acceleration absent and variability minimal/absent (Figure 139.6).[24]

Severity of decelerations

Paul *et al.*[25] correlated severity of late deceleration to fetal scalp blood pH (Figure 139.7a and b). They categorized cases into three subgroups according to the decrease in deceleration: mild late deceleration, less than 15 beats/min; moderate late deceleration, between 15 and 40 beats/min; severe late deceleration, more than 40 beats/min; and each subgroup was divided into two according to presence or decrease of baseline variability. The severity was significantly correlated with fetal acid–base status as well as the presence of variability.

Kubli *et al.*[26] also correlated severity of variable deceleration to fetal scalp blood pH in 85 cases. Their categorization was based on two parameters: nadir and duration of the deceleration. The average scalp blood pH in the severe variable deceleration group was 7.15 ± 0.069, significantly lower than in the mild and the moderate variable deceleration groups (7.29 ± 0.046 and 7.26 ± 0.044, respectively). In their study, they did not mention the variable deceleration with or without baseline variability, as Paul *et al.*[25] did. One drawback of using Kubli *et al.*'s categorization for variable deceleration is difficulty in recall, whereas Chao[27] created a mnemonic scale (Figure 139.8).

Regarding prolonged deceleration, Gull *et al.*[28] studied 27 prolonged decelerations just before vaginal delivery, and found a strong relationship between the length of loss of short-term variability and base deficit. They also noted that base deficit is significantly correlated with the duration and depth of prolonged decelerations, although these correlations were not as strong as the relationship to loss of variability.

Ancillary methods assuring fetal non-acidemia

To improve the specificity of FHR monitoring, two ancillary methods of assessing fetal acidemia are useful: fetal scalp blood sampling and fetal scalp stimulation. Fetal scalp blood sampling was developed as a method to assess intrapartum fetal well-being at almost the same time as FHR monitoring.[29] Clark *et al.*[30] subsequently showed that no fetus responding to scalp blood sampling with an acceleration of heart rate of 15 beats/min for 15 s had a scalp pH < 7.21. Since then, the fetal scalp stimulation test has replaced scalp blood sampling because it is simpler and less invasive.

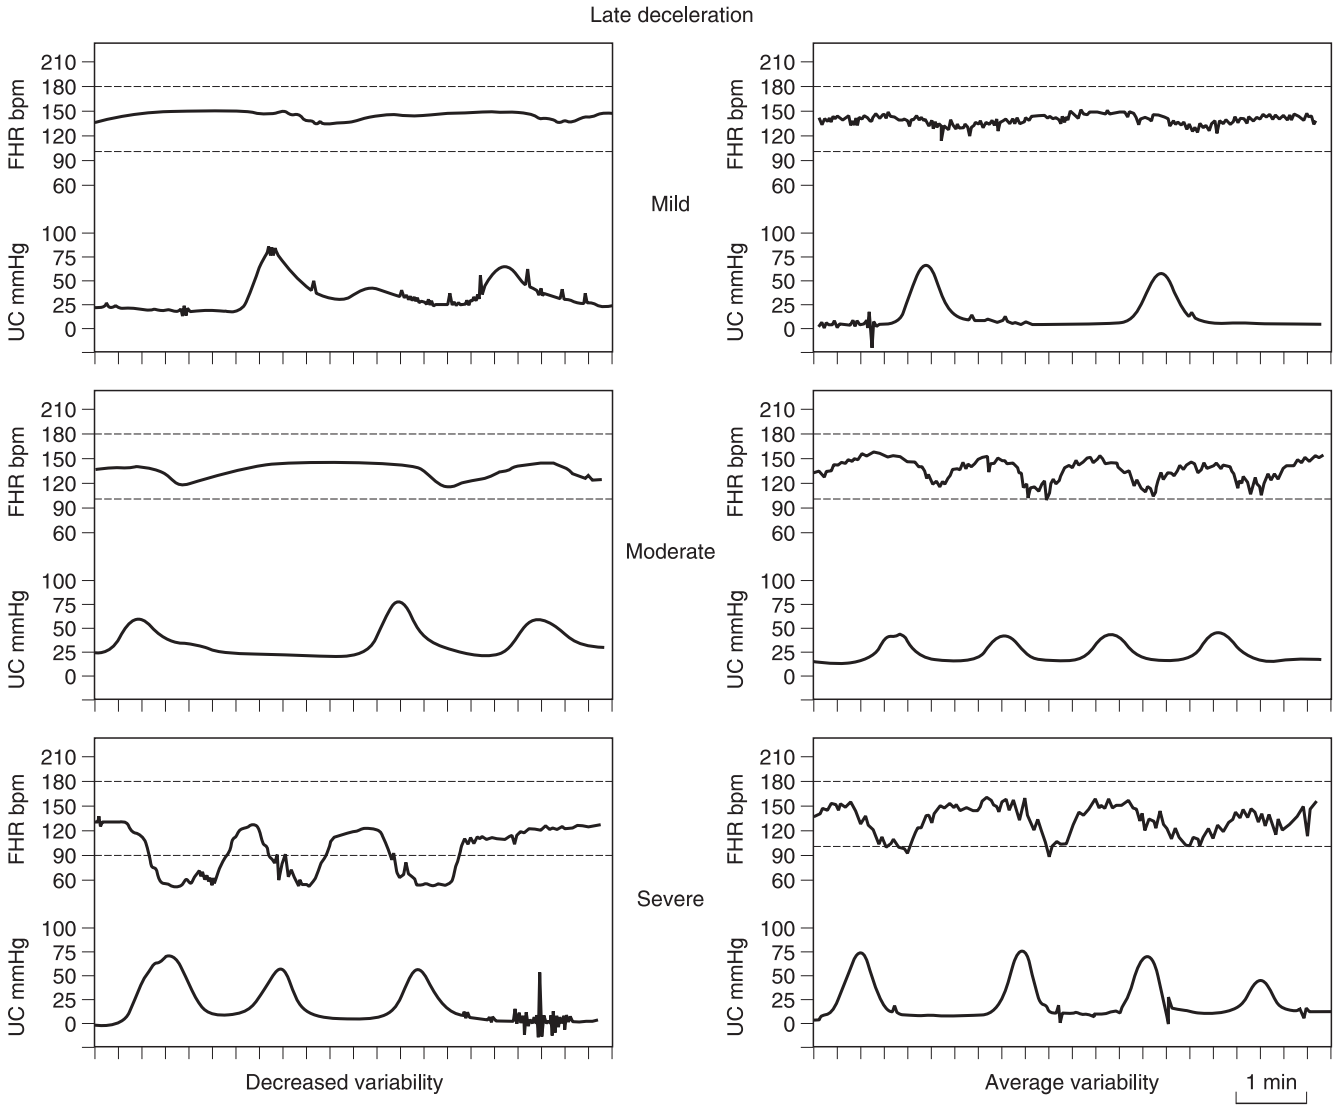
The presence of an accelerated FHR in response to tactile or atraumatic clamp stimulation virtually assures a fetal blood pH above 7.2.[31] Almost one-third of fetuses who did not show accelerations revealed fetal acidosis. Scalp stimulation can be a useful adjunct when delivery is remote and the FHR tracing is non-reassuring but not clearly indicative of fetal acidemia.

Utility of FHR monitoring in intrapartum management

To develop a strategy to establish a management algorithm, we should clarify the surrogate endpoint of FHR monitoring. *Fetal acidosis* is defined as < 7.1 or < 7.0 in umbilical artery or fetal sampled blood pH, the incidences of which are about 3% and 0.3%, respectively.[14] The incidence of organ damage is significantly increased when pH is less than 7.0.[32,33] *Base deficit or excess*, representing metabolic acidosis, is a more important surrogate because metabolic acidosis is a more critical factor in organ damage than respiratory acidosis. The threshold is usually 12 or 16 mEq/l.[34]

In comparison with blood acid–base status, a depression index of a newly born infant, such as low *Apgar score* and *time duration of initial spontaneous respiration*, could be affected by observer bias.

Neonatal seizure, one of the most important signs of neonatal encephalopathy, is another surrogate endpoint for efficacy of FHR monitoring, which occurs in 0.3% of cases.[14] One case-controlled study showed that 29% of neonatal encephalopathy was caused by intrapartum factors or antepartum plus intrapartum factors.[35] The meta-analysis by Thacker *et al.*[8] showed that the incidence of neonatal seizures in FHR monitoring cases were decreased to half of that in the cases managed with intermittent auscultation. This result is staggering, because 0.09%



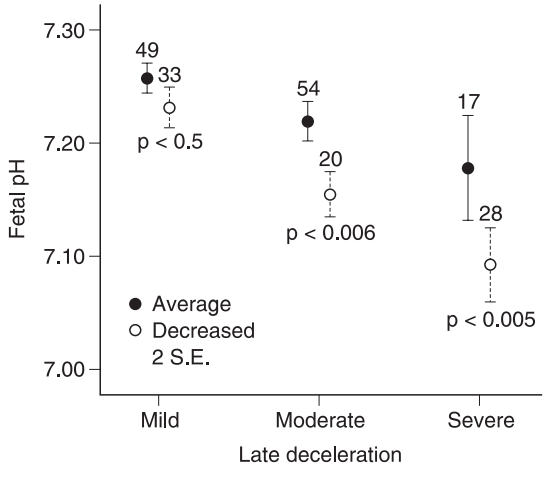


Figure 139.7 (a) Late deceleration FHR patterns are separated into mild (< 15 beats/min), moderate (15–40 beats/min), and severe (> 40 beats/min) groups. Examples associated with decreased variability, on the left, can be contrasted with those showing average or greater variability on the right. (b) As late deceleration patterns become more marked, the mean pH value falls. However, when FHR variability is present in association with late deceleration patterns, the mean pH is consistently higher than when it is decreased. From Paul *et al.*[25]

(0.3% × 0.29) is the incidence rate for neonatal encephalopathy in all pregnancies that is a target one hopes to avoid through use of intrapartum FHR monitoring.

Because the incidence of cerebral palsy is 0.2–0.3%, and less than 10% of all cerebral palsy cases are caused by intrapartum asphyxia, intrapartum FHR monitoring is of benefit in less than 0.03% of cases. Furthermore, it takes more than 12 months to make a diagnosis of cerebral palsy. Because of the problems of follow up and rarity of its incidence, cerebral palsy does not seem to be a

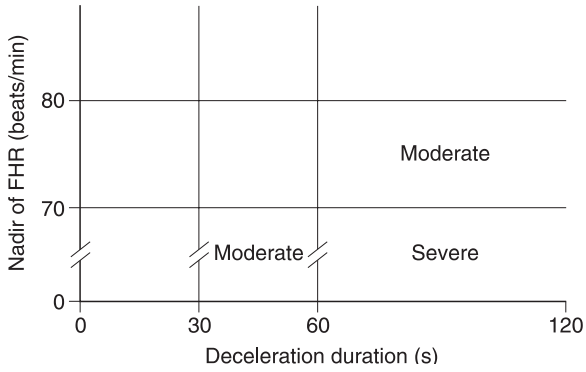

Figure 139.8 Chao's mnemonic for severity of variable deceleration.

feasible outcome measure for intrapartum FHR monitoring.

Another endpoint for intrapartum FHR monitoring is rates of cesarean section and operative vaginal delivery. It has been well known that cases managed with continuous FHR monitoring in labor and delivery tend to have an operative delivery. However, in a recent study using the cumulative meta-analysis of nine studies from 1976 to 1993, with more than 18,000 patients, the FHR group showed a relative risk of cesarean section of 1.21 compared with the intermittent auscultation group; for combined cesarean section and operative vaginal deliveries, the relative risk in the FHR group was 1.23.[8]

In conclusion, we recommend three major parameters as surrogate endpoints for efficacy of intrapartum FHR monitoring:

- umbilical arterial pH and base excess (or deficit);
- incidence of neonatal encephalopathy, especially neonatal seizure; and
- rate of operative delivery.

140 Quantitative fetal heart rate evaluation without pattern classification: FHR score and artificial neural network analysis

K. Maeda, Y. Noguchi, F. Matumoto and T. Nagasawa

Introduction

Fetal heart rate (FHR) monitoring, used by us in Kyushu University in the 1960s,[1] led to a reduction in the incidence of severe neonatal asphyxia, which in turn unmasked underlying neonatal intrinsic disorders, and facilitated the studies on congenital diseases. In the 1970s, in a controlled study at Tottori University, perinatal deaths were reduced by the use of fetal monitoring.[2] In addition, in the 1970–1980s, the use of full intrapartum monitoring resulted in the reduction of neonatal asphyxia, perinatal deaths and cerebral palsy at Yohka General Hospital, where the cesarean section rate was only 10%.[3] Pediatric neurologists have noted the reduction of cerebral palsy in whole births after the introduction of widespread fetal monitoring in the Tottori area in the 1980s.[4] Although it has been reported that monitoring with an internal fetal scalp electrode after rupture of the membranes does not improve outcome,[5] real improvements in outcome were achieved through external monitoring throughout pregnancy and labor.[2–4] Full intrapartum monitoring was not easy because all labors are monitored continuously by cardiotocography (CTG) watching and detailed FHR pattern classification.[2,3] It was thought that computerized FHR analysis and diagnosis would solve these problems.

Although FHR patterns are the main criteria in visual CTG diagnosis, it has been controversial even in modern classification. Therefore, quantitative analysis was required in precise studies and in clinical diagnosis. The more simple measurements of FHR tracing, based on manual analysis of FHR score, were adopted instead of pattern classification in the 1960s[1,6] and we introduced conventional computer diagnosis in the 1970s.[7,8] Recently, neural network computer assessment was introduced,[9,10] where the purpose is highly objective and easy FHR evaluation which cannot be carried out either with CTG observation or FHR pattern classification.*

FHR score in conventional computer systems

The conventional program was characterized by quantitative FHR evaluation without pattern classification from early studies on automated diagnosis.[7,8]

FHR score

FHR score was the first quantitative measure reported early in 1969. Although there were pattern classifications by Caldeyro-Barcia *et al.*[11] and Hon,[12] no criteria were present in the quantitative FHR measurement in the 1960s. We simply measured baseline heart rate, number of decelerations, its duration, nadir heart rate (dip HR), recovery time from the dip HR to the baseline, lag time of dip HR from the peak of the contraction, in 5 min of fetal monitoring (Figure 140.1).[1] No labor was intervened by rapid delivery because, in the trial, we did not know what the warning quantitative FHR signs were. The parameters of frequent changes

*Author contributions: KM worked on medical data and postprocessing, YN and FM dealt with the neural network computer, and TN performed the Fast Fourier Transform (FFT) analysis of FHR

were detected and each abnormality score was established according to the percentages of fetal death and neonatal depression (Table 140.1). Abnormality scores were accumulated to establish the FHR score repeatedly every 5 min and the highest FHR score in the labor was evaluated.[1]

The FHR score is easily compared to other numeric phenomena because it is a single quantitative value. The score correlated with the neonatal Apgar score, where the FHR score was 10 or more when the Apgar score was six or less (Figure 140.2). It also correlated with umbilical arterial blood pH and base excess (BE), where pH was lower than 7.20 when the FHR score was 10 or more (Figure 140.3).[1,6] The correlation was studied by meta-analysis of the results from the 1960–1970s, where an adverse outcome was suggested when the FHR score was higher than 10. The score also correlated with fetal scalp blood pH (Figure 140.4).[1] The correlation coefficient was 0.85 and subsequently scalp blood sampling was not considered to be indispensable during clinical monitoring. The technique was so easy that the FHR score was manually determined even before computer processing.[1,6]

After Dr Hon criticized the FHR scoring technique as there was no inclusion of FHR-baseline variability, new parameters were added to the new fetal distress (FD) index (Table 140.2). When umbilical arterial pH was higher than 7.25, FD index is 2 or less while when pH was 7.25 or less, FD index is 3 or more (Table 140.3).[13] Therefore, fetal blood pH may be assessed by FHR score as well as by FD index. The score and index flag fetal abnormalities during fetal monitoring with the conventional computer program.[7,8] We recognized the usefulness of quantitative FHR evaluation in studies on FHR score and FD index.

Conventional computer program for FHR analysis and diagnosis

An external fetal monitor is composed of a fetal heart beat detector, a fetal heart rate meter and a tocodynamometer.[14] The electrical output of FHR and contractions are each converted into 150 digital data in 5 min, saved in computer memory and analyzed. The program is divided into two parts: analysis and diagnosis.[7,8] The analytic computer detects FHR

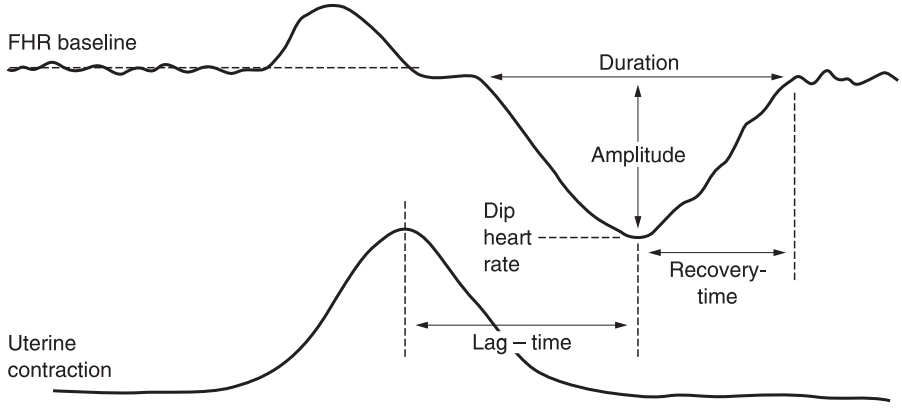

Figure 140.1 The FHR tracing has been quantitatively analyzed with simple measurement for the determination of FHR score since the 1960s.[1]

Table 140.1 Abnormality scores for the calculation of FHR score[1]

Signs	Apgar score (1 min) lower than 7 (%)	Abnormality score
FHR baseline		
110–130 or 160–180 bpm	27.5	1
< 110 or > 180 bpm	75.0	3
Deceleration		
Duration > 60 s	71.4	3
Dip heart rate < 100 bpm	37.1	2
Amplitude > 50 bpm	50.0	2
Recovery time > 40 s	63.2	3
Lag time > 40 s	71.4	3
No accompanied acceleration	44.7	2
W-shaped deceleration	100.0	4

FHR score = Total sum of abnormality scores detected in 5 min. FHR score is abnormally high when it is 10 or more, and severely abnormal when it is 20 or more

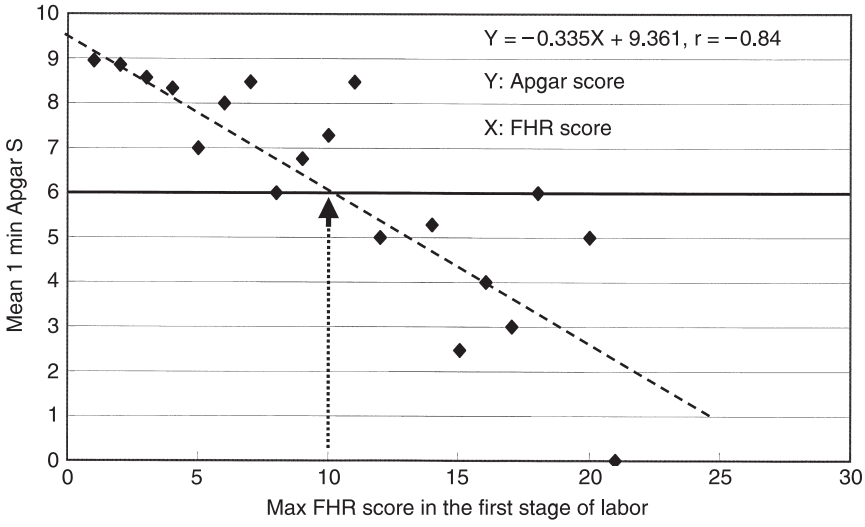

Figure 140.2 Maximum FHR score, even in the first stage of labor, correlates with the Apgar score at 1 min. Meta-analysis of original data, all obtained in the 1960s,[1] are presented in Figures 140.2 and 140.3 of the present study.

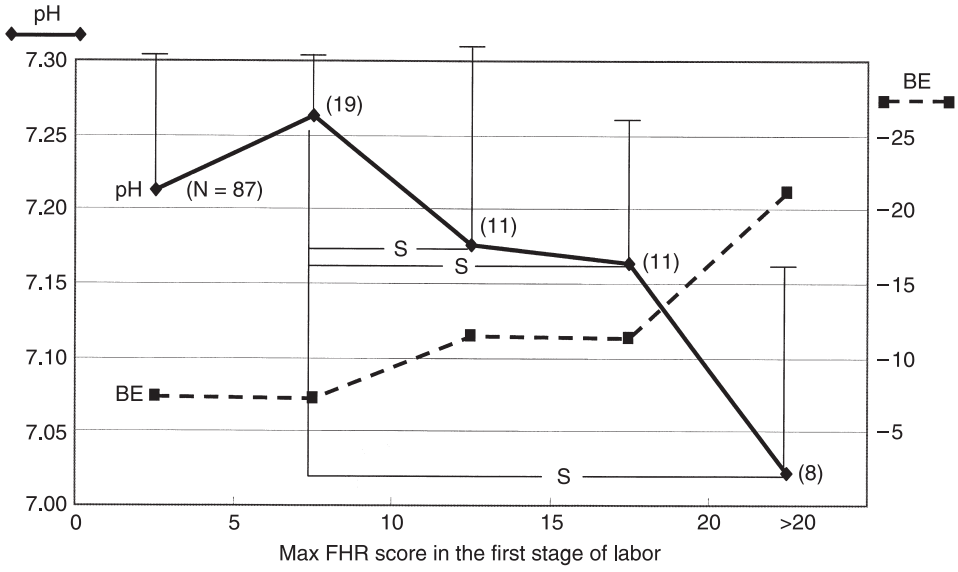

Figure 140.3 The maximum FHR score, even in the first stage of labor, correlates with umbilical arterial blood pH and BE at delivery. The pH is lower at 0–5 points of FHR score than at 5–10 points, while BE is equal in corresponding BE. It may show the metabolic nature of BE and the influence of respiratory acidosis on the pH. The figure is the meta-analysis of the data obtained in the 1960s.[1]

parameters, which are used in the FHR score and also in the artificial neural network in the recent studies.[9]

FHR data are divided into 20 steps in the analytic part. Data are averaged in the step where there are more and the result is the FHR baseline during 5 min. The average of all downslope variations is added to the baseline to form the upper reference line to detect the acceleration. The averaged variation is subtracted from the baseline to determine the deceleration below the lower reference line. Baseline variability is determined by excluding the acceleration and deceleration. The duration, dip HR, recovery time from the nadir to the baseline, lag time from the nadir to the contraction peak are measured in a deceleration.[7,8]

The dip area of a deceleration, which is the area surrounded by the baseline and deceleration, is divided by the product of duration and amplitude of the deceleration, to determine 'dip shape value'. Cord compression is suggested when the dip shape value is large and periodic deceleration is defined when the dip shape is small.[15] Late deceleration is determined in 15 min if all dip shape values are small, lag time is greater than 20 s and deceleration number is almost the same as the contractions. Non-reactive FHR is suggested if there is no acceleration in 20 min. An excessively large area under the contraction suggests uterine hyperactivity. Abnormal FHR is detected and fetal non-reassuring status is diagnosed by the high FHR score and index, as well as by baseline abnormality, loss of variability and abnormal decelerations in the diagnostic part of the computer. The study started in 1974 and was completed in 1980.[7,8] The program has been incorporated in various monitoring devices (TOITU†, Tokyo, Japan) and has been used by obstetricians for more than 20 years without major problems. The value and usefulness of quantitative FHR evaluation is confirmed in the conventional program.

† http://www.toitu.co.jp/e

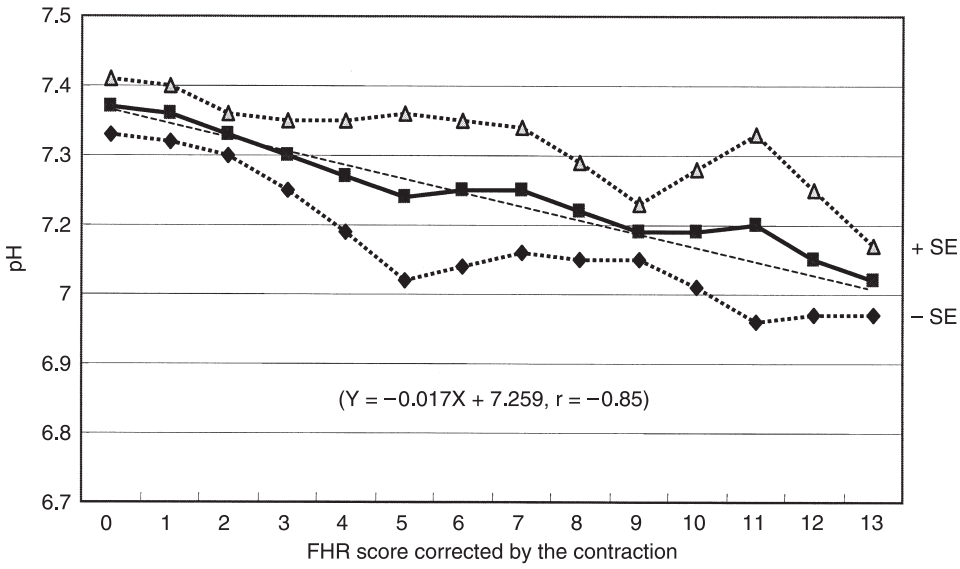

Figure 140.4 FHR score correlated with fetal scalp blood pH. The score was corrected by the state of uterine contraction, and the score was determined 20 min before blood sampling.[1]

Table 140.2 Calculation of FD index

Add 1 point
FHR score: 10–19
Loss of variability: the variability is less than 5 during 20 or more minutes
Late decelerations: quantitatively determined by 'dip-shape' and lag time
Bradycardia (100–110 bpm) lasted for 10–30 min
Tachycardia (>160 bpm) lasted for more than 30 min

Add 2 points
FHR score: 20 or more
Bradycardia (100–110 bpm) lasted for more than 30 min

Add 3 points
Bradycardia (<100 bpm) lasted for 5 min

The value 3 or more of total FD index suggests fetal distress[13]

Table 140.3 Umbilical arterial pH (UApH) is low if FD index is 3 or more at 30 min before the birth[13]

FD index	UApH is 7.25 or less	UApH is higher than 7.25	Total
3	19	4	23
<3	3	39	42
Total	22	43	65

Sensitivity: 86.64%, specificity: 90.70%, Fisher's exact test: $P=0.00000$; positive predictive value: 82.61%, negative predictive value: 92.86%

Artificial neural network computer analysis

Further highly objective evaluation is intended by the introduction of artificial neural network analysis under the collaboration of computer specialist Noguchi and colleagues. The computer is not programmed by experts' knowledge, instead it is educated by repeated training with eight FHR data of typical outcome cases. The FHR data are detected in 5 min and includes baseline heart rate, variability, sinusoidal heart rate, number of decelerations, and their duration, nadir heart rate, recovery time and lag time, by the analytic conventional computer from database, and sometimes by visual CTG analysis. Fifteen minutes of 24 parameters of 20 cases of known outcome are digitized and are manually input into the computer, instead of the full CTG data, which require enormous input units and long processing time, i.e. we selected a hybrid neural network system. The intermediate layer is composed of 30 units and the output layer is 3 units (Figure 140.5).[9,10] The computer is a common Dell PC that is automatically educated 10,000 times repeatedly by using a back propagation system to obtain the most effective neural network construction for outcome prediction. The computer education was successful and the internal check perfect. The network output is for probabilities to be normal, pathologic or suspicious outcomes. Output evaluation is easy because the probability is shown in percentages. We tentatively educated the computer with 50 min of data, and its accuracy was 86% in 50 min of 29 other cases.[9] Educated and completed neural network software can be transferred into any other computer with uniform diagnostic accuracy. No hardware board is used because it is educated in each computer, where no uniformity is expected in its diagnostic accuracy.

Computerized detection of fetal sinusoidal heart rate

Seven of the eight components are baseline and deceleration data detected by the conventional analyzing computer. However, when using the educated neural network computer for diagnosis, fetal sinusoidal heart rate (FSHR) becomes a complex problem in diagnosis with an educated neural network computer.

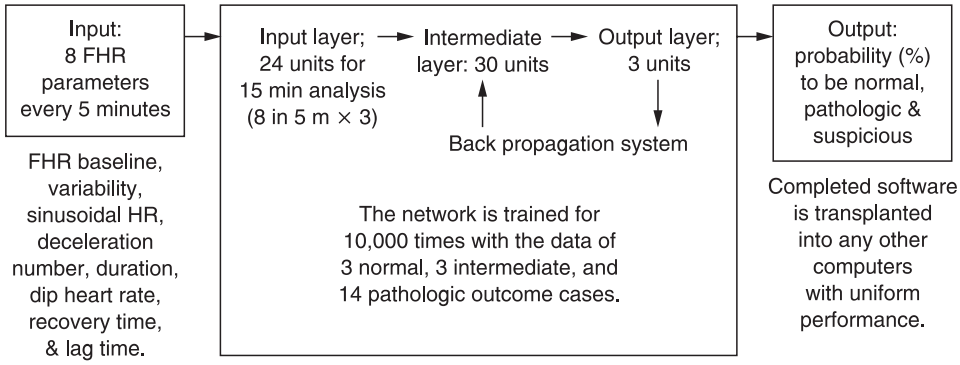

Figure 140.5 The artificial neural network computer is constructed of three layers and a back propagation system. It is repeatedly educated for 10,000 times using eight FHR parameters. The software of the completed neural network can be transplanted into any other computer.[9]

Table 140.4 Pathologic FSHR is diagnosed, when the ratio of La/Ta is 39% or greater and is combined with a PPSD value of 300 or more. If these criteria are fulfilled, the true positive rate is 100% and false-positive and false-negative rate are 0%[17]

La/Ta ratio 39% and PPSD 300	FSHR		
	Pathologic	Physiologic*	Total
Yes	9	0	9
No	0	12	12
Total	9	12	21

*Physiologic FSHR and normal FHR

FSHR should be able to be automatically diagnosed before input into the neural network computer. Physiologic and pathologic FSHRs, however, cannot be differentiated by simple CTG observation. An actocardiogram can detect physiologic FSHR,[16] but it is a visual diagnosis and it is not compatible with computer processing. We have to use FHR alone for the automatic detection of pathologic FSHR.

Therefore, the following data were collected, scanned, digitized and studied by FFT frequency analysis: nine FHR tracings of pathologic FSHR caused by fetal anemia or hypoxia, which resulted in unfavorable outcome, fetal therapy or cesarean section; seven physiologic FSHR including periodic fetal movements detected by actocardiogram in those who had normal vaginal delivery and normal outcome; five normal FHR. The area under the power spectrum between 0.031 and 0.1 Hz (2–6 cycles/min) is La and the area under the whole power spectrum is Ta; the La/Ta ratio is studied. Peak power spectrum density (PPSD) is another FSHR parameter. La/Ta ratio and PPSD are both large in pathologic FSHR, whereas physiologic FSHR shows small La/Ta ratio or small PPSD. Therefore, the combination of large La/Ta and PPSD is suitable to separate pathologic FSHR from normal physiologic FSHR (Table 140.4).[17] The algorithm will be installed into actual neural network systems for FHR diagnosis.

Outcome probability trend gram

We also studied the trend gram of the probabilities obtained in the neural analysis; i.e. the time train of outcome probability, which is obtained every 5 min by analysis of 15 min of data. Upward bars show normal outcome probability while pathologic and suspicious probability are shown by reverse downward bars (Figure 140.6).[9] A trend gram of such short duration as 1 h is easily evaluated, whereas prolonged trend gram, for example of 4 h duration, is difficult to evaluate by visual examination. No outcome is expected even by the line graph connecting pathologic probabilities in 4 h of monitoring. KM's trial was a manual averaging of all past pathologic probabilities every 5 min and formation of a line graph of averaged pathologic probabilities. Evaluation is still difficult by the pathologic probability curve.[10]

Neural index obtained by averaged outcome probability

The next trial is the comparison of averaged normal probability curves to pathologic probability. The final average of normal probability is higher than an averaged pathologic one immediately before delivery. The technique is useful in outcome prediction because the neonate is normal in the case. However, the method is not used because it is still a visual evaluation (Figure 140.7). In further progress in the development of this technique, averaged pathologic probability is subtracted from averaged normal probability every 5 min. After processing, a final single curve and a single value are obtained. We have named this value 'neural index' (Figure 140.8). The final stage of the neural index immediately before the birth is greater than zero and the neonatal state is normal in the case. Results show possible FHR evaluation even after very prolonged monitoring.

Nine trend grams were evaluated by the neural index. In four cases where all of the neonates were normal and showed no asphyxia, the neural index was greater than zero. However, in another five cases, neural index was below zero before delivery and the neonates were all depressed and showed various grades of neonatal asphyxia (Table 140.5). Case no. 3 shows the lowest index; it was continuously –100%,

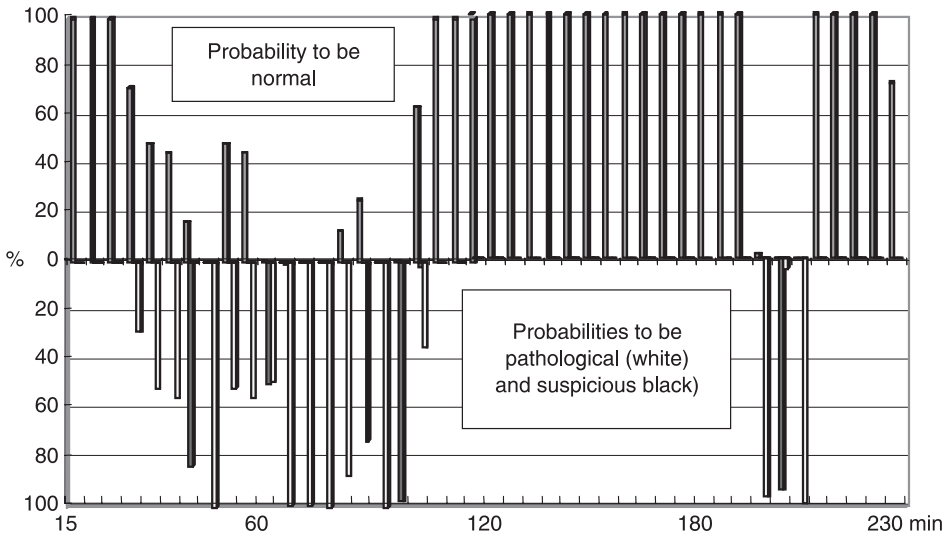

Figure 140.6 The trend gram bars show outcome probabilities obtained by the artificial neural network computer in case 1, who was monitored for 3 h and 50 min. Upward bar indicates the probability for normality, while reverse bars indicate probabilities for pathology (white) or suspicious (black).[9]

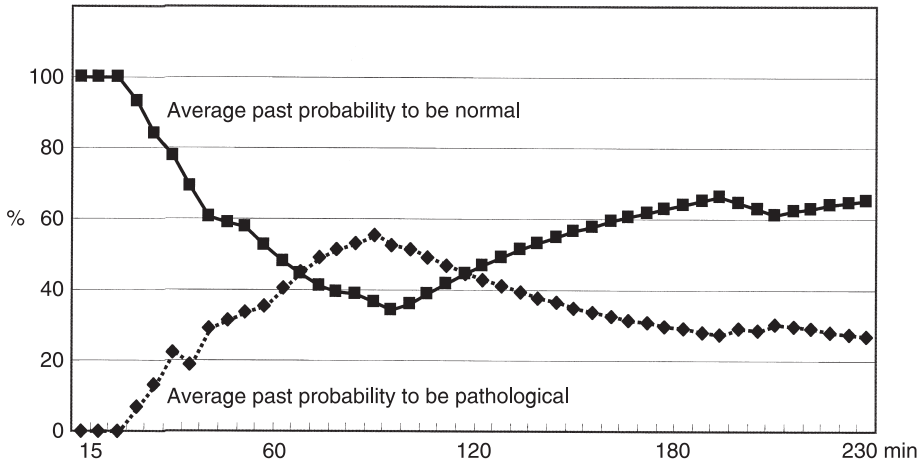

Figure 140.7 Past normal and pathologic outcome probabilities are averaged every 5 min and expressed as two line graphs in case 1.[10] Averaged normal probability is higher than the pathologic one. Neonatal condition is normal.

Apgar score was 3, and the infant expired 3 months later due to brain hemorrhage. Case no. 10, who was pathologic in the trend gram and in negative neural index, had an asphyxiated neonate.[10]

Using Fisher's exact test for statistical analysis, the neural index shows significant differences of neonatal states. The sensitivity, specificity, positive and negative predictive values are 100%. Therefore, the internal check of the neural index is perfect and a value lower than zero will inform of the danger of an intrapartum fetus during the monitoring process.

The place and role of neural index

The neural index can be used either in a personal computer connected to the fetal monitor, an intelligent individual monitor, or any other system where accurate and easy FHR evaluation is requested. We plan to carry out an external check of the neural system in a central monitor (TOITU MF-7400) after the installation of completed neural computer software. The system will be composed of a conventional program and a trained neural network. Both computers will analyze FHR and contractions. The central system monitors multiple pregnant women. The person responsible for the system studies the CTG and automatic diagnosis only after the system beeps when it alarms an irregular FHR, abnormal scores or abnormal indices. The display shows not only the neural index, but also outcome probability, CTG, alarming signs, FHR score, FHR findings in 5 min, and the contraction area that warns of uterine hyperactivity. The computer displays past CTG and its analysis on demand by the playback of computer memory. There is neither a CTG recorder nor a chart, but the CTG can be printed on demand. Original signals are stored in a large computer memory.

Monitoring by a central system is easy because computers monitor continuously without being subjected to sleepiness or fatigue, continuous CTG watching is not required and CTG display and automatic diagnosis are studied only after the alarm is sounded. There is no difficult pattern classification, but

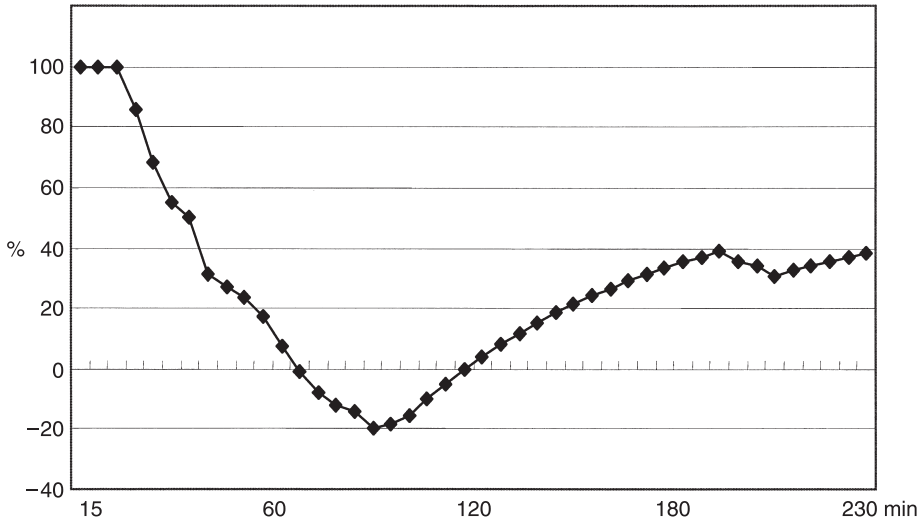

Figure 140.8 Averaged past pathologic outcome probabilities are subtracted from the averaged normal probabilities every 5 min in case 1, and the 'neural index' formed a single line graph. The final neural index is greater than zero and neonatal condition is normal in case 1.[10]

Table 140.5 Neural index correlates with neonatal condition[10]

	Neonatal depression		
Final neural index	**Present**	**Absent**	**Total**
< 0	5	0	5
> 0	0	4	4
Total	5	4	9

Sensitivity: 100%, specificity: 100%, Fisher's exact test: $P = 0.008$, positive predictive value: 100%, negative predictive value: 100%

instead, the pathologic outcome is shown by objective numeric values. Full monitoring of all births can be achieved. In a Seirei hospital where a central monitoring system was introduced without a neural network since 1996, the number of monitored cases increased 10-fold in 2 years. Objective and easy diagnosis will be further promoted by the neural network analysis.

Discussion

Quantitative FHR measurement made it possible to simply analyze FHR tracing and to express FHR condition with a continuous value. FHR score is quite different from FHR pattern classification, which has been commonly used and is helpful in fetal diagnosis. The method of pattern classification is to overlap an FHR change on typical templates proposed by the originators. The technique was generally accepted because it was similar to the diagnosis of a syndrome, i.e. the disease is diagnosed if the symptom complex coincides with the template of a syndrome. FHR pattern is classified when the FHR change overlaps clearly on a template. However, it is difficult to determine when the FHR change is far from any pattern in the classification. Although pattern classification has been accepted and is useful in fetal surveillance, FHR analysis is controversial and only its originator may be able to classify a difficult pattern. This may be the reason for various modifications which have been proposed by multiple originators.

As the pattern classification is of binary character, it evaluates FHR only by two categories. The pattern classification has been rarely studied by common scientific methods of regression and correlation with other biological phenomena. For example, its correlation with fetal blood acid–base or gas status has hardly ever been analyzed. Therefore, it was necessary to combine fetal scalp blood pH with CTG and was another reason of our quantitative FHR analysis.

FHR pattern classification needs multiple procedures. The first step is the study of FHR patterns to gain correct knowledge. Secondly, the FHR tracing is analyzed and patterns are classified. Thirdly, fetal pathophysiology has to be evaluated in the patterns. Finally, fetal status and prospective outcome are diagnosed by the observation of whole tracing. Obstetric and maternal conditions are simultaneously analyzed to plan any intervention. The presence of multiple steps may increase the risk of incorrect interpretation of the classification. Quantitative FHR score skips many analyzing steps in pattern classification to reach the score for which a certain outcome is expected. Neural analysis further indicates normal and pathologic probabilities using percentages. Finally, of these different methods, the neural index most clearly shows the outcome, economizing several steps which may present in pattern diagnosis.

Although pattern classification was useful in the initial stage of FHR diagnosis and its strict application promoted improved outcome in common obstetrics and in our past clinical studies,[1–4] its scientific analysis is difficult and it has a subjective nature. For example,

the delay time of late deceleration was undetermined and later Chik *et al.*[18] measured typical late decelerations and determined the delay time as 20 or more seconds. Modern classification does not define the delay time yet. The shape difference of periodic and variable changes has not been scientifically studied, while quantified technique made the separation possible with 'dip-shape value' in our study.[15]

The visual FHR evaluation with pattern classification is standardized at present only by the consensus of authorities, not on the scientific basis of objective measurement. The subjectivity and vague definition of FHR pattern might cause false-positive FHR diagnosis, although 50–70% of false-positive cases was reduced by the introduction of actocardiogram.[19,20] The FHR should be analyzed by scientific procedures to improve outcomes because, at present, continuous and non-invasive fetal surveillance through pregnancy and labor is achieved only by FHR monitoring. Obstetric care and patient management should not be hampered by complicated visual CTG classification. Similar to the automatic diagnosis of adult electrocardiogram, the analysis should be left to computer processing where fetal abnormalities are diagnosed and outcome is predicted automatically by an informed advanced computer. Time can be economized by the computer for the management of increased jobs to save the mother and child in modern obstetrics.

Apart from the complex pattern classification, simple measurement of FHR tracing is useful for the objective description. Regression and correlation analyses with other phenomena are easy in quantitative FHR analysis, e.g. FHR score and FD index were easily compared to Apgar score and fetal blood pH. The benefits are confirmed in this paper. Fetal blood P_{O_2}, P_{CO_2} or SPO_2, can be also analyzed with numeric scores and indices. Artificial neural network is introduced in our FHR studies on the basis of past beneficial evaluation of quantitative FHR analysis.

Artificial neural network analysis has been studied in various definitive purposes – the traveling salesman problem,[21] various business areas and widely in medicine, including EEG,[22] histology,[23] brain function,[24] brain tumor,[25] smear categorization,[26] visual field determination,[27] respirator fault detection,[28] coronary artery SPECT,[29] and HIV protein structure.[30] In our field, it has been used in ultrasonic fetal weight estimation,[31] estimation of the duration of the first-stage labor,[32] CTG feature extraction[33] and diagnosis of fetal hypoxia with FHR variability and pulse oximetry.[34] The aim of using a neural network in the present study is the highly objective FHR analysis, which is acceptable to general physicians.

In the past, conventional systems were mainly the experts' knowledge system, which was sometimes unacceptable to other scientists. In the artificial neural network, we used eight simplified FHR data obtained from normal and abnormal outcome cases. Data acquisition and its processing are totally objective and includes no opinion of experts. The outcome is shown by outcome probability and neural index. Details of FHR tracing are known by the conventional analyzing computer, if it is requested.

Although it is ideal to use all FHR data in the neural network processing, the data of FHR and the contraction will be 1500 in 15 min when the sampling interval is 2 s. A large number of units are required for input, and analysis time will be prolonged. For these cases, only off-line processing is suitable. We wanted real-time on-line processing in clinical monitoring and therefore, we selected a hybrid-type artificial neural network. The results are promising, and the completed neural network soft ware can be installed into clinical systems to achieve correct and easy fetal monitoring. All child births can be monitored by its application in the central system.

An artificial neural network will be useful not only in FHR analysis, but also in various other fields of medicine. An idea on the neural network is automatic diagnosis of ultrasound images. There are many tissue characterization reports in ultrasound images. Maeda *et al.*[35–37] reported a tissue evaluation by the gray-level histogram width, which was successful and clinical studies are promising. It will be also successful, if large sequential gray-scale data of typical diagnosis are input into a neural computer, which is completed by repeated education and used in actual diagnosis. The large volume of pixel data can be analyzed by off-line processing. Automatic diagnosis of malignancy, for example, will greatly contribute clinical medicine. The progress of computer technology is likely to make the author's ideas real in the future.

Conclusion

The FHR tracing is successfully evaluated by quantitative analysis of parameters including FHR score, FD index and artificial neural index without FHR pattern classification. The correlation and regression of quantitative FHR analyses to fetal blood pH and BE are successful, but not in pattern classification. The outcome of prolonged FHR monitoring is successful by the neural index obtained by the artificial neural network. Pathologic sinusoidal heart rate is diagnosed by a computerized frequency analysis. A high-grade CTG recorder and chart are not required in quantitative FHR evaluation. Difficult interpretation and study of pattern classification is of no use in quantitative evaluation, while late and variable decelerations are detected by the quantified computer analysis of FHR. Details of FHR tracing are displayed by the conventional analytic computer.

141 The fetal electrocardiogram

W. J. van Wijngaarden

Introduction

Electronic fetal monitoring (EFM), based on the recording and interpretation of the fetal heart rate (FHR), is practiced routinely in antenatal and intrapartum care throughout the world. This is analogous to diagnosing ischemic heart disease in adult medicine by recording an adult's pulse rate over a period of time. By only measuring the RR interval of the fetal electrocardiogram (FECG), as is done in EFM, a potential wealth of information on a fetus's well-being is discarded. During labor, the FECG is continuously available for analysis and reflects the cellular metabolic condition of the myometrium and the cardiac conduction system. FECG analysis in the detection of fetal compromise has been the focus of research of a relatively small number of groups for many years and has, in some instances, now reached the stage of clinical trials. Based on these, commercial enterprise is already advocating its implementation into clinical practice and is marketing specially devised monitoring systems.

The first FECG was recorded by Cremer in 1906[1] through silver electrodes attached to the abdominal wall and inserted into the vagina, with a simple string galvanometer used to display the very small signal. As concern over the maternal condition outweighed interest in fetal well-being, its clinical potential was not considered until many years later. However, already in 1930 it was recognized that for any analysis of the FECG to be made possible, the small FECG signal had to be amplified.[2] The potential of the FECG to aid diagnosis and management in certain conditions (drug effects on the fetal heart, congenital heart disease, umbilical cord problems, multiple pregnancies and abnormal labor) was suggested as early as in 1936.[3]

Signal processing

Technical difficulties with the small, transabdominally derived signal and background noise were first seriously addressed in the early 1950s with the introduction of bandpass filters, allowing only frequencies between 30 and 100 Hz to be amplified.[4] Thus QRS complexes were isolated and analyses of the FECG over longer periods were made possible. The first reports on changes in the FECG waveform during fetal hypoxemia were published in the 1950s.[5]

A major change in FECG research came with the introduction of the fetal scalp electrode in the early 1960s and as a result the main problems in obtaining transabdominal recordings (signal amplitude, signal identification and isolation) could be addressed. The ability to make accurate RR distance measurements led to the introduction of FHR analysis. However, low amplitude P and T waves were still often buried in background noise or filtered out when reducing the baseline drift of the signal which would otherwise interfere with signal detection. As a result, accurate, often manual, measurements were difficult to obtain and resulted in many inconsistencies in the earlier FECG waveform analysis studies. To amplify the FECG, so that the low amplitude waves could be identified and measured both automatically and accurately, a number of signal filtering and enhancement techniques have been developed.

The signal must be 'cleaned' from high and low frequency noise (such as baseline drift) by appropriate filters, leaving the frequency of the FECG waveform intact. In FECG recordings, a high pass cut-off of 0.16 Hz at −3 dB has been found to be adequate because of the shorter time intervals and higher heart rate than in adults where 0.05 Hz is a more appropriate high pass cut-off.[6]

Group averaging techniques were introduced by Hon and Lee[7] using a so-called 'CAT system'. This 'block averaging' technique meant stopping and resetting the system after each calculated averaged complex, which in the 1960s was an off-line and time-consuming procedure. An improvement on this was the development of 'sliding window' or 'running' averaging techniques, in which a new enhanced (averaged) complex is recalculated each time a new waveform is added to the calculation and the oldest is removed. Weighting of this running average was introduced later to allow for more transient changes to be detected. With this technique, all complexes are given a certain weight, with the latest the highest weighting factor or impact in the calculation of the enhanced waveform. With each new incoming

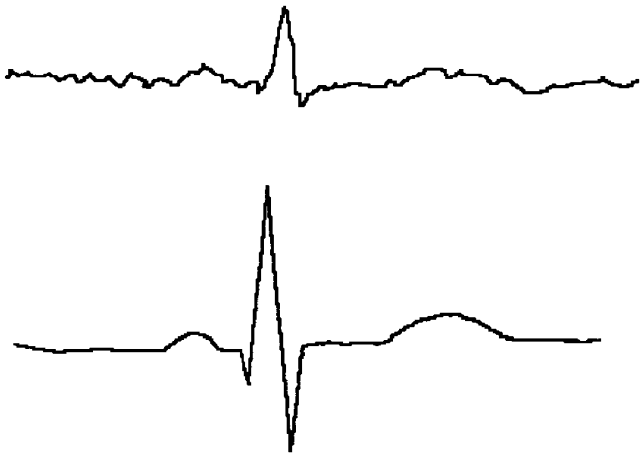

Figure 141.1 A raw fetal electrocardiogram (FECG) waveform (top) and enhanced FECG waveform after averaging (bottom).

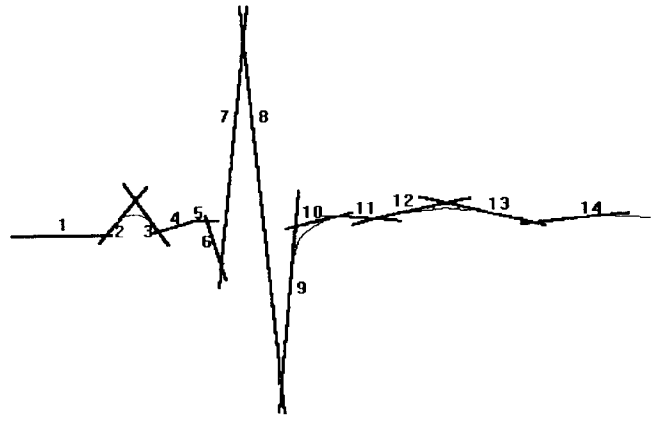
complex, all the previous weighting factors are changed and a new enhanced waveform is calculated.[8] The number of raw complexes and their respective input into the resultant averaged and enhanced signal can be varied. The result of this averaging or enhancement routine is the attenuation of electrical noise and other non-repetitive features such as movements, leaving the FECG waves recognizable and analyzable (Figure 141.1).

After having obtained an enhanced FECG waveform, several techniques can be applied to perform measurements. The Nottingham FECG analyzer measures the components of the enhanced FECG waveform by identifying the segments of the averaged complex using a 'line-fit routine'.[9] The location of the start, peak and end of each wave is calculated from the intersections of straight lines which are fitted by a linear regression technique to represent the incline and decline of each wave (Figure 141.2). The STAN 21 system (Neoventa) uses a set number of complexes for its block averaging technique. In exactly which way the changes in the ST segment are recognized and monitored is not public domain.

The developments of the above described techniques, aided by rapid developments in microprocessing technology, have made it possible to automatically and accurately identify the FECG waveform, reduce waveform distortion (fetal and maternal movements and electrical signals, 50 Hz interference) and to perform continuous on-line FECG analysis on small personal computer-based systems usable in a clinical setting. Furthermore, large amounts of generated data can now be handled easily and transformed into clinically interpretable patterns.

Signal acquisition

In human fetuses during labor, the FECG signal is obtained through a fetal scalp electrode. Single spiral scalp electrodes (Corometrics Medical Systems,



Point	*Intersection*
P onset	1 – 2
P peak	2 – 3
P end	3 – 4
Q onset	5 – 6
Q peak	6 – 7
R peak	7 – 8
S peak	8 – 9
S end	9 – 10
T onset	11 – 12
T peak	12 – 13
T end	13 – 14

Figure 141.2 Regression line-fit routine of the average fetal electrocardiogram (FECG) waveform.

Connecticut, USA and Cetro AB, Sweden) have a superior frequency response and a high signal amplitude with a low signal-to-noise ratio.[10] Although this may be of importance in morphological FECG analysis, the frequency response and signal-to-noise ratio of the Copeland electrode (Surgicraft Ltd, Redditch, UK) allows for adequate detection of the time intervals within the FECG. Therefore, both systems have been found to function satisfactorily in FECG time interval analysis but caution needs to be expressed when comparing FECG morphology measurements using different fetal scalp electrodes.

In FECG morphology analysis, changes in the various amplitudes are recorded within a certain cardiac vector. The direction of this vector is determined by the location of the reference electrode in relation to the exploring electrode attached to the fetal skin. In the fetal lamb, the changes in the T wave after an isoprenaline challenge were seen to be mainly in the YZ plane, whereas the routinely used bipolar lead system would only be optimal in identifying T-wave changes in the XZ axis of the fetal body.[11] In the standard bipolar configuration of a spiral fetal scalp electrode, the distance between the electrodes is small and has been suggested to be a cause for baseline drift, noise and fluctuating vector directions which may result in alterations in FECG waveform morphology.[12]

The Copeland fetal scalp electrode (also a bipolar configuration) has a long reference electrode which is less likely to cause vector fluctuations. It has been proposed that a unipolar configuration, with one electrode on the fetal scalp and one on the maternal thigh, would be more stable and better to detect changes in the longitudinal axis of the fetus (e.g. wave changes). Experience with the Nottingham FECG analyzer, however, would suggest a satisfactory detection of T-wave changes using a bipolar lead system and we have not found any benefit from using a unipolar system, nor were there any changes in the FECG waveform configuration seen when such a lead configuration was used. In humans, bipolar lead systems would appear as sensitive as unipolar systems to detect changes in the Y axis of the fetus. For obvious reasons, FECG time interval analysis is not influenced by potential errors due to different vector configurations.

Antenatal signal acquisition is usually performed transabdominally with Ag/AgCl skin electrodes. Signals can also be obtained by the detection of changes in the magnetic field caused by electrical fluctuations of the fetal heart[13] or directly during intra-amniotic procedures such as fetal cord blood sampling *in utero*.[14]

Other means of obtaining a fetal ECG signal include the placement of wire electrodes under the skin, which requires operative techniques and is commonly used in obtaining data in animal rather than in human studies.

FECG analyzers

A number of FECG analyzers have been used in direct signal sampling research over the past 10 years. Of these, the Nottingham FECG analyzer (University of Nottingham) and the STAN S21 analyzer (Neoventa Medical, Gothenburg, Sweden) are the only FECG analyzers used in an on-line real-time trial setting on the labor ward. The STAN S21 analyzer filters the incoming signal with a bandwidth of 0.05–100 Hz and digitizes it with a sampling rate of 500 Hz. A block averaging technique is applied to create an enhanced waveform using 10 accepted complexes.[15] The system is specifically designed to measure ST waveform changes but can also calculate the PR time interval. The waves are recognized by an amplitude search for the points of maximum deviation within a fixed time zone. For quality control, every 2 min the current average T/QRS ratio and averaged FECG complex are printed alongside a cardiotocographic (CTG) record.[16]

The Nottingham FECG analyzer filters the raw signal with a bandwidth of 0.16–150 Hz and digitizes the analog FECG signal at a sampling rate of 500 Hz. A matched filter is used to recognize the QRS complex by comparing of frequency spectrum characteristics. The averaged or enhanced FECG complex is created by using a 'time coherent' approach. This is established by correlating each new incoming raw complex, consisting of a total of 256 data points, with the enhanced waveform. Proper alignment of the new incoming and the enhanced FECG complex is ensured by cross-correlating 15 points around the R peak of the enhanced waveform with the R peak of the new ECG complex. In other words, the identified R peak becomes the fixed point around which raw FECG complexes are superimposed. The enhanced waveform is calculated after 'weighting' the complexes with the most recent signals having the most input. After this, a line-fit routine (see above) is applied to identify the individual waves. The capability of this time coherent weighted averaging routine to accurately isolate rapid changes of the unprocessed or raw FECG signal has clinically been validated by comparing fast changes in the raw signal with those detected in the averaged signal.[17] The Nottingham FECG analyzer measures 18 FECG waveform parameters (morphology as well as time interval) and calculates four more simultaneously at 2 s intervals including signal-to-noise ratio estimation for signal quality control. Only waveforms with a ratio exceeding 3:1 are included in the resultant waveform calculation. For quality control, the desired measurements are displayed in real time on a VDU screen along with the raw waveform and the averaged waveform (Figure 141.3). All 22 parameter measurements and calculations are stored in the system's memory for retrospective analysis.

The system used in Southampton in off-line intrapartum recordings used a band pass filter of 0.1–40 Hz and sampling rate of 1000 Hz. The system was designed to measure the T/QRS ratio. Measurements were performed on every second of four incoming raw complexes, thus at best, T/QRS ratios of only 25% of all incoming complexes were available.[18] Averaging of the T/QRS ratios was performed after the actual waveform measurements.

Cardiac electrophysiology

The electrocardiogram is a record of myocardial action potential fluctuations during the cardiac cycle. The electrical discharge of each cycle starts in the sinoatrial (SA) node. The membrane potential of the pacemaker cells of the SA node is unstable and declines continuously until a trigger level is reached. At this stage there is a dramatic increase of Na^+ ion influx and K^+ ion efflux, resulting in the depolarization of the SA node. This is accompanied by an increase in membrane permeability to Ca^{2+} ions and results in 'slow' inward current of Ca^{2+} ions which is responsible for the upstroke of the action potential in the SA node and, consequently, its frequency of reaching firing threshold levels or heart rate. This slow inward current of Ca^{2+} ions consists of three components. The main component responsible

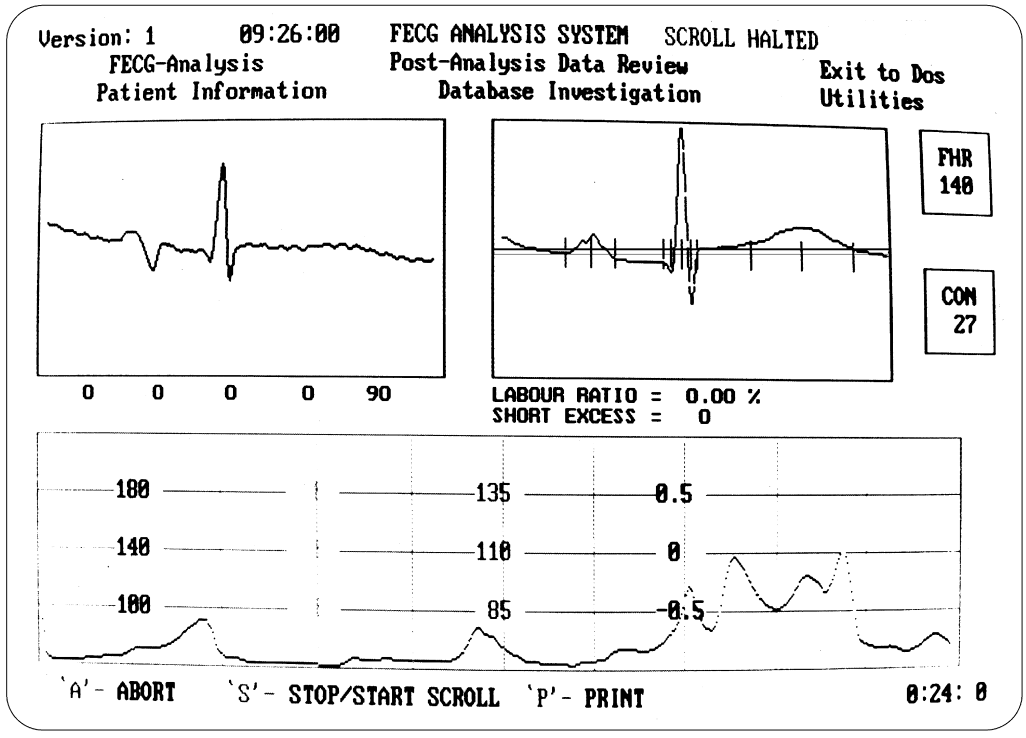


Figure 141.3 VDU display of the Nottingham analyzer: the raw waveform is displayed in the top left window, the averaged waveform in the top right window and the conduction index is displayed as a moving window at the bottom. The ratio index is displayed as a number next to 'labor ratio'.

for SA node repolarization is influenced by both adenosine triphosphate (ATP) and epinephrine which increase its conductance. As a result, during hypoxemia which is accompanied by reduced levels of ATP, the conductance is reduced. The atrioventricular (AV) node contains, in addition to 'slow' oxygen-sensitive Ca^{2+} channels, also fast Na^{+} channels which are less sensitive to oxygen.[19,20] Changes in oxygenation will therefore have less effect on the upstroke of the action potentials in the AV node than in the SA node.

Following the electrical discharge of the SA node, depolarization spreads through the atrial muscles. In the ECG this is represented by the P wave. Before the action potential is further propagated to the ventricles, it is delayed in the AV node. After the AV node, conduction is very rapid through the special conduction tissue of the bundle of His, which separates into the left and right bundle branches and the Purkinje fibers within the ventricular muscle mass. As the QRS complex is caused by ventricular depolarization, most of the PR interval reflects the conduction time (depolarization) of the AV node. Atrial repolarization is usually submerged in the QRS complex and ventricular repolarization is reflected by the T wave. The Na^{+}/K^{+} pump fuelled by ATP and activated by intracellular Ca^{2+} plays a central role in all these processes. The Na^{+}/K^{+} pump maintains the ion gradient across the cell membrane by Na^{+} ion efflux and K^{+} ion influx, with a resultant net positive extracellular charge. An increase in heart rate is a result of an increase in Na^{+}/K^{+} pump activity, which results in an increase in the outward current. This leads to a shorter repolarization time and therefore a shortening of the time to reach the following trigger level for depolarization. Under normoxemic conditions, this will not lead to any major changes in the morphology of the FECG waveform and the time intervals will shorten simultaneously.

The control of the FHR and the conduction of action potentials in the heart is complex. Spontaneous firing of the pacemaker cells of the SA node, the effect of baro- and chemoreceptor stimulation, autonomic nervous system reflexes and tone all directly or indirectly influence the SA and the AV node. Hypoxemia may not only induce an adrenal catecholamine release but also directly slow the conduction of action potentials in the myocardium[21] and the AV node.[22]

Normal values for the FECG waveform

Ranges for the normal values of FECG parameters using an old model of the STAN system and the Nottingham system have been reported for both acidotic and non-acidotic human fetuses during labor. Using the STAN-alyser system, a mean T/QRS ratio during labor has been quoted as 0.148, with an SD of 0.048.[23] A list of normal values for FECG waveform

Table 141.1 Normal values for fetal electrocardiogram (FECG) time interval and morphology parameters as measured with the Nottingham FECG analyzer during the first 20 min of recording time in the first stage of labor; time intervals in ms (from Mohajer[30] with permission)

Parameter	Mean values (SD)
Fetal heart rate	134.38 (13.3)
PR (interval)	102.72 (12.5)
P (duration)	63.34 (12.2)
QRS (duration)	43.61 (5.4)
R/S (ratio)	2.89 (0.6)
PRe (segment elevation)	97.49 (4.0)
STe (segment elevation)	102.86 (6.4)
RT (interval)	147.77 (21.3)
T (duration)	127.75 (24.1)
P (height)	9.44 (4.2)
Q (height)	10.77 (9.2)
R (height)	70.94 (15.2)
S (height)	24.58 (19.3)
T (height)	7.79 (6.7)
S/N ratio	9.39 (5.9)
P (area)	6.08 (3.5)
T (area)	10.63 (6.2)

measurements performed by the Nottingham FECG analyzer during the first 20 min of recording in first-stage labor of term pregnancies with uncompromised infants at delivery [umbilical artery pH > 7.20, base excess (BE) > −8 mmol/l] weighing over 2500 g is given in Table 141.1.

The FECG and changes during fetal compromise

All aspects of the FECG waveform have been analyzed and related to changes in biochemical markers or CTG patterns. The earlier studies in particular need to be interpreted with caution because of potential errors due to noise, inappropriate filter settings and manual measurement techniques. Furthermore, caution needs to be exerted when changes are reported in cross-sectional data sets, as individual trends may be of greater importance and more informative. The use of means and standard deviations in not normally distributed populations (such as the T/QRS ratio) should be avoided as it may lead to wrongly assumed definitions of abnormality.[24]

The P wave

The aspects of the P wave which have been studied are changes in its duration, height and area. P-wave duration increases progressively from the 17th week of gestation with increasing cardiac mass.[25] Changes in P-wave morphology (i.e. notching, inversion, biphasic), as well as its (sometimes transient) complete disappearance, have all been reported to occur in association with decelerations but not necessarily with an abnormal acid–base balance.[7,17,26–29] Care needs to be exerted when interpreting changes in the P-wave height using averaging techniques. It was found on examination of the raw FECG complexes that the P wave could be dislocated from its normal position during bradycardia beyond the FECG analyzer's ability of detection and consequently lead to a false apparent reduction in its height.[30]

The duration of the P wave may change during fetal respiratory acidemia[31] and was noted to be loosely related to umbilical vein norepinephrine levels.[17,28] The significant correlation between umbilical artery blood gases and change in P-wave duration during the last hour of labor was found to be too low ($r_{pH}=0.13$) for clinical use.[17] No significant difference was found between the duration, the height and the area of the P wave of non-compromised term fetuses, acidemic fetuses (umbilical artery pH < 7.16, BE < −10 mmol/l) regardless of gestational age and small-for-gestational-age fetuses (birth weight < 2500 g). Nor was any significant difference found when the first 20 min of these labors was compared to the last 20 min of labor of each group individually.[30]

The P-wave area has been seen to increase with fetal acidemia,[31] to decrease with fetal distress[27] and to be unrelated to fetal acid–base balance apart from a clinically impractical but significant correlation ($r_{pCO_2}=-0.15$) with umbilical artery pCO_2 levels over the last hour of labor.[17]

The PR segment

Changes in the height of the PR segment are common but have not been found to be related to any biochemical changes.[17,28] In FECG morphology measurements, the height of the PR segment is important when it is used as the isoelectric line, as is done by the STAN system. It may be a source of discrepancies when identical recordings are analyzed by different systems, as the Nottingham FECG analyzer and the system used in Southampton both use the pre-P segment as the isoelectric line.[32] No significant difference in the height of the PR segment was found when cross-sectional intrapartum measurements were compared between uncompromised term fetuses, compromised fetuses and small-for-gestational-age fetuses. Nor were there any significant differences between the first and last 20 min of labor in each of these groups.[30]

The PQ and PR intervals

In animals, manual measurements of the FECG waveform showed both a prolongation of the PQ interval during hypoxemia in lambs[33] and a lengthening of the PR interval after cord occlusion in baboons.[34] More recently, the changes in the PR interval seen during hypoxemia in fetal lamb experiments have been clearly documented. Acute maternal aortic occlusion was seen to be followed immediately by an initial prolongation of the PR interval simultaneous to RR interval lengthening (vagal reflex) and superseded by a shortening of the PR interval. This was reverted to a lengthening of the PR interval after release of the occluder.[35] The shortening of the PR interval following the vagal reflex is thought to be secondary to an increased adrenergic activity and the lengthening after release of the occluder as a result of baroreceptor stimulation. Murray[17] showed that the initial vagal reflex could be abolished with atropine premedication. In the same study, isoprenaline was shown to decrease both the PR and the RR intervals during normoxemia. Baro- and chemoreceptor reflexes probably do not have a great influence on this as the same changes were seen in experiments on very premature fetal lambs in which these reflexes are not yet fully developed (H. Murray, personal communication).

In humans, large changes in the FHR have been found to coincide with changes in the PR interval.[17] Table 141.2 displays the observations from various studies of changes in the PR interval in relation to periodic changes of the FHR.

In a study of 40 normal labors, the PR interval was noted to shorten significantly during contractions, whether induced by syntocinon infusion or not, without any significant change in coincident FHR pattern.[36] In one study, a significant difference in PR interval was reported when comparing male to female fetuses in labor.[37] Possible explanations for this phenomenon are the slightly higher heart rate and/or the higher sympathetic tone in males and exaggerated reaction to stress when compared with females.[38]

Earlier work suggested that the overall trend for the PR interval to shorten during normal labor did not have a relationship with biochemical compromise.[6,31] In a study comprising 309 labors, the mean PR interval duration was found to change little until the last hour of labor.[17] In 59% of labors, a significant shortening in the mean duration was noted during the last hour, although this was within the standard error of measurement in 13% of these. During this time, changes in the mean PR interval duration were significantly correlated ($r = 0.2$) to umbilical artery cord gas measurements, but were too weak for clinical use. This was supported by a later study which did not find a change in the PR interval between the first and last 20 min of labors in uncompromised fetuses but noted a shortening of 10% in the group with evidence of fetal compromise, which was statistically not significant.[30] Importantly, Murray[17] found the average PR interval duration over the last 15 min of labor to be inversely related to epinephrine ($r_{epi} = -0.47$, $P < 0.001$) and norepinephrine ($r_{norepi} = -0.26$, $P < 0.001$) levels in arterial cord blood. As catecholamine levels increase during the second stage of labor and even more so in the compromised fetus, a strong adrenergic influence on the AV node and therefore PR interval duration could be an explanation for the changes in the PR interval seen during labor.

Table 141.2 The relationship between the PR interval and periodic changes in the fetal heart rate

	Study	PR interval
Accelerations	Murray[17]	↓
	Mohajer[30]	↓

	Murray[17]	↓↑ *
	Mohajer[30]	↑
Variable	Roemer *et al.*[65]	↓
	Pardi *et al.*[27]	↓
	Murray[17]	↓ **
	Mohajer[30]	↓
Late	Pardi *et al.*[27]	↓↑ ***
	Murray[17]	↓
	Mohajer[30]	↓

↑ Lengthening; ↓ shortening; *shortens in 50%, lengthens in 50%; **shortens after an initial lengthening; ***lengthens during 'mild' and shortens during 'moderate' and 'severe' late decelerations

The R/S ratio

The direction of spread of depolarization through the ventricles is called the cardiac axis and is represented by the R/S ratio. Right axis deviation occurs in congenital heart disorders and in conditions where there is a strain on the right side of the heart leading to right ventricle hypertrophy. Left axis deviation can occur with hypertrophy of the left ventricle but is commonly due to conduction defects.

Mohajer[30] found a reduction trend in the R/S ratio when cross-sectionally comparing the first 20 min with the last 20 min of labor in both non-compromised and compromised fetuses, indicating a right axis shift. The opposite was seen in small-for-gestational-age fetuses. In addition, small-for-gestational-age fetuses were observed to start labor with a non-significant but substantially higher ratio than non-compromised fetuses.

No change in the R/S ratio was seen during or between contractions.[37] Symonds[39] observed acidosis and hypokalemia in the umbilical vein to be accompanied by a left shift of the cardiac axis during labor. This was also seen to accompany late decelerations and bradycardia. However, with increasing acidosis as measured by fetal scalp blood sampling, there was a tendency toward right axis deviation. This right axis deviation during labor was also noted to be associated with umbilical cord entanglement and hypoxemia at birth.[40] The association between a right axis deviation and acidemia was also seen by Strachan *et al.*[41] who found a significant correlation between a decreasing R/S ratio during the last half-hour of labor and an umbilical artery pH and BE of less than 7.15 and −8 mmol/l, respectively. Acute pressure changes in the umbilical cord vessels may lead to intracardiac pressure changes which can result in cardiac axis deviations. Chronic hypoxia, on the contrary, may cause left ventricular strain and result in left axis deviation.[42] The tendency for left axis deviation in small-for-gestational-age fetuses seen in other studies would support this.[30]

The QRS duration

The QRS duration represents the time for the action potential to spread through the ventricles. It is significantly longer in males than in females[37] and is, as in adults,[43] directly related to myocardial mass.[44] This would be in keeping with anatomical studies showing the male fetal heart to be heavier than the female fetal heart.[45] The relationship between the QRS duration and birth weight is highly significant ($r=0.38$, $P=0.001$)[37] and should be borne in mind when quoting and reporting normal values. Although early and variable decelerations have been seen to be associated with a shortening of the QRS duration,[26] no relationship between QRS duration and fetal compromise during labor has been found.[5,17,46] Contractions do not influence QRS duration.[37]

The observation that chronic impaired oxygenation may lead to an increase in QRS duration[47] is supported by the clear correlation found between ventricular depolarization time and hemoglobin levels in pregnancies complicated by rhesus isoimmunization.[48] Reactive myocardial hypertrophy, resulting in a larger QRS duration, appears a logical explanation for this. Therefore, it has been suggested that serial antenatal QRS duration measurements may improve the detection of fetal growth retardation. One report quotes a sensitivity of 82% and specificity of 93%.[49]

The QT and RT intervals

The QT and RT intervals are closely related to the FHR and, if corrected for this, little significance in the relationship with clinical features has been found.[28,30,42] The QT interval during episodes of hypoxia has been seen to decrease in rabbit experiments,[50] not to change after placental separation[46] and to increase significantly during acidosis in human fetuses.[42] A shortening has been observed during early and variable decelerations.[26] Although this was also observed in a recent study on 68 fetuses with metabolic acidemia at birth, a significant shortening rather than a lengthening of the QT interval was found at the end of the recording when compared with the beginning which was independent of heart rate.[51] Further work is awaited to clarify the potential of the QT interval in fetal monitoring.

The ST interval and T-wave duration

As in all the low-frequency waves, the setting of the filter characteristics is essential in the ability to identify the beginning and end accurately. If too high, the onset of the ST segment will smoothen and continue indistinguishable into the T wave. If too low, noise will swamp the signal, rendering it unidentifiable. Group averaging techniques and, to a lesser degree, moving windows weighted averaging techniques will artefactually lengthen the T wave as a result of changes in the RT interval, secondary to normal RR duration variation. Mohajer[30] observed a trend of shortening of the T-wave duration during labor which was not significant. Changes in the T-wave duration have not been found to be related to fetal intrapartum compromise.[52]

The ST segment and T-wave height

In adults, ST waveform changes occur during episodes of myocardial hypoxemia and infarction. These include ST segment height changes and both an increase and inversion of the T-wave height. The observation of similar changes in compromised fetuses forms the background of ST waveform analysis in the detection of fetal hypoxemia. Repolarization of the cardiac ventricles, as opposed to depolarization, is an active and energy-requiring process. Therefore, the morphology of the ST waveform is dependent on the sequence of ventricular depolarization, functional hemodynamic changes, the local metabolic status and substances influencing the Na^+/K^+ pump and, importantly, the vector of the leads used.[53] Reduced efficiency of the Na^+/K^+ pump, regardless of the cause, leads to potassium release, a change in membrane potential and consequently an elevation of the T wave. Quantitative measurements of the T wave are commonly expressed as the T/QRS ratio to eliminate changing amplification factors.

Controlled animal experiments have clearly demonstrated the presence of ST waveform changes during episodes of fetal hypoxemia.[33,54] In myocardial metabolism studies in fetal lambs, the decrease in high-energy substances during hypoxia was accompanied by a decrease in the T-wave amplitude when

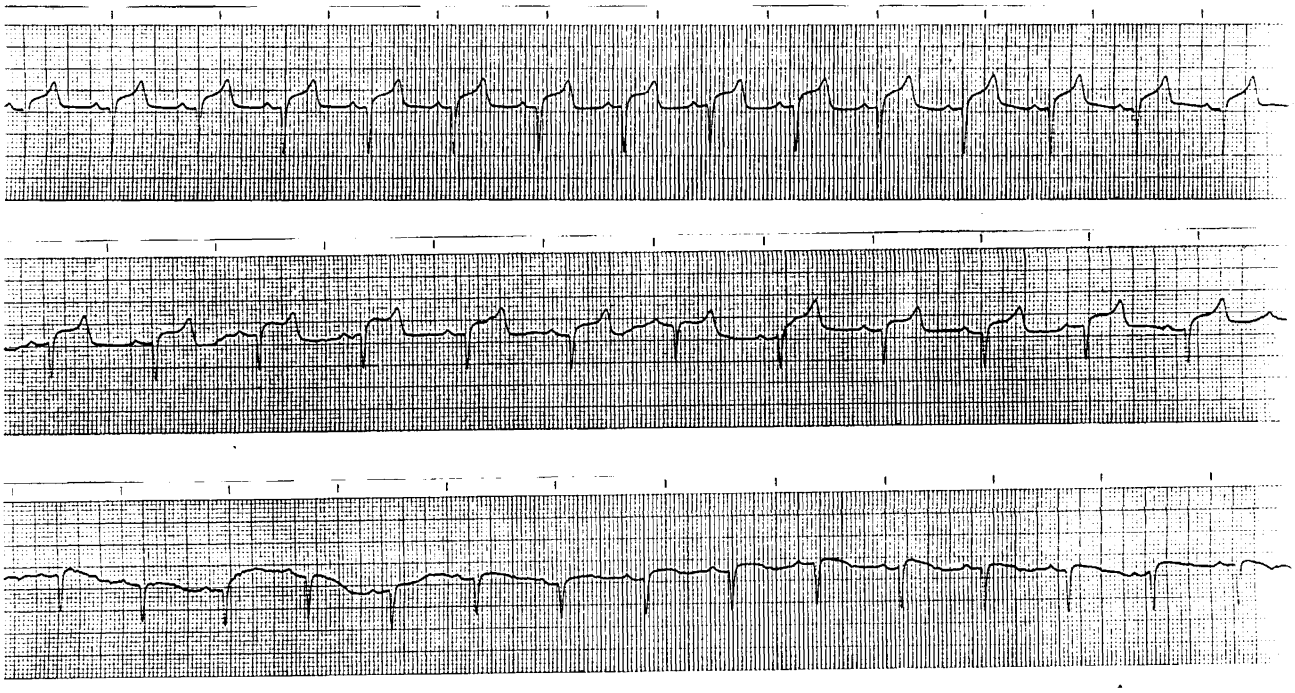

Figure 141.4 Reversion to normal of an elevated T/QRS ratio and ST segment elevation in a fetal lamb with a pH between 7.01 and 7.03 and a base excess between –14.8 and –17.8 mmol/l in fetal sheep experiments conducted by Drs H de Haan and THM Hasaart, Maastricht.

signs of failing cardiovascular functions occurred.[55] The decrease in amplitude of a previously elevated T wave during severe fetal compromise was also observed in another fetal sheep experiment and should caution against reassurance of a sound fetal condition with normal T/QRS ratios alone (Figure 141.4; van Wijngaarden, De Haan and Hasaart, unpublished data).

The rate of glycogenolysis has been found to be significantly correlated ($r=0.73$, $P=0.001$) with an increase in T-wave amplitude, indicating a relationship between myocardial glycogen utilization and T-wave amplitude.[55] Given the glycogenolytic effect of catecholamines, this is in keeping with the ST waveform changes seen with the administration of β-sympathicomimetics, epinephrine surges during hypoxia and the strong correlation between plasma epinephrine levels and the T/QRS ratio in mature fetal sheep.[35,56,57] The lack of this correlation in immature fetal sheep could be due to a different adrenergic response to hypoxia as a result of an immature neuroendocrine development.[35] A change in the normal adrenergic response to hypoxia may also be accountable for the different ST waveform changes seen in growth-retarded guinea-pig fetuses as compared to fully grown guinea-pig fetuses.[58] Perhaps a different setting of the basal sympathetic tone as a result of chronic stimulation, leaving little room for response to further excitation, may be responsible for this. However, as propranolol (a β-adrenoreceptor blocker) was seen to inhibit ST waveform changes during moderate but not during marked hypoxia, catecholamines alone may not be solely responsible for the observed changes.[57]

In studies on chronically instrumented fetal sheep, the T/QRS ratio was seen to have a linear relationship with hypoxemia and to be significantly correlated to acidemia, lactate and (nor)epinephrine levels and blood pressure.[59–61] As the acidemia was mainly due to increasing levels of lactate, increasing T/QRS ratios were suggested to indicate anaerobic metabolism.[59] T-wave changes have been observed to occur during normoxemia in combination with increased myocardial performance, indicating simultaneous epinephrine release. On the contrary, hypoxic episodes, with a decrease in oxygen content down to 64% without an increase in epinephrine levels, were not accompanied by ST waveform changes.[60,62] It has been suggested, therefore, that an increase in T-wave amplitude could serve as an index of myocardial energy balance which becomes negative when glycogenolysis sets in.[62] These findings and the correlation with lactate levels suggest that ST waveform changes occur when the fetal myocardium switches to an anerobic metabolism and the elevation of the T wave occurs when fetal adaptation to hypoxemia with an increased coronary blood flow is no longer sufficient.[63]

In a large study of 47 chronically cannulated lambs subjected to profound levels of hypoxia, the large changes seen in the T/QRS ratio and fetal biochemical status did not appear to be very well correlated.[64] The clinically important conclusion from this report was

that the T/QRS ratio is a poor predictor of fetal compromise.

Observational ST waveform studies in human fetuses during hypoxemia are more equivocal than those in animals. In early work, using manual measurement techniques, hypoxia was seen to be accompanied by ST segment depression and T-wave inversion,[42,65] but no relationship was found between ST waveform changes during late decelerations and fetal scalp blood pH.[27] Using the STAN-alyser (Cinventa, Sweden), Lilja *et al.*[66] found an increased T/QRS ratio in half of the fetuses with an abnormal FHR pattern. In another study, low Apgar scores were associated with an increased T/QRS ratio.[67] Using the Nottingham FECG analyzer, ST waveform changes were seen to accompany low arterial cord pH values.[28,68] The average increase in the T/QRS ratio of 1.02% (range –3.07% to 10.0%, $P < 0.004$) seen during contractions may be explained by catecholamine surges and transient hypoxemia.[69] It is of note that this increase in T/QRS ratio was significantly higher in pre-edited raw complexes, which emphasizes the potential inaccuracy of FECG waveform morphology measurements from noisy data.

Other studies, however, could not confirm a relationship between birth asphyxia and the T/QRS ratio.[18,70,71] One report found a raised T/QRS ratio to have a considerably lower detection rate for fetal acidemia during labor at term than a pathological CTG.[72] During normal labor, T/QRS ratios appear to wander greatly[18,24,73] and the average T/QRS ratio in normal labor varies substantially: 10%,[18] 15%,[23] 18–26%[73] and 20%.[64] The setting of the isoelectric line may be responsible for differences when different systems are used.[18,32,70] A study which compared electrical signal conduction of different fetal scalp electrodes using the STAN-alyser, suggested the T/QRS ratio to have a linear relationship with the amplitude of the QRS complex.[74] Although this could not be confirmed on the Nottingham FECG database using the Nottingham FECG analyzer (W.J. van Wijngaarden and B.K. Strachan, unpublished data), further studies are required.

As the T/QRS ratio is not normally distributed and varies greatly between cases, it may be better to perform analyses using individually calculated criteria for abnormality rather than cross-sectionally acquired derived cut-off levels.[24] In a retrospective analysis of 20 intrapartum fetal electrocardiogram recordings, only two were found to have a T/QRS ratio which was normally distributed.[75] An increase in the T/QRS ratio over the 97.5th and 99.5th centile for 2 consecutive minutes, with the centiles calculated on an individual basis, would appear to discriminate best between biochemically compromised and non-compromised fetuses. However, the effect on the intervention rate remains to be established. In no case the T/QRS ratio was seen to exceed 0.25 for periods previously described to be related to poor outcome. It was concluded that the use of an absolute threshold for T/QRS ratio abnormality based on the assumption of a normal distribution needs to be viewed with caution.

The first randomized controlled trial (RCT) on the clinical value of ST segment and T/QRS ratio changes in intrapartum fetal surveillance reported in 1993 and included over 2400 labors.[76] Intrapartum monitoring was performed by conventional CTG or by ST waveform analysis in conjunction with CTG. The results of this trial[76] suggest the STAN-alyser safe to use in conjunction with conventional CTG and may reduce the number of fetal blood samples (FBS) carried out (but not the number of patients having a FBS carried out). The numbers of operative deliveries for an abnormal FBS were similar in both groups, indicating similar sensitivities to detect an abnormal scalp pH. The operative intervention rate for presumed fetal distress was significantly higher in the control group but as both groups had a similar incidence of abnormal FBS results, this appeared to be based on CTG interpretation only. There was no difference in intervention rate with normal cord gas measurements between both groups. Although there were fewer cases with metabolic acidosis in the ST analysis arm of the trial, it was not clear whether these were actually identified by ST analysis, as the incidence of mild acidosis was almost identical in the two groups.

Another clinical analysis of the application of T/QRS ratio changes in the detection of fetal compromise during labor showed that, when using the T/QRS ratio only, with values over 0.25 for depicting abnormality, over 75% of abnormal FBS results would have been missed.[77] Although the first intrapartum trial suggests that during labor a normal ST waveform reassures the birth attendants of a sound fetal condition, the latter study emphasizes that a normal ST waveform should not be regarded to be reassuring in the presence of CTG abnormalities.

A new model of the STAN system was introduced in the late 1990s (STAN S21) by Neoventa Medical, Gothenburg, Sweden, which not only calculates the T/QRS ratio, but also reports on ST segment changes. A number of retrospective and prospective observational studies and one RCT have since been reported, most by or in association with the same research group in Sweden. The final report of a large Swedish-based European multicenter implementation study is awaited. In a prospective observational study on 573 labors in 12 Nordic centers, of a total of 15 neonates with neurological symptoms and/or acidemia (cord artery $pH < 7.05$ and base deficit > 12.0 mmol/l), five neonates had neurological symptoms and ST abnormalities during the first stage and eight showed ST changes during pushing.[78] Of the eight cases that had acidemia and a normal neonatal outcome, seven had CTG + ST abnormalities.

In another prospective observational study, of the 637 labors which were monitored using a STAN S21 system, only 70.5% was, for various reasons, available for outcome analysis.[79] Eighteen (4.0%) of the 22 of the neonates with metabolic acidosis (same definition as above) were in this group. Fetal scalp blood samples (total 192) with a pH < 7.20 were associated with ST changes in 67%, whereas this occurred in 11% of cases with a pH ≥ 7.20. In all five cases with an umbilical cord artery pH < 7.00, significant changes occurred in the ST segment 18–31 min before birth, whereas these were not present in seven of the 13 neonates with a pH between 7.00 and 7.04. In 57% of the 61 cases with ST segment changes > 10 min before birth the umbilical artery blood pH was < 7.15. Of note is that in the severe acidemia group of five cases, no neonatal sequelae were reported. Although it was concluded that CTG plus ST analysis was more specific in detecting fetal acidemia than CTG alone, it would appear from this study that a normal ST analysis result is not highly predictive for a normal scalp blood pH (89%) and a normal ST waveform should not lull one into complacency and CTG changes must be taken serious as always. It would appear from this study that the timing of ST changes before delivery of (severe) acidemic neonates warrants further efficacy studies.

In a recent retrospective study on 143 labors in a setting which relies on CTG interpretation without the routine use of fetal scalp blood sampling as a second-line screening tool for fetal well-being, a sensitivity of 43%, specificity of 74%, negative predictive value of 96%, and a positive predictive value of 8% for metabolic acidemia at birth (umbilical cord artery pH < 7.15 and base deficit ≥ 12 mmol/l) using the STAN clinical guidelines was found.[80] In this study, problems with good-quality FECG signals occurred in 11% of the recording time. Although the authors concluded that the STAN system has a poor predictive value sensitivity for metabolic acidosis, it should be emphasized that their definition of metabolic acidosis at birth is debatable.

In 2001, a Swedish multicenter trial was reported in which a total of 4966 term labors were recruited in three centers.[81,82] Significantly lower rates of metabolic acidosis (umbilical artery pH < 7.05 and base deficit > 12 mmol/l) and operative delivery for presumed fetal distress were found in the ST analysis group with a risk ratio (RR) = 0.47 (95% CI: 0.25–0.86) and with an RR = 0.83 (95% CI: 0.69–0.99) respectively. Of the nine cases with HIE grade II and III, eight occurred in the CTG-only group and one in the ST analysis group, a significant difference. It was concluded that CTG plus ST analysis may prevent intrapartum asphyxia and neonatal encephalopathy. Since then, a Swedish-based EU project to introduce ST analysis into clinical practice entailing 7823 term singleton labors monitored with ST waveform analysis clinical guidelines, was completed.[83] At the time of writing the final analysis of this study is awaited.

Although human observational studies and controlled animal experiments on the benefits of ST waveform analysis during labor are inconclusive, the Swedish RCT appears to indicate a positive role in the reduction of adverse neonatal outcome. It must be emphasized however, that at the basis of the ST waveform analysis algorithm of the STAN S21 system is the ability of proper interpretation of conventional CTG recordings. This is of concern as misinterpretation of the CTG and suboptimal response to CTG abnormalities are still major factors in case of perinatal death and cerebral palsy.[84,85]

A number of issues regarding the ST waveform analysis remain to be addressed. For instance, the non-Gaussian distribution and the large 'normal' range of the T/QRS ratio during labor. In the commercially available algorithm, the cut-off for normal is calculated on the false assumption that there is a normal distribution. Furthermore, the impact of ST waveform abnormalities during the second stage on the time to delivery and outcome is not clear. The potential for ST waveform analysis to be used as a substitute for fetal scalp blood analysis needs further work as is indicated by the results of a large observational study.[79]

Clearly, with perinatal death and cerebral damage, undisputedly as the most important outcome measures, being relatively rare, and in the interest of evidence-based medicine, larger RCTs in other populations are required to confirm the conclusions of the Swedish studies before establishing ST waveform analysis as a diagnostic tool in fetal monitoring as was already proposed by the Swedish study group.[86]

The PR–FHR relationship

Under normal conditions, normoxemic fetuses, healthy children and exercising adults all exhibit an inverse relationship between the PR interval and the heart rate.[28,87,88] During mild hypoxemia in fetal sheep, a brief vagally mediated lengthening of the PR interval was seen to be followed by a simultaneous increase in the FHR and a shortening of the PR interval and to be accompanied by an increase in epinephrine levels.[35] Further hypoxemia resulted in a slowing of the FHR but did not affect the reduction of the PR interval. The same reversal of the normally inverse relationship between the PR interval and FHR was observed in hypoxemic fetal sheep with and without blocking vagal influences with atropine.[17] This changing relationship was confirmed in the analysis of fetal sheep experiments, in which profound and prolonged hypoxemia and acidemia were induced comparable to levels in compromised human fetuses during labor[89] (Figure 141.5). In fetal sheep this changing relationship occurred simultaneously to the accumulation of serum lactate at a rate of at least 5 mmol/l per 30 min, indicating anerobic metabolic

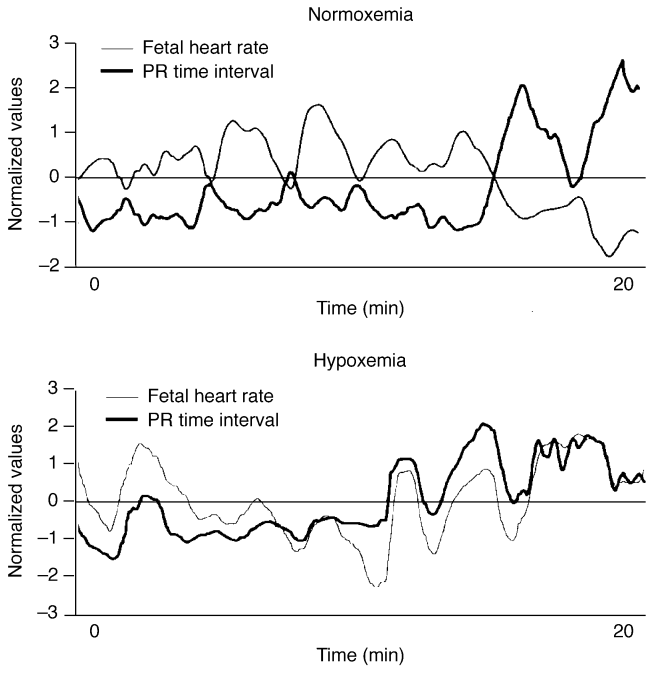

Figure 141.5 Two-second fetal heart rate (FHR) and PR interval measurement during normoxemia (top) and hypoxemia (bottom) in fetal sheep. Reprinted with permission from Bailliere Tindal.

circumstances.[17] Clinical observational studies indicated that a change of the fetal PR interval–FHR correlation during labor from negative to positive was associated with acidemia at birth, and in particular if sustained for 20 min or longer.[17,28]

An explanation for this reversal is the different response of the SA node and the AV node to hypoxemia.[17] The observed shortening of the PR interval during vagally mediated decelerations is contrary to how the AV node responds to parasympathetic stimuli and is more likely due to an increase in catecholamine levels associated with hypoxemia or stress.[17,90] Catecholamine levels rise during mild hypoxemia. This will increase the FHR and shorten the PR interval and sustain their negative relationship. Increasing hypoxemia will reduce ATP levels and affect the slow oxygen-dependent calcium channels of the SA node: the FHR will drop. The reduction in available oxygen does not yet affect the fast sodium channels of the AV node at this stage and the rising levels of epinephrine will continue to shorten the PR interval. Consequently, the PR–FHR relationship will change from negative to positive.[17]

The clinical application of this phenomenon in intrapartum surveillance has taken shape in two calculations to assess normality. The conduction index (CI) is a PR interval–FHR Pearson's correlation coefficient which is calculated by the Nottingham FECG analyzer every 2 s and, if it is positive for longer than 20 min, is thought to be an indication of recent fetal deterioration.[17] The ratio index (RI) is the product of the standard deviation values of the FHR and PR interval exceeding two positive standard deviations, expressed as a percentage of total recording (labor) time. It was found to be significantly related to umbilical artery pH, lactate, norepinephrine and hypoxanthine at birth, with a predictive accuracy of 89.4% when using 4% as a cut-off.[91] As this calculation incorporates data from the whole labor, it is thought to be an indicator of more chronic rather than acute fetal deterioration. A retrospective study of 250 high-risk labors indicated that the use of these two FECG parameters, in conjunction with CTG interpretation, could have resulted in an almost 50% reduction of unsuspected acidemia at birth and a reduction in unnecessary fetal blood sampling from 85.6% to 26.8%, without an increase in the assisted delivery rate.[92]

These findings prompted a randomized prospective trial which initially reported a significant reduction in fetal blood sampling of over 70%, with those taken more likely to be abnormal when FECG analysis was used in conjunction with EFM (RR = 1.61, 95% CI: 0.91–2.84).[93] The final report in 2000, including a total of 1038 labors, showed a trend toward fewer operative interventions for presumed fetal distress in the PR analysis plus CTG group (RR = 0.80, 95% CI: 0.59–1.08).[94] No significant difference between the groups was found in the number of cases with a cord artery pH ≤ 7.15 (RR = 1.01, 95% CI: 0.7–1.47), or in the frequency of unsuspected acidemia (RR = 1.17, 95% CI: 0.76–1.79). It was concluded that although there was a trend in decreasing operative intervention there was no significant benefit in the addition of PR time interval analysis to conventional CTG in neonatal outcome.

The effects of epidural analgesia on the FHR in relation to the PR interval have been studied in women in labor and the results suggest the possibility of a transient local anesthetic-induced effect on the fetal cardiac conduction system.[95,96] Further studies are required to assess the impact of repeated epidural 'top-ups' on the FECG during labor.

Combining FECG time interval and morphology analysis

Recent work suggests that the addition of the T/QRS ratio (with individualized cut-offs for abnormality) to the combination of EFM, RI and CI may reduce the number of unsuspected fetal acidemia at birth further but will simultaneously increase the number of unnecessary interventions.[24] This study showed further that the RI appears to be the most sensitive FECG parameter in detecting fetal compromise and the first to become abnormal during adverse situations. It was concluded that in future work more emphasis should be placed on this calculation of the PR–FHR relationship. It is clear that more research in combining FECG time intervals and morphology changes in the detection of fetal compromise is required.

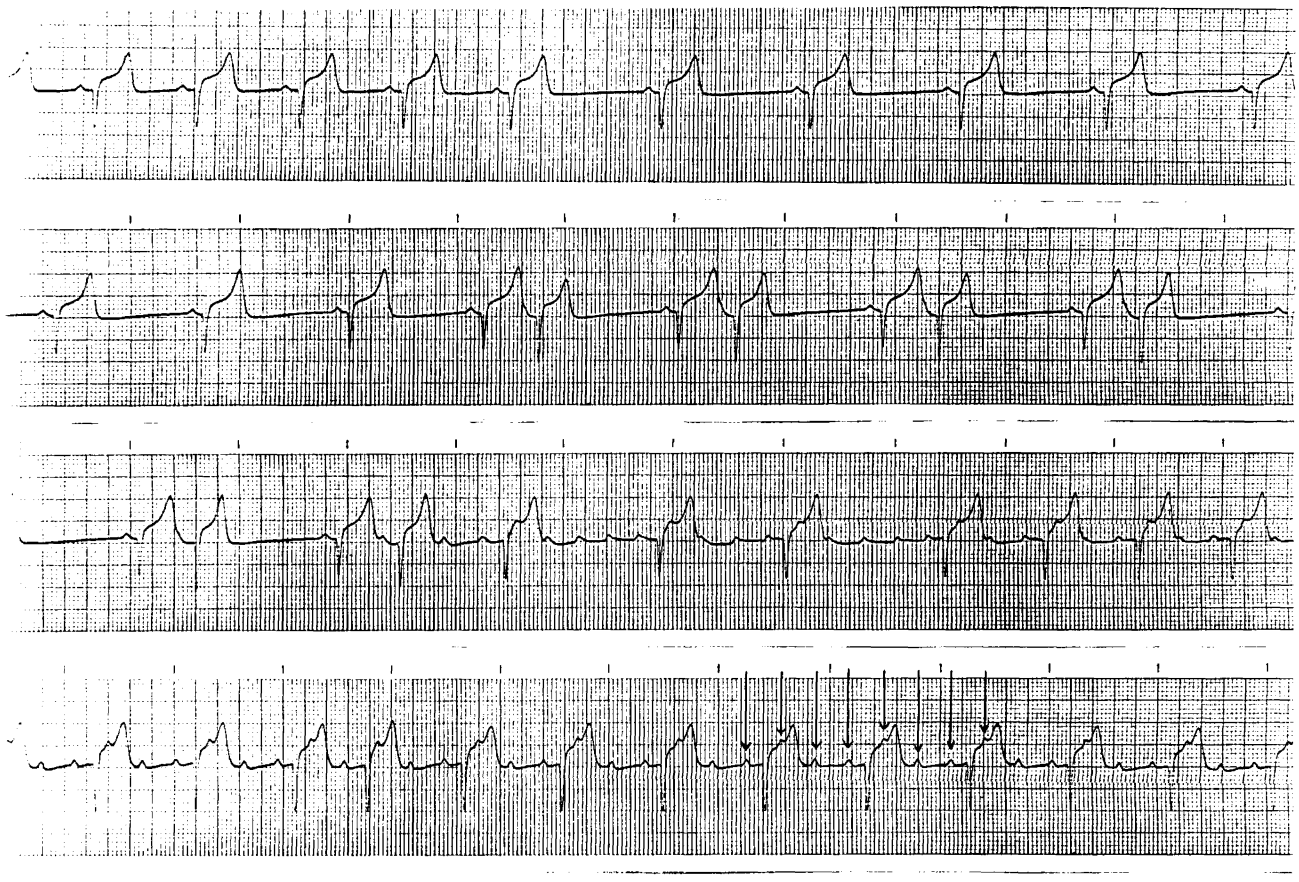

Figure 141.6 Conduction defects (bigeminy and second-degree AV block) at a pH between 7.06 and 7.10 and a base excess between –11.6 and –13.6 mmol/l in fetal sheep experiments conducted by Drs H de Haan and THM Hasaart, Maastricht.

Cardiac conduction defects

Cardiac conduction defects have been well described in adults suffering from coronary artery disease, myocardial ischemia, digitalis toxicity and electrolyte imbalances. In animal experiments, AV blocks have been induced by head compression and cord occlusion but not after vagotomy.[97,98] Yeh *et al.*[34] showed that in baboon fetuses myocardial conduction defects during vagal stimulation secondary to cord occlusion could be prevented by atropine. However, it was suggested that, apart from parasympathetic stimulation, these conduction defects could also be due to an increased sensitivity of the fetal myocardium to acetylcholine under hypoxic conditions. Pardi *et al.*[27] observed a prolongation of the PQ interval during 'mild late decelerations' and suggested that this was caused by mild vagal stimulation, resulting in a depression of the AV conduction system. Such a prolongation could continue to become the dislocation of the P wave from its normal position, as seen during bradycardia,[91] indicating a first-degree AV block. The third-degree AV block observed during severe variable decelerations indicates a complete disruption of conduction between the SA node and the AV node and may suggest hypoxic rather than vagal influences as a cause for this.[29] In controlled fetal sheep experiments, cardiac conduction defects in the form of second-degree heartblock and bigeminy were observed during profound hypoxemia and acidemia (Figure 141.6; van Wijngaarden, De Haan and Hasaart, unpublished data). These observations would confirm the potential of cardiac conduction defects in the detection of fetal compromise during labor. Although many decelerations are vagally mediated, those accompanied by a second- or third-degree AV heartblock may indicate a direct effect of hypoxemia on the myocardium or conductive tissues. The occurrence of such AV blocks during decelerations may therefore be an aid to distinguish between vagally induced decelerations and those associated with fetal compromise.[29] To detect these in real time, however, analysis of raw complexes is required. To achieve this, background noise and signal quality need to be addressed further to allow direct measurements of the filtered unenhanced FECG complex.

Fetal systolic time interval measurements

The pre-ejection period (PEP), the isovolumetric contraction time (IVC) and the ventricular ejection time (VET) are considered to be the most important fetal systolic time interval measurements.[99] Although

not absolutely required for the latter two, these are best measured by simultaneous FECG and Doppler ultrasound recordings. The PEP is measured from the onset of the Q wave to the opening of the aortic valve. The IVC is measured from the closure of the mitral valve to the opening of the aortic valve and the VET is measured from aortic valve opening to aortic valve closure. The PEP of the fetal heart reflects the inotropic and loading state of the heart and has the potential of an index for fetal hypoxemia and cord compression. The PEP has been reported to become prolonged during both cord compression without a change in the FHR and variable decelerations. During late decelerations, however, the PEP tends to shorten.[99] More recent animal and human studies suggest that the PEP and PEP/VET ratio in particular, are good predictors of fetal acid–base status.[100] Simultaneous measurement of the PR interval may have some benefit in clarifying the influence of the autonomic nervous system on myocardial contractility. However, the value of PEP measurements in intrapartum monitoring is yet to be established by further studies. In theory, it might be expected to be of more value antepartum in assessing cardiac function.

Transabdominal FECG recordings

Transabdominal FECG analysis has a number of potential benefits. The relationship between cardiac size and the QRS ratio have been well described and could be used as an aid in predicting fetal weight and intrauterine growth retardation.[49] Antenatal FECG analysis could be employed to detect congenital conduction defects such as prolonged QT syndrome and heartblock. Furthermore, it could be used as an adjunct to other methods in the assessment of fetal well-being, especially in circumstances where cardiac failure can occur. FECG time interval and morphology changes and the length of the PEP (time between the QRS complex and opening of the aortic valve) could be informative regarding the health of the conduction system and myocardium, fetal compromise and changes in (para-) sympathic tone.

Intrapartum transabdominal FECG analysis has the potential of being able to record the FHR simultaneously with the uterine myogram, producing a completely electronically derived 'cardiotocogram'. It is easy to apply, with less discomfort to the mother than when using conventional belts. The main problem, however, is the inconsistency and uncertainty in obtaining an analyzable signal.

Transabdominal signal acquisition of the very small amplitude FECG (usually $< 30\,\mu$V) with adult ECG surface electrodes is greatly hindered by noise generated by maternal muscular activity, maternal and fetal movements, maternal ECG signals and most of all by the enormous variation with which the electrical signals are propagated from the fetal heart to the maternal abdominal surface. Interference by maternal ECG complexes is not a problem since the introduction of a range of software routines successfully addressing this. It is still unclear how many electrodes should be used, which configuration of electrode positioning is optimal and during which fetal state the best recordings can be expected. From 20 weeks onward, the signal strength increases until 28 weeks, after which it decreases to a minimum at about 30 weeks. Following this, it increases again until delivery. The reasons for this have been suggested to be the formation of vernix caseosa with a 62-times decrease in electrical conductivity, and fetal fat formation with a 30-times decrease in electrical conductivity.[101] Oostendorp *et al.*[102] found that a multilead system of 32 electrodes which used vectors within a fetal reference frame could remove inter- and intra-individual variation of signal acquisition, but only before a gestational age of 28 weeks. The absence of vernix caseosa before 28 weeks, allowing for homogeneous conduction, has been suggested as a cause for this. The occurrence of gaps in the skin-covering vernix after 32 weeks could be responsible for the improvement in signal acquisition after this gestational age but, by its random nature, will result in a great variation in conduction and therefore optimal electrode positioning.[103] It is our experience that the best recordings are obtained with a simple two-lead system in a vertical midline configuration with one electrode at the fundus, one suprapubically and one ground lead on the arm or leg. This is supported by the observation that the maximum FECG amplitude is sometimes obtained between electrodes placed outside or at the edge of the maternal abdomen.[104] Ciccinelli *et al.*[105] reported signal acquisition rates as high as 93.6% in gestations from 29 to 42 weeks, with reliable P- and T-wave identification in 72.8%. These QRS detection rates have not been confirmed by other studies which quote maximum success rates ranging between 63% and 77%.[101,106,107]

A recent prospective cross-sectional observational study on 241 singleton, 58 twin and five triplets pregnancies with a gestational age ranging from 15 to 41 weeks of gestation, reported a significant reduction in signal separation success rate between 27 and 36 weeks of gestation.[108] A 12-lead system was used for all singleton pregnancies and a 16-lead system was used for all multiple pregnancies. Recordings took 15–20 min, typically providing approximately 5 min of data from which a 60-s sample with all the R waves available was selected visually for further processing. In singletons, the success rate of signal separation was 85%. T waves could be obtained in 78% with most failures before 24 weeks (63%). In twins and triplets, separate signals were obtained in 78% and 93%, respectively. Although P, Q, R, S waves were seen in all averaged FECG complexes, T waves could not be identified in 41% and 43% of recordings, respectively. Normal pregnancy FECG time interval reference ranges with gestation are reported.

Fetal magnetocardiography (FMCG) offers the potential of signal acquisition under circumstances with reduced electrical conductivity. As no electrodes are placed on the maternal abdomen, it is not influenced by interference of maternal ECG complexes and abdominal muscle action. Furthermore, the (hypothetical) insulating effect of vernix caseosa hindering successful acquisition of an electrode-derived transabdominal FECG as seen during late, mid and early third-trimester gestation, is negated.[109] A superconducting quantum interference device (SQUID), placed just above the abdominal skin without touching it, detects changes in the magnetic field created by changes in the intracellular current density of the fetal heart. Quinn *et al.*[13] obtained a 67% success rate in detecting the QRS complex. P waves and T waves were detectable in 75% and 72% of these, respectively. Horigome *et al.* reported a success rate of 68% and 43% for the detection of these waves, respectively.[110] More recently, much higher success rates were obtained by Lowery *et al.*[111] using a newly developed 151-channel magnetic sensor array. In 102 recordings between 27.5 to 39.5 weeks of gestation, they identified 100% of QRS complexes, 95.1% of P waves and 87.3% of T waves. Crowe *et al.*[112] showed the potential for FMCG to produce recordings of similar amplitude and quality to the FECG derived with abdominal electrodes. The main disadvantages of the system are the high cost of the superconductor, the prerequisite of a magnetically shielded environment to reduce interference and the specially purpose-built magnetically inert chair. In a series of 253 FMCG recordings (gestational age 15–42 weeks), Van Leeuwen *et al.*[113] showed that the antenatal determination of cardiac time intervals can be accurate and reproducible as long as signal-to-noise ratio and fetal maturation (signal amplitude) are taken into account.

The Enschede group in The Netherlands have developed a large FMCG database with time interval reference values on which they reported on in 2002.[114] It is based on FMCG recordings of a total of 582 uncomplicated pregnancies. The results compared to the time intervals found with transabdominal electrode recordings and in neonates. Although the scatter of measurements was wide (probably due to physiological variation, measuring system, signal processing and interobserver variation), fetuses with cardiac conduction disorders may be diagnosed with the help of this database.

With the development of new multichannel SQUID systems with a very high success rate of detecting all the waves of the FECG, it would appear that it is only the costs involved that would make one pursue further development of electrode-derived transabdominal FECG recordings. It is of great importance to note that the multichannel SQUID system can also be used to record auditory and visual evoked responses and brain activity antenatally. This opens the way to multimodal testing of fetal well being with a direct method of fetal neurological assessment.

142 Fetal magnetocardiography and fetal magnetoencephalography

T. Hosono and Y. Chiba

Fetal magnetocardiography

Introduction

Electrical activity of the heart and brain can be recorded on the body surface of a living body by a form of electrocardiogram and electroencephalogram, respectively. These electrical recording methods are widely used in clinical practice for newborns, infants, children and adults. Electrical activities of the heart and brain cause weak changes of the magnetic field. Since magnetic lines of force can pass through internal organs and skin without attenuation, magnetic activity of the heart and brain can be recorded without skin contact. Tracings of the magnetic activity of the heart and brain are magnetocardiogram and magnetoencephalogram, respectively.

Cardiac magnetic activity is measured in the order of 50 picotesla (pT) in adults and less than 10 pT in fetuses. These values are about one million times smaller than the static magnetic field of the earth. The first adult magnetocardiogram was recorded using induction coils.[1] However, since magnetic field strength caused by the fetal heart and brain are too small to record using induction coils, devices to measure fetal magnetocardiogram and magnetoencephalogram were anticipated, and as superconductor technology progressed, a superconducting quantum interference device (SQUID) was developed.

Fetal magnetocardiogram was first recorded about three decades ago using SQUID technology.[2] The amplitude of fetal QRS complex exceeded 5 pT and could be clearly distinguished from the maternal magnetocardiogram. Fetal QRS was more successfully recorded between 30 and 40 weeks of gestation when the fetus was in cephalic presentation with the left side facing the detector than when the right side faced the detector. The shorter the distance between the fetal heart and the detector, the weaker the fetal magnetocardiographic signals. The consecutive application of fetal magnetocardiogram to fetal heart rate monitoring was also reported.[3] Fetal heart rates were simultaneously calculated from fetal magnetocardiogram and electrocardiogram, and both tracings thoroughly coincided. However, after the initial development, fetal magnetocardiography has not progressed for nearly two decades. The improvement and advantage of fetal echocardiography and Doppler ultrasound technology for fetal heart rate monitoring also surpassed relatively primitive biomagnetism technology.[4] In the early 1990s, the usefulness of magnetocardiography has received more attention. The spread of fetal magnetocardiography is due to advances in several aspects of biomagnetism technology; a highly efficient magnetically shielded room and multichannel SQUID sensors of very high sensitivity.

Fetal magnetocardiogram provides clinicians with similar information to a fetal electrocardiogram. However, it is still difficult to record electrocardiograms because the surface of the fetal body is covered with caseous vernix in the latter half of the second trimester and the first half of the third trimester of pregnancy. The caseous vernix mainly consists of fat, which has low electrical conductivity. Thus, a fetal electrocardiogram is hard to record from the maternal abdominal surface. Direct fetal electrocardiogram, which attaches the leads of the fetal electrocardiogram to the fetal shoulder and buttocks by inserting needle electrodes via the maternal abdomen under ultrasonography guiding, is one solution of the problem, but is invasive.[5] Magnetic flux can pass through the caseous vernix and magnetocardiography is a non-invasive method to measure the electrical activity of the fetal heart.

Data processing of magnetocardiography

Multichannel system

Figure 142.1 shows a multichannel SQUID system (MC6400; Hitachi Hi-technologies Ltd, Tokyo, Japan) installed in the National Cardiovascular Center in Osaka, Japan. The system is placed in an active

Figure 142.1 Magnetocardiography system using multichannel SQUID sensors (MC6400; Hitachi Hi-technologies Ltd). The dewar, including SQUID sensors, is positioned above the abdomen of a pregnant patient lying on a bed.

magnetically shielded cabin in a non-magnetically shielded room in a hospital building. The active magnetic shield system produces compensating magnetic fields, which negate the magnetic fields of earth. The system is composed of 64-channel SQUID sensors with a sensitivity of less than 20 femtotesla (fT)/Hz. The gradiometer array is 8×8 matrix distributed and its sensor pitch is 25 mm. The array is installed in a dewar stored in liquid helium. The bed is positioned under the dewar and the patient lies on the bed usually after verifying the fetal heart position by ultrasonography. In other centers, a multichannel system such as a 37-channel system[6] and 67-channel system[7] have been used recently.

Data processing

The recorded magnetocardiographic signals are digitized and stored in a computer at a sampling frequency of 1 kHz. After passing through a low-pass filter, signals are processed several times. The removal of the maternal magnetocardiogram is indispensable for further signal processing. The maternal electrocardiogram is simultaneously recorded to aid the removal of the maternal magnetocardiogram. We calculated the average maternal magnetocardiogram by triggering R peaks of the maternal electrocardiogram. The averaged maternal magnetocardiogram is subtracted from the raw recordings at the time of each maternal heartbeat. Typical signal processing is the average triggered at R waves of the fetal magnetocardiogram. Since the P wave and T wave stay in the range of noises in the raw magnetocardiogram even when QRS complexes exceed the noise levels, averaging is required for a better signal-to-noise ratio to reveal the P wave and T wave. Our group adopted 100-times averaging from 2-min raw magnetocardiograms.

RR intervals in fetal magnetocardiogram are also often measured. The RR intervals are usually changed to the fetal heart rate, which is widely used in obstetrical practice.

Mapping

Although a multichannel system for magnetocardiogram has recently been commonly employed, only a few mapping techniques are available. The geometrical distribution of magnetocardiogram tracing is often used to display multichannel results.[4] The demonstration of all magnetocardiograms, usually averaged magnetocardiograms, at each of the used multichannels in one plane aligned along the baseline is designated 'butterfly plotting'.

The current-arrow map is a unique mapping technique showing the magnetic field and hypothetic current vectors in one plane.[8] The current arrows (I_x, I_y) are obtained from derivatives of the normal vertical component (B_z) of the fetal magnetocardiogram from the following equations:

$$I_x = +\mathrm{d}B_z/\mathrm{d}y$$
$$I_y = -\mathrm{d}B_z/\mathrm{d}x$$

Contour lines showing the strength of current arrows $[(I_x^2 + I_y^2)^{-1/2}]$ also visualize the current-arrow distributions. The current-arrow map is designed for obstetricians to better understand the current distribution although the current-arrow map is not the

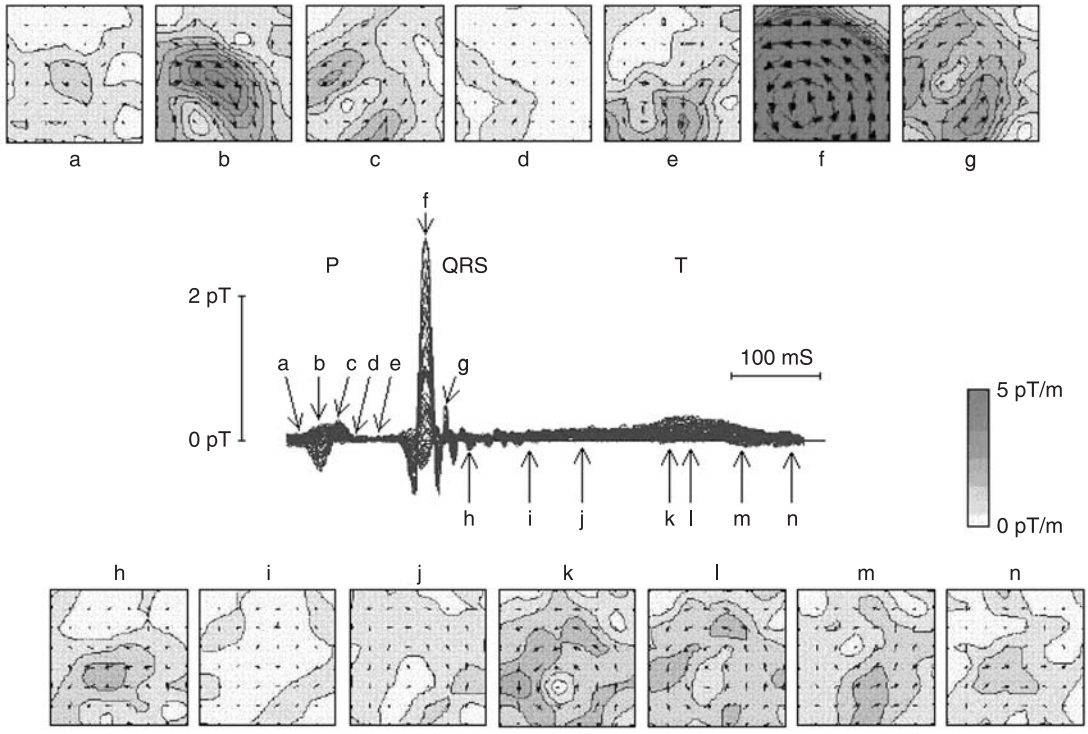

Figure 142.2 An example of an averaged fetal magnetocardiogram (center). P, QRS, T indicates the P wave, QRS complex and T wave, respectively. Figures with subscripts a–n are current-arrow maps calculated at the timing indicated in the averaged fetal magnetocardiogram.

complete solution of the so-called inverse problem. Figure 142.2 shows an example of a current-arrow map. Note that current-arrow maps at the R wave and T wave are in a circular pattern although the current-arrow map at the P wave is in a pattern aimed in one direction.

Standards of fetal magnetocardiogram

The peaks in the magnetocardiogram are called P, QRS and R similar to the electrocardiogram. The P wave indicates atrial depolarization preceding atrial contractions, the QRS complex indicates ventricular depolarization preceding ventricular contractions, and the T wave indicates ventricular repolarization preceding ventricular diastole. Indeed, the consistency of the fetal electrocardiogram and fetal magnetocardiogram is demonstrated by simultaneously recording the cardiograms.[4] Waveforms of the fetal magnetocardiogram, i.e. amplitudes, polarities and phases, vary depending on the spatial mutual relation between the fetal heart and detectors similar to waveforms of the electrocardiogram vary depending on the leads. Each component of the magnetocardiogram even in normal fetuses appears in a biphasic or negative pattern, but the causes of such patterns have not been clarified yet.

The amplitudes of the QRS complex, P wave and T wave increases with gestational age. However, the amplitudes of the P wave and T wave are often in noise levels, thus it is difficult to detect P and T waves in raw magnetocardiograms. Averaging the magnetocardiographic signals is the usual method to improve the signal-to-noise ratio and to analyze the waveforms of fetal magnetocardiograms,[9] but signal processing by averaging inevitably misses small beat-to-beat variations. Fetal heart position is also an important factor to improve the detectable limit of fetal signals. QRS complex can be detected by magnetocardiogram even at 17 weeks of gestation with a favorable fetal presentation. Kandori *et al.*[10] revealed by theoretical calculations that the depth between the sensor and fetal ventricular muscles is the most important factor for detection and that the fetal magnetocardiogram can be detected after 22 weeks of gestation if the depth between the sensor and the fetal ventricular muscle is 50 mm. The result of the theoretical analysis coincides well with practical data from 35 normal fetuses. If the distance between the fetal heart and the detector is 80 mm, the magnitude of the fetal magnetocardiogram stays at approximately 1 pT. If the detection limit of the fetal magnetocardiogram is as low as 1 pT, the minimum distance between the fetal heart and the detector is approximately 50 mm at 25 weeks of gestation, and is 80 mm at 35 weeks of gestation. Note that the distance between the fetal heart and the detector is approximately equal to the distance between the fetal heart and mother's abdominal surface. In clinical practice, the detection rate of the QRS complex is 67% by raw signals and the detection

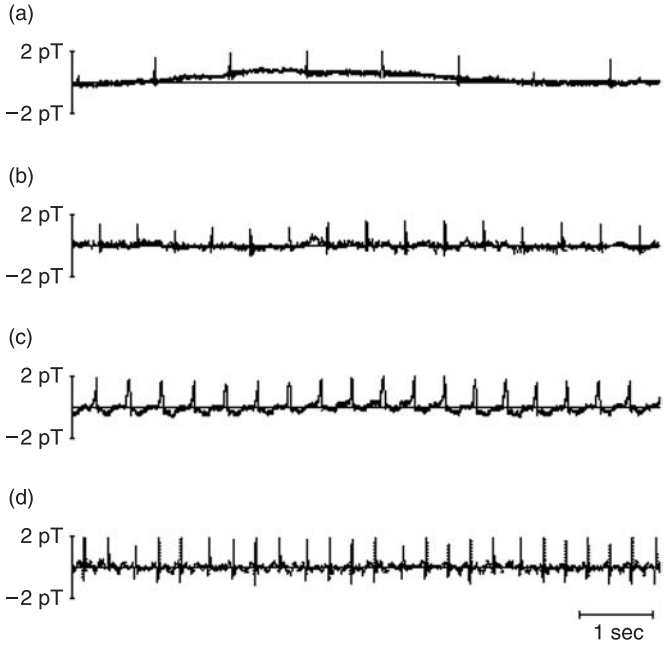

Figure 142.3 Examples of fetal arrhythmia: (a) complete atrioventricular block; (b) long QT syndrome; (c) WPW syndrome; (d) atrial flutter.

rates of the P wave and T wave in averaged fetal magnetocardiogram are 75% and 72%, respectively.[11]

The normal values for the components of fetal magnetocardiogram have also been studied. Horigome *et al.*[12] reported normal values of each component of magnetocardiogram for normal fetuses. The detected rates of P and T waves in averaged magnetocardiograms were 68% and 43%, respectively, although the detected rate of the QRS complex was 85% in raw magnetocardiograms. For a total of 150 magnetoencephalograms of normal fetuses of between 20 and 41 weeks of gestation, RR, PQ, QRS, QT intervals (durations) were 421 ± 27 (ms; mean $\pm$ SD), 100 ± 16, 49 ± 8, 223 ± 39, respectively. QT_c (corrected QT interval; QT interval divided by the square root of the RR interval) was 378 ± 52. Although QT and PQ intervals were constant between 20 and 41 weeks of gestation, the QRS interval increased as the gestational weeks increased. A similar gestational increase of QRS interval was also reported by Leuthold *et al.*[9]

Fetal arrhythmia

The diagnosis of arrhythmia has attracted a great deal of attention in fetal magnetocardiogram. Recently, prenatal diagnoses of fetal arrhythmias have been accumulated.

Bradyarrhythmia

One of the most life-threatening pathological bradyarrhythmias is atrioventricular block. Figure 142.3(a) shows a case of complete atrioventricular block. Magnetocardiographic observations of complete atrioventricular block coincide well with the findings by echocardiography, direct fetal electrocardiogram and neonatal electrocardiogram.[5] It is important to record completely independent P waves and QRS complexes in the diagnosis. Averaged fetal magnetocardiogram is also useful for the diagnosis because P waves are never detected in the averaged magnetocardiogram. Wakai *et al.*[13] reported an interesting case of complete atrioventricular block in which ventricular rates increase in association with the increase of atrial beats. Hosono *et al.*[14] reported a case of complete atrioventricular block with alternating ventricular pacemakers, which were revealed by the alternating amplitude of R wave recorded by magnetocardiography.

The diagnosis of QT prolongation is a good application of fetal magnetocardiography. QT prolongation, often by heredity, is rather hard to diagnose by echocardiography.[15] Hamada *et al.*[16] reported the first case of prenatal diagnosis of familial long QT syndrome by magnetocardiography. In this case, the mother was complicated with long QT syndrome and had a history of syncope at 10 years old. The nonstress test of the fetus at late gestation demonstrated a non-reactive pattern of fetal mild bradycardia of 110 bpm with decreased fetal heart rate variability. The QT interval was 410 ms, which is beyond the upper limit of 300 ms,[12] by averaged fetal magnetocardiography. The neonatal electrocardiogram coincided well with the fetal magnetocardiogram. Menéndez *et al.*[17] reported two additional cases, one of which was familial and the other was sporadic. Hosono *et al.*[15] also reported a case of familial long QT syndrome, which was suspected of sustained mild fetal bradyarrhythmia of about 110 bpm with decreased variability and maternal QT prolongation. Figure 142.3(b) shows a case of long QT syndrome. Kandori *et al.*[18] described two cases of long QT syndrome in which detailed diagnoses were achieved by current-arrow maps. The accuracy of magnetocardiogram in time domain exceeds further than that of echocardiography, and thus magnetocardiography enables the prenatal diagnosis of long QT syndrome, which requires precise determination of the QT interval.

Tachyarrhythmia

Fetal tachyarrhythmia often causes fetal heart failure and induces general hydrops fetalis. Supraventricular tachycardia and atrial flutter are the most common causes of fetal tachyarrhythmia. Atrial fibrillation is generally considered rare.

Wolff–Parkinson–White (WPW) syndrome was first successfully diagnosed by magnetocardiography (Figure 142.3c). Hosono *et al.*[19] reported the prenatal diagnosis of fetal WPW syndrome by magnetocardiography. In a case of fetal paroxysmal supraventricular tachyarrhythmia, a typical delta wave, short PR

interval and wide QRS duration were revealed by averaged fetal magnetocardiography. The averaged magnetocardiogram during the attack of supraventricular tachyarrhythmia showed normal QRS complex with normal duration and normal PR interval. In this case, cardioversion was obtained by prescribing oral propranolol to the mother. Fetal hydrops disappeared soon after sufficient dose administration. Another case of fetal WPW syndrome was described by Kähler *et al.*[20] The fetus exhibited intermittent tachyarrhythmia and hydrops fetalis after the administration of tocolytic agents. The magnetocardiogram at 33 weeks of gestation showed a delta wave. Oral flecainide, not digoxin, was prescribed and cardioversion was achieved within a few days. Digoxin is contraindicated in WPW syndrome due to the adverse effect of the atrioventricular conduction mechanism. Although digoxin has been widely used in therapy for fetal tachyarrhythmia, the prenatal diagnosis of fetal WPW syndrome by magnetocardiography may change the prescription of fetal therapy. The tachyarrhythmia and retrograde conduction of the P wave were also reported by Menéndez *et al.*[21] Wakai *et al.*[6] analyzed the initiation and termination of 13 cases of supraventricular tachyarrhythmia and revealed the mechanism of attack of tachyarrhythmias. The most common cause of fetal supraventricular tachycardia was revealed to be re-entrant premature atrial contractions. Kandori *et al.*[22] succeeded in the identification of accessory pathways in fetal WPW syndrome using current-arrow maps. The current-arrow maps at the time of the delta wave and the R peak of two cases of fetal WPW syndrome were produced and the vector sums of the current arrows were calculated. When the vector sum of the current arrows at the R peak was fitted to the position of the ventricular septum, the vector sum of the current arrows at the delta waves was revealed to be positioned at the left ventricle, indicating that an accessory pathway exists in the left heart. The WPW syndrome, which has an accessory pathway in the left heart, is type A, which shows a typical electrocardiogram with a high-voltage positive delta wave in the T1 lead. The neonatal electrocardiogram of each case exhibited a high-voltage positive delta wave in the T1 lead of the electrocardiogram.

Cases of atrial flutter have also been reported by several authors (Figure 142.3d).[21,23] Hosono *et al.*[24] also reported a case of fetal atrial flutter. The F wave, which represents fast atrial reciprocal excitation, appeared in a form of fluctuation of the baseline, similar to the teeth of a saw. The averaged fetal magnetocardiogram showed two P waves preceding the QRS complex, indicating 2:1 atrioventricular conduction. In another case, atrial flutter with 3:1 atrioventricular conduction was also demonstrated by magnetocardiography.[25] Kandori *et al.*[26] successfully made a differential diagnosis between atrial flutter and atrial fibrillation by evacuating QRS complexes from raw magnetocardiogram and by spectral analysis of atrial beats by fast-Fourier-transform processing. The spectrum of atrial flutter had a sharp peak at around 7 Hz, whereas the spectrum of atrial fibrillation was distributed diffusely in the range of 2–8 Hz. Since atrial flutter is caused by reciprocal pulse conductions of a certain frequency in the atrium, the spectrum showed a sharp peak at this frequency. However, since atrial fibrillation is generated by multiple independent pulse generators in the atrium, the spectrum might have a diffusely distributed pattern.

Ventricular tachycardia is rare in fetal arrhythmia. Menéndez *et al.*[21] succeeded in recoding *tosades de poites* of the fetus at 32 weeks of gestation.

Extrasystoles

Since extrasystoles are the most common fetal arrhythmia, extrasystoles have been reported since the pioneer period of fetal magnetocardiogram.[3] Van Leeuwen *et al.*[27] reported a variety of fetal extrasystoles such as ventricular extrasystoles, supraventricular extrasystoles, and sinoatrial block. Wakai *et al.*[28] reported a case of fetal complicated heart malformation that exhibited a fetal heart rhythm alternating between the period of normal sinus rhythm and the period of junctional rhythm associated with respiratory sinus arrhythmia. Single-channel magnetocardiography revealed the increase of fetal arrhythmia during ritodrine treatment for threatened premature delivery.[29]

Fetal heart rate monitoring

Magnetocardiography has been applied for fetal heart rate monitoring since the genesis era of fetal magnetocardiogram.[3,30] Since magnetocardiogram has a high resolution in the time domain, beat-to-beat variability of the fetal heart rate can be measured. The commonly used Doppler technique of ultrasound needs data processing of autocorrelation, and thus subtle beat-to-beat variability is essentially non-recordable.

Spectral analysis of fetal heart rate variability has been reported by several groups. Wakai *et al.*[31] analyzed fetal heart rate patterns from magnetocardiograms of 10 healthy fetuses and revealed a frequency distributed in a lower frequency range of less than 0.2 Hz in a fetal resting state but the spectrum is distributed in a wide range of less than 1.0 Hz during fetal respiratory arrhythmia. Rassi and Lewis[32] also performed spectrum analysis of the fetal heart rate and observed that the power spectral density at a high frequency of nearly 3 Hz increased as the gestational age increased, and thus variability of fetal heart rate increased in late gestation. Van Leeuwen and colleagues[7,33] calculated several statistical parameters from fetal heart rate tracings measured by magnetocardiography. They concluded that the significance of statistical parameters representing fetal heart variability and complexity reflects fetal development.

The monitoring of fetal heart rate using magnetocardiography is still in a pilot study and is beyond clinical application.

Instruments for fetal heart monitoring in recent clinical practice have employed the Doppler technology of ultrasound because of its convenience. Magnetocardiographic instruments generally require a magnetically shielded room. Baffa *et al.*[34] attempted to record magnetocardiograms using a single-channel SQUID system in an unmagnetically shielded environment and successfully detected the QRS complex. Spectral analysis of the fetal heart rate revealed that the spectrum of variability was distributed from 0.5 to 1.0 Hz.

Applications of magnetocardiography for other fetal heart diseases

Kähler *et al.*[35] reported an application of fetal magnetocardiography in congenital heart disease. Using the magnetocardiogram of a case of slight hypoplasia of the right ventricle with a small right ventricular outflow tract, prolonged duration of the QRS complex was revealed, suggesting morphological abnormalities of the pulse conduction system in the fetal heart. The magnetocardiographic findings were well coincided with the electrocardiographic findings of the neonate.

Horigome *et al.*[36] estimated the magnitude of the single current dipole of fetal heart by fetal magnetocardiography. The magnitude of current dipole was well correlated with gestational age in normal fetuses, indicating an increased amount of currents in myocardial muscles. However, in cases of cardiomegaly with myocardial abnormalities such as twin-to-twin transfusion, malformation of the Galen vein and endocardial cushion defects, the magnitude of dipole current exceeded the normal range, indicating excess increase of the cardiomuscular mass.

Hosono *et al.*[37] revealed that QT prolonged fetuses with severe congenital structural anomalies such as mitral atresia, transposition of the great arteries and so on, had poor neonatal prognosis of death within 28 days after birth in spite of specialist neonatal intensive care.

Magnetoencephalography

The strength of the magnetic field by the brain is far weaker than that by the heart. The range of magnetoencephalogram in fetuses is in the order of femtotesla whereas that of adults is in the order of picotesla.

Magnetoencephalography was first reported about a decade after the first fetal magnetocardiography.[38] When the fetal face is almost parallel to the mother's abdominal surface, verified using high-resolution ultrasonography, a total of 300 acoustic stimulus with a frequency of 1 kHz and a duration of 100 ms was applied through the maternal abdomen. The stimuli evoked magnetical responses of the fetal brain. Although the number of fetuses with complete recording was small, typical auditory responses were successfully revealed by averaging.

Wakai *et al.*[39] reported the success of fetal magnetoencephalogram nearly a decade after the pioneering work. A seven-channel SQUID detector was placed on the maternal abdomen located near the fetal auditory canal and external canthus. A total of 100 trials of auditory stimulus applied to a brief tone burst of 1.5 kHz frequency, 20 ms duration and 100 dB amplitude from the speaker placed about 1.5 m from the mother evoked distinct auditory responses with latencies of approximately 200 ms. The amplitude of auditory brain response was 100 fT. Evoked fetal auditory magnetoencephalographic signals were well coincided with the neonatal auditory magnetoencephalographic responses evoked by similar auditory stimuli.

Eswaran *et al.*[40] recorded fetal magnetoencephalographic-evoked auditory responses using a 100-ms tone burst of 120 dB intensity using 151-channel magnetoencephalography system specially designed for pregnant women. By consecutive trials of fetal magnetoencephalographic responses, they succeeded in recording at least one of several trial sessions. Eswaran *et al.*[41] also succeeded in recording visually evoked brain activity in fetuses using magnetoencephalography. Light pulses of 8800 lux, 33 ms duration and an approximately $2\,s \pm 50\,ms$ randomized interval were applied for 6 min (180 flushes). They succeeded in recording visually evoked electroencephalographic responses in four of 10 healthy fetuses. The amplitude of the magnetoencephalogram was about 30 femtotesla at maximum.

Conclusion

Fetal magnetocardiography has been shown as suitable to reveal a variety of fetal heart diseases during the second and the third trimesters of gestation. In particular, fetal arrhythmia is a good indication of fetal magnetocardiography. Magnetocardiographic analysis revealed detailed cardiac activity of the fetal heart, which has not been detected by fetal echocardiography. However, the number of reports on the application of fetal magnetocardiography in other fetal heart diseases such as structural heart diseases and fetal heart hypertrophy is still small. Fetal heart rate monitoring by fetal magnetocardiography is attractive because magnetocardiography can estimate beat-to-beat variability, but it has not been used in routine clinical practice.

Fetal magnetoencephalograms are still a significant area of study. Evoked auditory responses have been

successfully measured in healthy fetuses, but evoked visual responses were recorded by only a few groups.

The amplitudes of fetal magnetocardiogram and magnetoencephalogram are in the order of picotesla and femtotesla. The SQUID system requires superconducting substances of low transition temperature, which inevitably requires liquid helium. A more portable SQUID system which clinicians can use at the bedside without a magnetically shielded room is anticipated.

143 Fetal pulse oximetry

P. P. van den Berg and H. W. Jongsma

Introduction

Accurate assessment of the fetal condition during labor is a major problem in clinical obstetric practice. Electronic fetal monitoring (EFM) was introduced into clinical practice in the 1960s without proper validation. Subsequent performed randomized trials failed to show the real benefit of EFM compared with intermittent auscultation.[1–4] No clear differences were found in direct neonatal course or long-term follow-up between the two groups.[5,6] There was, however, an increase in obstetric interventions in the EFM group. When EFM and fetal scalp blood sampling (FBS) are combined, the efficacy of fetal surveillance improves.[7] Although this concept has gained worldwide recognition, in the majority of obstetric units FBS is not consistently used.[8,9] One of the reasons may be that blood sampling requires a blood gas analyzer which needs maintenance and frequent calibration. Others objected to the method being invasive, cumbersome and disliked by the patients.[9,10] It is also a disadvantage that the information is only available at the time of sampling and further samples are needed to determine a trend. This has led to the situation that EFM is still used in most labor rooms as the single diagnostic tool to assess the fetal condition instead of EFM being used as a screening method and FBS as the method to verify the fetal oxygenation.

Pulse oximetry, which measures the arterial oxygen saturation (SaO_2) continuously, has become a standard monitoring technique in anesthesia, intensive care and neonatal care, and may become equally helpful for the obstetrician in monitoring the fetal condition during labor. It is minimally invasive and easy to use. Moreover, the SaO_2 is an adequate parameter to measure oxygen supply, because 99% of the oxygen in the blood is bound to hemoglobin.[11] Fetal SaO_2 values (range 30–80%) are on the steep part of the oxygen dissociation curve, due to a relatively low fetal partial pressure of oxygen. Consequently, minor reduction in oxygen supply will lead to a detectable decrease in fetal SaO_2 (Figure 143.1). Optimism about pulse oximetry, as an alternative technique for assessing the fetal intrapartum condition, rose when it appeared possible to obtain signals from the fetal scalp during labor for prolonged periods.[12–14]

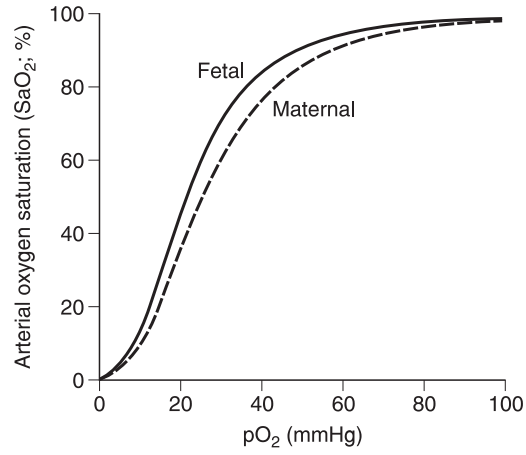

Figure 143.1 Maternal and fetal oxygen dissociation curve.

Principles of the measurement

Basic principles of pulse oximetry

The oxygen saturation of hemoglobin is expressed as a percentage ratio of the concentration of oxyhemoglobin (HbO_2) to the sum of the concentrations of oxyhemoglobin and deoxyhemoglobin (Hb). The measurement of oxygen saturation in arterial blood with pulse oximetry is based on two principles.

The first is that oxyhemoglobin and deoxyhemoglobin differ in their absorption spectrum. Figure 143.2 shows the absorbance spectra of HbO_2 and Hb.[15] Pulse oximetry uses two wavelengths in the red and infrared region of the light spectrum. In the red region (around 660 nm), deoxyhemoglobin absorbs much more light than oxyhemoglobin, while in the infrared region of the spectrum (890–940 nm) this is vice versa. These absorption differences of oxyhemoglobin and deoxyhemoglobin lead to the visible difference between well oxygenated arterial blood, which looks bright red, and less oxygenated venous blood, which appears more brown-violet.[16]

The second principle is that cyclic changes of the blood volume in tissue, caused by arterial blood, result in detectable pulsatile changes in the absorption of red and infrared light. During systole the blood volume in

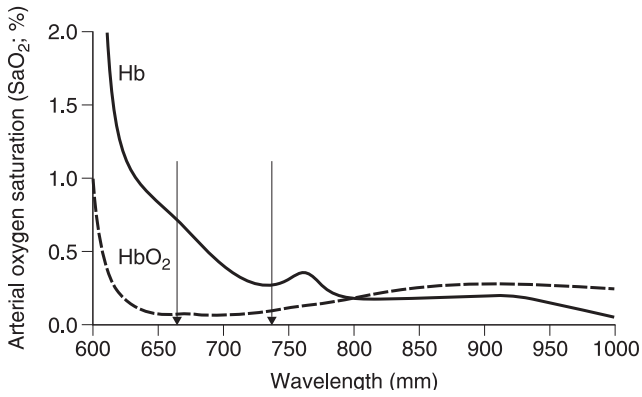

Figure 143.2 Absorbance spectrum of oxyhemoglobin (HbO_2) and deoxyhemoglobin (Hb). Arrows indicate 660 and 735 nm wavelengths.

the tissue increases, which causes an increase in the absorption of both red and infrared light. During diastole the blood volume in the tissue, and correspondingly the absorption of light, decrease.

The absorption of red and infrared light, which is caused by the skin, subcutaneous tissue, venous blood, non-pulsatile arterial blood and other absorbers in the light paths, leads to an additional, non-pulsatile component in the total absorption. The pulsatile or alternating component (ac) and the non-pulsatile or direct component (dc) of both red and infrared (IR) light are used to calculate a red to infrared ratio $[(ac_{red}/dc_{red})/(ac_{IR}/dc_{IR})]$. This ratio is assumed to be dependent only on changes in absorption in the arterial vascular tissue. In the pulse oximeter, the measured red/infrared ratio is converted into an oxygen saturation value, usually denoted by SpO_2, which is displayed. As the pulse oximetry principle assumes that pulsatile signals are caused by pulsations of arterial origin, other pulsatile signals (such as venous pulsations or rhythmic motion artifacts) may cause false SpO_2 readings.

Adaptations for fetal use

Reflectance sensor

To adapt this technique for fetal application, changes were made. In transmission sensors, which are commonly used for monitoring anesthetic patients and neonates, the light emitting diode (LED) and the photodetector are placed on opposite sides of the tissue. Light absorption is measured across the vascular bed. These sensors are placed on fingers or earlobes and are not suitable for application on the fetus during labor, as the presenting part is usually the fetal head. Reflectance sensors were designed, where LED and photodetector are placed on the same side of the tissue and light absorption is determined from light that scatters back to the surface. This made fetal utilization possible.

Plethysmographic signals from the fetal scalp can also be obtained by the transmission principle by using a hollow spiral scalp electrode containing an optical fiber; light is transmitted through the vascular bed from the spiral tip to the surface of the skin.[17]

Application of the reflectance sensor

In early studies, the sensor was applied to the fetal scalp using suction, gluing, clipping or using an incorporated spiral electrode[18] for fixation.

After the early results,[12–14] it became obvious that the fetal scalp is not the ideal area for measurement. Reduced peripheral perfusion, due to caput succedaneum, as well as hair, may lead to signal attenuation or erroneous measurements. When caput succedaneum is present, significant optical shunting may occur via the edematous area. In this case, light reaches the photodetector without passing through vascularized tissue. Dark hair absorbs a significant amount of light, particularly red light, and this reduces the signal amplitude. To avoid this, Nellcor Puritan Bennett and also Gardosi *et al.*[19] developed a reflectance sensor which is placed at the side of the fetal face (temple or cheek area) and held in place by means of the pressure of the uterine wall (Figure 143.3a). However, with this approach the sensor cannot be seen during application and monitoring, which is a potential problem. Incorrect apposition of the sensor may lead to false readings.[20,21] Therefore, the sensor should incorporate a means of assessing the correct placement on the fetal skin. In the sensor developed by Nellcor Puritan Bennett, this was realized by impedance measurement across contact points in the sensor as an indication of adequate sensor to skin contact (Figure 143.3b).

Side-effects

Thermal safety has been investigated in non-perfused tissue in an *in vitro* model. Under these conditions, the temperature increase is less than or equal to 3.0 °C. In well perfused tissue like the fetal face, the temperature increase is expected to be smaller because of the cooling effect of the blood flow. Sensors of this design have been extensively used in different centers worldwide in over 10,000 patients; complications such as uterine wall perforation, umbilical cord trauma, eye or ear injury, were not reported.[22] No significant difference in estimated blood loss and maximum recorded postpartum temperatures was found.[23]

Problems specific for fetal pulse oximetry

Calibration

The calibration of reflectance pulse oximetry for fetal use is more complicated than the calibration of transmission pulse oximetry for adult or neonatal use,

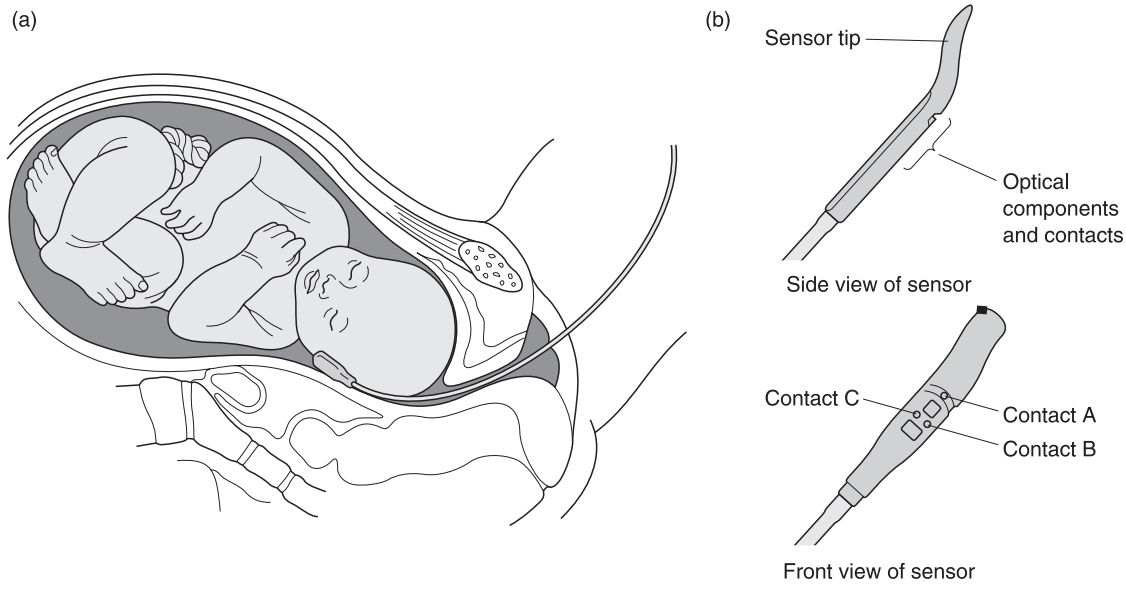

Figure 143.3 (a) Sensor positioned between the temple or cheek area of the fetal face and the uterine wall; (b) FS-14 sensor: the fetal oximeter and the sensor used in most studies reported were developed by Nellcor Puritan Bennett. The sensor consists of a flexible silicone tip curved toward the uterine wall. After insertion, the sensor is gently pulled back and wedged between the fetal face and the uterine wall. The sensor is supplied sterilized and meant for single use only. Dimensions of the sensor head are 3×1 cm. All surfaces are smooth, and the materials of the sensor have been tested for sensitization, pyrogenicity and irritation on different body regions. Adequate contact between the sensor and the fetal skin is verified by measuring the impedance between conductive contacts on the sensor. Low impedance values indicate that the contacts are immersed in amniotic fluid and that there is no adequate fetal skin–sensor contact. In this case the fetal oximeter will not accept data. After confirmation that the sensor is contacting tissue, the oximeter must determine whether the obtained pulsatile signals (plethysmograms) originate from fetal arterial blood.

as sample SaO_2 values cannot be obtained in the human fetus. Normal values of SaO_2 in the human fetus range from 30% to 80%.[24] The human adult is not a suitable subject because normal fetal SaO_2 values are mainly below 70% and it is unsafe to subject adults to such low saturation levels. In critically ill neonates, SaO_2 values may become as low as 60%,[25] an SaO_2 value still not low enough for a fetal calibration. Therefore, animal models are used to calibrate reflectance pulse oximetry against blood sample SaO_2 measurements.

For the comparison of two methods measuring the same quantity, i.e. SaO_2, it is recommended that the mean difference and standard deviation of differences is calculated.[26] The mean difference is called the bias and may show a systematic over- or underestimation of a method relative to the standard method. The standard deviation of differences is called the precision and represents the random 'variability' of the system. Another measure for the random 'variability' of the system can be obtained by calculating the standard deviation of residuals with linear regression analysis. The standard deviation of residuals and the precision will be equal if the bias is zero. The correlation coefficient is not a sufficient measure of accuracy. If the accuracy of a reflectance pulse oximeter is evaluated in the same study in which the reflectance sensor is calibrated, the bias will be zero and will give no additional information.

The accuracy of various reflectance pulse oximetry systems has been reported in animal models. Initial reports indicated a precision of 2.5–6.6% for sensors with 660 nm red wavelength and 890, 925 or 940 nm for the infrared LED.[27–31] Subsequent studies with a greater number of animals showed a much lower precision between 7.3% and 12.9%.[32,33]

Alternative approaches in sensor design

From the reviewed studies, it is clear that reflectance pulse oximetry is much more sensitive for all kinds of physiological variables in the fetal SaO_2 range of 10–80% than transmission pulse oximetry in an SaO_2 range of 70–100%. Alternative approaches in sensor design must therefore be considered for intrapartum use. One theoretical suggestion is using three photodetectors at different distances of the LEDs.[34]

Changing the red wavelength from 660 to 735 nm (Figure 143.2) leads to less attenuation of the red light at low SaO_2 levels. In a theoretical Monte Carlo model based on both absorption and scattering of light, Mannheimer *et al.*[35] predicted a significantly better similarity of light propagation for a 735/890 nm combination of LED than for a 660/890 nm combination of LED. A prototype reflectance sensor with a combination of 735 and 890 nm LEDs, and with a photodetector at a distance of 10 mm from both LEDs, developed by Nellcor Puritan Bennett, yielded much better results in six piglets compared with the

660/890 nm sensor[33]; the precision was 5.4%. A new version of this prototype sensor developed for intrapartum use, in which the LED–photodetector distance was changed from 10 to 14 mm, was evaluated in two independent laboratories.[36] The precision was around 5% with a small bias of 1.6% between the laboratories. Measurements were made over an SaO_2 range of 17–100%, with various sensors at several positions on each animal.[36]

Hemoglobin

Differences in the light absorption characteristics of hemoglobin of other species in the spectral range might lead to a different calibration line for the human fetus, although no differences were found at 660 and 940 nm for dogs and rabbits.[37,38] Presumably, hemoglobin light absorption characteristics of other mammals will not differ substantially from humans.

Being a two-wavelength device, a pulse oximeter can only measure the ratio of concentrations of HbO_2 and Hb, which makes it specifically sensitive to changes in SaO_2. However, other hemoglobin derivatives, like carboxyhemoglobin (COHb) and methemoglobin (MetHb) also absorb light in the visible range and might therefore lead to errors in the SpO_2. The error caused by the presence of 10% COHb appeared to be insubstantial over the whole SaO_2 range, for the wavelengths 660 and 940 nm.[15,39] In the presence of 10% MetHb, the pulse oximeter will underestimate the SaO_2 above 70% and overestimate below 70% SaO_2.[15,39–41] However, concentrations of 10% COHb and 10% MetHb are not expected in the human fetus during labor. In non-smoking pregnant women and their newborns, COHb concentrations are reported to be $< 0.5\%$. COHb concentrations in blood of newborns of cigarette smoking mothers were 1.9% (SD 1.2%).[42]

Human fetal (HbF) and human adult hemoglobin (HbA) differ slightly in their spectra in the visible range.[15] Commercial pulse oximeters programmed with a calibration curve derived from studies in healthy adults will not be affected by high concentrations of HbF in the neonatal SaO_2 range of 70–100%.[43] However, at an SaO_2 level of 25%, such commercial pulse oximeters will underestimate the SaO_2 by 5%.

Composition of the tissue compartment

The attenuation of the light received at the photodetector is not only caused by absorption, but also by scattering of light in tissue. The scattering of light by erythrocytes (e.g. velocity, size and shape) is of special importance, because it causes most of the fundamental problems in pulse oximetry at low saturation values. The scattering is largely determined by the hematocrit, blood flow conditions and blood volume changes. Erythrocyte differences between human subjects and between animals might have an effect on the accuracy of pulse oximetry but this factor has not been studied yet.

The effect of hematocrit, blood flow and blood volume fraction have been studied in *in vitro* models and animal models. In general, variation of these factors has hardly any effect above 70% SaO_2.[44] However, at SaO_2 values of 25%, a substantial bias can be observed.[45] Also varying the pressure on the sensor can cause bias, probably by variations in the venous blood fraction in the tissue.[46]

Sensor–skin interface

Scattering of light occurs in all situations where there are variations of the refractive index, i.e. at cross-sections of different tissue layers, at the boundaries of blood vessels and even within the cells themselves (e.g. by the mitochondria). It is therefore likely that differences in skin structure between animals and humans will influence the calibration of reflectance pulse oximetry. For none of the animal models is the magnitude of this effect known.

All intravascular dyes or pigments on the skin, which cause an unequal absorption of red and infrared light, may also cause an inaccurate reading. For example, meconium-stained skin caused an inaccurate oxygen saturation reading in a neonate because red light is more readily absorbed by meconium than infrared light.[47]

Optical shunting through hair is also mentioned as a possible cause for inaccuracy. However, differences between measurements on wet hair or shaved skin were not observed in fetal lambs.[32] Improper contact of the sensor to the skin can lead to erroneous pulse oximeter readings, if the light is directly shunted toward the photodetector.[21]

Technical problems

Certain technical situations may interfere with a reliable estimation of the SaO_2. Some problems related to the use of fetal reflectance pulse oximetry will be discussed in this paragraph, i.e. small pulses and signal analysis, and the choice of the LED wavelengths.

Small pulses

The fetal plethysmographic signals obtained with reflectance pulse oximetry are typically one-tenth of the adult transmission pulse oximetry signals. The amplitude of the pulsatile component of the signal is often below 0.2% of the total signal, which is at the lower limit of signal acceptance for some commercial transmission pulse oximeters.[48,49] These small pulses lead to a lower signal-to-noise ratio and, as a consequence, a less accurate device. To optimize signal quality, fetal plethysmographic signals should be maximized while the noise is minimized. Pulse oximeters use several ways to enhance the signal

processing. The fetal electrocardiogram can be used to cardiosynchronize the red and infrared pulses. A high-pass filter is used to detect the red and infrared peak and trough and the pulse oximeter verifies if the red and infrared peak and trough are in phase with each other. A weighted moving average of red to infrared ratios is calculated over several heart beats[22] and the average value is converted into an SpO_2 value. If the red and infrared pulses are not properly synchronized to the fetal electrocardiogram or not in phase with each other, inaccurate SaO_2 estimations may be the result.[50] Such phase shifts of the red and infrared pulses with the heart rate were observed by placing a 660/940 sensor on a caput succedaneum.[50]

Wavelength accuracy

The LEDs used in commercial transmission sensors are not ideal light sources. The LEDs emit light in a narrow spectral range. However, the center wavelength of the emitted light varies between diodes of the same type of sensor, by up to 15 nm.[16] A shift in the wavelength results in a different extinction coefficient (Figure 143.2) and hence in an error in the estimated SaO_2. The effect of variation in the center wavelength will be greater for the red (660 nm) than for the infrared wavelength because its absorption spectrum shows a steeper slope. This problem can be solved in two ways. First, LEDs with center wavelengths which fall outside a specified range may be rejected. Second, the pulse oximeter may be programmed to accept several ranges of LED center wavelength for both the red and infrared, and to correct for these different wavelengths internally.[49]

Another problem related to the 660 nm LED is that a small amount of light in the infrared region is often emitted in addition to the center wavelength.[16] Although this so-called 'secondary emission' does not influence the accuracy at high SaO_2 values, it might influence the accuracy at low fetal SaO_2 values.

Clinical studies

In the first reports of this technique used in the human fetus, the investigators used equipment that was designed for adults, without suitable calibration curves and using sensors of their own design. This may explain the wide range in mean values that were reported during normal labor.

Clinical studies published since 1996 were performed with the improved 735/890 nm sensor. These studies are reported in a separate paragraph. Studies published before 1996 were performed with older type sensors that are less reliable.

Normal values

The first studies reported a mean SpO_2 value of 68% (range 11–81%) in the early part of the first stage of labor, which decreased to 58% (range 29–81%) at the end of dilation,[51] a mean SpO_2 value of 82% (range 50–95%),[20] and a median value of 60% (range 10–95%).[52]

Dildy *et al.*[53] were the first to report normal values using an oximeter and sensor (660 nm red wavelength) especially designed for fetal use, and validated in adult volunteers and fetal sheep. He reported adequate signals during 40–60% of the time. The mean SpO_2 was 58% (range between 45% and 59%).

Breech presentation

In the fetal lamb, the difference in oxygen saturation across the ductus arteriosus is 4–5% and remains the same even during hypoxia, when redistribution of the blood flow occurs to protect the vital organs.[54] In a clinical study, saturations of 27–32% lower than vertex presentation were reported,[20] probably because these breeches indeed had lower saturation values.

Relationship with scalp blood

Correlations between oxygen saturation and pH in fetal scalp blood and SpO_2 values have been investigated by several groups.[55,56] Correlation coefficients were low ($r^2 < 0.5$) in all cases, as might have been expected.

Maternal oxygen therapy

The effect of maternal oxygen therapy was studied by McNamara *et al.*[57] and Dildy *et al.*,[58] both using validated equipment (Nellcor Puritan Bennett). In these studies, a significant increase in SpO_2 values was found, when 100% oxygen was given to the mother. McNamara *et al.* found an increase of 11%, Dildy *et al.* reported an increase of 14%. When lower concentrations of oxygen were given to the mothers, inconsistent results were obtained. McNamara *et al.*[57] observed an increase in fetal SpO_2 of 7.5% when 27% oxygen was administered to the mother. However, Dildy *et al.*[58] found no increase in SpO_2 after supplying 40% oxygen to the mother. This discrepancy in results was the reason for the re-evaluation of the data reported by Dildy *et al.*[58] by van den Berg and Jongsma.[59] They found that maternal oxygen administration with both high (100%) and moderate (40%) inspired oxygen concentrations was beneficial to those fetuses whose oxygen saturation is near a critical lower limit (40%).

Correlations with neonatal outcome

Pulse oximetry readings were compared with SaO_2 measurements in the umbilical cord blood at delivery. McNamara *et al.*[60] and Langer *et al.*,[55] both using validated equipment (Nellcor Puritan Bennett), observed a significant correlation with the venous

oxygen saturation, arterial pH and venous pH, but not with SpO_2. McNamara *et al.* analyzed the data only when there was an acceptable signal within the 30 min before the birth of the child. Langer *et al.* analyzed the data when the oximetry signal was obtained within 15 min of birth.

Studies for the validation of this method in the human fetus have limitations. During the period between the last obtained SpO_2 values and umbilical cord blood sampling, large differences in placenta perfusion and thus in fetal arterial pO_2 may occur. As fetal oxygen saturation values are on the steep part of the oxygen dissociation curve, a small difference in pO_2 will result in large differences in arterial oxygen saturation.

Carbonne *et al.*[61] defined a desaturation index as the difference between the mean SpO_2 of the last hour of stage 1, and the mean SpO_2 of the last 5 min of available recordings (interval between last SpO_2 measurement and birth < 10 min). This index correlated with the umbilical vein pH ($r = 0.62$) and the 1-min Apgar score ($r = 0.71$).[61]

Seelbach-Göbel *et al.*[62] correlated the duration of time below an SpO_2 level of 30%, between 30–60% and above 60% and the umbilical artery pH. The duration of low SpO_2 values was significantly longer in neonates with an umbilical artery pH < 7.15 compared to neonates with an pH ≤ 7.15. Another approach to address the efficacy of fetal pulse oximetry is to investigate the potential effect of adding fetal pulse oximetry to fetal heart rate (FHR) monitoring. In that study,[63] four expert obstetricians retrospectively evaluated intrapartum FHR tracings initially without and then with SpO_2 values obtained with an 660/890 nm reflectance sensor. They were requested to indicate if they felt there was a need for intervention. They were also requested to estimate the umbilical artery pH. In the 119 patients evaluated in the study, the clinicians managing labor were blinded to SpO_2 values obtained with fetal pulse oximeters. Acidosis and fetal compromise was defined as an umbilical artery pH < 7.15. Sensitivity and specificity for fetal compromise was determined for each referee. With the SpO_2 information, all of the referees would have intervened less often and in most of the cases predicted a higher pH value. The authors state that fetal pulse oximetry would not only lead to less unnecessary interventions but may also lead to undetected fetal acidosis. They raise the concern that SpO_2 may be falsely reassuring. One of the reasons for this might be the amount of signal loss (mean percentage of adequate signal was 65%).

Studies with the 735/890 nm sensor

Several groups have used the Nellcor 735/890 nm reflectance sensor (FS 14) during labor. The mean percentage of time with adequate signal during measurement ranged from 65% to 80%.[64–67] The reproducibility of two double-sensor studies showed a mean absolute saturation difference between two sensors on the same fetus of −0.7% and 6.3%, and with a standard deviation of a single sensor of 5.3% and 6.3%, respectively.[65,68]

Normal values are reported in several studies, i.e. in which the neonatal outcome showed an umbilical artery pH > 7.15 and Apgar score at 5 min ≥ 7.[65–69] Mean values of SpO_2 during labor ranged between 42% and 50%. No significant difference was seen during phase I (dilatation phase) and phase II (pushing phase). All individual SpO_2 values ranged between 30% and 70% for fetuses with a normal outcome.[65–69] Occasionally, an SpO_2 of below 30% was seen, but always with a quick return to values above 30%.[69] These values agree with blood sample values in the awake fetal lamb in which the SaO_2 could be decreased to 30% before metabolic acidosis became apparent.[70,71] Weak but significant correlations were found between the mean fetal SpO_2 during the last 30 min before birth and the umbilical artery and vein SaO_2, as with the umbilical artery pH and base excess.[66]

The 735/890 nm sensors were further used to study SpO_2 in cases with meconium aspiration,[72] and in cases of severe FHR abnormalities.[64,73] In both situations, SpO_2 values were significantly lower compared to normal situations, i.e. with normal FHR patterns and without meconium aspiration.[64,72,73] However, more studies are needed of these specific situations before definite conclusions can be drawn.

In two studies, intrapartum monitoring of fetal SpO_2 was used as a diagnostic test to predict acidosis at birth.[66,74] Alshimmiri *et al.*[66] concluded that fetal SpO_2 was of limited use in predicting acidosis at birth, regardless of the SpO_2 cut-off value used. For predicting acidosis at birth, Carbonne *et al.*[74] concluded that the predictive value of intrapartum fetal SpO_2 with a cut-off value of 30% was as equally predictive as fetal scalp blood analysis with a cut-off value of pH ≤ 7.20. Fetal pulse oximetry became superior at higher threshold levels.[74]

A multicenter randomized trial to study the efficacy of fetal pulse oximetry was published in 2000.[75] The primary hypothesis was that the cesarean delivery rate for non-reassuring FHR patterns would be halved if SpO_2 was used as an adjunct to EFM.

However although this rate was reduced by more than 50%, the overall cesarean rate was unchanged between the control and the study group. This was due to an increased percentage of cesareans for dystocia in the study group. Further analysis could not explain the reason for this increase. A follow-up study found that women with more clinically worrisome FHR patterns had a significantly higher incidence of cesarean for dystocia although co-monitored with SpO_2.[76] In a randomized trial in 146 patients with term pregnancies, in labor and abnormal FHR patterns, the hypothesis was tested if pulse oximetry in addition to EFM and FBS reduces

operative deliveries performed because of non-reassuring fetal status. A reduction of 50% in operative deliveries and FBS was achieved without an increase in cesarean section for dystocia.[77]

Current status

The aim of fetal surveillance during labor is straightforward: to identify fetal distress which may, if uncorrected, cause short-term morbidity, death, or possibly long-term morbidity. Undeniably, improved obstetric care, together with cardiotocography, has led to a decrease in perinatal mortality in Western countries since 1960. The expected decrease in perinatal and long-term morbidity, however, was not observed and, due to a poor predictive value of cardiotocography, operative interventions during labor increased dramatically. In an effort to improve this unfortunate clinical situation new techniques which supply objective parameter about the fetal status are warranted.

Fetal monitoring with SpO_2 with the Nellcor device was approved by the FDA in May 2000 for clinical use in the USA and became commercially available. In Europe, fetal pulse oximetry is available from Nellcor (Pleasanton, CA, USA) and OB Scientific (Germantown, WI, USA).

In September 2001, the American College of Obstetricians and Gynecologists (ACOG) released a Committee Opinion on fetal pulse oximetry (no. 258). There were three main concerns: signal registration time, possible false-negative readings and lack of proven cost benefit. The committee recommended that new prospective randomized clinical studies are needed to establish the role of fetal pulse oximetry during labor.[78]

In March 2002, the Society of Obstetricians and Gynaecologists of Canada published guidelines for fetal surveillance during labor. It stated that fetal pulse oximetry as an adjunct to EFM in patients with non-reassuring fetal status, should not be considered a standard of practice.[79]

In early 2003, FDA labeling for the Nellcor monitor was revised. This was based on postapproval surveillance of over 12,000 cases. The conclusion was that FPO is meant as an adjunct to EFM, not as a replacement.

The future of fetal pulse oximetry as an adjunct to EFM is still uncertain and its value can only be established by further clinical research.

144 Intrapartum fetal monitoring – objective and subjective assessment of the main methods

E. Saling and S. Schmidt

Introduction

Fetal blood analysis (FBA) was first performed in June 1960 and published in 1961.[1] It was the first method which allowed the human fetus to be directly examined by sampling its blood.[2] Fetal blood analysis was one of the four essential clinical methods with which Prenatal Medicine or so-called Fetal Medicine started.[3]

The first continuous cardiotocogram conducted from an anencephalic fetus was described by Caldeyro-Barcia in 1958.[4] In 1966, with his CLIP-electrode that could be inserted vaginally after the membranes were ruptured, Hon introduced direct fetal electrocardiotocography during labor.[5] Widespread clinical utilization of cardiotocography (CTG), particularly in cases with intact membranes, could not start earlier than 1968 because of the lack of suitable equipment, which has been developed by Hammacher in co-operation with Hewlett Packard. We reported on these and other historic landmarks in 1988.[6] The combined intrapartum electronic–biochemical supervision by CTG and FBA was introduced by us in 1968[7] shortly after the first cardiotocographs became available for widespread clinical application. Since then, this combination continues to provide the safest supervision of the fetus during labor to prevent serious hypoxia and to minimize unnecessary operative interventions.[8–13]

The purposes of both methods are:

(1) Cardiotocography as a way of continuous electronic monitoring should enable the obstetrician:

   (a) To confirm the undisturbed condition of the fetus in all cases with normal cardiotocogram (CTGm); and

   (b) To select all fetuses with abnormal CTGm. Less than half of them are really threatened by hypoxia, but the majority of the fetuses in this group is not endangered.

(2) Fetal blood analysis from the presenting part, as a biochemical method, should only be employed as a complementary measure in cases of abnormal CTGm:

   (a) To clarify whether or not biochemical changes confirm imminent fetal hypoxia and/or acidosis which has been indicated by CTG; and
   (b) To help in deciding whether further important clinical consequences like tocolysis for inhibition of uterine contractions and conservative improvement of fetal supply or termination of labor by operation are necessary.

In this way, by using both CTG and FBA if necessary, it is possible to achieve a minimum of operative deliveries, which is of advantage to the mothers (cesarean) and to the fetuses (difficult vaginal intervention), with an optimal safety for the fetuses (low incidence of hypoxic morbidity).

One of the main disadvantages of using electronic fetal heart rate monitoring – this means CTG on its own – is a high rate of erroneously diagnosed cases of fetal hypoxia and consequently a relatively high number of unnecessary cesarean sections and of avoidable difficult vaginal deliveries, the latter in cases of abnormal CTGm early in the second stage when the presenting part is still high.

So, for instance, after an evaluation together with Goeschen *et al.*[14] in our department we found in cases with abnormal CTGm that an operative termination of

Table 144.1 Fetal blood analysis (FBA) is indicated when the heart rate patterns shown in the table are present

Heart rate pattern	Time	Precondition
Acute bradycardia	Immediately	Presenting part not yet on the pelvic floor or in the pelvic outlet, as then a vaginal operation to terminate labor should be performed without FBA
Late decelerations Variable decelerations if ≥ 30 bpm Early decelerations if ≥ 60 bpm	After three decelerations or at the latest after 10 min	
Variable decelerations if < 30 bpm	After six decelerations or at the latest after 20 min	

labor was indicated when using the Hammacher score in 73% of women, but when pH values were used simultaneously termination was indicated in only 14% of women. This means that when CTG is used on its own, about 60% unnecessary operations would have been performed.

How very subjective the interpretation of CTGm can also be from highly experienced colleagues has been impressively studied and published, particularly by Donker *et al.*[15] from the research group of van Geijn *et al.*[16] Logically, CTG can only be used as a method of selection of suspicious cases and not as a method for diagnosis of fetal hypoxia in all its stages. Therefore, the best way to solve this problem is the use of an additional biochemical method in all cases with abnormal fetal heart rate patterns.

Suitable blood parameters

For clinical routine, the actual pH values are the most suitable parameters to differentiate whether imminent or progressive fetal hypoxia is present or not. In each stage of intrauterine hypoxia, namely in the early mainly respiratory complication, and later in the stage of anaerobic glycolysis, the pH values are decreasing. Additional use of blood gases can certainly be of help in the differentiation of the character of the disturbance but is not essential for clinical decisions. So, for instance, pCO_2 values can help to differentiate the degree to which respiratory disturbances are also present – mostly in acute complications – or whether metabolic disturbances predominate when the pCO_2 values are not increased so much. The use of oxygen saturation values in the form of fetal pulse oximetry has in the meantime reached clinical usable state[17] but it has not found a wide acceptance in routine work up to now.

Indications for FBA

Fetal blood analysis is indicated in all cases when the CTGm shows patterns which lead to suspicion of hypoxia. For about 36 years, after CTG became available for clinical use in 1968, the schematic, but practicable, indication scheme shown in Table 144.1 has been used in routine practice in our department with success.

Repetition of FBA and clinical consequences

Fetal blood analysis should be repeated, depending on the character of the disturbance. When an acute complication (occurrence of acute bradycardia) is suspected, it is recommended to take a blood sample as quickly as possible, then immediately a second one and if necessary a third.

In order not to lose any time in cases with hypoxia, two other measures should be taken at the same time:

(1) Inhibition of the contractions through tocolysis; and
(2) Warning should be given for the operative team to be ready in case an emergency cesarean section should be necessary.

If further FBA do not show a critical fall in pH, then one should wait. Usually the fetal heart rate pattern recovers within a short time. If, however, the pH values decrease in spite of preventive measures, a cesarean section should be performed immediately or, if the labor is so far advanced, a vaginal operation should be performed to deliver the baby.

All other suspicious heart rate patterns indicate a complication advancing relatively slowly. The first FBA should be made after about 10 min. When decelerations are persistent, particularly if the pattern becomes more marked, and the first pH value was not suspicious, further blood samples should be taken at intervals of about 15 min. If the pH values remain suspicious after two or three samples have been taken, and if the heart rate pattern concerned does not occur again in a stronger or more marked form, then further FBA can be made at longer intervals or dispensed with.

If a normal pH value (such as 7.3) was measured from the first blood sample after suspicious decelerations have occurred, then the blood analysis should be repeated at short intervals of 5-10 min in order to establish the trend of the blood acidity if there is a further fall in pH values.

When the intensity remains the same or when the suspicious heart rate patterns disappear, the intervals

between the blood sampling can be gradually lengthened and finally further blood analysis can be dispensed with if the pH values increase again. Should the pH values continue to decrease to prepathologic (pH 7.20–7.24) or even to pathologic values (pH < 7.2) in spite of tocolytic therapy, an operation to terminate the labor should be performed.

There is one possibility which leads to slightly different consequences, namely the so-called maternogenic increase of fetal acidity. This situation is caused by overflow of lactic acid from the mother to the fetus. Maternogenic acidity increase is not as dangerous as acidosis caused by fetal hypoxia. Therefore, it is not necessary to terminate the labor immediately by operation. To rule out such cases with maternogenic origin of acidity increase, we recommend measuring maternal and fetal acidity simultaneously. If the difference between mother and fetus is less than 0.15 pH units, maternogenic acidity increase is confirmed.[18] The incidence of cases with maternogenic acidity increase is relatively low. Out of all cases with acidosis (pH < 7.2), it occurs in about 9% and of cases with progressed acidosis (pH < 7.1), it occurs in 1%.[19]

The aim of modern supervision of the fetus during labor

The combined use of electronic and biochemical monitoring of the fetus should enable an obstetrician to detect all fetuses endangered by hypoxia during labor. While intrapartum mortality was mainly used as an important factor of quality control in the past, recent studies have focused more on the morbidity of the newborn. In this context the neurologic outcome is a decisive parameter for judging the validity of fetal monitoring methods.

The one measure of neonatal outcome which has shown significant results by more intensive intrapartum monitoring have been neonatal seizures. Due to the result of randomized trials this effect seems to be restricted to electronic fetal monitoring backed by fetal pH measurement.[20]

A 50% reduction in the risk of neonatal seizures, associated with continuous monitoring of the fetal heart and fetal acid–base analyses, is potentially very important. Indeed, between a quarter and a third of babies who suffer neonatal seizures die, and a further quarter to a third are seriously impaired in childhood.

But such considerations of the neurologic status should not ignore the other pathophysiological events caused by longer-lasting intrauterine hypoxia. The fetus consists of many organs, not only the brain, even though many authors focus their investigations on the central nervous system. If the certainly important central system is less endangered during labor than otherwise assumed, a variety of other organs and functions still exist which may very well suffer from hypoxia and acidosis.

As we demonstrated, there is a close connection between manifest acidosis and the overall well-being of the infant. In the literature several authors report about the dangers of severe hypoxia, e.g. Shankaran *et al.*[21] and Low *et al.*[22]

According to these considerations fetuses at hypoxic risk should therefore be identified as early as possible for instance shortly after abnormal CTG appears and long before a dangerous chock syndrome with all its pathological consequences can develop in fetal organ systems.

Intermittent character of FBA

This so-called disadvantageous property of FBA is compensated to a certain degree by the fact that most intrauterine complications – more than 90% – progress so slowly[23] that there is enough time to detect the disturbance also under such conditions of intermittent diagnostic insight and to react properly in the clinical routine, i.e. if one consequently follows the CTG, and, if abnormal patterns occur, the obstetrician starts early enough with fetal blood sampling.

Methods for continuous measurement of pH, PO_2 and PCO_2 (sometimes simultaneously) have been under development for more than 20 years. These measurements have mainly contributed to the understanding of the physiologic status of the fetus.[24] No method has up to now been convincingly reliable or suitable for use in routine practice. The electrodes commonly used for continuous tissue pH measurements have been unsatisfactory for a number of reasons.

They are large, fragile and tend to become detached. Continuous transcutaneous PO_2 monitoring is still unsatisfactory.[25] The occurrence of caput succedaneum and compression of the electrode influence the reliability of these measurements. Transcutaneous PCO_2 monitoring looked the most promising from a theoretical and technical point of view, but the problems common to all methods of continuous biochemical monitoring still have to be solved.[26] None of these new techniques has been tried in more than a relatively small group of fetuses.

The newly available sensor for spectroscopy (NIR) (modified laser spectroscopy) for fetal physiologic measurements provides information about biochemical parameters and is potentially an additional technique for fetal surveillance.[27] Using laser spectroscopy, it was possible to trace changes in absorbances at four different wavelengths and to calculate relative changes of HbO_2, desaturated hemoglobin, total hemoglobin, and cytochrome aa_3. NIR has been used as a research tool and holds the promise of a non-invasive surveillance providing continues monitoring. Up to now NIR is not clinically accessible with an adequate monitor and sensor.[28]

Pulse oximetry allows measurements of oxygen saturation. It is based on the premise that light transmission by blood varies with the change in blood

volume in a tissue with each pulse of a fetal sensor (SpO_2). The sensor is placed against the fetal cheek. Studies indicate that results may be obtained from 2 cm dilation in between 45% and 60% of cases.[29] Although results vary between studies, a SaO_2 of more than 30% is indicative of fetal well-being as this is the level below which anaerobic respiration begins.[30,31]

More recently this borderline has been validated further by the demonstration that SaO_2 of less than 30% for longer than 10 min correlated well with low scalp pH if the signal loss is limited.[32] A prospective randomized trial implicates a reduction in cesarean section rates in cases with pathologic heart rate pattern.[33] A further improvement of the sensor for routine application seems essential, since a reliable SpO_2 signal is precondition. The reliability during clinical applications to detect disturbances early enough has been questioned.[34,35]

Frequency of false-positive findings with fetal monitoring during labor

It is the aim of clinical obstetrical care to perform an operative delivery in those cases where the risk is adequately identified. Due to the large number of false-positive heart rate patterns the considerable increase of unnecessary interventions during continuous electronic monitoring is a logical consequence. FBA as additional biochemical method is particularly suitable to resolve this problem. Van den Berg *et al.*[36] showed how convincingly the rate of cases with false-positive findings can be reduced by means of combined supervision with FBA.

A misleading clinical conclusion is to consider infants who were born in a good condition after intrapartum pathology as diagnostically false-positive cases, as has for instance been described by Sykes *et al.*[37] The inevitable confusion resulting from this has led to some scientifically untenable conclusions. The aim of supervising the fetus during labor is to recognize threatening, real fetal distress situations, namely falling pH values, and to draw the correct clinical conclusions before the infant has gone into a state of depression due to hypoxia or has become severely acidotic. From the special study which we performed, the frequency of correct positive findings was 94% out of 110 controlled cases using additional fetal blood sampling.[13]

Critical appraisal of prospective studies on fetal monitoring during labor

In spite of the evidence of the benefit of the additional use of the FBA during fetal monitoring in prospective randomized trials its clinical use is not generally accepted.[38] This obvious discrepancy between scientific findings and clinical acceptance has been discussed in recent publications.[39]

Perhaps, it can be explained by the characteristics of the papers mentioned on prospective randomized trials concerning fetal monitoring. Sometimes one gets the impression that it would be more worthwhile to examine what went wrong in the application, or in the performance of such prospective studies. It seems that a number of researchers prefer to use highly sophisticated statistical rather than established clinical methods. For our critical appraisal we have chosen two studies particularly often cited in the past. In the study by Haverkamp *et al.*[40] the groups were small. The termination of labor in cases of fetal distress was performed late, namely when fetal acidosis was already present. Consequently, the overall number of acidotic and depressed newborns was high. The important finding in Haverkamp *et al.*'s study was the reduction of operative deliveries using FBA, compared with the use of CTG without FBA.

In the frequently cited largest prospective Dublin study,[41] only umbilical vein blood samples were used. However, it is well known that such samples are not representative for the fetal condition compared with umbilical artery blood. Blood in the umbilical vein has passed the placenta and has accordingly been changed in its composition. Thus it cannot reflect the situation in fetal tissues as umbilical artery blood can after it has passed parts of the fetal body. Moreover, the pH measurement in umbilical blood was performed in only 500 of the 6500 cases. If one projects the differences found between the examined groups to all the cases in this study, then an apparently significant difference can be established, i.e. not only a significantly higher incidence of seizures of newborns was found in the Dublin study in the auscultation group, but also a significantly higher number of acidotic newborn ($pH < 7.1$) must have been present. These important results have, as far as we know neither been stated in the publication concerned nor recognized by any other author who has cited this study.

How do the results of prospective randomized trials correlate with large databases?

The evaluation of a perinatal survey in Germany that included a large number (> 500,000) of cases focused on death rate of mature infants in the intrapartum and perinatal period as well as during the first days of life. The authors found that structural problems in small obstetrical units (< 500 deliveries per year) were the major cause of perinatal death.[42] Furthermore, the data of this survey indicate an improved perinatal outcome in the cases with pathologic heart rate pattern and additional use of FBA in regionalized obstetrical care.

Direct comparisons of electronic fetal monitoring, with and without additional FBA, show that access to scalp sampling reduces the number of cesareans due to fetal distress, with no clear differences in neonatal

outcome. Data from indirect comparisons point both to better maternal and better neonatal outcome if FBA is used.

Subjective considerations of FBA

Fetal blood analysis is sometimes exposed to subjective considerations such as 'it is labor intensive' or 'it is inconvenient for the mother'. But in view of the incomparable higher expenses caused by unnecessary caesarean sections, which can be prevented by FBA, such opinions must be seen as subordinate and objectively as untenable.

The interpretation of the results and drawing the consequences – clinical measures after FBA – are relatively simple. Thus the use of FBA might be enhanced when the given evidence of benefit is adequately addressed.

Future prospects

In the future, we will probably discontinue the subjective visual interpretation of fetal heart rate patterns. More and more a computer-assisted evaluation will take place which allows a more objective assessment. For the antepartum supervision such a Sonicaid system, developed by Dawes and Redman at Oxford University has been available since 1977. In the meantime, Sonicaid also prepared a version available for intrapartum use.

Later in 1980, Maeda created a computer software for an automatic fetal heart rate analysis during labor with warning system in case abnormal heart rate patterns occur. Apart from this, a so-called QCTG-program system is available developed by Roemer* in Detmold (Germany) and a Trium CTG-Online System developed by M. Daumer† in Munich (Germany).

But even with computer assistance, we should be aware that CTG is in principle an indirect biophysical 'detour-method' which we clinicians try to use for the diagnosis of biochemical problems as hypoxia. Therefore the same reliability as can be achieved by FBA, which is a direct biochemical method, cannot be expected from CTG.

This means that the number of false-positive findings by use of computer-assisted CTG will apparently be reduced, but not definitely eliminated. Thus, for an expert FBA will maintain its clinical value.

Summary

Combined intrapartum electronic–biochemical supervision of the fetus during labor by CTG and FBA was introduced by us in 1968, shortly after the first cardiotocographs became available for widespread clinical application. By using both CTG and, if necessary, additional FBA, it is possible to achieve a minimum of operative deliveries (cesarean sections and difficult vaginal interventions), which is of advantage for both mother and fetus, with an optimum safety for the fetus by minimizing the incidence of hypoxic morbidity. The best suitable blood parameter of FBA is the actual pH value because it reflects the biochemical situation of the fetus in each stage of intrauterine hypoxia. FBA is indicated in all cases when abnormal CTGm shows patterns suspicious of hypoxia. Repetition of FBA depends on the character of the assumed intrauterine disturbance. In acute cases (bradycardia), FBA should be repeated as quickly as possible. All other suspicious heart rate patterns indicate a slower advancing complication. FBA should be repeated depending on the severity of the CTGm pattern within 5–10–15 min. In cases with slow progressive decrease of fetal blood pH, maternogenic acidity increase should be diagnosed and clinically interpreted accordingly.

The aim of modern supervision of the fetus during labor is primarily to minimize short-term morbidity of the fetus and the newborn and secondarily to prevent cerebral palsy and other organ injuries. The intermittent character of FBA can be compensated to a high degree by the fact that most intrauterine complications during labor progress rather slowly and there is generally enough time to detect the disturbance and to react properly within the clinical routine. The frequency of false-positive findings with FBA is much less than erroneously described. Some of the frequently cited prospective studies concerning fetal monitoring during labor have supported the additional use of FBA in cases with pathologic heart rate pattern.

Direct comparisons of electronic fetal monitoring, with and without additional FBA, show that access to scalp sampling reduces the number of cesareans due to fetal distress. Data from indirect comparisons including postnatal morbidity point to both better maternal and better neonatal outcome if FBA is used.

Due to the evidence of the benefit of the additional use of the FBA during fetal monitoring in prospective randomized trials, its clinical value should generally be accepted. The interpretation of the results and drawing the consequences – clinical measures after FBA – are relatively simple. Thus the use of FBA will be enhanced when the given evidence of benefit is adequately addressed. Alternative methods for continuous biochemical monitoring of the fetus such as $tcPO_2$, $tcPCO_2$, pH and NIRS are at this stage not accessible for clinical use.

Pulse oximetry, which has been in discussion during the last few years, could be useful in

*Michael.Roemer@Klinikum-lippe.de

†Trium CTG Online is a class IIb CE-marked product, see <http://www.trium.de>

combination with FBA, in spite of all reservations, provided that SpO_2 sensors could be improved to better prevent registration gaps. Of all the investigated techniques for continuous biochemical monitoring of the fetus, SpO_2 is the only one that proved beneficial during a prospective randomized trail.

In the future, computer-assisted evaluation of heart rate patterns will very probably find more acceptance for a better objective assessment of cardiotocograms in clinical routine. The number of false-positive findings will be reduced, but not definitely eliminated. Thus FBA will maintain its clinical value.

145 The epidemiology of multiple births

R. Derom, J. Orlebeke and A. Eriksson

Secular trends

The number of twins born per 1000 pregnancies differs considerably between different parts of the world as well as between different periods of time. In Europe and North America, for example, the twinning rate averaged between 12 and 14 per 1000 maternities during the first seven decades of the 20th century. In contrast, it was only about six per 1000 in Japan[1] and about 40 per 1000 in Nigeria[2,3] during these same years. In addition, the twinning rate has varied widely over the past three centuries in those countries where twin births were registered. In Scandinavian countries, epidemiologists have at their disposal registers of births that are kept for centuries by the churches. From these old data sets, it appears that, prior to 1900, several albeit unknown conditions led to considerably higher twinning rates than have been recorded in the 20th century. In the Scandinavian countries, for example, the frequency of twin births was about 17 per 1000 maternities during the second part of the 18th century and even higher (more than 20 per 1000) in areas with a low migration rate, such as the islands in the Baltic Sea.[4] The fluctuations in twinning rate over the last 250 years in Sweden are illustrated in Figure 145.1.

Since 1900, the twinning rate in most European countries has stabilized at around 11–13 per 1000. Official figures for the Netherlands, kept by the governmental Central Bureau of Statistics since 1907, are presented in Figure 145.2, and exemplify the general Western European trend from the 19th to 20th century.

The decreasing twinning rate from the previous to the current century has presumably to be ascribed to the disappearance of isolated societies within nations and the concomitant process of industrialization and urbanization.[5] An even more important reason for the gradual decline in the number of multiple pregnancies could be the lowering of mean maternal age and the smaller total number of maternities per woman (parity). When twinning rates in different countries and different years are corrected for differences in maternal age and parity, temporal and regional variations in the twinning rate can still be observed.[5–7] This has been convincingly documented for Sweden during the period 1870–1970[8,9] (Figure 145.3), a 100-year period uncontaminated by modern obstetric techniques for the improvement of fertility.

After about 1960, a sudden rapid decline in the twinning rate was observed in most European countries. The nadir of this decline occurred in the middle of the 1970s when twinning rates fell to between nine and 10 per 1000 maternities. Beyond that point, an equally rapid recovery to the pre-1960 figures, or even to the high values of the 19th century in recent years, took place. The U-shape of these shifts between 1960 and 1990 in six representative countries can be seen in Figure 145.4.

Such a remarkable and fast change in an otherwise rather stable biological phenomenon, presenting itself in nearly the same manner in several countries, is challenging. There is strong evidence that the decline in twinning rate between 1960 and 1975 can be predominantly ascribed to a parallel drop in maternal

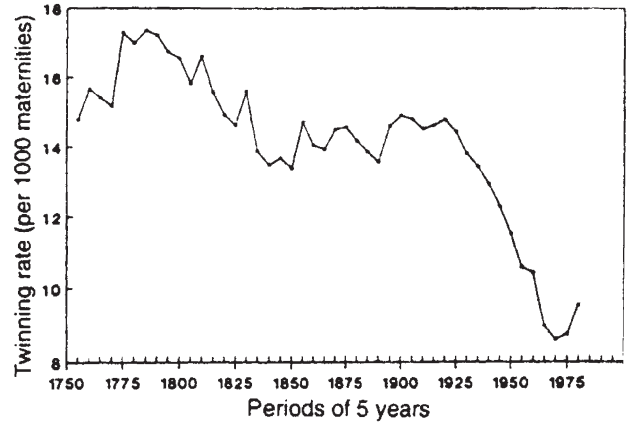

Figure 145.1 Secular variations in twinning rate in Sweden between 1756 and 1990; data are averaged per 5-year period.

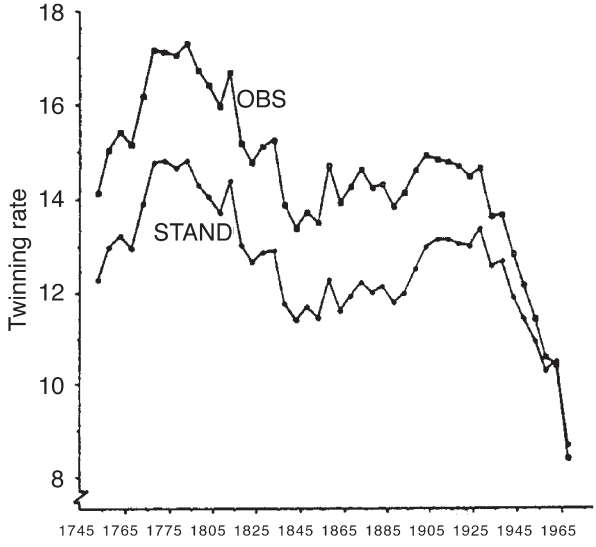

Figure 145.3 Secular variations in twinning rate in Sweden between 1751 and 1970: upper curve gives observed values (corresponding to those in Figure 145.1); lower curve represents same data, corrected for effect on twinning rate of changes in the maternal age. OBS, observed; STAND, standardized.

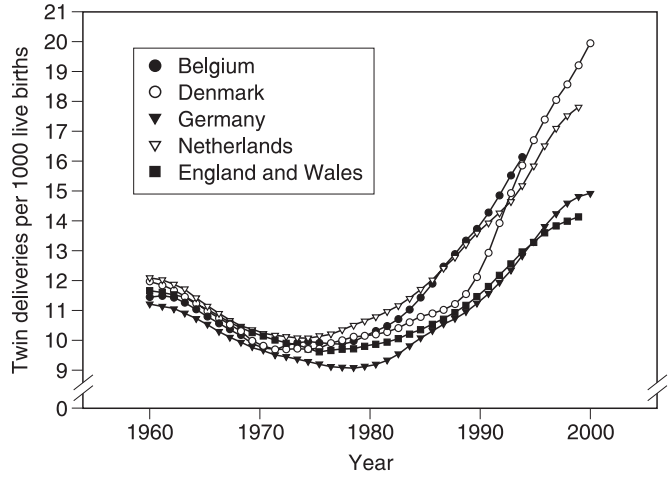

Figure 145.4 Twinning rates between 1960 and 2002 for six European countries.

age at delivery. We have tested this for the Netherlands. Several investigators[10,11] have shown that the probability of a dizygotic (DZ) twin pregnancy doubles in mothers between 35 and 40 years of age compared with mothers below 25. In the Netherlands, the 1960–1975 fall in the total twinning rate was accompanied by a parallel decline in maternal age at delivery. Figure 145.5 shows both the maternal age and the twinning rate changes over time.

As can be seen in Figure 145.5, the increase in the twinning rate after about 1984 is stronger than might be expected from the continuing increase in general maternal age. This 'additional' growth is very likely due to the increasing influence of modern obstetric technology. The excess number of twin pairs (i.e. more than may be expected from the quantitative relationship between the twinning rate and the proportion of deliveries by mothers $\geq$30 years) was about 300 in 1990, or about 10% of all twin pairs born in that year. This number equals the outcome of an independent calculation carried out by Merkus (personal communication) based on the number of women treated with hormones, in most cases clomiphene citrate (Clomid®). Or, to put it another way, the left

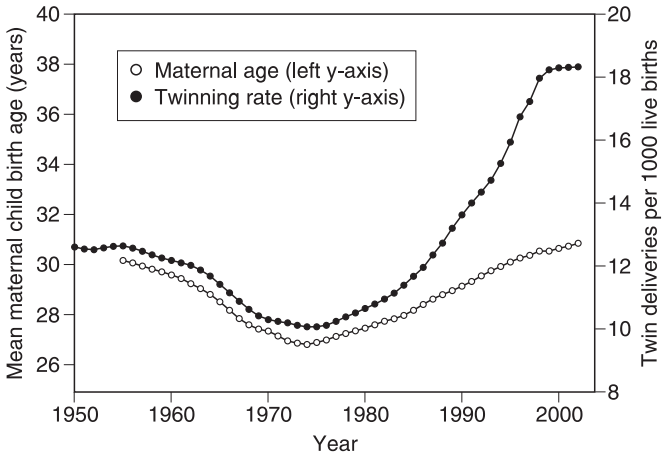

Figure 145.5 Correspondence in the Netherlands between changes in twinning rate and changes in maternal age (operational as percentage of maternities from mothers of 30 years and over). Recent years show disproportional growth in twinning rate relative to increase in maternal age.

sides of the U-shaped curves in Figures 145.4 and 145.5 very likely reflect only the influence of a rapid change in the mean age at which women become pregnant (an interesting societal phenomenon, manifest in most European countries: mean maternal age in the Netherlands, for example, was 30.2 years in 1995; maternal age at first pregnancy was 28.6 years on average; both these figures were never so high during the 20th century). In contrast, the right sides of the Us are produced by a combination of the increase in maternal age and the application of fertility-improving techniques. The relative contribution of these two factors (from the mid-1970s until the present) obviously varies between countries.

Zygosity

Figures 145.4 and 145.5 present data on all twin maternities. The question of to what degree the epidemiological changes in twin prevalence cited above are related to the occurrence of DZ twins, monozygotic (MZ) twins or both cannot be answered unequivocally. Zygosity of a twin can be ascertained with reasonable reliability with the aid of testing for blood groups or DNA. For epidemiological purposes, these methods, however, cannot be used for both practical and budget reasons. A classic method used frequently to estimate the relative contribution of MZ and DZ twin maternities to the total twinning rate was proposed by Weinberg[12,13] and applied many times since. According to this Weinberg rule, the number of MZ twin births equals the difference between all twin births and twice the number of twin births of unlike-sexed twin pairs. This method assumes that the number of unlike-sexed DZ twin pairs equals that of like-sexed twin pairs. Applying this method to a year-to-year time series of twin maternities in a given country consistently demonstrates that the changes in total twinning rate can predominantly be ascribed to changes in DZ twinning rate. In contrast, the MZ rate varies much less and hovers around 4 per 1000 maternities. Figure 145.6 gives the results of the application of Weinberg's rule to recent twin prevalence figures in England and Wales, and in the Netherlands.

Figure 145.6 also shows that the MZ twinning rate increased slightly after 1975. This trend has been recorded in several countries.[14] The hypothesis that the use of oral contraceptives is responsible for this phenomenon[15] appears to be untenable because, in several countries, the increase in the MZ rate began before the (widespread) use of oral contraceptives, whereas in others it started later. A different explanation was proposed by Orlebeke and colleagues,[16] who contend that the rise in the MZ twinning rate is the artificial consequence of another phenomenon, that is, the decrease in twin maternities of unlike sex relative to the number of DZ like-sexed twin maternities. If the latter hypothesis is true, then Weinberg's differential rule loses its basic assumption, that is, the equality of DZ like-sex and DZ unlike-sex prevalence. A relatively low number of DZ unlike-sexed twin pairs automatically leads the Weinberg method to overestimation of the MZ rate.[16] Several other authors have also expressed doubt about the DZ like-sex/DZ unlike-sex equality assumption,[17–20] but still others[21,22] opine that the assumption underlying Weinberg's rule is correct, at least in some countries. The discussion is not purely academic because the Weinberg rule is the major tool available for the study of trends in MZ and DZ twinning rates. A lively debate exists, which we will try to summarize in the following paragraphs.

A number of authors[16–20] adhere for several reasons to the hypothesis of a change in the proportion of like/unlike-sex DZ twinning, a change leading to a flaw of the Weinberg rule. First, if one considers the Weinberg-based year-to-year time series of DZ and MZ twinning rates, then a basic prerequisite for the justification of the use of the Weinberg rule is the absence of a correlation between the two series. This is so because the underlying mechanisms of MZ and DZ twinning are unrelated. Only if some common external factor would influence the frequency of MZ and DZ twinning or if the assumption about equality of DZ like-sex and DZ unlike-sex frequencies is incorrect could a correlation between the two time series be expected. Orlebeke and colleagues[16] calculated this correlation for the Netherlands (period 1904–1989), Denmark (1910–1985), Sweden (1961–1985) and Norway (1931–1985). The Pearson correlations for each country were $r=-0.69$, $r=-0.42$, $r=-0.56$ and $r=-0.12$, respectively. A closer look at the data additionally reveals that the calculated MZ twinning rate has increased very slowly from the beginning of the 20th century until the present decade. Stated

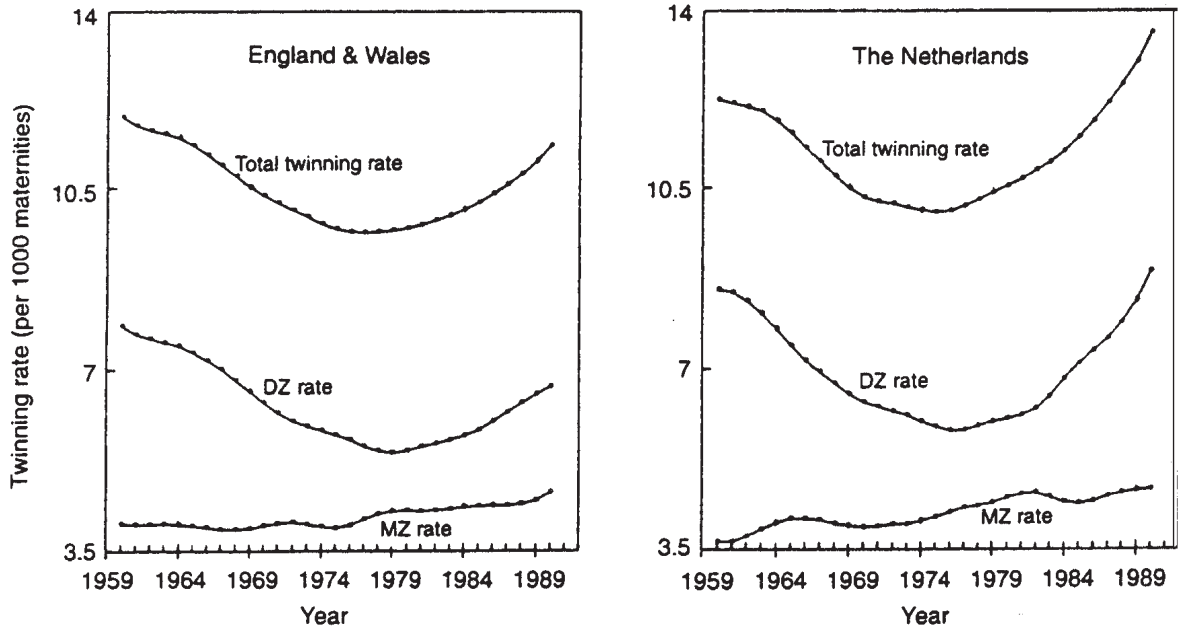

Figure 145.6 Application of Weinberg's differential rule to twin prevalence figures in England and Wales and in the Netherlands, 1959–1989, DZ, dizygotic; MZ, monozygotic.

another way, the increase in 'Weinberg-estimated' MZ frequency is not a recent phenomenon (although it has gone up during the past decade), but rather seems to have been present since the beginning of the 20th century. In Germany, for example, the MZ twinning rate was about 3.25 per 1000 during the second decade of the 20th century, 3.70 during the 1960s and about 4.4 during the past few years. A comparable trend is present in the Netherlands: 3.50 per 1000 around 1915, 3.90 in the 1960s and 4.60 during the past few years. In Denmark, these figures are 3.67, 4.40 and 4.60, respectively, and for England and Wales 3.38 during the early 1940s (we did not analyze older data), 3.55 during the 1960s and 4.50 in recent years. These arbitrarily selected examples make plausible the concept that a gradual shift in the Weinberg estimations of MZ twinning rate is not a phenomenon of the past one or two decades, but rather one that was present long before the introduction of oral contraceptives and ovulation-inducing drugs, although the latter might be held responsible for the very fast changes in MZ rate during the past decade.

Second, analysis of secular variations in sex combinations of twins in the Åland and the Åboland archipelagos (of Finland) demonstrate that the estimated rate of MZ twin maternities increased consistently during the six 50-year periods between 1650 and 1949.[23] It remains possible that this observation is the result of incompleteness of registrations. Mistakes and omissions in the registrations may diminish the proportion of MZ twins, because the frequency of stillbirths is higher among MZ than among DZ twins.

The above-mentioned negative correlation between the DZ and MZ time series, combined with the observations of James[20] and others, strongly suggests that the observed MZ twinning rate increase can be ascribed to a gradual shift in the DZ unlike/like-sex ratio from about unity (or maybe even higher) during roughly the first half of the 20th century to less than unity in later years. Another indication that the number of unlike-sex twin pairs is decreasing comes from the following observation. In all countries from which the total twinning rate is presented in Figure 145.4 the proportion of unlike-sexed pairs, relative to all twin pairs, is consistently higher (about 30.5%) during the period of a decreasing total twinning rate between about 1965 and 1975 relative to the comparable right part of the curve (about 29%). In other words, when the total twinning rate is the same, then DZ unlike-sex twinning rate declines nevertheless. This trend is summarized in Table 145.1. It is possible that this observation reflects an increasing MZ rate. Figures from the Dutch Twin Register, however, support the former interpretation. Of 4186 twin pairs in the register (all children below the age of 6), zygosity was assessed with the help of a questionnaire filled out by the parents. The parents of 392 twin pairs did not answer the questions (mostly because they were too uncertain). From the remaining 4186 pairs, 986 were classified as MZ, 1740 as DZ like-sex and 1460 as DZ unlike-sex. Application of the Weinberg rule would lead to an estimated number of MZ twins of 1266 (instead of 986) and a number of DZ twins of 2920 (instead of 3200).

Table 145.1 Mean proportion of dizygotic (DZ) unlike-sex twin pairs relative to all twin pairs

	Period	
Country	**1**	**2**
Belgium	29.9%	27.8%
Denmark	30.4%	28.6%
England and Wales	30.4%	28.6%
Netherlands	30.9%	29.4%
West Germany	31.0%	28.9%

Period 1: period of decreasing total twinning rate; period 2: comparable subsequent period of increasing total twinning rate

The first group of authors[16–20] conclude that there must be some mechanism that has led to a decrease of the number of DZ unlike-sex twin pairs relative to the number of DZ like-sex pairs. The nature of that mechanism is still unclear; it has produced an artificial enhancement in the Weinberg-based estimations of MZ twinning rate during the past 10–20 years compared with earlier years. It is possible that the assumption of a constant MZ rate is better for the calculation of zygosity proportions than Weinberg's assumption that DZ unlike-and like-sex numbers are equal.

An opposite view has been put forward by a second group of authors who do not consider the presence of a correlation between the MZ and DZ twinning rates as a reason to invalidate the Weinberg rule. Bulmer,[24] writing in 1970, stated: 'It should be observed that *m* (the MZ rate) and *d* (the DZ rate) are negatively correlated since the number of unlike-sexed twins occurs in the formulas for both of them but with a different sign. This negative correlation means that *m* is likely to be an overestimate of the true value when *d* is an underestimate, and vice versa', Moreover, in a large population-based registry of multiple births, the East Flanders Prospective Twin Survey (EFPTS),[22] no reason was found to invalidate Weinberg's rule. This survey is characterized by accurate zygosity determinations. A total of 2589 twin pairs were investigated, of which 2577 were of known zygosity and placentation. The estimates of Weinberg's rule agreed well with the results of the direct zygosity determination. As pointed out by James,[25] in the East Flanders study, the area of uncertainty could be reduced in the group in which zygosity diagnosis is most difficult, that is, the group of same-sexed dichorionic pairs. In such pairs, monozygosity cannot be diagnosed with certainty. In each pair, according to the number of similar markers, a probability of monozygosity should be computed, which should reach at least 0.95 and, ideally, more than 0.99. In the EFPTS study, about one-half of the 401 same-sex dichorionic pairs classified as monozygotic had probabilities of monozygosity of less than 0.95. Husby and coworkers[26] describing a Danish series of 352 consecutive pairs in which direct determination of zygosity was performed, also came to the conclusion that their data were consistent with Weinberg's formulation. James[25] concludes his critical analysis by stating, 'The conclusion of both sets of authors that their data at present are consistent with Weinberg's rule is true but they are also consistent with the hypothesis that the rule is appreciably flawed'.

As suggested by James,[25] one way to solve the controversy would be to retest/those pairs (or those who survive), especially those with lower probabilities of monozygosity. The uncertain pairs would then be rediagnosed as DZ or reassigned a higher probability of monozygosity. Another way would be to perform population-based studies of placentation. Two-thirds of MZ twins are monochorionic. It follows that the number of MZ twins can be calculated by multiplying the number of monochorionic twins by 1.5.

Recent data of EFPTS[1] on a greater number of twin pairs ($n = 5703$) and a lower number of uncertain zygosity pairs ($n = 117$) confirmed the former results. In addition, the spontaneous twins and the iatrogenic twins were considered separately. The results in both groups validated Weinberg's rule. So, the second group of authors firmly recommends the use of the rule in population-based studies, at least in Caucasian populations. They also doubt that, in recent decades, the proportion of DZ-unlike sex and DZ-like sex differs from unity.

Prevalence of triplets

Compared to the change in twinning rates during the past 20 years (about 30–50% produced by an increasing maternal age and by use of fertility-enhancing techniques), the increase in triplet deliveries has been much more dramatic. In England and Wales and in West Germany, the triplet rate increased about 170% between 1975 and 1990. In the Netherlands, the increase was more than 300% and in Belgium (figures only available until 1988), the increase was still higher. Figure 145.7 depicts the triplet rates between 1971 and 1990 for the countries mentioned above.

Without doubt, ovulation induction and *in vitro* fertilization (IVF) are the principal causes of this change. Data on the etiology of triplet maternities were collected for 112 triplet sets born between the end of 1986 and the summer of 1991. All sets were part of the Dutch Twin Register. Only 30 sets were spontaneous; 39 were induced and 39 the result of IVF. Four sets were of unknown etiology. Most of the excess triplet sets are trizygotic (TZ). The epidemiological counterpart of the Weinberg rule for the estimation of zygosity proportions among triplets was proposed by Allen in 1960:[28]

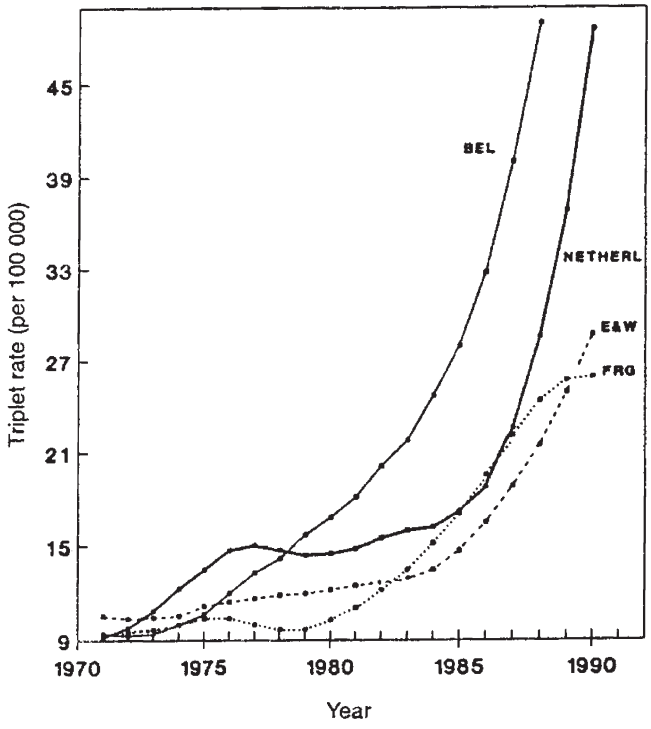

Figure 145.7 Changes in triplet rate during 1971–1990 in four European countries. BEL, Belgium; NETHERL, the Netherlands; E&W, England and Wales; FRG, Germany.

$$\text{Number of MZ triplets} = L - \frac{1}{2}D - \frac{1}{4}T$$

$$\text{Number of DZ triplets} = D = 2\ (\text{MZ twinning rate} \times \text{DZ twinning rate})N$$

$$\text{Number of TZ triplets} = T = (U - \frac{1}{2}D)\ 1/3$$

In these formulas, L is the number of like-sex triplets, U is the number of unlike-sex triplets and N is the total number of maternities. Application of the Allen formula to all triplets born in about the same period as the 112 registered triplet sets leads to estimated proportions of 4.5% MZ, 20.3% DZ and 75.2% TZ. This corresponds rather well with the empirical proportions among the registered 112 triplets: 6.3%, 21.4% and 72.3%, respectively. The Allen method, thus, seems to be a useful approximation for the estimation of zygosity rates in triplets. If we apply the method to triplet prevalence figures from before 1970 (i.e. when ovulation induction and IVF were still unknown or at least not widely used), zygosity proportions appear to be rather different from those of today, roughly about 20% of all triplets estimated to be MZ, 40% DZ and 40% TZ.[28] In other words, modern obstetrical technology has not only increased the triplet rate in general, but has also changed the proportional contributions of zygosity types to the total number of triplets.

Factors determining rates

Twinning rates are influenced by genetic and environmental factors. Some of the latter are undoubtedly related, a circumstance that increases the difficulty of assessing the importance of each factor on its own. Moreover, the actions of genes and the environment are interrelated in some instances. Finally, highly significant temporal fluctuations also impact on many of these environmental variables. As a result, great caution is required before assigning a significant role to any of the environmental variables discussed below.

In addition, at least in most industrialized countries, as will be discussed later in this chapter, iatrogenic twinning rates have reached such proportions that sensible studies can no longer be performed on a number of factors such as maternal age, parity, geographical variation, seasonality and genetics. Vital statistics, for instance, will be strongly biased unless the spontaneous and the induced sets of multiplets can be distinguished. Except in East Flanders, Belgium[30] such data are not available.

Maternal age

Duncan,[31] the famous Scottish obstetrician, was clearly aware of the relationship between maternal age and twinning frequency. In 1865, he stated, 'From the earliest childbearing period till the age of 40 is reached, that is till a period when fecundity has become extraordinarily diminished the fertility of mothers in twins gradually increases'.

Waterhouse[32] analyzed the total births in England and Wales for the 10-year period 1938–1948 in an attempt to understand how the twinning rate varies with maternal age and parity (Figure 145.8). Clearly, increased maternal age and increasing parity exert separate and independent positive influences on the twinning rates. However, recent data from the USA do not corroborate the British findings (Figure 145.9). According to data from Taffel,[33] only in first US births does the twinning rate increase with maternal age. In subsequent live births, the rates either remain approximately at the same level or fall. This contrast is of interest and obviously must be explained. To begin with the respective periods of observation differ by almost 40–50 years (between 1938–1948 and 1987). During this time, essentially the second half of the 20th century, the entire way of life has changed dramatically. Of all possible changes, the status of women and their reproductive behavior has been modified in ways that could hardly have been conceived in the first part of the century. Much of this change relates to availability of contraception, age at first pregnancy, abortion on demand, smaller family size, infertility treatment and probably also other factors. Further studies clearly are needed to track down the reasons behind this remarkable new phenomenon in the epidemiology of twinning.

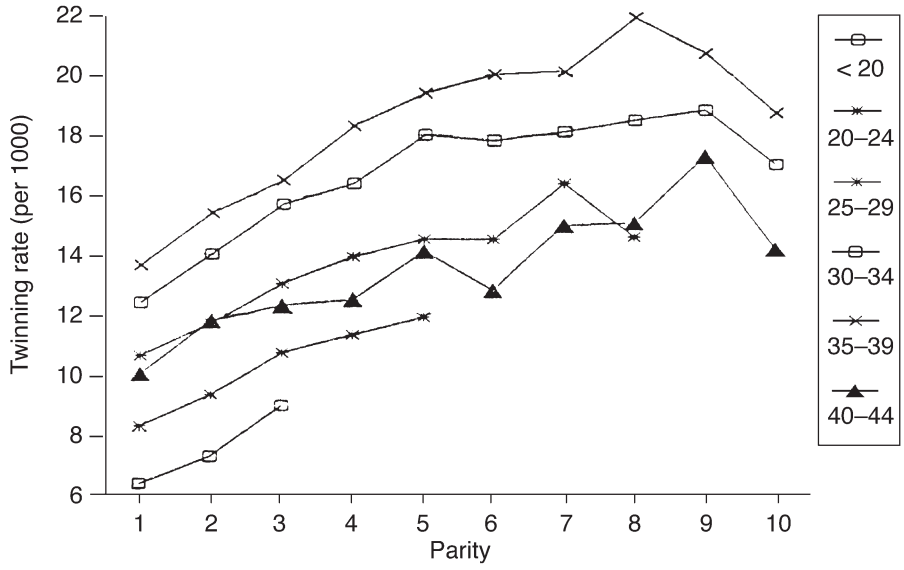

Figure 145.8 Twinning frequency according to maternal age and parity. England and Wales 1938–1948. Drawn from data of Waterhouse.[32]

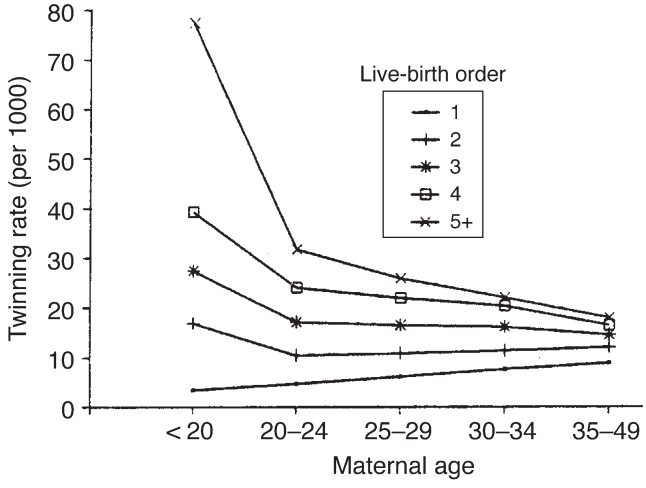

Figure 145.9 Twinning frequency according to maternal age and parity, US whites 1987. Drawn from data of Taffel.[33]

Parity

Both the British and American data show the positive influence of parity or live-birth order, respectively, on the twinning rate. There are no directional changes in these trends, as is the case with maternal age, but substantial changes in magnitude are present. Note, for instance, that in the age bracket of 25–29 years, the rates in 1938–1948 increased by 37% from parity 1 to 4 (Figure 145.8) but this increase amounted to 129% in 1987 (Figure 145.9). This almost three-fold difference will also require explanation by epidemiologists in the future.

It is not possible to determine the exact influence of parity derived from US live-birth certificates, because each live-born twin in a twin delivery is assigned a different, adjacent live-birth order. For example, in a parity 2 twin delivery, the first-born child is assigned live-birth order 2 while the second will be assigned live-birth order 3. Clearly, despite this shortcoming, one may safely surmise that higher parity is associated with increasing prevalence rates of twinning.

Height

As early as 1877, Tchouriloff[34] suggested that an association was present between height and the rate of twinning in a population. He observed that men rejected for military service because of small stature came from various parts of Europe in which the rate of twinning was known to be low. Studies of the height of mothers of MZ and DZ twins, performed in Oxford, England, and Aberdeen, Scotland, respectively, support the hypothesis that mothers of DZ twins are taller than those of MZ twins. In reality, the mean difference between the two groups is estimated at 1.03 ± 0.74 cm: mothers of MZ twins resemble mothers of singletons.[35]

Geographical variation

Studies indicate that the further north, the higher the twinning rate: the relationship, though, is far from close and is limited to DZ twinning. According to James,[36] the correlation coefficient between latitude and age-standardized DZ twinning rates in Europe in the late 1950s and the early 1960s reached a value of $+0.68$ ($P < 0.01$). This trend seems consistent with

time, because similar findings had been reported by Davenport[37] in 1930 for the total twinning rate. For US whites, the correlation is +0.54 ($P < 0.001$); for US blacks it is positive (+0.31) but not significant. Bulmer[24] speculated that geographical variations in DZ twinning rates in Europe might have some genetic basis. James[36] observed that there is no reason to suppose that genetic clones in the Old World are duplicated by latitude in the New World. Indeed, the fact that the latitudinal variations in DZ twinning are similar in Europe and the USA suggests an environmental rather than genetic cause.

Superimposed on latitude variations are differences between countries and regions. It is not meaningful to report on all or even most national and/or regional figures. Only some examples of differences not fitting the latitude differences will be mentioned. Earlier in this chapter, Finnish and Swedish twinning rates were noted to vary between the mainland and islands or groups of islands in which endogamy was important.[4,5,23] Data from France, collected between the years 1858 and 1865, show regional variations ranging from 8.1 per 1000 in the southwest to 11.8 per 1000 in Alsace/Lorraine in the north.[38] In Italy, between 1892 and 1904, not only was there a decrease from north to south, which fits the latitudinal model, but also higher frequency of twins was noted in the east than the west, at least in the upper part of the country.[39] Finally, the twinning rate in the Irish Republic is higher than that in the UK. In 1968, it was 13.6 per 1000 vs. 10.8 per 1000 in Northern Ireland and 10.0 per 1000 in England and Wales, respectively. Only part of the difference is accounted for by the higher age and, to a very small extent, the higher parity of the mothers of the Irish Republic, indicating that the standardized twinning rate is higher in Ireland.[42]

Seasonality

Seasonality in the birth rates has been demonstrated in a number of European countries. The peak rate occurs, in April–May and the troughs appear in November–December.[41] The question arises whether twinning rates show similar variation. It could even be surmised that, during the more fertile months of the year the twinning rate would rise as well. According to James,[42] there is good evidence that, at least in England and Wales, the incidence of opposite-sexed (and by inference, DZ) twin births is seasonal, being about 5% higher in December than in June. Triplet births also show a similar seasonal variation but with double the magnitude. Evidence with regard to seasonal variation in MZ twinning rates is equivocal. Richter and coworkers[43] evaluated twinning rates over a period of 250 years (1611–1860) in Görlitz, Germany. The rates were relatively stable in spring and fall, but varied greatly in winter and summer. In contrast, analysis of data from the Aberdeen City District (1969–1983) showed little variation in either DZ or MZ twinning by month of last menstrual period.[11] These are but three reports from a voluminous literature, which have been critically analyzed by MacGillivray and coworkers.[11] Unfortunately, in many studies, clear-cut conclusions cannot be drawn, because of methodological problems, e.g. the use of improper statistical analysis, and the possibility that artifacts in the seasonal patterns are caused by the determination of zygosity by the use of an indirect technique such as the Weinberg formula.

According to MacGillivray and coworkers,[11] and this is also our view, the seasonal evidence has been inconclusive until the middle of the present century. However, circumstances have changed during the past decade or, possibly, since the 1970s. Figure 145.10 shows the seasonal variations in singleton and twin births in the Netherlands from 1987 to 1991. Peaks and troughs for twins are relatively higher and lower than for singletons. Considering the fact that as many as 50% of these pregnancies were planned in Western Europe during these years, one may speculate that these variations are the results of the parents' choice as to the best period of the year to have a baby. Since 1988, the seasonal variations are clearly more pronounced with the twin deliveries. Dionne and colleagues[44] compared birth dates of all twins that were born between 1984 and 1990 in the state of Washington, USA, with birth dates of singleton brothers and sisters from the same families. Thus, only families with both a twin pair and a singleton sib could enter the sample of 1168 families. It appeared that especially DZ opposite-sex twins (thus, presumably all DZ twins) were procreated significantly more than their singleton siblings during summer periods. The authors consider this finding as support for their view that the longer periods of sunlight increase the probability of multiovulation, mediated by the pineal gland.

Genetics

Twins undoubtedly run in families. The mode of inheritance, however, is not clear. Most authors agree that MZ and DZ twinning must be considered separately, and that the evidence for inheritance is much stronger in the latter. Although only a few studies have examined the heredity of MZ twinning, the strong similarity in their results is remarkable: on the one hand, there is a low increase in the probability of repeat MZ twinning among the relatives of MZ pairs; on the other, there are a small number of case studies of families with more than one pair of MZ twins among the first three degrees relationship.[45] The best hypothesis seems to be that of monogenic, dominant inheritance with a low penetrance. However, the inheritance seems to be restricted to only a small fraction of the MZ twin families.

Weinberg[12] was the first to investigate the heredity of DZ twinning. He discovered that, in Stuttgart and the

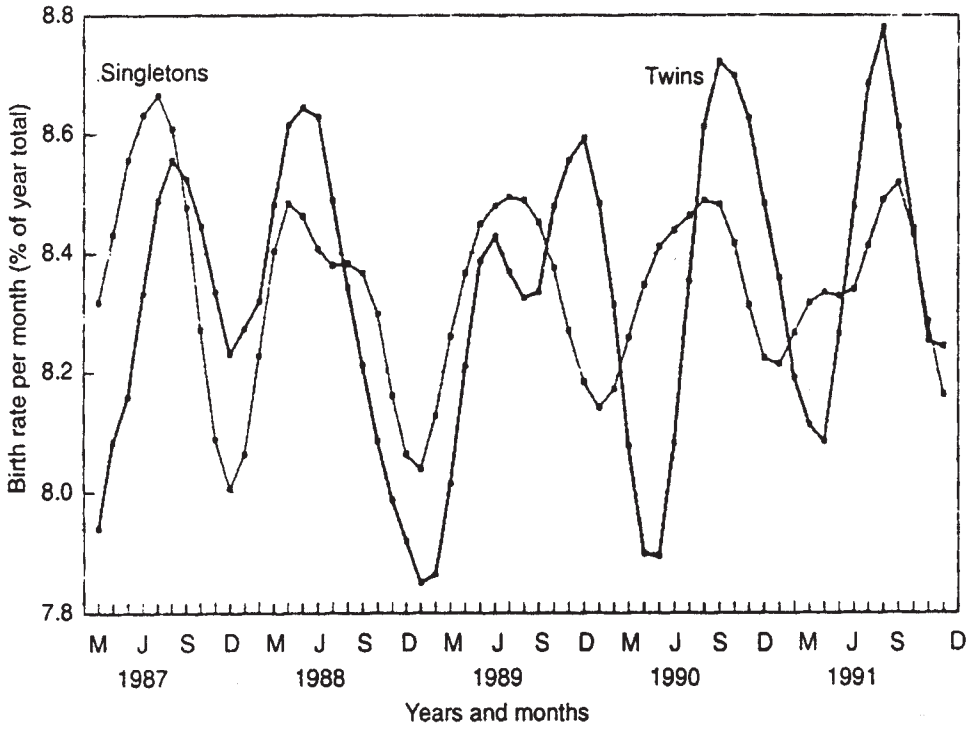

Figure 145.10 Seasonal variation of singleton and twin birth in the Netherlands, 1987–1991.

areas surrounding Würtenberg, Germany, the twinning frequency was increased by almost 54% among mothers of twins and the sisters and daughters of the mothers, but was not elevated or was even lower among the relatives of fathers of twins. He concluded that the inheritance of DZ twinning is restricted to the female line. A similar study was conducted in the Orkla valley in Norway.[46] Wyshak and White[47] analyzed the offspring of unlike-sexed twin pairs using the archives of the Genealogical Society of the Church of Jesus Christ of Latter Day Saints in Utah, USA. The DZ twinning frequency computed by the Weinberg method among the offspring of the female twins and their sisters amounted to 14.45 and 16.52, respectively, per 1000 maternities compared with 6.86 per 1000 maternities among the offspring of the male co-twins. These findings led Wyshak and White to accept the theory of a maternal autosomal recessive mode of inheritance. Although this point of view is supported by earlier studies,[12,46] questions about this type of research remain. As the hereditary factor interferes with normal ovulation by causing the production of two or more ova, phenotypic proof of the presence of the gene or genes fails on the paternal side. The unobserved transmission in a pedigree through the males may mislead scientists. Indeed, instead of investigating the offspring of the male twin or his male sibs, scanning the offspring of the daughters of the male DZ twin and of his male sibs should reveal comparable results. This observation underlines once more the important problem of the sex-limited expression. No doubt, rather large samples are needed to detect effects that are diluted 50% by additional segregation.

Starting from a working hypothesis, Bulmer[24] approached the problem in the same manner as Wyshak and White,[47] evaluating recessiveness and dominance, but based on a theoretical background rather than on empirical data. He assumed that DZ twinning is controlled by a pair of genes, *T* and *t,* and that women with either of the genotypes *TT* or *Tt* have a twinning rate p_1, while the twinning frequency among *tt* women amounts to p_2, Supposing that both genes, the dominant *T* and the recessive *t,* appear at the same frequency, this results in phenotypic frequencies of 3/4 and 1/4 for p_1 and p_2, respectively, given random mating and a Hardy–Weinberg equilibrium. This allowed the calculation of the gene frequencies using the twin-bearing probability, which can be regarded as a random variable with its own probability density function and mean. Bulmer rejected the dominant-gene hypothesis but adopted recessiveness as the mode of inheritance. Limiting himself to this single hypothesis, he could not find the reason why the twinning rate among mothers of TZ triplets was double the rate among the DZ twin mothers, although both had the same *tt* genotype. Referring to the long tail in the graph of the distribution of twinning rate *p,* the possibility of another group of women with a higher predisposition for DZ twinning seems to be the most logical explanation. Polygenic models are not rejected by these data.

Eriksson and Fellman[23,48,49] conducted extensive studies on the secular changes of the DZ twinning

rates in Finland and Sweden. These two countries possess the oldest population statistics in the world for a whole nation. In the Åland archipelago in the Northern Baltic Sea, for example, as well as in Sweden, the DZ twinning rate has decreased, particularly in the past half century. Until recently, these island populations, particularly the outer parishes, had DZ twinning rates that were significantly higher than on the mainlands of Sweden and Finland. The higher frequencies of multiple maternities in these insular populations may well reflect the effect of inbreeding and endogamy. Indeed, these populations, which have descended from a relatively small group of founding settlers, have a more markedly decreasing trend of twinning, especially DZ twinning, compared with the mainland populations. This steep decline in twinning cannot be explained simply by a lower maternal age and parity. The decrease may be partly a consequence of the changes in matrimonial migration patterns, by breaking up of the isolation and by reducing the endogamy. In this case, the high twinning frequencies of previous centuries on these islands are consistent with a recessive mode of inheritance for the DZ twinning process.

In the recent analysis of multiple births by Eriksson and colleagues,[50] high frequencies of multiple maternities were found on the maternal side of families with triplets. The twinning rate among mothers with triplets was four times that of normal mothers. According to the senior author of this investigation, a simple genetic model is not sufficient to explain this high frequency. Eriksson's hypothesis is that this higher propensity for twinning, particularly on the maternal side, is caused by multifactorial inheritance.

To conclude, in the majority of instances, the inheritance of DZ twinning possibly results from a recessive character caused by an unknown number of genes. However, recessiveness does not seem to be the only potential mode of inheritance. Indeed, several authors[24,46,51] have already suggested that other modes of inheritance must also be investigated for a dimensionally undefined group of twin mothers. Besides the genetic propensity, environmental factors, such as maternal age, parity and race, increase the individual probability of twin bearing.

Considering the variety of models that have been suggested to date, and especially the necessity to investigate more fully the hereditary transmission through the female as well as the male line, our group has teamed up with the Genetic Epidemiology Division, Department of Medical Informatics, University of Utah, to conduct a large-scale study of the genetics of twinning in Belgian and Dutch population-based samples. The inheritance of spontaneous DZ twinning was investigated in 1422 three-generation pedigrees of mothers of spontaneous DZ proband twins. DZ twinning was modeled as a trait of the mother and defined as a dichotomous phenotype. Complex segregation analysis showed that the trait of 'having DZ twins' was inherited by an autosomal monogenic dominant model with a gene frequency of 0.035 and a female-specific penetrance of 0.10.[52]

The same model applies to DZ twinning among relatives of induced DZ twins, i.e. twins born of artificial induction of ovulation, one of the many modes of treatment of infertility. It seems, therefore, that women over-reacting to the administration of ovulation-inducing drugs are those carrying the twinning gene.[53]

The hereditary transmission through the female as well as the male must be investigated. Confusion with the sex-limited expression of the factor not only pushed scientists to come to the wrong conclusions but also obscures the transmission along the male side. Generally, one can consider female as well as male carriers. Future research should focus on the hereditary paradox: male vs. female inheritance, recessiveness vs. other manners of transmission and environmental vs. genetic twinning.

Infertility treatment

Recent data pertaining to twin- and triplet-delivery rates in six European nations have been analyzed in the first part of this chapter. Part of the increase has resulted from treatment of infertility. In all six countries, the rates are soaring, but in different degrees. As already stated, part of the increase is associated with the new methods of infertility treatment. In the East Flanders Prospective Twin Survey (EFPTS), the origin of the pregnancy has been recorded since 1976. From January 1, 1976, to 31 December 31, 1991, a total of 437 multiple births that resulted from artificial induction of ovulation (AIO) and Artificial Reproduction Technology (ART) were recorded. Only the pregnancies in which one of the children weighed more than 500 g or, if birth weight was unknown, the gestational age was greater than or equal to 22 weeks, have been considered for the present discussion. The zygosities of these pregnancies were compared with the zygosities of spontaneously occurring multiple pregnancies in terms of their relative frequency. All dichorionic MZ twins and trichorionic DZ triplets born after AIO had a probability of monozygosity and dizygosity, respectively, of at least 0.95.

Figure 145.11 shows the yearly numbers of spontaneous and induced twin births registered by EFPTS between 1976 and 2002.[30] In 1976, the total number of registered twin births approached 140 per year, whereas since 1991, the total has numbered more than 200. Figure 145.1 clearly documents that the increase in the total number of twins is entirely due to the use of fertility-enhancing agents, because the number of spontaneous twin births did not rise appreciably during these years. Between 1976 and 1985, the number of induced twin births increased slowly but substantially whereas after 1985, it was more dramatic. To be exact, AIO and ART pregnancies accounted for more than one-third of all twin births in 1991 and 1992 and almost one-half in 1996. The

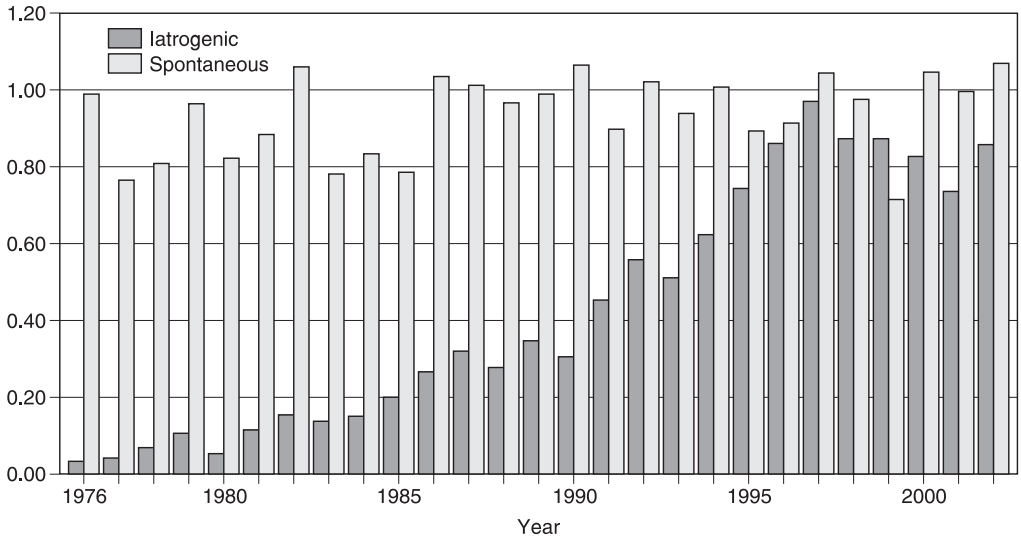

Figure 145.11 East Flanders Prospective Twin Survey, 1976–2002: yearly numbers of spontaneous and iatrogenic twins and iatrogenic twin maternities.

decline in the number of spontaneous twin births during the years 1983–1985 was due to a decrease in the total number of births. Figure 145.12 extends the analysis by showing the relative frequency of twins and triplets born after AIO and ART (1%) between 1976 and 1996. As was the case in the other countries cited above, the increase in the number of triplet births far outweighed the concomitant increase in the number of twin births.

Pooling the data over the years, Figure 145.13 shows that most of the induced multiple gestations in Figures 145.11 and 145.12 do not result from the advanced technologies of assisted reproduction such as IVF and embryo transfer (IVF–ET), gamete intrafallopian transfer (GIFT) and zygote intrafallopian transfer (ZIFT). Rather, they result from the use of fertility-enhancing drugs alone. In 80% of the iatrogenic twin pregnancies and 78% of the iatrogenic triplet pregnancies, AIO was the only treatment. Clomiphene and the sequential use of human menopausal and human chorionic gonadotropin were the regimens most commonly used in the mothers of these multiplets. Before 1986, the use of IVF–ET, GIFT and ZIFT was limited in East Flanders. In the past 4 years, however, the number of pregnancies resulting from these procedures represented more than 35% of all induced twin pregnancies, so their contribution to the increase in multiple births can no longer be neglected or denied.

In contrast with common expectation, all induced twin and triplet pregnancies were not DZ or TZ (Table 145.2). As reported earlier,[54] the frequency of zygotic splitting after AIO (1.0%) is higher than that observed after spontaneous ovulation (0.45%). There is no significant difference in the rate of zygotic division between the pregnancies that resulted from AIO only and those that occurred after IVF–ET, GIFT or ZIFT, or between the pregnancies induced by clomiphene and those induced by gonadotropins.

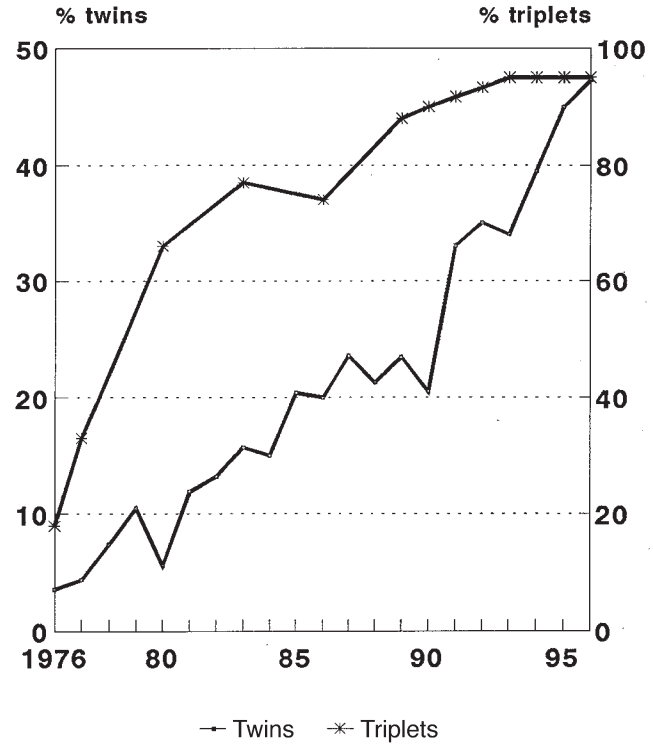

Figure 145.12 East Flanders Prospective Twin Survey, 1976–1996: relative frequencies of induced twin and triplet maternities. Twin maternities are shown on 50% scale, triplet maternities are shown on 100% scale; frequencies refer to the total number of twin and triplet maternities.

The increase in the rate of multiple pregnancies represents an important public health problem. If this trend continues, the rates of very preterm births and very low birth weight infants will undoubtedly rise, as in multiple, compared to singleton, pregnancies, the trend toward infants whose birth weight is less than 1500 g is dramatic. Because very low birth weight

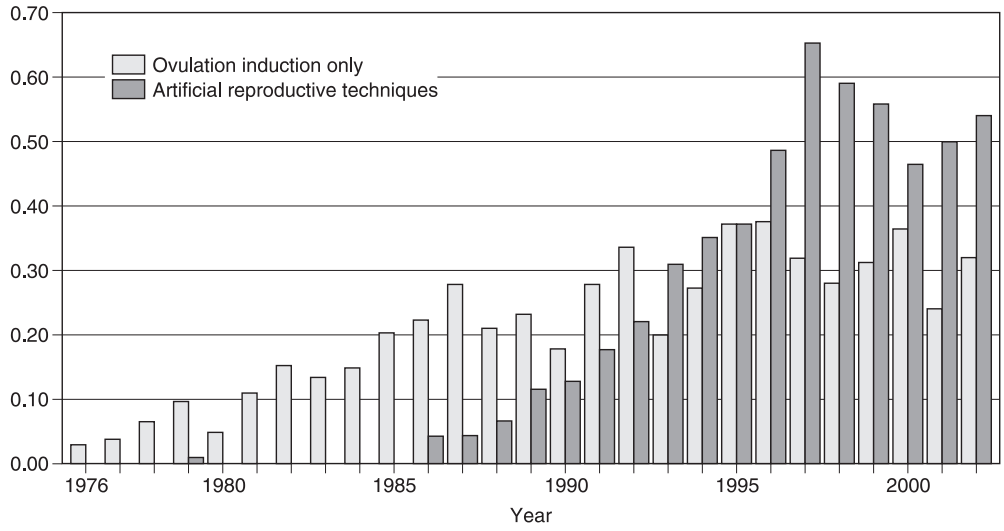

Figure 145.13 East Flanders Prospective Twin Survey, 1976–2002: yearly numbers of iatrogenic twin deliveries according to type of treatment, ovulation induction only and artificial reproduction techniques (ART).

Table 145.2 East Flanders Prospective Twin Survey: 1976–2000. Zygosity of twins and triplets born after artificial induction of ovulation

	Twins	Triplets
Monozygotic (MZ)	74	0
Dizygotic (DZ)	1442	16
Trizygotic (TZ)	—	112
Unknown	12	0
Total	1528	128

Frequency of zygotic splitting in iatrogenic DZ twinning:

$$\frac{\text{number of DZ triplets}}{2 \times \text{number of (DZ twins} + \text{DZ triplets)}} = \frac{7}{2 \times (1442 + 7)} = 0.0055$$

infants have high perinatal mortality and morbidity rates, they represent a high cost to the community in terms of an increased patient load to the neonatal intensive care units and an increased number of lifelong physical and mental handicaps.[55–57]

The fact that a number of MZ twins are born after AIO and ART and that the frequency of zygotic division after AIO and ART is higher than after naturally occurring ovulation is of fundamental biological importance. It is clear that hormonal induction of ovulation acts not only on the ovary but also on the zygote in as much as it stimulates division. To date, no conditions were known that could influence the MZ twinning rate. Treatment with clomiphene and/or gonadotropins is the first exception.

The spectacular iatrogenic increase of the rates of multiple maternities upsets the epidemiology of twinning and higher-order multiple births. When comparing population data from countries or regions where ART and ovulation induction are commonplace, the proportion of MZ/DZ twinning should be duly considered. The number of unlike-sex pairs should be mentioned and the Weinberg rule applied. Appropriate statistics can be applied if there are significant differences. By the way, the same procedure allows valid comparison between ethnicities with high and low DZ rates.

Perinatal and infant mortality

Innumerable studies on perinatal mortality of multiple births have been published worldwide. The major specific variables considered were, and still are, birth order, placentation, zygosity, maternal age, parity, height, social class, birth weight, mode of delivery, differences in rates in like- vs. unlike-sex pairs, etc. Many of these studies, however, are only of historical importance, mainly because of the changes in the definitions of stillbirth and live birth. Recently, excellent recent studies have been performed on US multiple[58] and Scottish[59] twin births.

Two population-based studies will be considered in this chapter: they are based on data from the US vital statistics and the East Flanders Prospective Twin Survey (EFPTS).

United States National Natality files[60] have been used to generate intrauterine growth curves for twins, and the linked Birth/Infant Death files to analyze the risk of neonatal and infant death for US black and white twins. As demonstrated in Figures 145.14 and 145.15 twins have a survival advantage over singletons at certain ranges of both birth weight and gestational age. Despite this, the overall risk of infant death among twins continues to be four to six times greater than that of singletons. Optimal duration of twin gestation and birth weight are 39 weeks for whites and 37–38 weeks for blacks, and range from 2750 to 3500 g for whites and from 3250 to 3500 g for blacks.

In the EFPTS, the structure of the fetal membranes and the zygosity have been determined at the time of

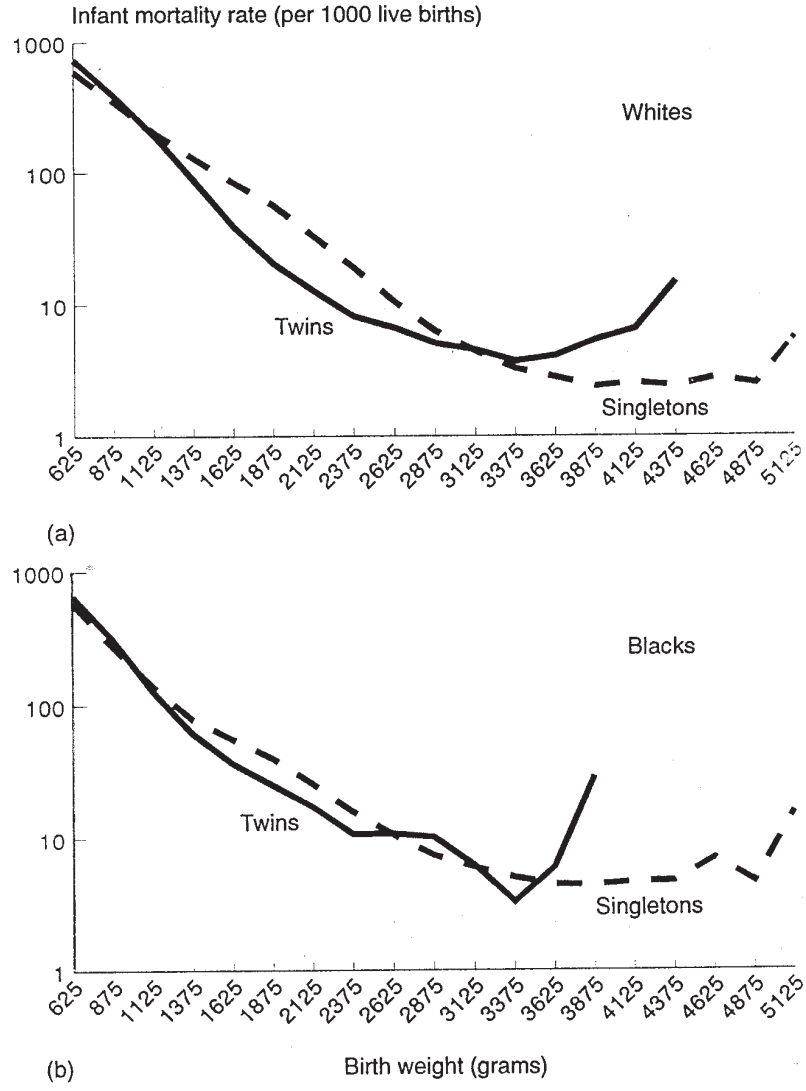

Figure 145.14 Birth weight-specific infant mortality for US white (a) and black (b) singletons and twins, calculated from linked Birth/Infant Death files for 1983–1985.[60]

birth.[61] These data allow differentiation of the perinatal mortality rates according to zygosity and chorion type. In MZ dichorionic twins (Table 145.3), the rate is not increased compared with that of DZ twins (data not given). In monochorionic twins (which are MZ), the rates are clearly increased, less so in the diamniotic than in the monoamniotic subgroups. Cord entanglement and conjoined twins are responsible for the very high rate in the latter subgroup.

As shown in Table 145.4 the second twin is, independently of the chorion type, at greater risk of mortality than the first twin, but much less so in the 1980s and 1990s than in the two preceding decades.

Congenital anomalies

If there is an epidemiological domain that is bedeviled by ascertainment biases, it is most probably that of congenital anomalies. Besides the usual biases, e.g. definitions, diagnostic criteria, extent of investigation to ascertain the presence of malformation and length of time that a population is followed, there are biases specific to twin studies: accurate zygosity diagnosis, calculation of concordance rates, sample size (small number of twins with malformations), etc. The reader is referred to several reviews[62–64] for detailed discussions of these problems.

Studies of congenital anomalies in twins are of major interest because they allow differentation of genetic from antenatal environmental influences in their origin (nature vs. nurture). However, except for occasional case reports in which concordant or discordant malformations were found in MZ twins, only a handful of studies of sufficient size meet the criteria mentioned above.

Major findings in the numerous studies of congenital anomalies in twins are summarized below:

(1) Although few studies have compared singletons and twins with adequate methods, overall, the prevalence rates are higher in twins.[64]
(2) The higher prevalence is probably greatly or entirely to be attributed to MZ twins.[64,65] Indirect

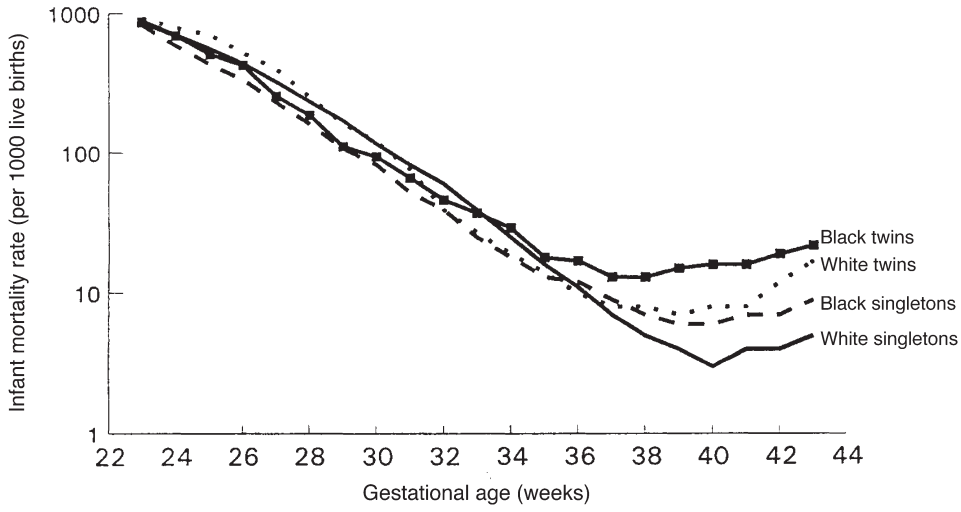

Figure 145.15 Gestation-specific infant mortality rates for US singletons and twins, calculated from linked Birth/Infant Death files for 1983–1985.[60]

Table 145.3 East Flanders Prospective Twin Survey (EFPTS): 1964–1989. Monozygotic twins: perinatal mortality according to placentation[61]

		Perinatal mortality, *n* (%)	
Placentation	**Number of pairs**	**Twin 1**	**Twin 2**
Dichorionic (PMZ ≥ 95%)	438	14 (3.2)	26 (5.9)
Monochorionic–diamniotic	871	65 (7.5)	84 (9.6)
Monochorionic–monoamniotic	30	9 (30)	7 (23)

PMZ, probability of monozygosity

Table 145.4 East Flanders Prospective Twin Survey (EFPTS): 1964–1989. Perinatal mortality rates (%) according to chorion type and birth order, twin 1 vs. twin 2

Time Period	Number of pairs	Chorion type	Twin 1	Twin 2
1964–1979	1852	MC	10.3	13.1
		DC	5.0	8.0
1980–1996	2766	MC	7.5	8.5
		DC	2.5	3.5

MC, monochorionic; DC, dichorionic

evidence is provided by many studies in which the frequency of anomalies among like-sex twins has been higher than that among unlike-sex twins. Few studies have been reported in which zygosity has been determined by a direct method.[64]

(3) In MZ twins, the prevalence varies according to placentation: lowest (possibly not increased) in the dichorionic, highest in the monochorionic–monoamniotic and intermediate in the monochorionic–diamniotic subgroups.[65]

(4) Specific to twinning are acardia and conjoined twinning (which occur only in monochorionic–monoamniotic pairs), and fetus *in fetu*.[64]

(5) In MZ pairs, most anomalies are discordant. Clearly, antenatal environmental factors must play an important role in their origin.[65]

(6) Cardiac anomalies are a good example to illustrate what we have discussed in the preceding paragraphs. Preliminary results show that they are more frequent in monochorionic pairs, pointing to the role played by the twin-to-twin vascular anastomoses as a possible causal mechanism.[66]

(7) A large majority of conjoined twins are of the female sex. This is probably not related to the malformation itself but to the placental structure: the overall proportion of males/females of monoamniotic pairs is very low.[66]

Table 145.5 Relative number of male infants born per 1000 females in US births (1915–1948)[72]

Total born living	1055
Twins	1043
Triplets	1007
Quadruplets	940
Quintuplets	935

Table 145.6 Sex proportion of spontaneous twins in EFPTS (1970–2000) according to zygosity and placentation

Zygosity and chorionicity	Sex proportion
Dizygotic	0.514
Monozygotic–dichorionic	0.501
Monochorionic–diamnionic	0.499
Monochorionic–monoamnionic	0.212
All monozygotic	0.494
All ($n=3765$ pairs)	0.506

(8) Whether ART or AIO increases the risk of congenital anomalies makes doctors and patients uneasy. Only four methodologically valid studies have been devoted to this disquieting question.[67–70] They conclude that the outcome of twin pregnancies obtained with ART is comparable with that of normally conceived twins. The number of cases is limited and does not allow ruling out any teratogenic action. Hypothetically, such action should be considered because in ISCI natural selection of the fertilizing sperm is surpassed, a potential risk of facilitating congenital anomalies. No data are available on the outcome of twin pregnancies following induction or enhancing of ovulation. A warning, therefore, is mandatory and additional research is needed.[71]

Sex proportions at birth

The proportion of males in multiple births has been and still is a matter of lively debate. Clearly, there are differences between singletons and multiplets. The question remains, however, of the explanation for these differences and whether the differences could throw some light on the mechanisms of the human sex proportions at birth.

The proportion of males in the human species decreases with each increase in the number of fetuses per pregnancy. An overview in the white population of the United States is given in Table 145.5.

Twins

In twins, the lower male/female proportion is for the greater part due to the MZ twins (Table 145.6). In the EFPTS series, the sex proportions of the DZ pairs and the singletons did not differ significantly. To our knowledge, no other studies comparing the sex proportions between MZ and DZ twins and singletons have been published. James has studied the sex proportions extensively, and has reviewed the literature on MZ twins whose sex was ascertained at birth.[73–75]

Adding the data from nine studies on Caucasian samples with known placentation, the male/female proportions were as follows: overall 0.499, monochorionic pairs 0.492 (in five of the nine reports, monoamniotic twins have been omitted) and dichorionic twins 0.571 (only three of the nine authors reported data on these twins). The ratio of 0.499 is lower, but not significantly lower, than that estimated for all Caucasian pairs, 0.5047 ± 0.001, by Bulmer.[24] James concludes that there is direct (although admittedly inconclusive) evidence here that MZ twins have a lower male/female proportion than DZ twins.

According to our data from East Flanders and those of the literature, it may be concluded that the male/female proportion in MZ twins with monochorionic placentas is lowered, albeit to a smaller extent in the diamniotic and a much greater extent in the monoamniotic variety. One can only speculate about the reasons for this remarkable biological phenomenon. Various hypotheses have been put forward. James[76] and Guerrero[77] independently suggest that the sex of a human zygote is influenced by the time of its formation within the menstrual cycle, with more male zygotes being formed, on average, both early and very late in the cycle, whereas more female zygotes are formed during the middle of the cycle. Experiments in lower vertebrates such as fish, amphibians and chickens have led to MZ twins by retarding the development of the fertilized ova, depriving them of oxygen or maintaining them at a lower temperature. Delayed ovulation seems to induce MZ twinning in rabbits.[78] As suggested by James, it seems possible that the delay hypothesized as being associated with the formation of female zygotes runs parallel with the delay associated with the splitting of the ovum. If this is the case, then MZ twins could be composed of a higher proportion of females.

One or two percent of MZ pairs of twins share the chorion and the amnion at birth. They represent twinning that occurred after the differentiation of the amnion (on about day 7). Fusion of the embryos[79] gives rise to conjoined twins and could occur even later, after the second week of development. Because of the rarity of conjoined twins, it is as yet unknown whether further subdivision of the monoamniotic twins into unjoined and conjoined pairs will clarify the enigma of their very low male/female proportion. As only three conjoined pairs (all of them female) emerged in our relatively large series, only a registry of almost continental scale could provide the amount of data needed to answer this question. It is well documented that conjoined twins include a high proportion of girls.[80]

It is useful to enquire whether female embryos are more likely to undergo delayed splitting than male

embryos, or if embryonal or fetal mortality in the late-splitting group predominantly affects the male embryos. In their series of spontaneously aborted twins, Uchida and colleagues[81] found two male conjoined pairs with normal chromosomes, the result of consecutive abortions in the same mother. Because both conjoined twins and male monoamniotic twins are rare, this single finding could suggest a predominantly male early fetal mortality in monoamniotic twins. With regard to the first question, Burn and associates[82] hypothesized that unequal lyonization may represent a cause of late twinning unique to female embryos. If this is true, analysis of the DNA methylation patterns of the X chromosome[83] of monoamniotic twins should throw more light on the question. We have performed such an analysis.[84] It shows that the earlier the splitting, the more unequal lyonisation, invalidating the hypothesis of Burn and associates. The sex proportions discussed so far deal with spontaneous twinning, rather than iatrogenic twins. A series of studies have addressed this question, but the results are not in agreement. No large-scale population-based inquiries have been performed. Hence, one can question whether the samples are representative. In the EFPTS, the sex proportions of the iatrogenic and the spontaneous DZ twins do not differ significantly.

Triplets

One finding of the increase in triplet rates (especially TZ) is a decreasing male/female sex proportion. In the population in general, about 1000 girls are born per 1045 boys: a ratio of 1.045. Among the 336 triplet individuals from the Dutch Twin Register there were 157 boys and 179 girls: a sex ratio of 0.88. The Dutch population triplet male/female ratio (i.e. triplets born during about the same period as the sample studied) is 0.87. A closer look at the triplet sets from a different etiology reveals that only among the induced triplets does the ratio deviate significantly from unity: 50 boys and 67 girls. This supports James' hypothesis[85–87] that hormonal induction of ovulation increases the mother's gonadotropin levels at the time of conception and that this, in turn, increases the probability of female offspring. In the EFPTS, however, opposite results are found: 47 girls and 66 boys.

Whether the decreasing male/female ratio in triplets is unevenly distributed among the three zygosity groups is unknown. Very few population-based studies of zygosity in triplets have been published. In all of these, the number of cases is too small to enable a firm conclusion to be made.

146 Monozygosity

I. Blickstein

Zygosity of multiple pregnancies

The human female is programmed to ovulate once in every menstrual cycle, and if ovulation results in fertilization, a single zygote will develop, i.e. a monozygotic (MZ) pregnancy. This is the case in 99.2% of pregnancies following spontaneous conceptions. In the remaining 0.8%, more than one oocyte is ovulated, resulting in polyzygotic pregnancies [i.e. dizygotic (DZ) twins, trizygotic triplets, etc]. Such polyzygotic pregnancies seem to have a phenotypic and genetic background as they occur more often in tall, heavily built, older, parous, and black women. Moreover, a genetic trait is strongly supported by the fact that DZ pregnancies have clear racial differences and occur more frequently in women who have 'twins in the family'.[1] On the whole, polyzygosity represents a reproductive anomaly whereby more than the usual single zygote is formed during a single ovulatory cycle.

This situation, however, changed profoundly with the implementation of assisted reproductive technologies, which share a common denominator – creating a higher number of oocytes available for fertilization, irrespective of whether fertilization occurs *in vivo* or *in vitro*. Current data indicate that where assisted conceptions are widely available, the frequency of DZ twins increases from 66% to 95%.[2]

Whereas polyzygotic multiples are common in many species, the human female is among the unique species (the other is the nine-banded armadillo) in which the product of conception – the zygote – is able to undergo splitting into MZ twins. This is a rare phenomenon observed in about 0.4% (4/1000) of births following spontaneous conceptions. As will be discussed below, and as is the case with DZ twins, all methods of assisted conceptions are associated with increased splitting rates of the zygote.[3]

Placentation

Each fetus comes along with a set of placenta and placental membranes. This design, obvious in singletons, is also true for DZ twins. However, because the uterine cavity is of limited space, placentas may develop very near to each other and eventually become fused. It follows that DZ twins have dichorionic–diamniotic (DC–DA) fused or separate placentas. In MZ twins, on the other hand, the type of placenta depends on the time of splitting. According to the current theory, the twin placenta resembles the (double) singleton placenta in early (< 3 days after fertilization) splitting. It follows that some (about one-third) of MZ twins may have a DC placenta, indistinguishable from that in DZ twins. The bad news is that DZ twins who have the same gender (comprising 50% of the cases) cannot be distinguished from MZ twins with a DC placenta, unless sophisticated genetic analysis is performed to establish zygosity.

When the split occurs after the chorion has already been developed, the remaining MZ twins (about two-thirds) must have one chorion and are termed monochorionic (MC) twins. The vast majority of these splits occur within 1 week when the amnion is not yet differentiated, and the MC twins have two amniotic sacs (MC–DA). However, in cases when the split occurs even later, the amnion is also differentiated, and the resulting pairs are nested within a single amniotic cavity – monoamniotic (MA) twins. MA twins (essentially MC–MA) are very rare and comprise less than 1% of all twins.

One may wonder what causes a zygote to undergo division. In the absence of a clear explanation, and in the presence of a much-increased frequency of anomalies, it is assumed that the mechanism(s) involved in zygotic splitting is/are also involved in the generation of anomalies. The most bizarre anomaly emerges when the zygote is split at a very advanced age after fertilization, after the amnion is already formed (i.e. MA twins) and the only remaining structure to be divided is the fetus itself. In this case, conjoined twins are formed. Figure 146.1 is a schematic presentation of the relationship between chorionicity and amnionicity.

Antenatal and postnatal diagnosis of zygosity/chorionicity

From the previous section it is clear that zygosity can be determined with certainty only if the twins are of unlike sex (in this case they must be DZ) and when an

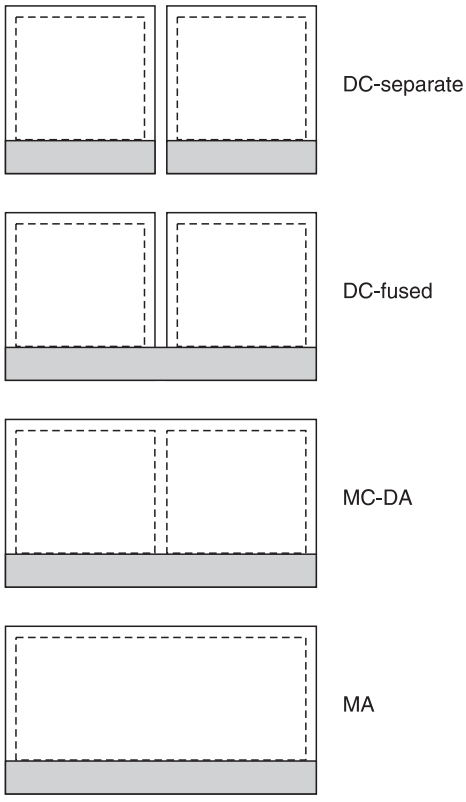

Figure 146.1 Schematic presentation of the relationship between chorionicity and amnionicity.

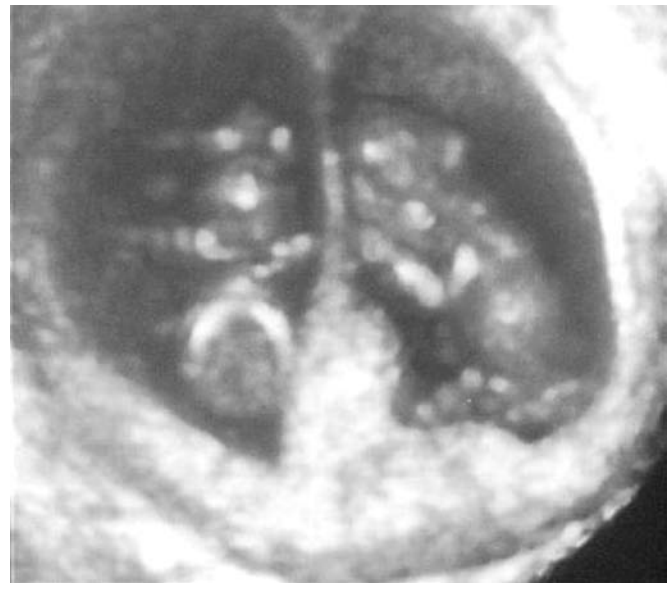

Figure 146.2 3D image of the twin peak (lambda) sign in dichorionic placentas.

MC placenta is found (in this case they must be MZ). It follows that we are blind to zygosity in as many as half of the DZ twins who are of the same sex and in one-third of the MZ twins who have a DC placenta. Altogether, these amount to 4/9 of the twins (44%).[3] An interesting approach to improve the detection of MZ conceptions comes from the Australian study of the number of corpora lutea in the ovary in a twin gestation.[4] According to this innovation, if there are two corpora lutea, it is likely that there were two ovulations, and the twins are likely to be DZ. Conversely, if there is only one corpus luteum, the twins are likely to be MZ. Although this method is by no means practical, it still represents the urge of clinicians to improve the antenatal (in this case, postconceptional) prediction of zygosity.

Irrespective of the above-mentioned difficulties to ascertain zygosity, the important clinical information is not zygosity but chorionicity. As it appears, the most complex pathology involves an MC placenta. Hence, it is imperative to establish the presence of MC twins as early as possible.[5] The fact is, however, that it is much easier to exclude MC placentation than to prove it. As early as 1992, the presence of a triangular decidual projection between the double bilayer of the intertwin membrane was described in practically all DC placentas.[6] This so-called 'twin peak' or lambda sign (Figure 146.2) is easily seen in first-trimester ultrasound but may diminish by the mid-pregnancy increase in the volumes of the amniotic sacs.

In the absence of the lambda sign, the clinician should look for signs of MC placentation. In most cases, a simple reflection of a rather thin intertwin membrane – the tau sign – can be visualized (Figure 146.3). Admittedly, the thin intertwin membrane might be elusive at first scan leading to an erroneous impression of MA twins. The diagnosis of chorionicity is relatively easy during the first trimester and becomes increasingly difficult when looked for after 20 weeks' gestation. At this stage, one may rely on ancillary sonographic signs such as number of layers (Figure 146.3) membrane thickness, same-sex twins, and single placenta.

It goes without saying that zygosity cannot be determined from postpartum examination of the placenta. At the same time, however, every effort to establish chorionicity should be done after each twin delivery. The placenta should be delivered with minimal trauma. Two separate or a single fused placenta is easily discerned and differentiated from the single placenta. At the fetal side, the insertion of the umbilical cords is noted. Very adjacent cords are commonly seen in MA twins (Figure 146.4). Velamentous insertion of umbilical cord found by ultrasound and/or placental examination is quite common in MC placentas and should alert the clinician to that possibility. Machin[7] reported on 45% of MC having velamentous cord insertion, and that the combination of one twin with centrally inserted cord and one with a velamentous cord was found in 53% of pairs. Moreover, this combination constitutes a subgroup at risk because such setting was associated with highest rates of growth discordance > 20%, unequal placental parenchymal sharing, uncompensated anastomoses and perinatal demise.[7,8]

Figure 146.3 Intertwin membrane comprising a double amniotic layer. The reflection of the membrane from the placenta is referred to as the tau sign.

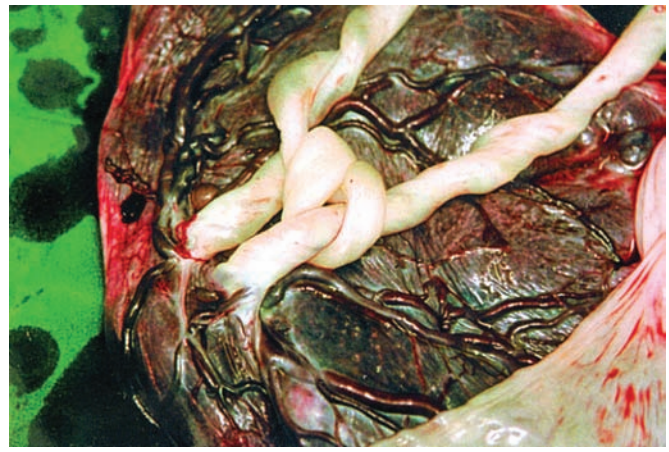

Figure 146.4 Close insertions of entangled umbilical cords of an MA placenta.

The 'gold standard' of monochorionicity is by counting the number of layers in the intertwin membrane. Careful peeling of the layers can do this; however, when the membrane is disrupted, histological examination may distinguish between the two-layer and the four-layer membranes in MC and DC placentas, respectively. Importantly, the number of the layers can sometimes be counted by ultrasound (Figure 146.3).

One of the most important observations in the MC placenta is the presence of intertwin, transplacental anastomoses. In fact, practically all MC placentas show intertwin connecting vessels, which might be arterio-arterial, veno-venous, and arterio-venous. The latter form is the putative anastomosis active in the twin–twin transfusion syndrome (TTTS), but the other types are probably involved in compensating mechanisms that reduce or balance the unidirectional shunt.[9]

Zygosity can be estimated in populations of spontaneous pregnancies by using the Hardy–Weinberg rule. The basic assumption behind this rule is that like- and unlike-sex pairs occur at the same frequency in DZ twins, and therefore, the number of DZ twins is twice the number of unlike-sex pairs in a population. The difference between the total number of twins and the number of DZ twins is the number of MZ twins. It should be remembered that there are reservations about the Hardy–Weinberg rule in general and in particular in a population of mixed spontaneous and iatrogenic twins.[3]

Etiology of MZ twinning

The reason why a single zygote splits to form MZ twins is unknown. For certain, this phenomenon is obviously abnormal and, therefore, it is not surprising that MZ twinning is associated with so many pathologies. Hall proposed the first of the current two hypotheses for MZ twinning in the mid-1990.[10] Normally, the cells of the zygote-blastocyst – the blastomeres – undergo condensation to form the inner cell mass. Hall suggested that different cells of the early embryo might develop differently during the same period and that this developmental discordance between adjacent cells might cause repulsion (rather than condensation) and splitting of the early embryo.

The second, and more widely cited hypothesis, describes the splitting event as the division of the early embryo during hatching. The mechanism responsible for the division presumably causes a breach in the integrity of the zona pellucida, herniation of blastomeres, and splitting of the embryo.[3] This hypothesis is based on the reported increased frequencies of MZ twins after all methods of zona manipulation used in assisted reproduction. However, observations from conceptions following ovulation induction also show increased MZ rates.[2] The latter observations suggest that the trigger for zygotic splitting might be at the stage of ovulation induction (the common denominator of all assisted pregnancies) rather than tampering the zona pelucida.[3]

Regardless of the etiology, the most comprehensive population-based analysis of twins – the East Flanders Prospective Twin Survey – where all like-sex dichorionic twins undergo genetic evaluation of zygosity, recently showed that spontaneous MZ twin comprise about 0.45%, MZ births after ovulation induction occur in 6.3% (16-fold increased rate), and those after *in vitro* fertilization (IVF) techniques occur in 2.6% (sixfold increased rate). The latter finding is in full accord with the estimation of the frequency of MZ twins after IVF procedures based on single embryo transfers.[11] This method assumes that if multiples occur following single embryo transfer in an IVF procedure, they must be MZ.

Chromosomal anomalies

It is assumed that because the two fetuses are derived from the same zygote, they must be genetically identical. However, a plethora of evidence suggest that postzygotic events exist and lead to discordant genetic anomalies as well as to the more puzzling phenomenon of heterokaryotypic MZ twins. As mentioned above, a potential reason for repulsion of the blastomeres – the basis for the cell-repulsion theory for MZ twinning[10] is genetic differences in these cells, including aneuploidy, X-inactivation, and imprinting. The literature cites many cases of XY or XYY/XO, male/female, 'identical twins', and randomization of X-inactivation may result in MZ twin girls who are different in respect to X-linked diseases such as muscular dystrophy, color blindness, Hunter disease, etc. Moreover, the pattern of X-inactivation confirms the timing of late splitting events.[12] Uniparental disomy – when a cell has both chromosomes from the same parent – may also occur after zygotic division. For example, imprinting of the gene responsible for the Wiedemann–Beckwith syndrome usually manifests in only one of the MZ twins.

A subset of genetically discordant MZ twins is the case of polar body fertilization, whereby one spermatozoon fertilizes the oocytes and another fertilizes the polar body (containing the same haplotype set of chromosomes as the oocytes) derived from the first meiotic division. In the human, this phenomenon was implicated in the pathogenesis of an acardiac (twin reversed perfusion – TRAP sequence) twin of a normal co-twin.[13]

Despite the potential genetic differences between MZ twins, the majority is concordant in terms of the usually obtained genetic karyotype. Because the risk of double sampling during genetic amniocentesis outweighs the risk of heterokaryotypic twins, most clinicians would sample one of the two sacs in cases that are definitely MZ, i.e. in MC twins.

Structural anomalies

Twins have more structural anomalies compared to singletons and most texts cite a two- to threefold increased risk. It is currently believed that the excess of malformations is limited to MZ pairs. Anomalies in twins are categorized under four subheadings[14] (Table 146.1). The first category includes malformations that are more frequently seen among multiples. The second type involves malformations found in MZ twins only such as TRAP sequence and the various manifestations of conjoined twins. The third category relates to consequences of placental malformations, in particular the MC placenta, resulting in the TTTS and higher frequency of velamentous cord insertion. The last type involves postural abnormalities such as clubfoot that are caused by intrauterine crowding.

Table 146.1 Categories of structural defects in twins

Category of malformation	Defect
More common in twins than in singleton	Neural tube defects
	Hydrocephaly
	Congenital heart disease
	Esophageal and anorectal atresia
	Intersex
	Genitourinary tract anomalies
Unique to monozygotic twins	Amniotic band syndrome
	TRAP sequence
	Conjoined twins
	Twin embolization syndrome
Placental malformations	Single umbilical artery
	Twin–twin transfusion syndrome
	Velamentous cord insertion
Intrauterine crowding	Skeletal malformations

Importantly, some of the malformations may impact on the non-malformed twin. For example, in the TRAP sequence, the circulation of the severely anomalous acardiac–acephalic twin is entirely supported by the normal (the so-called 'pump') twin. Without intervention, this cardiac overload may eventually lead to cardiac insufficiency of the 'pump' twin. In TTTS, where both twins are completely normal, the transplacental shunt of blood may cause serious morbidity in both twins. The most striking example is the case of single fetal demise in MC twins, whereby the live fetus may die *in utero* soon after the death of its co-twin, or – if it survives – serious end-organ damage is reported in as many as 30%.

Growth

Compared with the recognized adverse outcomes among MC twins (increased early pregnancy loss, perinatal mortality and morbidity, congenital anomalies, and long-term sequelae), the relation between MC twinning and growth aberrations is less clear. Most authors agree that MC twins are more likely to exhibit absolute growth restriction and low birth weight.

Similarity between MC twins, arising from a single zygote, is intuitively assumed to be greater than that between DC twins, comprising DZ as well as MZ sets. The alleged similarity between MC twins is therefore assumed to be associated with fewer or similar, but no more, growth discordance compared with DC sets. Counterintuitively, however, there were conflicting views regarding the frequency of discordance among MC twins, with reports showing a doubled risk of severe discordance,[15–17] and, on the other hand, reports that find similar discordance frequencies in the MC compared with DC twins.[18–21] Figure 146.5 shows the comparison between 939 DC and 216 MC

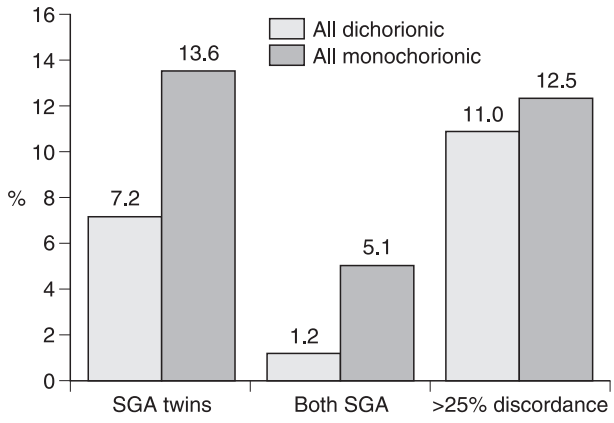

Figure 146.5 Frequency of small-for-gestational-age infants and severely (> 25%) discordant pairs by chorionicity. Data from the Northwestern Twin Chorionicity Study.

twin pregnancies from the Northwestern Twin Chorionicity Study (Blickstein *et al.*, unpublished observation) showing that small for gestational age (SGA) infants are less frequent among DC twins [odds ratio (OR) 0.4], fewer sets with two SGA infants exist among DC than among MC pairs (OR 0.3), but twins of all placental types have similar gestational ages (not shown) and frequencies of discordance > 25%.

Single fetal demise

Single fetal death has an entirely different connotation in MC twins compared with DC twins. In DC twins, unless the reason for fetal death endangers the entire pregnancy (i.e. chorioamnionitis), the survivor is generally unaffected. This is not the case in MC sets, where the co-twin frequently dies soon after the first demise, and, if not dead, the survivor quite often suffers from end-organ damage (brain, kidneys, etc.). In the past, products of fetal decay (the so-called thromboplastin-like material) were believed to embolize via the intertwin anastomosis and cause damage in the survivor – the so-called fetal embolization syndrome. Postmortem studies in the early 1990s, however, did not find any embolus in the brains of survivors that succumbed during early infancy. Subsequently, the 'embolic' theory was replaced by the 'ischemic' theory, whereby acute shunting of blood from the survivor to the low-resistant circulation of the demised twin causes acute hypertension, ischemia, and damage. Importantly, ischemic injury via acute shift of blood can occur during pregnancy even without fetal death and cause end-organ injury in one of the twins.[22]

Because the actual timing of fetal death is rarely known, any form of intervention, especially preterm, should be balanced against the risks of prematurity to the survivor. The idea behind treatment, beside prompt delivery, is that if acute feto-fetal hemorrhage occurs at the time of death, an immediate intrauterine transfusion may save the anemic survivor. This management includes proof of anemia in the survivor (either by cordocentesis or by measuring the peak systolic velocity of middle cerebral artery) followed by rescue therapy in the form of blood transfusion to the umbilical vein.[23–25] The reported outcomes, however, are less than optimistic.

To date, when fetal death is diagnosed before term, and the surviving fetus seems to be intact, most clinicians will not intervene, as the real risk of preterm birth is greater than the potential risk from the fetal embolization syndrome. Imaging is necessary to exclude visible end-organ lesions. At near-term, especially when the etiology of fetal demise is unknown, immediate delivery instead of continued close monitoring of the pregnancy might be a valid option.

Twin–twin transfusion

An unbalanced, deep, arterio-venous anastomosis, probably existing in MC placentas only, is necessary for the development of the TTTS. TTTS has been known for centuries, but only in the last two decades a significant change occurred in understanding the underlying process. As late as the mid-1980s, the diagnosis of TTTS was usually made postpartum, when weight and hemoglobin discordant pair was born. By the end of the 1980s and with the advent of ultrasound, a conceptual change has been introduced and TTTS became an antenatal diagnosis. At the same time, innovative and exciting methods to treat TTTS were proposed.[26]

Due to blood shunting, one twin – the so-called 'donor' twin – becomes anemic and hypovolemic. The co-twin – the so-called 'recipient' twin – becomes plethoric and hypervolemic. The discordant cardiac load soon results in discordant urinary output and the oligo-polyhydramnios sequence. Eventually, the small donor might be 'entrapped' within its amnion and pushed to the side of the uterus by the polyhydramnios surrounding the larger recipient, giving rise to the sonographic image of the 'stuck' twin. These findings constitute the first degree of TTTS of what is currently known as the Quintero criteria[27] (Table 146.2). In the next stage, the urinary bladder of the donor is no longer visible. In the third Quintero stage, abnormal Doppler findings are seen, representing an advanced decompensation of the cardiovascular systems of the twins. The ongoing cardiac overload in the recipient may lead to hydrops fetalis – which constitutes Quintero stage IV. Finally, at the last stage, either twin may die *in utero*.

TTTS may occur as early as the beginning of the second trimester and, rarely, intrapartum. When TTTS occurs late in pregnancy, most clinicians will opt for delivery because the fetal condition can be better managed in the neonatal intensive care unit. It

Table 146.2 Quintero's criteria for severity of TTTS

Stage	TOPS (O < 2 cm, P > 8 cm)	Absent bladder in donor	CADs (A/REDV, Rev DV, Puls UV)	Hydrops	Demise
I	+	−	−	−	−
II	+	+	−	−	−
III	+	+	+	−	−
IV	+	+	+	+	−
IV	+	+	+	−	+

TOPS, twin oligo (O) poly (P) sequence. Numbers relate to amniotic fluid index. CAD, critical abnormal Doppler measurements; A/REDV, absent/reversed end-diastolic velocity; Rev DV, reversed flow in ductus venosus; Puls UA, pulsatility in umbilical vein

follows that the earlier TTTS occurs the greater the risk for the twins. Consequently, clinicians tend to buy time by some form of intervention,[28] and currently – by stage tailored therapy.[29,30] At this stage, the three most common interventions are amnioreduction (removal of a large quantity of amniotic fluid) with or without septostomy (puncturing the intertwin membrane), fetoscopic laser ablation of the putative anastomoses, and fetocide (by cord occlusion). The latter method is reserved for Quintero stage III–IV cases[31] and it is currently not yet established whether to terminate the donor or the recipient.

Although amnioreduction and endoscopic laser surgery differ conceptually as well as in the technology and expertise involved, they yielded similar outcomes. However, a recent randomized trial comparing laser surgery with amnioreduction showed that the laser group had a higher likelihood of survival of at least one twin to 28 days of age (76% vs. 56%) and 6 months of age. Infants in the laser group also had a lower incidence of brain injury (6% vs. 14%) and a lower incidence of neurological complications at 6 months of age (52% vs. 31%).[32]

Twin reversed arterial perfusion sequence

TRAP sequence is a condition whereby one twin transfuses its co-twin via an arterio-arterial anastomosis. Hence, the transfused twin receives blood by an artery instead of a vein – giving rise to reversed perfusion clearly seen on Doppler studies. The recipient in such cases is usually extremely malformed – the so-called acephalic–acardiac twin (Figure 146.6). The main clinical problem comes from the total dependence of the acardiac twin on the circulation of the 'pump' twin. Sooner or later, the 'pump' twin may develop cardiac insufficiency, and, as a result, the cardiac condition determines the time of delivery. A proxy to impending cardiac insufficiency is the relative size of the acardiac twin compared with the pump twin.

Figure 146.6 The acardiac–acephalic twin in the TRAP sequence.

TRAP sequence is easily diagnosed in the second trimester, when the typical ovoid mass, lacking the usual fetal structure, is visualized. When the diagnosis is made early enough, selective reduction of the acardiac twin by cord occlusion is recommended. However, in more advanced gestations, the cord might be too thick for bipolar coagulation and more invasive, intrahepatic coagulation might be necessary.[33]

Monoamniotic pregnancies

MA twinning is rare, occurring in less than 1% of all spontaneous twins. Before the availability of ultrasound, the diagnosis was made postpartum, when two dead fetuses with entangled cords were born. Indeed, cord entanglement is the rule rather than the exception in MA twins (Figure 146.4), and can be found as early as the beginning of the second trimester by dedicated Doppler ultrasound visualizing the characteristic braid of umbilical cords. With modern sonographic equipment, it should not be difficult to exclude MA placentation, especially if

chorionicity/amnionicity is assessed in the first trimester. In that case, counting the number of yolk sacs may be misleading and repeated sonography, with different angles of scanning is recommended.

In addition to all the problems associated with an MC twinning (except for a lower probability to develop TTTS), the MA pair is at increased risk for cord entanglement and for the consequent morbidity and mortality of one or both twins. This risky situation is usually unexpected, and demands intensive monitoring. Many clinicians would feel more comfortable to hospitalize the patient for twice or thrice daily monitoring, starting at 28–29 weeks. Lung maturity is usually enhanced by antenatal corticosteroids. Delivery, usually by cesarean section, is performed at 32–33 weeks' gestation. A more conservative approach is based on the assumption that with advanced gestation, the potential space for fetal movements as well as the risk of tightening the cords is reduced. Consequently, it was proposed that if nothing happened until 32 weeks, the likelihood for tight entanglement is low. This policy should be carried by those who are able to assess the tightness of the cord by Doppler velocimetry.[34]

Conjoined twins

Conjoined twins are very rare, and the average obstetrician is not likely to see more than one or two cases in his lifetime. Obviously, the mechanism of conjoining is by itself a formidable malformation. If the parents want to continue the pregnancy, the most important clinical problem of the attending obstetrician is to estimate the feasibility of postpartum separation surgery.

Currently, 2D and 3D ultrasound, combined with Doppler assessment and supplement with magnetic resonance imaging, provide excellent visualization of the conjoined structures and the level of risk to the twins after separation. Because separation of conjoined twins is rare, it is advisable to consult with centers that gained experience in such difficult procedures.

Cerebral palsy

It is not clear whether cerebral palsy (CP) is more common in MC twins without TTTS or in the absence of fetal death.[35] This ambiguity is a result of the lack of series with established chorionicity/zygosity and adequate neurodevelopmental follow-up. Moreover, failure to register vanishing twins or fetal deaths may lead to a significant underestimate of the risk of CP in multiple gestations and an overestimate of the risk in apparently singleton infants.[22] To circumvent this difficulty, researchers compared the prevalence of CP in like-sex vs. unlike-sex pairs. In a recent review, Pharoah[22] commented that a greatly increased risk of CP among multiples is associated with MC placentation. This risk is particularly notable in the surviving twin with fetal or early infant death of the co-twin. Pharoah proposed, in addition to the above-mentioned theories for damage in the fetal embolization syndrome, that hemodynamic instability during pregnancy may cause bidirectional shunting of blood between the two fetuses. This may have caused lethal damage in one twin and CP in the other, and would explain the finding of increased prevalence of CP among survivors in twin pairs in which one of the twins died in the neonatal period.

It is currently believed that funisitis – inflammation of the umbilical cord – is a very sensitive marker for CP. The Northwestern Twin Chorionicity Study[36] examined the question whether discordant inflammation depends on chorionicity. In a retrospective analysis of 1156 twin placentas, the authors evaluated the association between chorionicity and discordant chorioamnionitis and funisitis in twin gestations. This study found that in the case of chorioamnionitis in DC twins (with either separate or fused placentas), the non-presenting twin is less frequently affected than the presenting twin. Such discordant inflammation is not apparent in MC twins. The results were somewhat accentuated in the case of funisitis – a more advanced state of inflammation (including inflammatory evidence within the walls of umbilical vessels or in Wharton's jelly). Whereas the difference between DC and MC twins persists, discordant funisitis was greatest among separate DC twins, less so among fused DC twins, and was absent among MC twins. The interpretation of these results was that DC placentas confer significant protection against the spread of chorioamnionitis from the presenting to the non-presenting sac. The difference between the separate and fused dichorionic twins implies that the paranchymal separation between these placentas and not the DC septum might be responsible for the protection. In simple terms, the different morphologic features of a four-layer intertwin membrane and the separate placentas may restrict the spread of inflammation. These findings might be relevant in the discussion of the presumable increased risk of CP among MC twins.

As attractive as these theories are, the excess risk of CP in MZ twinning in general and in the subset of MC twins in particular has to be established.

Summary

Monozygosity is a mysterious phenomenon in human conceptions. Splitting of the zygote destined to become a singleton is by itself an abnormal event, and it is not surprising that such pregnancies are associated with increased morbidity and mortality. Most of our knowledge about MZ twinning comes from the subset of MC twins because we are unable to differentiate the MZ–DC from the like-sex DZ–DC twins. This problem seems negligible because most of the pathology

associated with MZ seems to be associated with MC twins. Modern diagnostics – mainly ultrasound and Doppler – are able to diagnose most of the associated pathologies quite early in pregnancy and help clinicians in counseling, planning appropriate follow-up, and tailoring treatment when necessary.

147 Population-based risk of perinatal mortality and morbidity among multiple births

M. S. Wingate, G. R. Alexander, S. Boulet, R. Kirby and H. Salihu

Introduction

Over the past two decades, infant mortality (death of a liveborn up to 1 year of life) has declined significantly. From 1980 to 2001, infant mortality rates have decreased 46% (12.6 to 6.8 per 1000 live births, respectively). Neonatal death (death less than 28 days after birth), has dropped from 8.5 to 4.5 per 1000 live births, a decline of 47%. Though less marked, the rate of fetal death (death occurring at 20 weeks' gestation or greater per 1000 live births plus fetal deaths) has declined as well, from 9.1 fetal deaths to 6.5 per 1000 live births plus fetal deaths, from 1980 to 2001.[1] This overall improvement in perinatal survival appears to be due in large part to decreasing risks of birth weight and gestational age-specific mortality.[2,3] These improvements can likely be attributed to the technological and medical advances in high-risk obstetric and neonatal care, including antenatal steroids, ultrasound, high-frequency ventilation, and exogenous surfactant.[4–16] Also, regionalization of perinatal services and an increase in early entry into prenatal care seem to have increased the utilization of these services among high-risk populations.[17–19]

While these advances have influenced the health and well-being of many children, there are still many challenges in the perinatal field. The risk of morbidities associated with low birth weight (LBW) (less than 2500 g) and preterm birth (delivery prior to 37 weeks' gestation) has increased as the number of babies born too small and too soon has risen steadily over the past two decades. LBW rates climbed from 7.0 to 7.8 per 1000 live births from 1990 to 2002. Preterm birth rates increased 13%, from 10.6 per 1000 live births in 1990 to 12.0 per 1000 live births in 2002.[1,20] The rise in LBW and preterm birth has numerous causes. One of the most often cited contributions to this increase is the dramatic rise in multiple births over the past 20 years.[20] Multiple births, having higher mortality rates compared to singleton deliveries, are at an increased risk of preterm birth and LBW.[21,22] At least one-half of twins and almost 90% of triplets and higher-order multiples are LBW and/or preterm.[23] From 1980 to 2002, the number of twins in the USA rose by 65%, from 68,339 to 125,134. In 2002, the rate of triplets or higher-order multiple births continued to decline after an increase of nearly 400% between 1980 and 1998.

Several factors have been suggested for this rising incidence of multiple births in the USA. A frequently cited factor of this trend is the development and use of assisted reproductive technologies (ART).[22,24,25] The explosive increase in triplets and quadruplets due to ART has led to a call by obstetric and gynecologic organizations to actively reduce the multiple birth delivery associated with ART.[26–28] Those infants who are products of higher-order multiple pregnancies are at increased risk of complications, such as ventricular hemorrhages, cerebral palsy, and other conditions that can lead to morbidities in later life.[29]

Simultaneous to the rise in ART is the shift in the age demographics of mothers in the USA. Over the past two decades, the average age of the mother at the time of delivery has risen markedly.[20] In most developed nations, the rise in the rates of multiple births, particularly twins and triplets, can also be attributed to the increase in maternal age, as older mothers have an increased likelihood of spontaneous multiple births. In addition, an association has been shown between advancing maternal age and the use of ART as the conditions that influence infertility increase with age.[22–24] Previous studies indicate that

Table 147.1 Trends in mortality rates among multiple births

	Singletons			Twins			Triplets or higher		
	White	Black	Ratio	White	Black	Ratio	White	Black	Ratio
Fetal Mortality									
1985–88	6.0	12.0	1.99	24.6	28.3	1.15	36.3	43.6	1.20

'White' and 'Black' may include persons of Hispanic ethnicity because of the change in birth certificate reporting of race/ethnicity in 1989
Fetal mortality rate: death in utero 20 weeks' gestation or greater per 1000 live births plus fetal deaths
Hebdomadal mortality rate: death less than 7 days after live birth per 1000 live births
Neonatal mortality rate: death less than 28 days after live birth per 1000 live births
Infant mortality rate: death less than 1 year after live birth per 1000 live births
Ratio: Black/White rate ratio

between one-fourth and one-third of the increase in the twin and triplet rates can be attributed to the increase in maternal ages without the influence of fertility treatment.[21]

While the rise in multiple births is of great concern, another important issue related to perinatal health pertains to racial disparities, particularly between blacks and whites. While infant mortality among blacks and whites has declined since 1980, the black/white infant mortality rate ratio has increased from 2.0 to 2.5.[1,30] This disparity is apparent across all measures of mortality including fetal, neonatal, postneonatal, and perinatal mortality. While the disparity between blacks and whites continues to exist for outcomes such as LMW and preterm birth, rates of both LBW and preterm birth for blacks have declined since 1990 in contrast to observed increases among whites. The proportion of preterm deliveries decreased for blacks, while it increased for whites over the past decade.[31] However, in 2002, 17.5% of black infants were born prior to 37 weeks' gestation, compared to 11.0% of white infants.[1] For multiple gestations, as expected, the rate of preterm birth increased among whites and blacks, but the relative increase was larger among whites. While there has been an overall increase in multiple births, the increase among whites was almost twice that of blacks from 1989 to 1997.[32] As the USA has one of the most diverse populations in the world, it is imperative to examine these trends by specific population; however, few studies have examined the racial disparities in outcomes of multiple births.[32]

This chapter describes the population-based risk of perinatal mortality and morbidity among multiples with a particular focus on racial disparities. First, we describe the trends in mortality rates for singletons and multiple births by racial/ethnic groups between 1985–1988 and 1995–1998. Next, we examine the mortality rates by gestational age, plurality, and race. Finally, we examine the risks of mortality and morbidity among multiple births and specific racial/ethnic populations. We compare and contrast rates and risks to evaluate patterns involved in morbidities and mortalities among multiple births by racial and ethnic group classifications. For these analyses, we use the U.S. National Center for Health Statistics 1985–88 and 1995–98 Linked Live Birth/Infant Death Cohort files and the Fetal Death files from the U.S. Perinatal Mortality data file, as well as the 1995-98 Matched Multiple Linked files.[33–41]

Results

Trends in mortality

Table 147.1 presents the trends in mortality among multiple births by race and plurality. This table presents mortality rates from 1985–1988 and 1995–1998, along with the percent change for each race and the race rate ratio. Fetal mortality rates decreased for whites in all plurality groups. As the plurality increases, that is, from singleton to twin, the negative percent change reveals improvement

Perinatal mortality rate: fetal deaths plus infant deaths per 1000 live births plus fetal deaths

in the fetal mortality rate. The fetal mortality rate among white singleton infants decreased from 6.04 in 1985–1988 to 5.46 per 1000 live births plus fetal deaths in 1995–1998, an overall decrease of 9.60%. The percent change for twins and triplets or higher-order multiples is 25.70% and 29.78%, respectively. Among black infants, variations in fetal mortality rates among singleton twins were less apparent. Compared to white twins with a percent decrease of 25.70, the fetal mortality rate of black twins decreases from 28.26 per 1000 live births plus fetal deaths in 1985–1988 to 27.59 in 1995–1998, a 2.37% decrease. Among black triplets, there is an almost 39% increase in fetal mortality rate from 1985–1988 to 1995–1998.

While the data suggest that there has been some improvement in fetal mortality among whites and blacks, it should be noted that there is an increase in the percent change of the race rate ratios for each plurality group. For example, among twins, the race rate ratios increase from 1.15 in 1985–1988 to 1.51 in 1995–1998, a 31.40% increase. Hebdomadal mortality rates (death less than 7 days after birth per 1000 live births) had a similar pattern, but the percent change among blacks is similar to that of whites, contrary to the fetal mortality data. While an increase in the percent change of the race rate ratios is apparent, the increase is not as marked among multiples for hebdomadal mortality as for fetal mortality.

Similar patterns are also noted for neonatal and infant mortality. As plurality increases, the percent change for race rate ratios for neonatal mortality (death less than 28 days after birth) also increases. In addition, the rate ratio percent change among singletons is 9.7% and 28.0% among triplets or higher order multiples. Considering infant mortality, there was a moderate increase in the race rate ratio among singletons and twins from 1985–1988 to 1995–1998, but for triplets and higher-order multiples, the increase was almost 48%. Overall, for all mortality classifications, the percent change from 1985–1988 to 1995–1998 in mortality rates were less marked among blacks compared to whites, particularly among multiple births.

Gestational age-specific perinatal mortality

Table 147.2 provides the gestational age-specific perinatal mortality (fetal death plus infant deaths) for blacks and whites as well as the race rate ratio. Figure 147.1 illustrates the gestational age-specific perinatal mortality race rate ratios for singletons and twins using 1995–98 data. For singletons, blacks have a lower perinatal mortality rate compared to whites, until roughly 34 weeks' gestation, at which the rates are roughly equal. At approximately 36 weeks' gestation, a crossover is observed in which the perinatal mortality rate of blacks begins to exceed that of whites and the disparity continues to grow.

Among twins, a crossover occurs at 30 weeks' gestation, where white perinatal mortality rate (53.16 per 1000 live births) is less than that of blacks (56.57 per 1000 live births). As seen among singletons, the

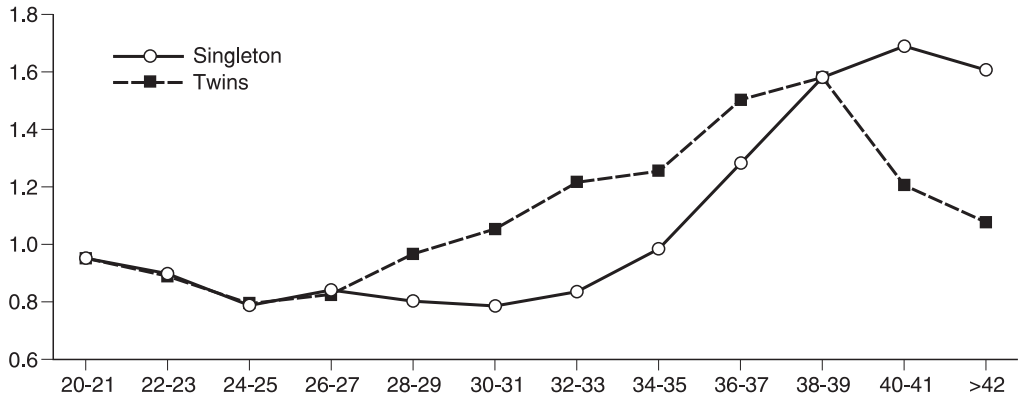

Figure 147.1 1995–98 Gestational age-specific perinatal mortality race rate ratios (Black/White).

disparity between blacks and whites grows, but the overall race rate ratio is less compared to that of singletons. Interestingly, at 38 weeks, the perinatal mortality rate for black singletons is equivalent to that of white twins at 38 weeks' gestation. Among triplets or higher-order multiples, the pattern is less delineated and, for the most part, whites exhibit better survival than blacks. The racial disparity exists but, unlike among singletons and twins, there is no distinct crossover for an improvement in the white mortality. The greatest rate ratio occurs at 26 weeks (1.88). Due to the small number of triplets or higher-order multiples among blacks, it is not possible to calculate the race rate ratio for all gestational ages.

Mortality rates for selected maternal characteristics

Tables 147.3 and 147.4 provide mortality rates for selected maternal characteristics by race. Table 147.3 provides fetal and hebdomadal mortality rates. Table 147.4 provides neonatal and infant mortality rates. The mortality rates differ slightly from Table 147.1 because the data in Tables 147.3 and 147.4 are for non-Hispanic whites and blacks, whereas the rates found in Table 147.1 are those of blacks and whites. Prior to the 1989 change of the birth certificate, the reporting related to ethnicity was poor.

In Tables 147.3 and 147.4, high and low education for age is defined according to an algorithm referenced in Petersen and Alexander, 1992.[44] High education for age is defined as 2 or more years above grade level appropriate for age. Low education for age is defined as 2 or more years below grade level appropriate for age. High gravidity for age defined as having had more than 6 pregnancies at any age; more than 2 pregnancies less than age 18; 3 pregnancies less than age 22; 4 pregnancies less than age 25; and 5 pregnancies less than age 30. The prenatal care utilization index (R-GINDEX) is defined further in Alexander and Cornely, 1987.[45]

Fetal mortality

Among singletons, white fetal mortality rates were lower than those of blacks for all selected maternal characteristics. For older mothers (≥35 years), higher education for age, primigravid, previous pregnancy loss (PPL), hypertension, diabetes, incompetent cervix, and adequate and inadequate prenatal care utilization, the difference in mortality rates was greater than twofold. Among twins, fetal mortality rates were lower among unmarried and teenage black mothers than among whites. The rates were two times higher for blacks compared to whites among mothers with hypertension and diabetes. For triplets, unmarried black mothers had much lower fetal mortality rates (84.46 per 1000 live births plus fetal deaths) compared to white mothers (152.53 per 1000 live births plus fetal deaths), but the mortality rate was much lower for older (35 years) white mothers (14.99 per 1000 live births plus fetal deaths) compared to older black mothers (47.62 per 1000 live births plus fetal deaths).

Hebdomadal mortality

Among singleton births, black infants have a hebdomadal mortality rate that is 2.64 times greater than that of whites. While there is a disparity among twins and triplets or higher-order multiples, the relative differences in mortality rates are not as apparent. Among singletons, there is a threefold difference between black and white mothers with high education for age and PPL. For twins, the overall mortality rate for whites is 17.46 per 1000 live births and for blacks it is 32.82 per 1000 live births, a rate ratio of 1.88. For all selected maternal characteristics, blacks have an increased mortality rate, particularly among those with PPL. For triplets, blacks have a decreased mortality rate among women with low education for age and for PPL compared to whites, but the hebdomadal mortality rate among blacks is almost five times higher compared to whites among women with hypertension.

Neonatal mortality

Overall, black mothers have higher neonatal mortality rates compared to whites. Specifically among singletons, the race rate ratio is 2.5, thereby indicating

†Rate per 1000 live births plus fetal deaths
‡Rate per 1000 live births
Fetal mortality rates: per 1000 live birthplus fetal deaths
Hebdomadal, neonatal, and infant mortality rates: per 1000 live births

that the neonatal mortality rate among blacks is 2.5 times greater compared to whites. For all of the selected outcomes, black mothers have higher neonatal mortality rates than whites, with particular differences noted for older mothers, mothers with high education for age, and PPL. Among twins, neonatal mortality rates are higher for black mothers in all the selected characteristics. However, the race rate ratios for most characteristics were lower compared to those of singletons. For triplets or higher-order multiples, a similar pattern is seen as compared to twins; however, the mortality rate of black mothers with low education for age and PPL is less than that of white mothers.

Infant mortality

As seen for all other mortality classifications, infant mortality rates among blacks are higher compared to whites. Among singletons, the race rate ratios indicate that among older mothers, mothers with higher education, and those with PPL, black mothers have much higher infant mortality rates, 2.80, 2.73, and 2.61 per 1000 live births, respectively. Among twins, a similar pattern is seen. For triplets, black women who have low education for age and PPL have lower mortality rates compared to whites.

Mortality rates of selected infant characteristics

Table 147.5 provides the mortality rates of selected infant characteristics by race and plurality. Fetal mortality rates are lower for whites and blacks among twins and triplets compared to singletons with adverse infant outcomes of LBW, very LBW, preterm, and very preterm. For hebdomadal mortality, a similar pattern is seen among some outcomes, but for LBW and preterm infants, the mortality rates increase for triplets or higher-order multiples. Among black infants, hebdomadal mortality rates increase among very LBW infants, while for whites, there is a decrease. For neonatal mortality, the mortality rates of twins with certain outcomes are higher compared to those of triplets or higher-order multiples. While the pattern for infant mortality is less clear, there do appear to be differences in the changes in rates for blacks and whites.

Table 147.6 Adjusted odds ratio for mortality risks by race and plurality

	Blacks		
Mortality	**Singletons**	**Twins**	**Triplet or higher order multiples**
Fetal mortality	1.28 (1.25–1.30)	0.78 (0.74–0.84)	0.72 (0.55–0.94)
Hebdomadal mortality	2.23 (2.18–2.29)	1.60 (1.50–1.69)	1.58 (1.27–1.96)
Neonatal mortality	2.13 (2.09–2.18)	1.60 (1.51–1.69)	1.54 (1.26–1.89)
Infant mortality	1.95 (1.92–1.98)	1.66 (1.58–1.74)	1.75 (1.45–2.11)

Reference group, white non-Hispanic; controlling for marital status, age, education, gravidity, female sex, PPL, and smoking

Among singletons, while there is evidence of disparity among blacks and whites for some infant outcomes, the differences are not as pronounced as previously noted. Very low birth weight black infants have a lower fetal mortality rate (203.46 per 1000 live births plus fetal deaths) compared to white infants (242.17 per 1000 live births plus fetal deaths). A similar pattern is seen for very preterm infants and for very LBW twins. For triplets or higher-order multiples, the race rate ratios indicate greater differences for selected infant outcomes. For example, the hebdomadal mortality rate among black VLBW infants was only slightly higher than that of white VLBW infants. For neonatal and infant mortality, a similar pattern is seen, with the race rate ratios being lower for very LBW and very preterm infants.

Adjusted odds ratios

Table 147.6 shows the mortality risks of black singleton, twins, and triplets or higher-order multiples compared to whites. After controlling for marital status, age, education, gravidity, female sex, PPL, and smoking, these data suggest that among singletons, black infants are at an increased risk of all mortality outcomes compared to whites.

Among twins, blacks are 22% less likely to experience fetal mortality, yet they are roughly 60% more likely to experience hebdomadal, neonatal, and infant mortality. A similar pattern is noted among triplets and higher-order multiples with a protective effect (28% decreased risk) of fetal death among blacks compared to whites.

Comments

Overall, this study indicates that the racial disparities in mortality noted among singleton births persist in multiple births. The data indicate that there has been improvement in the mortality rates over the last decade and the decline is more notable in multiple births compared to singletons. However, a less-marked decline has been noted among blacks. While it is beyond the scope of this study and ability of the data to tease out the underlying factors of the decrease in mortality, these findings do suggest an improvement in clinical management of multiple births. While the advances have lessened the overall impact of the dramatic rise in multiple births on perinatal indicators, there is some indication in these findings that there may be disparities in the access to and utilization of these advances. Discussion of these potential disparities has been noted elsewhere.[43]

It should be noted that the same pattern of improved survival observed among black singleton infants is seen among twin births, with the crossover point at an earlier gestational age. Fetal, hebdomadal, and neonatal mortality rates among very preterm and VLBW black infants are roughly equivalent to or lower compared to whites for singletons and twins, again indicating an increased survival at lower gestational ages and birth weights.

The information presented in this chapter has important clinical and public health implications. It is noteworthy that certain maternal and infant characteristics, while eliciting higher mortality rates among black singletons, may actually be protective in multiples. For example, fetal mortality rates among black infants are lower among those who are unmarried than among those who are married. This information could be useful in further classification for treatment and interventions.

148 Prevention of preterm birth in single and multiple pregnancies

E. Papiernik

We will describe in this chapter how the policy for prevention of preterm birth was successful in France from 1972 to 1988, and how the recent increase in preterm births can be explained. The results are very different for single pregnancies for which prevention did work; the reduction of spontaneous preterm births was clearly found in singleton pregnancies,[1] while an increase was observed for indicated preterm (by medical decision) in single pregnancies.[2] The global increase of preterm births since 1988 was not observed for single pregnancies, whose rates remained stable or with a non significant increase in national representative samples in 1995 and 1998.[3] But for twin and triplet pregnancies no comparable reduction in preterm birth has been measured; on the contrary, a significant rise in preterm births was demonstrated for two associated reasons: first, an increase in the rate of twin pregnancies and second, an increase of the rate of preterm births in twin pregnancies.

Prevention in this chapter will be understood as primary prevention, before the beginning of the disease, before any sign of preterm labor, and will not address the treatment of preterm labor and the treatment given to the mother for an advanced maturity of the newborn.

The task of preventing preterm delivery is very different if the risk is obvious, for women with a previous preterm birth or a previous second-trimester spontaneous abortion, or in the absence of such a previous history. The risk is very different in single pregnancies and in twins or triplet pregnancies. We will first address the situation of single pregnancies with an obvious risk factor, and then those without a risk factor, and address later the problem of prevention of preterm births in twin and triplet pregnancies.

In spite of remarkable progress in the efficacy of neonatal care, prevention remains an important aim, especially the prevention of very early preterm births, as the risk related to preterm birth for the newborn exponentially decreases with each week of gestational age, measured in deaths, severe disease, and hospital neonatal costs[4] as well as by risk of development delay and of cerebral palsy.[5]

Single pregnancies with an obvious risk factor

The major predictor of risk of preterm delivery is the outcome of the previous pregnancy, as established by all scoring systems;[6] the risk is important if the previous pregnancy ended in a preterm birth, and even more important if the mother had two preterm births or one preterm and one second-trimester spontaneous abortion. The risk of a second preterm is 15% if the mother had a first preterm delivery and 32% if she had two previous preterm deliveries.[7,8]

Cervical incompetence is difficult to define but is described by McDonald[9,10] as 'the history of one or two mid-trimester abortions, with early rupture of the membranes, usually before onset of labor. The labor is short and relatively pain-free'. Repeated middle-term abortions at the same time of gestation are significant.

For women with two previous losses as preterm births or late spontaneous abortions, controlled trials have shown that a cerclage has a measured efficacy for the reduction of the recurrence rate of preterm birth. The most important is the trial of the MRC/RCOG Working Party on Cervical Cerclage,[11] which compared 454 cases and 451 controls, and showed that in this high-risk group defined by two losses (either previous second-trimester miscarriage or preterm delivery), cerclage did reduce the risk of delivery before 33 weeks (odds ratio: 0.61, 95% CI: 0.40–0.93) and reduced the risk of miscarriage, stillbirth, or neonatal death (odds ratio: 0.54, 95% CI: 0.33–0.90). But no efficacy was shown for women in lower level risk groups, in the MRC/RCOG trial and by Lazar *et al*.[12]

For women with a history of one previous preterm delivery, cerclage does not help to reduce the risk of a preterm birth in the next pregnancy. But treatment with progestins had been demonstrated to be effective in reducing the occurrence of a second preterm birth in women with a previous spontaneous preterm birth.[13–17]

Single pregnancies without an obvious risk factor

For the majority of women without any obvious risk factor known before or at the beginning of pregnancy, the reasons for preterm birth are more difficult to understand and the task of prevention is not easy.

In 1895, Adolphe Pinard was the first to propose that preterm delivery could be the effect of exposure of poor single mothers to excessive workload; this hypothesis resulted from an observation.[18]

These women, most often young, unmarried, and without social support, worked in a standing position for many hours, 6 days a week. His intervention was simple, by removing these women from their normal working environment to 'rest homes', a simple lodging, kept clean by themselves, with proper meals and adequate sleeping accommodation. His experiment was successful, as the women included in the program had more often deliveries at term, with normal-weight babies, in striking contrast to the frequent preterm deliveries in women not included in this program. The principle that heavy work could be the cause of preterm births became the basis for the medical program adopted for pregnant women as part of the health policy advocated by the League of Nations in 1932.[19]

At the end of World War II, in 1945, all European countries voted for laws for the protection of mothers and children, including several weeks of work leave before the expected date of delivery and after birth, with financial compensation of the salary.

The early focus on reduction of physically arduous work as a preventive measure for reducing preterm births has had an important impact on French perinatal health policy, which was put into place in the 1970s. The proposal that reduction of physical effort was a key intervention during pregnancy for the prevention of preterm birth formed the basis of the national prevention policy proposed in 1972,[20] for women for whom a risk factor would be recognized by a systematic screening, using a risk scoring system,[6] or for those for whom exposition to hard working conditions had been identified. For those women with identified risk factors, a reduction of physical effort or a medically prescribed work leave for employed women would be recommended. This policy remains an active part of the French policy. This intervention on physical effort was part of a global improvement of prenatal care, which will be presented. At present, hard work is no longer a risk factor for the majority of pregnant women in France.

The policy for prevention of preterm births, effective in France since 1972, was designed with several components: (1) early and equal access to prenatal care for all women; (2) provision of information that would convince women to change their lifestyles; (3) recognition, during prenatal care, of warning signs increasing the risk of preterm birth; and (4) appropriate use of maternity work leave and reduction of physical activity.

The French prevention programs target all women and not only high-risk cases. Initial studies on the impact of the prevention program were tested on a demonstration intervention including all women who were delivered in a region of eastern France, in Alsace, in the city of Haguenau on 16,000 women from 1971 to 1982. The reduction of preterm births was demonstrated with the progressive acceptance of the new policy.[21] In this program, it was clear that the reduction of preterm births was not observed for women with high-risk predictors; this is shown in Table 148.1. No reduction of preterm birth could be measured for women with a previous preterm birth, for those with a history of stillbirth, or for those with an episode of bleeding in the second or third trimester.

However, a statistically significant reduction was observed in the middle-risk women, those with 'soft' risk predictors,[22] those in their first pregnancy, those less than 21 years of age, or 36 years or older, those with a low or average level of education measured by the number of years of school attendance. Not surprisingly, the program was not efficient for women in the low-risk groups, such as those with the highest level of education or those in their second or third pregnancy.

This finding was incorporated into policy: prevention efforts to be comprehensive and applied to every pregnant woman. In this regard, the French policy for the prevention of preterm delivery follows the public health approach to the prevention of cardiovascular diseases, which does not target only 50-year-old men who are sedentary, obese, with high cholesterol and high blood pressure, but is directed to the entire population, before risk factors are obvious.

These programs were also focused on those risk factors that could be modified during the present pregnancy, such as information to the woman on her pregnancy, quality of care, or physical effort during pregnancy. It was obvious that the major risk factors, which are important for their predictive value,[6,23,24] could not be used for prevention as they could not be modified during the actual pregnancy. This is true for age, low level of education, low income, or single status, or with a previous adverse history of preterm birth, second-trimester fetal loss, or stillbirth, or for women with an episode of bleeding during the second or the third trimester, with a low-lying placenta, or if the pregnancy is of twins or triplets.

Early and equal access to prenatal care is the basic condition for reaching every pregnant woman and convincing her to be followed and to accept some of

Table 148.1 The rate of preterm births among women delivered at the maternity in the city of Haguenau, in the 'Perinatal Study at Haguenau', for whom a prevention program was proposed, for three successive time periods of observation (1971–1974, 1975–1978, 1979–1982), and the progressive acceptance of the program

Period of observation		1971–1974	1975–1978	1979–1982	*P*

Bleeding in the third trimester	Yes	24/140 (17.1%)	8/68 (11.8%)	20/87 (23.0%)	n.s.
	No	179/3392 (5.3%)	159/3967 (4.0%)	194/5429 (3.6%)	<0.001

The reduction in preterm births was observed only in women without major risk factors, but no reduction of preterm birth rates was observed in women with an obvious risk factor, such as previous preterm birth (among parous women), a previous history of stillbirth (among parous women), age below 21 years, or 36 years and above, 8 years of education or 9–12 years of school attendance, an episode of bleeding during the second or third trimester. (Trimester measured among those women who were followed at the prenatal clinic of the Haguenau maternity during the second or the third trimester of pregnancy.) PTD, preterm birth; SB, stillbirth

the proposals for prevention. Free prenatal care in France is a reality and has been so since 1945. All women, regardless of income, educational accomplishments, or legal or alien civil status have access to this as a right. Although the cost of care is variably addressed either privately or in public hospital systems, significant effort has been devoted to convince pregnant women to be included early in basic prenatal care. The choice of the team for antenatal care and the choice of the site of delivery are the patient's decision, and the decision to deliver at a level III institution may be made early on the basis of patient preference or later on the basis of physician referral.

The French national perinatal surveys show that this principle of providing early and adequate care for pregnant women has been successfully implemented, for instance, by the proportion of pregnant women with seven or more prenatal visits measured on representative samples of all French births:[25] 22.2% in 1972, 33.9% in 1976, 54.9% in 1981, 90.5% in 1995; the proportion of pregnant women without any prenatal visit during the first trimester was at 3.6% in 1976 and 2.4% in 1981. A comparison with other European countries shows that France is one of the more successful among its European neighbors in ensuring timely access to medical care during pregnancy.[26]

This effective outreach for most pregnant women is only limited by recent immigration, for women less used to utilizing the facilities offered free to them; this has been measured in a recent study on all women delivered in Seine-Saint-Denis, a poor district northeast of Paris, on more than 40,000 women in 1998/1999,[27] as shown in Table 148.2. For this population, even if a larger proportion among the new immigrants (not born in France) than among women born in France did not have the national social security coverage, the complementary system proposed to all pregnant women by the local district authority, called Protection Maternelle et Infantile (PMI), allows a high proportion of pregnant women to be included early in prenatal care, measured by the proportion with no visits in the first trimester or the proportion of women with

Table 148.2 National insurance coverage, trimester of first prenatal visit, by country of birth, district of Seine-Saint-Denis, October 1998–December 2000, 48,746 singleton live births (after Zeitlin *et al.*[27])

Country of birth of the mother	Continental France ($n = 22,875$)	French Caribbean & Indian Ocean ($n = 1752$)	Southern Europe ($n = 3266$)	Northern Africa ($n = 7602$)	Sub-Saharan Africa ($n = 5803$)	Southeast Asia ($n = 2778$)
National health insurance						
No coverage	1.0	2,2	6.3	5.7	18.7	10.7
Coverage	99.0	97.8	93.7	94.3	81.3	89.3
(% Missing)	(4.1)	(6.9)	(6.7)	(6.9)	(8.8)	(10.2)
First antenatal visit:						
First trimester	94.1	89.8	89.2	90.2	84.4	86.6

Less than four antenatal visits	3.5	5.6	5.9	6.5	9.2	6.0
No. of antenatal visits (mean)	8.3	8.2	8.0	8.0	7.2	7.8
(% missing)	(9.0)	(10.7)	(10.2)	(9.4)	(11.8)	(11.2)

This table shows that the coverage by national health insurance varies with the site of birth of the mother, in reality with the proportion of recent immigration, with two categories of non-covered, from southern Europe or North Africa, or from sub-Saharan Africa or Southeast Asia. The absence of health insurance coverage is reflected by the proportion of women without a first prenatal visit during the first trimester, but few women have their first prenatal visit during the third trimester, and few have less than four prenatal visits

less than four antenatal visits, or the mean number of antenatal visits.

Here also, collective social agreement reached in France did participate in supporting 'lifestyle changes' during the pregnancy that recognize two facts. The first is that this social agreement accepts that the 9-month period is the only chance the mother will ever have to 'gestate' her baby and help ensure its future as much as possible. The second is the disastrous consequences of preterm delivery in terms of morbidity, mortality, and immediate and long-term familial and societal costs.

French women are informed by articles in the lay press and television networks about the need for lifestyle change and the benefits that can derive from this measure. This is particularly true for the need to obtain work leave and the reduction of physical effort. This is also true but more difficult to implement for women not working outside their home, for whom the rate of preterm birth remains higher than for those employed.

The proposal was to collect two major clinical signs during every routine antenatal care visit following a risk scoring.[6] The first is uterine contractions, the second is the clinical measure of cervical length.

To help the mother to be able to recognize a uterine contraction by herself, obstetricians, midwives, and nurses must take the time to explain what are uterine pains to women who have had no previous pregnancy and are not able to recognize the symptoms. The most common expression for this abnormal feeling is the description of low abdominal 'pressure'. The prenatal attendants should question this woman to discern what circumstances precede the onset of contractions. When questioned carefully, pregnant women describe precisely the circumstances in their daily life that induce uterine contractions. For some women, it is a fast walk; for some, it is carrying an older child; and for others, it is bearing heavy loads at work or working in an imposed rhythm. For still others, it is working in a standing position for hours and for the rest, it is the stressful events in professional or private life.

The second clinical sign is a repetitive quantification of the length and opening of the uterine cervix, which is measured by digital vaginal examination. The efficacy of this proposal for risk screening was confirmed by a prospective study of 8303 pregnant women, which clearly demonstrated the value of these clinical signs in measuring the risk of preterm delivery.[28] The predictive value for the risk of preterm birth of the precocious opening or shortening of the cervix has been documented by the presence of fetal fibronectin in cervical secretions[29] and/or by the shortening of the cervix by vaginal ultrasound measure of cervical length.[30,31] The fibronectin measure or

the ultrasound measure of the length of the cervix has not been accepted as routine in France; this corresponds to the available meta-analysis showing no effect in the reduction of preterm births, in spite of their good predictive value.[32]

In France, the local tradition from the end of the 19th century is to use a clinical measure of the length of the cervix at every prenatal visit, even though the efficacy of this practice was not evident. The only available controlled trial on the use of the clinical measure of cervix length did confirm its predictive value,[33] but did not test its usefulness for prevention of preterm birth. No specific intervention was proposed to those women with a short cervix. The statement of this study on the non-usefulness of cervical examination as one of the steps included in the policy of prevention of preterm birth could be a misleading inference[34] as the only action was on the diagnosis side, without any specific action to prevent preterm deliveries for women with a short cervix. This is not different from the statements of Iams[35] or Faron[32] that the diagnostic tools of ultrasound or fetal fibronecin do not by themselves help to reduce preterm births.

In the years following the demonstration of the value of documenting cervical change, physiologic studies have shown that cervix distensibility is a good predictor for preterm labor, because a distended cervix prematurely reaches the low resistance normally observed at term.[36] The mechanism of premature start of labor for women with a short cervix shows that infection or vaginal colonization is a major mechanism of secondary trigger, as infection or vaginal colonization by itself does not increase the risk of prematurity, but the same vaginal infection or colonization is a risk factor for those women with a short or open cervix.[37]

Swedish politicians decided in 1935 to grant for all pregnant women maternity leave during the last weeks of pregnancy for the prevention of preterm birth (and a work leave for several months after delivery to improve breast-feeding), and other Scandinavian countries soon followed suit. Of equal importance, women who went on leave received financial compensation and job protection. Finally, maternity leave became mandatory by law for all women and, along with free prenatal care, was an important part of the European 'System for Protection of Mothers and Children'.

During the year 1945, immediately after the end of World War II, all countries from West as well as East Europe decided to provide all women with maternity leave with financial compensation of the salary for the specific purpose of preventing preterm birth. Leave begins during the last 6–8 weeks of pregnancy in Belgium, France, Germany, Ireland, Italy, and The Netherlands; 10 weeks prenatally in Sweden; and 12 weeks before the expected date of delivery in Norway and the United Kingdom. In France, Belgium, Bulgaria, Germany, The Netherlands, and Poland, salaries are compensated at 100%, up to a stated limit, during maternity leave. In Czechoslovakia, Denmark, and Sweden, salaries are compensated at 90%. In Italy and Greece, the compensation rate is about two-thirds.

All countries also provide a possible addition of sick leave to maternity leave, for as long as necessary during pregnancy, although the proportion of salary compensation for sick leave is less than that given for maternity leave.

During the 1960s, it became obvious that the French policy since 1945, with a maternity prenatal leave for the 6 last weeks, beginning at 35 weeks of pregnancy, was not more adapted to the present needs, not at all adapted to the improvement of survival of those preterm infants born much earlier than 35 weeks. This maternity leave was adapted only to the women in the labor force, and did not target the unemployed women. Thus, a means for earlier intervention had to be proposed, and this was accomplished by proposing to reduce the pregnant woman's workload.[6] This proposal was based on the knowledge available at that time.

It was known that nurses who worked in standing positions were more prone to preterm births, particularly if they worked in very demanding jobs such as in a neonatal intensive care. This information was confirmed by other studies showing that hard work was a risk factor during pregnancy,[23,38–42] even before the start of maternity work leave.

However, such a major intervention as workload reduction could not be proposed for all women, because the cost would be enormous and many women would not accept it. It was therefore necessary to define an intervention and a specific group of women for whom it would be effective and acceptable.

A decision was made to propose the intervention of reduction of physical effort in daily life for those women who had some risk factors identified at the prenatal visit, the risk factors being either a complaint of uterine contractions or evidence of uterine cervix shortening, softening, or opening.

In some cases, the reduction of physical effort could be achieved by a simple change in behavior, with slower walking, not carrying an older child, not shopping for a period, or avoiding long-distance travel by car. If uterine contractions were related to work, however, such as to long hours in a standing position, bearing heavy weights, or commuting 2 h or more every day, then simply changing habits would not effectively reduce physical exertion. In these situations, the only way to modify the physical load was to propose leave from work. At that time, French law did not permit maternity leave to begin earlier than 35 weeks. (The law was changed in 1976 to permit 2 weeks of maternity leave before 35 weeks if medically needed). Under these circumstances, the only solution was sickness leave, and we were able to convince the physicians in the social security system responsible for approving sickness leave that during pregnancy this should be considered as a preventive intervention.

The use of sickness leave was monitored on representative samples of all French women delivering in

Table 148.3 Proportion of employed women with a medical prescription of work leave since the first year of the French national perinatal program in 1972, in which a medical prescription of work leave for prevention of preterm births was provided (after Saurel-Cubizolles and Kaminiski[43])

Percentage of employed women with a prescription of work leave by trimester of pregnancy	1972	1976	1981
French national representative samples *N* women	5727	2463	2955
First trimester	12.5	18.2	23.2
Second trimester	18.4	26.6	33.3
Third trimester	24.0	36.4	40.8

The proportion of employed women with a medical prescription of work leave did increase progressively; in 1995, less than a third of employed women did work during the third trimester

1972, 1976, and 1981,[43] as shown in Table 148.3. The main fact is that the proportion of employed women effectively working in the third trimester of pregnancy was remarkably reduced.

Hard work and work in a standing position were also monitored. The hardness of work decreased over the years for reasons unrelated to the prevention program, but to evolution of the working conditions in all industrial sectors ($P < 0.001$, comparing 1972 with 1976 with 1981).[43]

Leave prescribed by medical doctors, general practitioners, or obstetricians was carefully analyzed, as was the distribution of this intervention by trimester of pregnancy.[43] The proportion of employed women on work leave in the third trimester in 1995 reached 68.5%.[3] These changes represented a major change in the working habits of pregnant women in France.

In France, the prescription of work leave for prevention of preterm labor was accepted by the national insurance system, in addition to the work leave given to all women at 35 weeks, keeping in mind that this prescription was used to reduce the difference with the systematic maternity work leave proposed to all pregnant women in the United Kingdom at 28 weeks or in Sweden at 30 weeks.

The reason for prescription was not directly measured; it could be the presence of a warning sign observed during prenatal care, or just the patient's request, without direct relationship with the presence of a warning sign. At present, less than one-third of employed women work during the third trimester.

Evaluation of this intervention is not easy, as it was not constructed on an experimental basis, as all pregnant women in France were exposed to the intervention without a possible control population.

One of the only possible evaluation tools was to determine that the risk factor of hard work did lose its predictive value for the risk of preterm birth. In fact, the predictive value of hard work disappeared in France, but this was not the case in other European countries in which the prescription of work leave was not as commonly accepted as in France. This differential evolution was measured in a multicenter European study called EUROPOP (for European Study on Preterm Delivery Related to Work) (Table 148.4). This study compared global policies by countries with different practices of frequent or infrequent work leave prescriptions. This was a case–control study in 17 maternities (one per country) between 1994 and 1997, including all consecutive preterm births in the participating clinics (5145 preterm births from 22 to 36 weeks) and a control group including every 10th consecutive term birth (7911 births at or after 37 weeks[44] of which 2369 preterm and 4098 term births were to women employed during pregnancy, as shown in Table 148.4. The two risk factors related to work condition are the number of working hours per week, comparing 30/39 to 40/42 and 43+, and the number of hours of work in a standing position, comparing < 2, 2–6, and > 6 h/day. Three groups of countries were compared, the first group with low figures of infant mortality (below 8 per 1000 births) and frequent prenatal work leave (France, Germany, Italy, Slovenia, Czech Republic); a second group of countries with low infant mortality and infrequent prenatal work leave (Finland, Greece, Ireland, Scotland, Spain, Sweden, The Netherlands); and the third group of countries with infant mortality figures of 10 per 1000 or more and infrequent prenatal work leave (Hungary, Poland, Romania, Russia).

The high number of working hours per week is not predictive of preterm birth in the first group, but is predictive of the risk of preterm birth in the second and the third groups. The same is true for more than 6 h of work in a standing position (Table 148.4). The predictive value of hard work is not more observed in countries with frequent prescriptions of work leave in Europe, but remains as a risk factor for preterm birth in those European countries with infrequent prescriptions of work leave during pregnancy.

Table 148.4 Preterm births related to working conditions (after Saurel-Cubizolles *et al.*[44]) by working hours per week, by group of countries with different policies of prenatal work leave. The predictive value of long working hours per week is not more statistically significant in the group of countries with the practice of long prenatal work leave in group A1, but remains predictive in countries of group A2 without the practice of long prenatal leaves, and is predictive of preterm in countries with less developed perinatal care

Adjusted* odds-ratio of preterm birth related to working conditions	A1 (infant mortality < 8/1000; frequent long prenatal work leave)	A2 (infant mortality < 8/1000; infrequent long prenatal work leave)	B (infant mortality > 10/1000)
Number of employed women after the third month of pregnancy	1833 term births, 936 preterm births	1600 term births, 853 preterm births	616 term births, 534 preterm births
Working hours per week			
30–39	1	1	1
40–42	0.85 (0.4–1.1)	1.20 (0.9–1.5)	1.43 (1.0–2.1)
43 +	1.12 (0.8–1.5)	1.40 (1.0–1.9)	1.65 (1.0–2.7)
Standing position hours per day			
Less than 2	1	1	1
2–6	0.98 (0.8–1.3)	1.09 (0.9–1.4)	1.15 (1.1–2.3)
More than 6	1.06 (0.8–1.3)	1.38 (1.1–1.7)	1.55 (1.1–2.3)

Preterm birth related to working conditions, more than 6 h/day, is not more predictive of the risk of preterm birth in the group of countries with the practice of long prenatal leaves (A1), but remains strongly predictive of premature birth in the group of countries with no practice of long prenatal leaves (A2), and in the countries with less developed perinatal care. A1: France, Germany, Italy, Slovenia, the Czech Republic; A2: Finland, Greece, Ireland, Scotland, Spain, Sweden, The Netherlands; B: Hungary, Poland, Romania, Russia

*Adjusted for age, educational level, marital status, obstetrical history, and country. One model was calculated for each of the variables describing working conditions

France is one of the few countries in which a decrease in the preterm birth rate has been documented over the past 30 years. In other European countries with low rates of preterm births, the trends have not been measured; no information is available on the effect of the program for protection of pregnant mothers and children effective since 1935 in Sweden; no estimate before the program can be compared to the low figures observed; and in the same way, no information is available on the effect of 12 weeks of work leave before the expected due date in use since 1945 in the United Kingdom.

In France, the proportion of deliveries before 37 weeks for singleton pregnancies decreased from 8.2% in 1972 to 6.8% in 1976, 5.6% in 1982, and 4.9% in 1988.[1] This reduction was more marked for early preterm births and in the number of very low birth weight babies. The most important results were in deliveries at less than 34 weeks: these decreased in national representative samples from 2.4% of deliveries in 1972 to 1.7% in 1976, 1.2% in 1981, and 0.9% in 1988.[1] In addition, the incidence of very low birth weight babies (less than 1500 g) decreased from 0.8% in 1972 to 0.7% in 1976 and 0.4% in 1981; it remained stable or increased to 0.5% in 1988.

The decrease was observed for all singleton deliveries, but should be described separately for spontaneous or indicated preterm births, as these two components show a different evolution. A significant decrease in spontaneous preterm deliveries was observed. On the other hand, indicated preterm births (after induction of labor or after scheduled cesarean section before spontaneous onset of labor) did increase during these years, as shown in Table 148.5, with a change in the proportion of indicated preterm vs. spontaneous preterm births.[1]

This decrease could not be explained by the technique to measure the duration of gestation, as ultrasound scans were used since 1972, and as the mean birth weight of premature born babies decreased after introduction of first-trimester ultrasound scans.[1]

While data exist to prove that preterm birth rates have declined in France and data also exist to show that policy goals were achieved – a high proportion of women receive timely care and there is a clear reduction in physical activity and workload during

Table 148.5 Preterm births among all live births in the national French representative randomized samples, for singleton and multiple births (after Bréart *et al.*[1] for 1972, 1981, 1988 and Blondel *et al.*[3] 2001 for 1995 and 1998). The preterm birth rate did decrease significantly from 1972 to 1988 ($P < 0.001$); after this year, the rate of preterm birth increased

Year	1972	1981	1988	1995	1998
< 37 weeks (%)	6.89	5.39	3.80	5.43	6.27
Spontaneous	6.38	4.66	2.80	3.51	3.86
Induced	0.51	0.73	1.00	1.92	2.31
% Induced	7.3	13.5	26.5	35.4	36.0

The rate of spontaneous preterm births was reduced from 1972 to 1988 by 45%, but began to increase after that year, but remaining at a rate under 4% of all births, much less than the rate at 6% before the preventive intervention. The rate of induced preterm, either after induction of labor or after scheduled section before spontaneous labor, shows a progressive and significant increase, with a rising proportion of induced vs. spontaneous preterm births, describing a major change in obstetrical practice

pregnancy – it is much more difficult to show that these links are causal.

Experimental evaluation of public health policies is very difficult because for interventions proposed to all women in the population, no possible controls exist, if in reality all women were included. This is the case in France, since this policy was directed at the entire population and not just a subgroup of women. This is why we used historical trends, using the fact that for any intervention, there is a gradient in the acceptance of the new policy, and this gradient could be monitored and used for evaluation, for instance, in the Perinatal Study of Haguenau,[45] or for the national data in France.[1]

But this trend for less premature births has changed since 1988, with a progressive increase in the incidence of preterm births (for all births) observed in national figures for 1995 and 1998 (Table 148.6).[3] There are several causes for this increase: the first is the change in medical attitude when a fetal growth restriction is recognized by an ultrasound scan, the second is the progressive rise in the number of multiple births and the rise in preterm deliveries among multiples.

The proportion of medically decided preterm births has increased in 1995 and even more in 1998 in French national samples of all births (Table 148.5). The evolution is in relation with the technical progress allowing a better recognition of fetal growth restriction; this was monitored on a population basis in the district of Seine-Saint-Denis.[46] This study has shown how obstetrical practice did change,[47] with more medical decisions, before 37 weeks, to induce labor or to decide a scheduled cesarean section before spontaneous onset of labor.

On this total population basis was measured the rate of preterm birth for singleton live births, for the years 1998/1999, for women born in France or for new immigrant women born in southern Europe, North Africa, south and east Asia. The rates were low for all these groups, in spite of recent immigration and important differences in income and education among groups. These groups do not show differences in the rates of severe preterm births, and no difference in the proportion of spontaneous and induced preterm births (Table 148.7). Two groups of women were measured with higher rates, women born in the French Caribbean Islands or in the Island of Reunion in the Indian Ocean, and women born in sub-Saharan Africa. These two groups are different by education and income, which are lower in the new immigrants from sub-Saharan Africa, but they share the same African ethnic origin. In these two groups, the rate of spontaneous preterm is significantly higher, as is the rate of severe preterm birth before 33 weeks; the rates are higher for spontaneous preterm births, and the relative risk is higher for induced preterm births when compared to the group of women born in France, southern Europe, North Africa, or south and east Asia. This study also showed that both groups of women with African roots share higher rates of high blood pressure and pregnancy complications related to this high blood pressure.

This prevention policy would not have been successful had our program targeted only high-risk women. Indeed, we have been unable to reduce the risk of preterm delivery in women with a major risk factor, such as previous preterm birth or bleeding in the second or third trimester, or teenagers not included in a shelter program, or women over 35 years of age.[22] Clearly, preventive effort is not effective if applied to high-risk women. This is not surprising, as primary prevention works only before the disease occurs, and before the highly effective risk predictors are present. This concept has been well established in the management of other health problems, including coronary heart disease. Confusion develops because the same word 'prevention' is used to refer to secondary prevention, which is the reduction of disease incidence in people with high-risk factors (obesity, hypertension, high cholesterol), and primary prevention, which is the reduction of disease incidence in people without high-risk factors. Whereas secondary prevention is addressed to individuals, primary prevention must be addressed to all people in a given population.

Our program for prevention of preterm birth did exactly what it was supposed to do. It achieved a risk reduction. Obvious risk factors were reduced in the population, such as a history of a previous preterm birth or the incidence of bleeding during the second or the third trimester (Table 148.8), as demonstrated in the perinatal study of Haguenau,[22] resulting in fewer spontaneous preterm births. Several European countries proposed the same policy for the prevention of preterm

Table 148.6 Preterm births in the French randomized representative samples among all births in 1995 and 1998 (Blondel *et al.*[3])

Preterm births <37 weeks	1995			1998			*P*
	No. of births	No. of pretem births	%	No. of births	No. of preterm births	%	
All live births	13,105	710	5.4	13,358	837	6.2	0.008
All single live births	12,777	577	4.5	13,073	613	4.7	n.s.
All twin live births	316	124	39.2	453	212	46.8	0.04

The increase in the rate of preterm birth is mostly related to twin pregnancies, with an increase in their incidence (from 2.41% in 1995 to 3.35% in 1998), and an increase in the proportion of preterm births among multiples. The rate of preterm births among singleton pregnancies did not show a significant small increase from 1995 to 1998

Table 148.7 Preterm births by country of birth of the mother (percentage and odds-ratio compared to the results for women born in continental France) for singleton pregnancies for all pregnant women delivered in the district of Seine-Saint-Denis, northeast of Paris in the years 1998–1999, with rates of births before 33 weeks, from 33 to 36 weeks, for spontaneous and indicated preterm births, with rates and odds ratio for the comparison of the groups to the results for women born in France, adjusted for age and parity (after Zeitlin *et al.*[27])

Country of birth	Timing of preterm birth			
	< 33 weeks GA (%)	Adjusted OR* (CI)	33–36 weeks GA (%)	Adjusted OR* (CI)
Continental France	0.9	1	3.7	1
French Caribbean/ Indian Ocean	2.3	2.67 (1.91–3.78)	5.5	1.52 (1.22–1.88)
Southern Europe	1.0	1.15 (0.77–1.71)	4.0	1.07 (0.88–1.32)
Northern Africa	1.0	1.12 (0.86–1.46)	3.7	0.99 (0.87–1.14)
Sub-Saharan Africa	2.1	2.43 (1.93–3.05)	5.1	1.39 (1.21–1.59)
Southeast Asia	0.8	0.94 (0.61–1.44)	4.3	1.16 (0.95–1.41)
Test of equality between coefficients			$P=0.0003$	
	Onset of preterm birth			
	Spontaneous GA (%)	Adjusted OR* (CI)	Indicated GA%	Adjusted OR* (CI)
Continental France	3.5	1	1.0	1
French Caribbean/ Indian Ocean	4.6	1.34 (0.91–1.38)	2.9	2.91 (2.14–3.95)
Southern Europe	3.9	1.12 (0.91–1.38)	1.1	1.06 (0.73–1.56)
Northern Africa	3.3	0.96 (0.83–1.11)	1.2	1.15 (0.90–1.47)
Sub-Saharan Africa	4.7	1.38 (1.19–1.58)	2.3	2.26 (1.82–2.80)
Southeast Asia	3.8	1.09 (0.89–1.35)	1.1	0.99 (0.67–1.46)
Test of equality between coefficients			$P=0.0003$	

CI, confidence interval; GA, gestational age; OR, odds ratio
The rates of preterm birth for immigrants from southern Europe, northern Africa, and Southeast Asia are not different from those observed for women born in continental France, but rates for women born in the French Caribbean or Indian Ocean French possessions or those born in sub Saharan Africa are significantly higher

Table 148.8 Evolution of the frequency of risk factors after the acceptance of the prevention policy in the Perinatal Study of Haguenau, during three observation periods, for the risk factors of previous preterm birth among parous women, bleeding during the second trimester, and bleeding during the third trimester (after Bouyer *et al.*[22])

Study period	1971–1974	1975–1978	1979–1982	*P*
Births/period	5622	4824	5852	
Previous preterm parous week	428/3418 (12.5%)	259/2604 (10.0%)	280/3357 (8.3%)	< 0.001
Bleeding in the second trimester	151/2134 (7.1%)	99/2961 (3.3%)	187/5948 (2.8%)	< 0.001
Bleeding in the third trimester	143/3630 (3.9%)	71/4122 (1.7%)	88/5572 (1.6%)	< 0.001

A prevention policy achieved what was expected, a reduction in the proportion of pregnant women with a major risk factor, either from their previous pregnancy (fewer parous women with a previous preterm birth) or during that index pregnancy (fewer women with an episode of bleeding, during either the second or the third trimester)

births, as was determined by the EUROPOP study, and show similar results as those observed in France. In countries without any policy for work leave during pregnancy, such as the United States, the proportion of births prior to 37 weeks has increased from 9.4% in 1981 to 12.1% in 2002.[48]

Prevention of preterm births in multiple pregnancies

As shown in all population based registers, the rate of preterm birth among twins has increased; the question then is to ask if prevention of preterm birth is at all possible, and if yes, to define the goals that could be reached by a prevention policy of preterm birth for twin pregnancies. The question of prevention of preterm births is even more important in twin pregnancies than for single pregnancies, as the risk of cerebral palsy is higher for twin-born infants than for singletons, and even higher for triplets,[49] with the rate for infants with cerebral palsy being 2.3 per 1000 survivors in singletons, 12.6 per 1000 survivors in twins, and 44.8 per 1000 survivors in triplets. Confirmation of these facts was given by the meta-analysis of Stanley *et al.*[5] showing a higher risk of cerebral palsy with an odds ratio of 5.5 (95% CI: 4.34–12.06); this difference is even higher for triplets with an odds ratio of 18.21 (95% CI: 8.74–31.15); the major risk factor is to be born too early or to be born too small.

No program was able to show a reduction in the rate of preterm births in twins and triplets. This chapter will show that many programs were able to reduce the rate of very early preterm births in twins, with a subsequent reduction in neonatal deaths. A program for prevention of preterm births in twin pregnancies should focus on the extreme preterm births.[50]

By comparison with the problem of prevention of preterm delivery in single pregnancies, the problem to address in twin or triplet preterm birth prevention is very different as the risk for preterm birth in twin pregnancies is 50% and for triplet pregnancies, 90%. This means that the risk of severe preterm birth before 32 weeks of gestation is eight times higher for twins than for singletons in the United States, according to the CDC/NHCHS data collection,[51] and the risk of birth before 32 weeks for triplets is 26 times higher than for singletons in the same study.

Prevention should be an important point of discussion as the rate of twin pregnancies continues to rise in the USA[52] and Europe,[53] and the rate of preterm births among twins also continues to rise. Prevention should be an important focus of prenatal care as the consequences of preterm births from multiple pregnancies are better measured on familial impact.[54]

The rate of preterm birth in twins has increased since 20 years, due to more medical interventions aiming at preventing fetal death or fetal disease related to fetal growth retardation.

The rate of preterm births among twins in the United States[55] increased from 40.9% in 1981 to 55.0% in 1997. Twin births account for an ever-increasing percentage of all preterm births from 8.3% in 1981 to 13.0% in 1997. The spontaneous preterm birth rate among twins did not change for US twin births from 1989 to 1997; the proportion of twin births after induction of preterm delivery showed a small change, but an increase has been measured for preterm twin births after scheduled cesarean section for 1995/1997 by comparison with the figures for 1989/1991 and those for 1992/1994.

During these years, the increase of preterm deliveries in twins was contemporary to a remarkable improvement in infant mortality rates[55] for all twin births, for all durations of gestation. Newborn twins have benefited from the transformation of neonatal intensive care, and also from the improvement of obstetrical practice.

The same observation was made in other developed countries;[53] the French national figures show an increase in preterm births among twins,[53] and at the same time an increase of twin births.

In France, this evolution of medical practice toward more medically decided preterm births in

twin and triplet pregnancies can be measured on the register (FIVNAT) of all pregnancies following *in vitro* fertilization (IVF) and related assisted reproduction techniques (ART).[56] In this register, we studied the reasons for preterm deliveries and the relationship with fetal growth retardation.

The FIVNAT register shows the differences in the rates of preterm births, comparing single to twin and triple pregnancies. The major difference is in the rate of early preterm births, here defined as births at less than 33 weeks, with 2.3% in singletons, 8.4% in twins, and 30.4% in triplets.

This register collected information about the spontaneous beginning of preterm birth, or after induction of labor or scheduled cesarean section before onset of labor. In single, twin, or triplet pregnancies, there is a clear relationship between fetal growth restriction and medically decided preterm birth.

The proportion of scheduled cesarean sections is not different for single, twin, and triplet pregnancies in the 22–27-week period; between single, twin, and triplet pregnancies at weeks 28–32; and for twin and singleton pregnancies at weeks 32–35. But it is higher for triplet pregnancies, $P < 0.0001$, at weeks 32–35, much higher for twins compared to singletons at week 36, and weeks 37 and above, and even higher in triplets.

This description of the progressive rise of twin births and of prematurity among twins does not mean that nothing can be done; the possible action varies with gestation duration.

It is useful to distinguish three periods within the large proportion of preterm births among twins, with different risk status for the infants born from twin pregnancies, with the inclusion of new knowledge about the risk of cerebral palsy among twin infants.

The risk of cerebral palsy is not the same for different periods of gestation among preterm twins; this gives a strong argument for distinguishing three different periods in the description of preterm births in twin pregnancies, in relation to differences in the risk of cerebral palsy risk among twin infants.

For twins as well as singletons, the risk of neonatal death, severe neonatal disease, long-term developmental handicap, and, specifically, cerebral palsy depends first on the severity of prematurity, measured by the shortness of gestation duration, but the risk might be higher for twin-born infants compared to singletons of the same gestational age,[57,5] with three periods with varying relative risk.

In the period from 22 to 27 weeks, the risk of cerebral palsy is higher for twin infants compared to singletons of the same gestational age, with an odds ratio of 1.94 (95% CI: 1.16–3.24).[5] My proposed interpretation of this higher rate in twins compared to singletons is the specific contribution of monochorial twin pregnancies with the adverse effect of twin–twin transfusion syndrome. The aim of prevention would be to reduce the occurrence of extreme preterm births for cases not related to a twin–twin transfusion syndrome. Strong arguments are in favor of effective prevention of these very early births in twins.

In the period from 28 to 32 weeks, the risk of cerebral palsy is the same for twin and singletons infants, with an odds ratio in the meta-analysis of 1.03 (95% CI: 0.65–1.62). This period is the most important for the prevention program, as it is not in competition with the need to consider fetal growth retardation, as in the next period.

In the period of late preterm births, from 33 to 36 weeks, the risk of cerebral palsy is higher in twins than in singleton infants, with an odds-ratio of 2.25 (95% CI: 1.35–3.74). My interpretation of this fact is based on the different proportion of fetal growth restriction, much higher in twins than in singletons.[5,57] During this period from 32 to 36 weeks, the aim of prevention of preterm births is in opposition to the action adopted in relation to possible fetal growth restriction and the aim to reduce the potential danger to the fetus as a consequence of fetal growth restriction. This risk could be a good reason for termination of pregnancy by induction of labor or by scheduled cesarean section before the spontaneous onset of labor. The prevention policy is only aimed at twin pregnancies without fetal growth restriction of one or both fetuses.

The risk of preterm birth is high for twin pregnancies and is acknowledged as soon as the diagnosis of twinning is made; prevention can be proposed as soon as the first ultrasound scan is performed, and as the mean gestation duration for twin births is 36 weeks, it means that about 50% of all twin pregnancies will end before 37 weeks. But the real problem is to be able to recognize those women at risk of extreme preterm (22–27 weeks) births and early (28–32) preterm births.

The late recognition of twin or multiple gestation is an important risk factor for preterm delivery and perinatal deaths, as shown by the results of a controlled trial with or without a systematic ultrasound scan in the first trimester;[58] the rate of preterm birth is higher in the absence of early diagnosis. The observed difference was for extreme preterm births, with a higher rate for the control group without scan. This difference had an impact on the final result, with neonatal deaths at 27.8 per 1000 births for twin babies born to women with the systematic scan, compared to a neonatal mortality rate of 105.8 per 1000 twin births for the group of women without the systematic scan.

It is also of importance to recognize chorionicity, as monochorionic twin pregnancies show specific complications and a higher rate of extreme preterm births before 28 weeks, in relation to twin–twin transfusion syndrome.[59] This was measured in a population-based study including all twins delivered in a study of perinatal deaths among 67,819 births in the district of Seine-Saint-Denis,[60] where 551 twin deliveries were included beginning at 22 weeks up to the first month of live birth (28 days). Monochorionic twin pregnancy complications explained 50% of all fetal and neonatal

deaths, when the proportion of monochorionic pregnancies was not different from the rate of 30% commonly recorded. Complications of extreme preterm births before 28 weeks occur more frequently in monochorionic pregnancies, mostly with the loss of both twins, often with a direct relationship to a twin–twin transfusion syndrome.

Nuchal translucency thickness at 10–14 weeks of gestation is a predictor of severe twin–twin transfusion syndrome.[61] Twin–twin transfusion syndrome can be a specific cause of neurological damage of the fetus and the developing child.[62] In twins resulting from ART, these complications are not observed, as most of the twin pregnancies from ART are dichorionic.

Lack of prenatal care always was and still remains a major risk factor, measured in all twin births in the United States for the years 1998–2000, with a significant difference in the rate of preterm births, before 37 weeks, for twin pregnant women: 57.2% without and 51.2% with prenatal care for Caucasian women, 70.3% vs. 61.6% for African-american women.[63] Women with intensive use of prenatal care for twin pregnancies show the lowest infant mortality rates, compared to those with inadequate prenatal care.[55]

To belong to a high-level social group with good access to information and the capacity to choose the obstetrical team best qualified to follow a twin pregnancy has been shown as a predictor for a better outcome as measured by the study of perinatal deaths for all twin infants born from 1989 to 1991 in the district of Hauts de Seine southwest of Paris, France.[64]

The social status of the mother measured in years of education and level of income is related to important differences in the perception of risk related to a twin pregnancy, and to the choice by the mother of the prenatal outpatient clinic and the maternity.[65] This study was population based and included all twin deliveries in this district of 2,000,000 inhabitants, and between 250 and 300 twin pregnancies per year, in 541 mothers delivered from October 1, 1989, to September 30, 1991, with a direct questionnaire the day of delivery or during the next 2 days, in the 22 maternities of this district where the delivery took place. There were questions on the level of education measured by years of school attendance, income from herself and her husband or companion, the perception of specific risks for the children related to the twin pregnancy, or for the mother herself, the reason for the choice of the maternity. Data were collected on gestation duration, beginning at 26 weeks (and 500 g or more of birth weight), including fetal deaths, and neonatal outcome up to 28 days for all infants, back at home or admitted in a pediatric department. The perception of specific risk for the children or the mother in relation to the twin pregnancy is described in different terms and is less for women of low socioeconomic level; the more educated women have a higher degree of concern ($P < 0.01$). The difference of attitude is also measured by the choice of the maternity in which they decide to be followed; women belonging to the higher socioeconomic level show a more frequent choice of a level 3 maternity, in a perinatal center with on-site availability of neonatal intensive care.

An important progress in the risk assessment has been made by the measure of cervix length by transvaginal scans. A prospective study showed that twin mothers whose cervical length at 24 weeks was 35 mm or more were at low risk of spontaneous delivery before 34 weeks.[66] A meta-analysis of 46 studies including 31,577 women confirms the importance of this technique; cervical length shortening and cervical funneling, alone or in combination, appear to be useful in predicting spontaneous preterm birth in asymptomatic women.[67] The change of cervical length in repeated systematic transvaginal ultrasound scans shows that shortening of the cervix and change of the shape of the inner os, opening with tunneling, can be recognized early in those women who deliver early, before 34 weeks. The median shortening rate was 2.9 mm (0.8–5.2) per week in women who gave birth preterm and 1.2 mm (0.8–2.4) per week in those who gave birth at term.[68]

While the predictive value of cervical length measurement is well established, there are no intervention studies that have evaluated the importance of this measurement in the prevention of preterm birth.

Among the clinical signs collected at the prenatal clinic, the length and orientation of the cervix, the height of the presenting part remain good predictors for the risk of early preterm birth in twins. In spite of the lack of precision, clinical cervical assessment appears to be safe and may be effective in monitoring twin gestation, if transvaginal ultrasound is not available or is too expensive; clinical examination is more subjective and less reproductible.[69–71]

Home uterine activity monitoring can be helpful in identifying women at increased risk of preterm labor before cervical dilation occurs; this information has not resulted in a reduction in the incidence of preterm labor, of advanced cervical dilatation at presentation or preterm birth in controlled trials.[72–75]

The classical risk factors are of interest, such as height and prepregnancy short stature of the mother, limited weight gain[76,77] with a protective value of higher body mass index and of significant weight gain.[78]

Most of the techniques used for the reduction of prematurity in twin or triplet pregnancies have not proven their effectiveness in controlled trials.

Bed rest is the oldest proposed method for the prevention of preterm deliveries in multiple pregnancies. A meta-analysis of six controlled trials[79] involved 600 women and 1400 babies. Systematic bed rest in hospital did not reduce the risk of preterm birth or perinatal mortality. There is a trend to decrease the number of low birth weight babies, with an odds ratio of 0.79 (95% CI: 0.63–0.99), but there is no difference

in the number of very low birth weight infants or in neonatal outcome. On the other hand, bed rest in hospital for women with an uncomplicated pregnancy did increase the rate of very preterm births, below 34 weeks, with an odds ratio of 1.84 (95% CI: 1.01–3.34). The only positive outcome related to bed rest is the reduced risk of pregnancy hypertension, with an odds ratio of 0.55 (95% CI: 0.32–0.97).

Prophylactic cerclage has not been shown to be effective in twins,[80] through a meta-analysis of six randomized controlled trials comparing cervical cerclage in low- and moderate-risk women for second-trimester pregnancy loss with expectant management during pregnancy, describing a total of 2175 women. Four trials compared prophylactic cerclage with no cerclage and two examined the therapeutic role of cerclage when ultrasound examination revealed a short cervix. Pooled results failed to show a significant reduction in pregnancy loss and preterm delivery, although a small reduction of births at less than 33 weeks was seen in the largest trial. Cerclage was associated with mild pyrexia, increased use of tocolytic therapy, and more hospital admissions, but no serious morbidity. The conclusion of this meta-analysis was to propose that the effectiveness of prophylactic cerclage in preventing preterm deliveries in mothers with a low or medium risk of second-trimester pregnancy loss was not proven.

Prophylactic betamimetics have not been shown to be effective in twin pregnancies,[81–85] but progestins have been proven as of interest for high-risk single or twin pregnancies, as shown by a meta-analysis by Keirse[86] with the use of 17 alpha hydroxyprogesterone caproate, with an odds ratio of 0.50 (95% CI: 0.30–0.85), with a major confirmation for women with a single pregnancy but at very high risk of recurrent preterm births.[87] But the only specific controlled trial on twin pregnancies has shown a negative result.[88]

Treatment of the mother with systematically prescribed antenatal corticosteroids was not effective for improvement of neonatal outcome for twin neonates,[89] with no reduction of respiratory distress syndrome, with an odds ratio of 0.7 (95% CI: 0.2–2.0), but with a reduction in mean birth weight in term babies of 129 g (95% CI: –218 to 33).

Weight gain during pregnancy might be a protective factor against preterm birth in twin pregnancies. No controlled trial is available to measure the possible effectiveness of recommending high weight gain for mothers of twins, but this question is of interest as mothers with a significant weight gain early in pregnancy, before 24 weeks, are less at risk of preterm births and low birth weight babies.[90,91] The Higgins Nutritional Program in Canada[92] recommended a 1000-cal regimen over recommendations for singleton pregnancies, which resulted in an 80-g increase in twin birth weight and a 15% reduction in preterm birth below 37 weeks. The specialized care described by Luke *et al.*[93] includes a nutritional intervention on the amount of calories and vitamins as well as calcium, magnesium, and zinc, and claims for this non-random study a significant benefit in reduction of early preterm deliveries, a significant difference in birth weight of twin babies, a significant difference in neonatal hospitalization days, and better results at 3 years of age. But it is difficult in this multiproposal intervention to decide whether this was the effect of nutritional intervention or the effect of other proposals for better prenatal care, or the effect of the personal choice of the women in the program compared to those not included in the program.

Work leave prescription on medical advice and life style modifications by information given to the mother are the basic techniques of a policy for prevention of preterm deliveries addressed to all French women,[94] and have been effective for the reduction of spontaneous preterm births in singleton pregnancies. For twin pregnancies the same program has been proposed, but has to be set in action early in pregnancy, as the major goal is the prevention of extreme preterm births. The proposal is a prescription of work leave for employed twin pregnant women between 22 and 24 weeks. No controlled trial is available to test the potential effectiveness of this policy.

The evaluation of this policy was to measure if its application for all twin pregnant women of a given population would reduce the commonly observed social differences in preterm deliveries and in perinatal mortality figures.

A specific study has measured the results of such a policy proposed for all pregnant women with twins in the population of a French district (Hauts de Seine) in the years 1989–1991, 546 women for whom the mean gestation duration at prescription of work leave was 22.6 weeks.[64] The goal of the prevention policy was that this proposal should be available for every pregnant woman, regardless of her social level. The effective action was measured by the mean gestation duration at the first prenatal visit, the mean gestation duration at the first ultrasound scan, the number of prenatal visits, the number of ultrasound scans, the gestation duration at prescription of work leave. It was not the aim to measure the effect of work leave itself, as this specific proposal was included in a much larger prevention policy.

The reality of equal access for all women, regardless of their social level, to the prenatal care proposal was measured by the fact that no difference was observed for time at the first prenatal visit, time at first ultrasound, time for prescription of work leave by socioeconomic level. The observation of results by socioeconomic level showed no difference in the distribution of gestation duration, but there was a higher but not significant difference in births before 28 weeks for the lowest socio-economic group. The only difference between socioeconomic groups of women was in the choice of the maternity,[65] the the best-informed chose more often a level 3 maternity unit, with intensive neonatal care available on site.

The major outcome measure was the rate of preterm births from 26 to 32 weeks, which was 6%, when available comparisons on populations show higher figures, such as 11% before 32 weeks for all US twin births.[95]

This low rate of early and extreme preterm birth seems to explain the low rate of perinatal deaths at 22 per 1000, with a fetal death rate at 8 per 1000 (8/1082) and a low neonatal mortality rate at 15 per 1000 (16/1074) live births, with no significant difference by socioeconomic group. These figures are lower than the perinatal mortality rates for all twin births in United States in 1989/1991 of 28.7 per 1000.[51]

The twin clinic

Several programs have described special sessions in the outpatient department devoted to mothers with multiple pregnancies, conducted by a trained team of doctors and midwifes or nurses offering specific attention to these mothers, specific education on the risk factors, on the importance of limitation of physical activity and avoidance of heavy work, nutritional advice, and specific educative sessions. Such a specialized outpatient twin clinic also gives an opportunity for twin mothers and fathers to meet and provide mutual support. The first description of such a proposal and of effective results was given in Germany.[96]

The first historical comparison with a demonstration of the positive effect of a twin clinic for all twin pregnant women of a region was given in Scotland.[97] In this setting, there was a reduction of extreme preterm births below 28 weeks, and of babies of less than 1500-g weight, in the two last historical periods, 1976/1980 and 1981/1983, compared to the four previous historical periods from 1956 to 1975. The improvement is in the number of neonatal deaths, from a mean level of 60 neonatal deaths per 1000 twin live births to figures of 18.4 per 1000 and 16.2 per 1000, since the twin clinic was made available for all twin pregnant women in Dundee, Scotland.

This type of care has been proposed in many other settings.[98] The specialized prenatal care proposed by Luke *et al.*[93] is another example of a twin clinic with several proposals, including early work leave, information about reduction in physical effort, more visits with a well-informed member of the team, and specific nutritional advice; this intervention claims a significant reduction in the rate of preterm births and a better outcome for twin newborns and twin infants followed at 3 years of age.

A preventive proposal should be proposed not only at the outpatient clinic of the department, but also to all women in the population with a twin pregnancy.

The difficult task of preventing preterm birth in twin pregnancies and the impossibility of prevention of preterm births in triple pregnancies is a strong argument for the prevention of multiple pregnancies in IVF and related techniques, up to the point of preventing twins, by the transfer of a single embryo.[99–102]

In triplet pregnancies, no improvement of gestation duration can be seen comparing earlier and present publications. The mean gestation duration remains in all publications at about 33 weeks, even if there has been a remarkable improvement in the rates of perinatal deaths (PND) from the earlier series to recent ones, from Itzkovic[103] on 59 mothers in 1946/1976 with 132 PND/1000 and Holcberg *et al.*[104] on 78 mothers in 1975/1988 with 312 PND/1000, to better results reported by Lipitz *et al.*[105] on 78 mothers in 1975/1988 with 93 PND/1000, Newman *et al.*[106] on 198 mothers in 1985/1988 with 66 PND/1000, Pons *et al.*[107] on 91 mothers in 1975/1993 with 80 PND/1000, to the more recent period with Ballabh *et al.*[108] in 1993/2000 on 116 mothers with 47 PND/1000 and Barr *et al.*[109] on 51 mothers in 1993/2002 with 40 PND/1000.

The rate of preterm birth in triplets is very different from the rate in twins or singletons, as given, for example, in the French register of all births following IVF or related techniques,[56] in the FIVNAT register for the years 1986/1999. The rate of extreme preterm births below 28 weeks is 3.3%, 1.9 times more than for twins and 5.5 times more than for singletons. The rate of severe preterm births at 28–32 weeks is 27.1% of all triplet births, 3.9 times more than for a twin pregnancy and 15.9 times more than for a singleton pregnancy in the same register. But an improvement in gestation distribution would have been difficult to measure because for triplets, as for twins, a significant proportion of preterm deliveries result from a medical decision, after a better recognition of growth retardation of one, two, or three fetuses with the decision to induce labor or to go in for a scheduled cesarean section. The register FIVNAT gives a comparative description of the decision of elective cesarean section for triplet pregnancies, by duration of pregnancy in six gestation periods. At 28–32 weeks, the proportion of births following elective caesarean section is 57% in singletons, 49% in twins, and 58% in triplet pregnancies, with no significant difference between single, twin, or triplet pregnancies. A difference was measured for the next period, 33–35 weeks, with 48% in single or twin pregnancies and 82% in triplet pregnancies ($P < 0.001$).

Few techniques used for prevention of spontaneous preterm births were tested by controlled trials, none of them with proven efficacy in triplet pregnancies.

Bed rest was tested by a controlled trial,[110] comparing bed rest beginning at 28 weeks with conventional care and normal physical activity at home, with a not significant longer gestation duration for the group at bed rest, a higher birth weight of the newborn babies, and a shorter stay in the neonatal unit, but the meta-analysis did not confirm this difference.[111] The study of Skrablin *et al.*[112] comparing hospital bed rest since the beginning of the second trimester with hospital bed rest at 28 weeks, by choice of the mother herself,

shows a benefit for the group of women accepting early bed rest, for gestation duration at delivery, mean birth weight, and perinatal mortality rates. But this is not a controlled study, and the results of the 'normal care' group were very bad, with a mean gestation duration at 30.0 weeks, a mean birth weight at 1228 g, and a perinatal mortality rate of 430 per 1000 births, opening a real question on the negative consequences of the personal choice of the mothers who did not accept the hospital bed rest proposal in this non-randomized study. Adams *et al.*[113] claims a better birth weight of the newborn in a historical comparison of women with or without hospital bed rest; for women offered bed rest at hospital, less intraventricular bleeding was observed in the newborn babies, but no difference in gestation duration and no difference in perinatal mortality rates.

Cerclage with a stitch on the uterine cervix, proposed systematically and not for specific indications for a previous second-trimester pregnancy loss, has not proven its efficacy for triplets,[105,114,115] with an improvement in gestation duration but no difference in neonatal mortality rates.[116]

Systematic prescription of betamimetics has not been proven to improve the results for triplet pregnancies, but has proven that accidents related to utilization of betamimetics perfusion were possible, even early in gestation.[117]

The only proven technique to reduce preterm births related to triplet pregnancies or twin pregnancies is to avoid multiple gestations by a better use of ART and the transfer of only two embryos at routine[99,102] and even only one embryo at a time.[100,101]

149 The vanishing fetus in multiple pregnancy

H. J. Landy and L. G. Keith

Introduction

The 'vanishing twin' phenomenon has been well described over the past two decades. Ultrasound scans performed during early pregnancy have demonstrated that the number of conceived multiple pregnancies exceeds the multiple birth rate. Spontaneous first-trimester fetal loss of multifetal gestations occurs relatively frequently.[1,2] Over the years, spontaneous pregnancy loss in multiple gestations has been confirmed in both animals and humans, especially after technological advancement in sonographic techniques and the introduction of assisted reproductive technologies (ARTs).[1]

Diagnosis and frequency

Early pregnancy fetal disappearance likely involves resorption and/or formation of blighted ova, though the precise mechanisms of this phenomenon have yet to be elucidated. Reports of the vanishing twin from the 1970s and 1980s inaccurately suggested a wide range of occurrence; however, technological progress has helped to refine these numbers.[1,2] In the past, reports of high rates of multiple gestation likely resulted from sonographic error in the misinterpretation of normal early embryonic structures or of other conditions (e.g. subchorionic hematomas or collections of subchorionic fluid).[1–3] Sonographically defined characteristics were first proposed by Blumenfeld *et al.* in 1992 in order to better recognize a true intrauterine gestational sac and minimize interpretive error.[4] These characteristics include: (1) a double contour; (2) identification of a yolk sac within the gestational sac; and (3) recognition of an embryonic heart beat after 6 weeks of gestation.[4]

Transvaginal sonography, available since the late 1980s, provides detailed visual information regarding early pregnancy. Early resorption in multiple gestations has been well described over the last 20 years. The figures included demonstrate the sonographic images of pregnancies in which the vanishing twin phenomenon has been documented (Figures 149.1–149.3).

Figure 149.1 Sonogram demonstrating one viable twin in the right sac and a non-viable twin in the left sac. One week earlier, two viable twins were seen.

Figure 149.2 Sonogram of the same patient as in Figure 149.1 4 weeks later demonstrating one viable twin in the left sac and the resorbing, vanishing twin in the right sac.

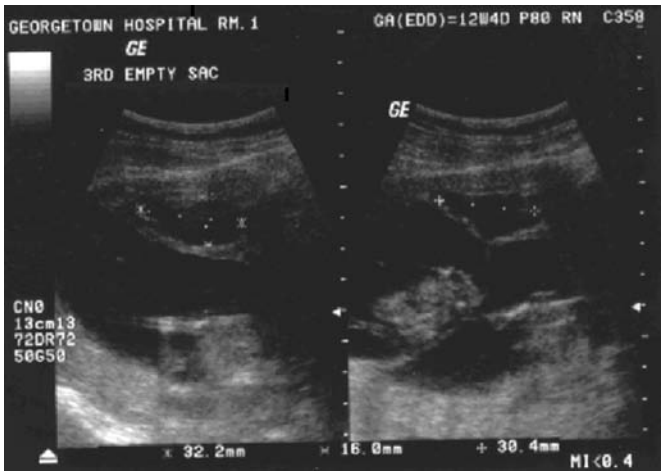

Figure 149.3 Sonogram demonstrating a third empty sac (measuring 32.2 × 16.0 × 34.4 mm) in a previously viable triplet gestation.

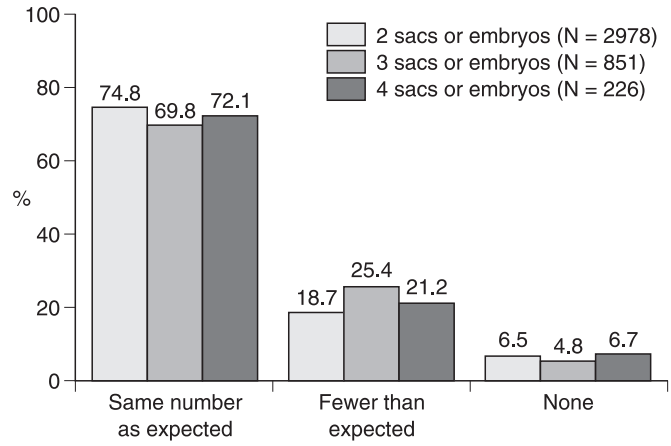

Figure 149.4 Outcome beyond the first trimester after the sonographic diagnosis of 2–4 gestational sacs and/or embryos: Number of fetuses after the sonographic diagnosis of 2 sacs or embryos, 3 sacs or embryos, and 4 sacs or embryos.[4–15]

Until recently, most published data described pregnancies with two or three gestational sacs or embryos.[4–14] One of our earlier papers cited information based on the few quadruplet pregnancies reported by the 1998 publication date.[1] In 2003 and 2004, however, several papers included sizable numbers for pregnancies with four sacs and/or embryos.[15–17] Despite this, there is little information available for pregnancies of higher order. Combining current data suggest that approximately 70% of pregnancies with multiple sacs or embryos continue with the same number of fetuses as expected (Figure 149.4). This 70% maintenance rate appears to be constant for pregnancies that began with two, three, or four sacs or embryos. Spontaneous resorption occurred in 18.7% of twins, 25.4% of triplets, and 21.2% of quadruplet gestations (Figure 149.4).[4–15] Further stratification of these data is seen in Figure 149.5. The growing body of literature confirms that the prevalence of fetal disappearance in multiple gestations is fairly constant.

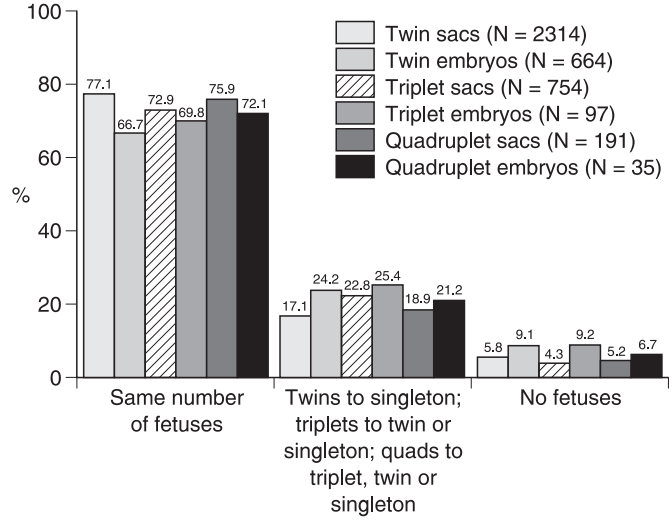

Figure 149.5 Outcome beyond the first trimester after the early sonographic diagnosis of multiple sacs or embryos: Pregnancy outcome after the sonographic diagnosis of twins (N = 2978), triplets (N = 851), or quadruplets (N = 226).[4–15]

Are there differences in the vanishing twin rate in different populations? One questions the impact of ART on this area. Answering this question is confounded by the fact that most published data on early pregnancy loss in multiple gestations describe ART pregnancies rather than spontaneous conceptions. Figures 149.6 and 149.7 demonstrate available data comparing spontaneous pregnancies and those conceived using ART (*in vitro* fertilization, IVF; intracytoplasmic sperm injection, ICSI; and ovulation induction), evaluating loss rates after the sonographic diagnosis of two sacs (Figure 149.6) and two embryos (Figure 149.7). Higher loss rates are seen when only gestational sacs are demonstrated sonographically rather than when embryos are visualized. Data obtained for Figures 149.6 and 149.7 have been compiled from different studies where very few patients with spontaneous conceptions are reported compared to those conceived with ART.[4,5,8–13,15–18] Moreover, many patients with spontaneous conceptions underwent ultrasonography because of pregnancy complications such as vaginal bleeding. These data, especially for those spontaneously conceived, therefore, should not be extrapolated to the general population. With the ultrasound identification of viable twins, loss of one twin occurs in 29.7% of IVF/ICSI conceptions, 32.5% of pregnancies conceived with ovulation induction, and 10.2% of spontaneous conceptions (Figure 149.7).

Disappearance of gestational sacs or embryos has been described throughout the first trimester, although unconfirmed beyond 13 weeks.[4,5] Spontaneous reduction rates are higher earlier in gestation, though precise frequencies per given gestational week cannot be extrapolated.[4–6,18]

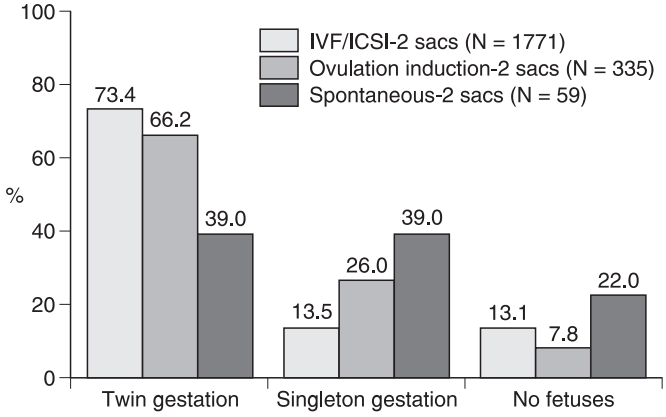

Figure 149.6 Outcome beyond the first trimester in assisted vs. spontaneous conceptions after the early sonographic diagnosis of two sacs (N=2135): Comparison of IVF/ICSI, ovulation induction, and spontaneous conceptions.[8,9,11,12,16,17]

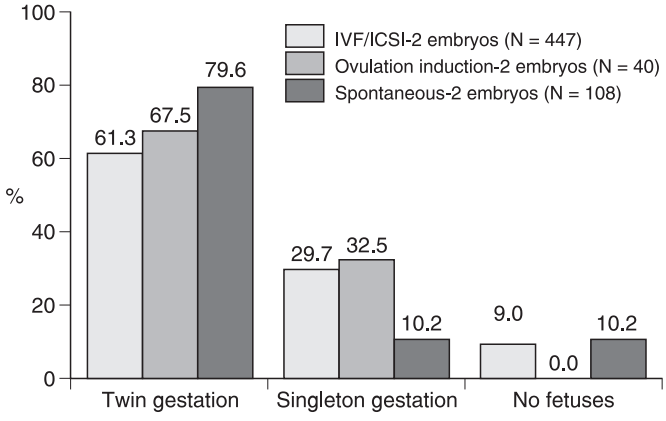

Figure 149.7 Outcome beyond the first trimester in assisted vs. spontaneous conception after sonographic diagnosis of 2 embryos (N=595): Comparison of IVF/ICSI, ovulation induction, and spontaneous conceptions.[4,5,10,13,15,18]

Complications and prognosis

Vaginal bleeding

Vaginal bleeding or spotting, commonly reported in the first trimester by all pregnant women, appears to be the only apparent complication associated with disappearance of an embryo or a gestational sac. Rates as high as 76.5% have been reported, varying with study and patient populations.[1] The finding of clinical bleeding seems to coincide with the vanishing process. Regardless of chorionicity, the prognosis for continuing a pregnancy associated with spontaneous resorption is good.[1,18]

Continued viability

Predicting continued fetal viability among sonographically identified twin gestations early in pregnancy may be challenging. More reliable prognoses can be made at later gestational ages and in the absence of abnormal sonographic findings (e.g. subchorionic hemorrhage). Disappearance rates occur more than twice as often in monochorionic compared to dichorionic twin gestations (50% compared to 21%).[18] Increasing maternal age is associated with higher spontaneous resorption rates in some studies,[8,17] though results are conflicting.[7,15] In one study, no association was seen between twin resorption and maternal age, spontaneous vs. induced conception, or indication for sonography.[7] Further, La Sala *et al.* did not discern a correlation between early spontaneous loss of multiple gestations and the starting number of embryos transferred in IVF patients.[15]

Though identification of an embryonic heartbeat confirms a viable pregnancy, its initial presence cannot guarantee continued fetal viability in multiple gestations. Kelly *et al.* found a more reliable predictor of ongoing viability to be the rate of increase of serum human chorionic gonadotropin levels rather than the presence of embryonic cardiac activity.[10] Differences in crown–rump length measurements between embryos may be associated with fetal aneuploidy or congenital anomalies[19] as well as a vanishing twin.[13]

Cerebral palsy

Worldwide data demonstrate that the prevalence of cerebral palsy increases with plurality, being more common with a higher number of fetuses.[20] Higher cerebral palsy rates are seen with preterm and low birth weight infants.[20] Though studies describe higher risks of cerebral palsy in children resulting from ART,[21,22] confounding issues include high frequency of multiple gestations, low birth weight and premature deliveries.[20] Higher rates of cerebral palsy are described in monochorionic twin survivors after demise of a co-twin and in cases of the twin transfusion syndrome.[23,24]

In 1997, Pharoah and Cooke hypothesized that cerebral palsy of unknown etiology in singletons could be attributable to the early loss of a previously unrecognized monochorionic twin.[25] They theorized that the survivor's antenatal neurological development would be impaired, resulting in the clinical manifestation of spastic cerebral palsy.[25] A similar line of thought was proposed in a Norwegian study in 2000.[26] Though intriguing, a follow-up report from this same group of authors was not supportive of their original hypothesis.[27] Further, this concept is not supported by tangential evidence, given the lack of reported cases of cerebral palsy following multifetal pregnancy reduction, a procedure that is not unlike the vanishing twin phenomenon.[20]

Miscellaneous

Though surviving co-twins in multiple gestations associated with a vanished twin have not been found to have an increase in congenital anomalies, the case series by Casale *et al.* proposes that blighted conjoined twinning may result in cloacal exstrophy variants.[28] The vanishing twin phenomenon perhaps may

explain some isoimmunization cases that develop during gestation in which a Rh-positive twin disappears in a previously unsensitized Rh-negative mother.[1,2] The emotional needs of the mother who has experienced a vanished twin requires sensitivity and humanistic communication.[29]

Pathological considerations

Pathological documentation of the resorption process can be confirmed by histological findings from the fetal surface of the placenta. Such findings include sacs or cysts; placental nodules or plaques; areas of degenerated chorionic villi; fibrin deposition or fibrinoid degeneration; embryonic remnants; and macerated embryos.[1,2,30,31] The vanishing twin phenomenon has been used to explain discordant chromosome results, including various trisomies, triploidy, tetraploidy, and sex chromosome discrepancies.[1,2,31–33]

Conclusions

In summary, the 'vanishing twin' phenomenon is a common sonographic finding among multiple pregnancies. The risk of resorption appears to be relatively constant at approximately 20% of conceptions, whether the pregnancy begins with two, three, or four sacs or embryos. Disappearance is more frequently described earlier in the first trimester. Higher resorption rates are reported in pregnancies conceived using ART though the numbers of spontaneously conceived multiple gestation are lacking. Better outcomes are seen with dichorionic rather than monochorionic twin gestations. The main complication associated with embryonic or fetal resorption is vaginal bleeding. Detailed sonographic evaluation is recommended to follow the progression of the resorption process as well as to assess viability and evaluate growth in the remaining fetus(es). Though conflicting data exist regarding risks of cerebral palsy to the surviving infants, the association does not seem likely. Close inspection of the placenta and membranes after delivery may confirm earlier sonographic findings.

With continued technological advances, sonography of early pregnancy will continue to provide a thorough understanding of embryonic development and the relationship of early pregnancy loss in multiple gestations.

150 Sonographic evaluation of multiple pregnancies

A. Matias, N. Montenegro and I. Blickstein

… The day will come soon
when a routine ultrasound examination
will be offered to every pregnant women …
Ian Donald, 1974

Over the last decade, perinatal mortality and morbidity in multiple pregnancies have fallen due to advances in fetal medicine and improvement in perinatal care. One of the most decisive contributing factors was the widespread use of ultrasound evaluation in early pregnancy, defining the number of fetuses, assigning chorionicity and screening for major aneuploidies and malformations.

Diagnosis of chorionicity and amnionicity

Clearly, it is chorionicity rather than zygosity that determines several aspects of antenatal management and perinatal outcome. Thus, the routine assignment of chorionicity and the earliest possible diagnosis of monochorionic twinning are highly desirable, though seldom achieved in practice.

Zygosity refers to the type of conception whereas chorionicity denotes the type of placentation. The type of placentation depends on the time of splitting of the fertilized ova: if it occurs too early, two placentas will be found and a dichorionic diamniotic twin pregnancy will be identified; if it occurs after the third day, a single placenta, that is, a monochorionic twin pregnancy will be established.

Caution should be taken when using the number of chorionic sacs (Figure 150.1) and the number of yolk sacs alone to determine the number of embryos. Shortly after the sixth postmenstrual week, embryonic heartbeats are visible and one can confidently count the number of embryos by the number of beating hearts.

By that time, to determine the number of amnions in a monochorionic twin pregnancy, in which two embryos are seen within the chorionic sac, it is wise to wait until the eighth postmenstrual week to ascertain amnionicity. The amniotic membrane is so thin that it may remain inconspicuous until 8–9 weeks, leading to the incorrect consideration of a monochorionic–monoamniotic gestation. After that gestational age, it is clear that no amniotic membrane is present

Figure 150.1 (a) Early scan at 5 weeks of gestation showing a dichorionic twin pregnancy with two chorionic sacs. (b) Early scan at 6 weeks of gestation showing three chorionic sacs and defining a trichorionic triamniotic twin pregnancy.

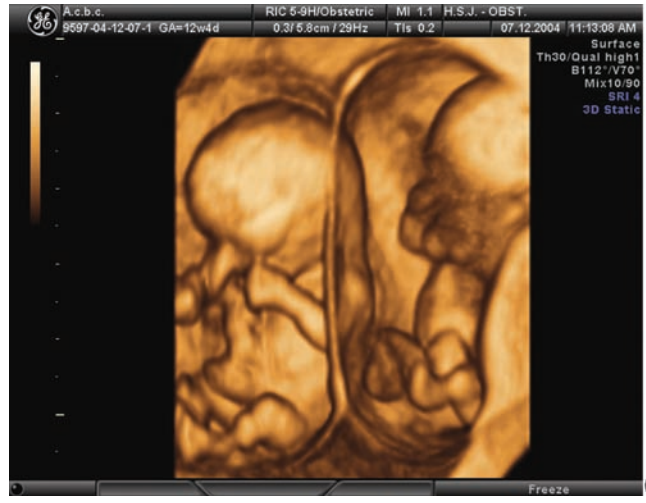
(b)

Figure 150.2 (a) Lambda sign at 11 weeks of gestation, depicting a thick layer of chorion between the two layers of amnion, and defining a dichorionic dimaniotic twin pregnancy. (b) Example of a dichorionic diamniotic twin pregnancy with two differently located placentas.

(a)



(b)

Figure 150.3 (a) Example of a monochorionic twin pregnancy at 11 weeks of gestation showing a thin dividing membrane without chorion between the amnion layers. (b) 3D imaging of a monochorionic diamniotic twin pregnancy at 11 weeks showing the thin intertwin membrane with two layers of amnion.

between the embryos and only one yolk sac is visualized. From then on it is important to look for sonographic signs of cord entanglement, potentially depicted as early as 12 weeks, with the help of color Doppler.

When two embryos or fetuses assume a parallel, head-to-head position, conjoined twins should be suspected. A jerk with the probe should be inflicted to induce movement between the two fetuses, away from each other or close together when conjoined twins are in question.

At 10–14 weeks, the gold standard 'window' for chorionicity definition, the chorion frondosum is sufficiently thick to be identified between the two layers of amnion as a wedge-shaped structure in a dichorionic twin pregnancy (not obligatory dizygotic twin pregnancy), yielding the fully diagnostic 'twin peak' or 'lambda' or 'delta' sign (Figure 150.2a and b).[1,2] However, the number of 'twin-peak' signs is no secure indication of how many chorionic sacs exist within a given pregnancy. If two fused layers of amnion, without any chorion interposed, are found in the scan creating a T-shaped 'take-off' (T sign), showing a very thin membrane with strictly two layers (Figure 150.3a and b), a monochorionic twin pregnancy can be diagnosed with 100% certainty.[3]

After 16 weeks, physiologically the chorion frondosum regresses and chorionicity becomes a more confounding issue. The delta sign disappears[4] and, if sexes are alike, monochorionicity can be wrongly inferred. It is the conjugation of several sonographic criteria that approaches the correct diagnosis of chorionicity, the most and ultimate determinant of perinatal prognosis. Therefore, an adequate first-trimester scan of a multifetal pregnancy makes the subsequent second- and third-trimester evaluation much more meaningful, simpler and faster.

Identifying a single placenta with a paper-thin, reflective hair-like septum without chorion between the two amnions, with a very thin septum with less

Figure 150.4 Thick intertwin membrane with chorion interposed in a dichorionic diamniotic twin pregnancy at 11 weeks of gestation.

Figure 150.5 Thin intertwin membrane with two layers of amnion without chorion interposed in a monochorionic diamniotic twin pregnancy at 11 weeks of gestation, better imaged by zooming in.

than 2 mm and like-sex twins, placentation will most probably be monochorionic. If contrarily one finds two separate placentas of different location, or two fetuses of a different sex or a thick membrane >2 mm with more than two layers (Figure 150.4), dichorionicity is strongly suggested. Note that to identify the interfetal membranes, a right-angled orientation of the probe in relation to the membranes should be obtained to take advantage of the axial over the lateral resolution. In order to count the number of layers one must 'zoom in' (Figure 150.5). In contrast, a membrane placed parallel to the ultrasonic beam will appear thinner and poorly imaged, rendering it impossible to be sure about the number of layers of the intertwin membrane.

Down's syndrome screening in multiple pregnancies

Down's syndrome is the most prevalent autosomic chromosomal abnormality in the human race (birth prevalence of about 1 in 800) and accounts for almost 50% of all aneuploidies.

Maternal age has been a widely accepted screening method since it is cheap, universally available, has no intra- or interobserver variation, is non-invasive and is understandable by the women screened, but yields a sensitivity dependent on the prevalence of women with maternal age over 35 years (50% sensitivity for a 15% prevalence of women older than 35 years). In the late 1980s, the quantification of various fetoplacental products in the maternal circulation (*biochemical screening*) was introduced.

In the 1990s, screening by a combination of maternal age and fetal *nuchal translucency* thickness (NT) at 11–14 weeks for a given crown–rump length was introduced, identifying about 75% of trisomy-21-affected fetuses for a screen-positive rate of about 5%.[5] More recently, combining NT and nasal bone[6] with two biochemical markers between 11 and 14 weeks of gestation [free β-human chorionic gonadotropin (β-hCG) and pregnancy-associated plasma protein-A (PAPP-A)],[7,8] provided a detection rate of 95% for a screen-positive rate of 2%.

Screening for chromosomal abnormalities in twin pregnancies implies, however, a different reasoning.[9,10] The overall probability that a multiple gestation contains an aneuploid fetus is directly related to its zygosity. In *dizygotic* pregnancies, each fetus has an independent risk of aneuploidy; thus, the risk for chromosomal abnormalities for each twin may be the same as in singleton pregnancies, but the chance that at least one fetus is affected by a chromosomal defect is twice as high as in singleton pregnancies. This means that for dizygotic twin pregnancies, the pregnancy-specific risk is calculated by summing the individual risk estimates for each fetus.

In *monozygotic* twins, the risk of an affected fetus approximates the risk of a singleton pregnancy and, in the vast majority of cases, the risk for one fetus is, in expectation, the same as the risk for the other.

If zygosity is unknown, the risk of at least one aneuploid fetus can be approximated as five-thirds (1.667) that of the singleton risk. This is based on the assumption that a third of all twin pairs are monozygotic.[11]

Counseling based on chorionicity, clinically more feasible than zygosity, results that in monochorionic twins both fetuses can be affected equally. If the pregnancy is dichorionic, the parents should be counseled that the risk of discordance for a chromosomal abnormality is about twice that in singleton pregnancies, whereas the risk that both fetuses would be affected is a much rarer event, corresponding to the singleton

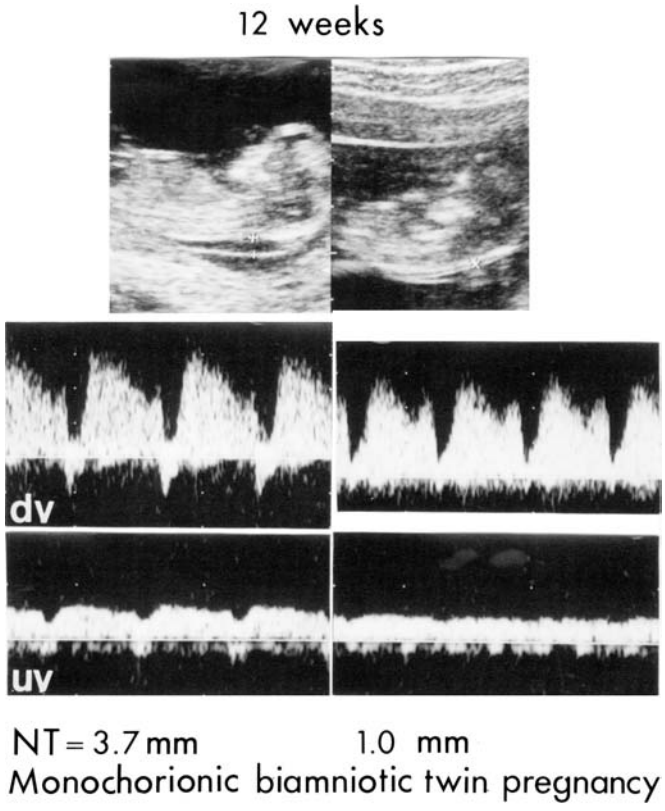


Figure 150.6 A monochorionic diamniotic twin pregnancy was established at 12 weeks of gestation. Doppler blood flow waveforms in both fetuses were obtained in the umbilical vein (UV) and ductus venosus (DV) in the same scan. A nuchal translucency (NT) discrepancy was noted (NT = 3.7/1.0 mm). The fetus with increased nuchal translucency shows an inverted A-wave in the DV and dicrote pulsatile flow in the UV. TTTS developed at 17 weeks and the patient was referred for laser ablation of anastomosis.

risk squared. For example, in a 40-year-old pregnant woman with a risk for trisomy of about 1 in 100 based on maternal age, in a dizygotic twin pregnancy the risk that one fetus would be affected would be 1 in 50 (1 in 100 plus 1 in 100), whereas the risk that both fetuses would be affected is 1 in 10,000 (1 in 100 × 1 in 100). Unlike all monochorionic pregnancies that are always monozygotic, only about 90% of dichorionic pregnancies are dizygotic, so these calculations are slightly inaccurate.

When calculating the risk of higher order multiples, estimates can be made multiplying the singleton risk by the number of fetuses.[12] This method assumes unique chorionicity for each fetus, though monozygosity can occur more frequently than usually thought at higher rates in multiple gestations through assisted reproductive techniques (Wenstrom *et al.*, 1993; Blickstein *et al.*, 1999).[13]

In twin pregnancies, interpretation of biochemical screening is clearly more problematic since each serum marker necessarily relates to the pregnancy and is not specific to the fetus, deriving solely a pregnancy- and not a fetus-specific risk. As biochemical screening in twins is still investigational and far less powerful than in singletons, it should not be recommended in general practice. Even if prospective studies demonstrate that biochemical screening in twins is effective, there is a 10% lower detection rate for an acceptable high false-positive rate and if screening is positive there is no distinctive feature to identify which of the fetuses is affected.

In contrast, the availability of a more credible sonographic parameter for trisomy 21 risk assessment in the first trimester of pregnancy shifted the consideration of a *pregnancy-specific risk* to a *fetus-specific risk*. If it is proved that the distribution of NT measurements in twin fetuses with trisomy 21 is similar to that in singletons,[13–16] NT can be considered the gold standard of screening in twins.

In a monochorionic twin pregnancy, presumably, both fetuses will be affected or both will be unaffected. It is therefore appropriate to take the average of the two NT measurements, so that a single risk estimate can be calculated (*averaging method*). Prevalence of increased NT was found twice as much as in monochorionic than in singleton pregnancies, but concomitantly the likelihood ratio of developing twin-to-twin transfusion syndrome (TTTS) in those twins with increased NT was higher (3.5 times).[17,18] In those cases, our group has demonstrated that the combined evaluation of NT and ductus venosus (DV) at 11–14 weeks could anticipate which of them would develop TTTS. In those cases presenting both increased NT and abnormal flow in the DV, TTTS eventually developed (Figure 150.6). In contrast, whenever NTs were discrepant but with normal flow in the DV, no cases of TTTS were found (Figure 150.7).[19,20]

In a dichorionic twin pregnancy, the twins are dizygotic in about 90% of the cases, which means that one of the fetuses, or both fetuses could be affected. As each fetus has an independent risk, the risks derived from NT measurements should be summed (*summing method*) (Figure 150.8). The 10% of dichorionic twin pregnancies that are monozygotic will incorrectly have their risks calculated by the summing rather than the averaging method, but the effect on screening performance will be a negligible one.

For higher-order multiples more credible data have been obtained using NT alone to assess risk in triplets or more.[20] Not only was it feasible and reproducible, but also mean NT was similar for both groups.[21]

Considering that biochemical screening alone cannot specifically identify the fetus at risk in the presence of twins discrepant for Down's syndrome, it seems reasonable to combine NT and maternal biochemical markers, as suggested by Spencer.[22] In this modeled study, it was demonstrated that biochemical screening would add a further 5% to the detection rate obtained by using NT alone and thus offering a detection rate for Down's syndrome of about 80% compared to the 90% in singleton pregnancies, which could be a worthwhile addition. Interestingly, the combined test is more discriminative in monochorionic than

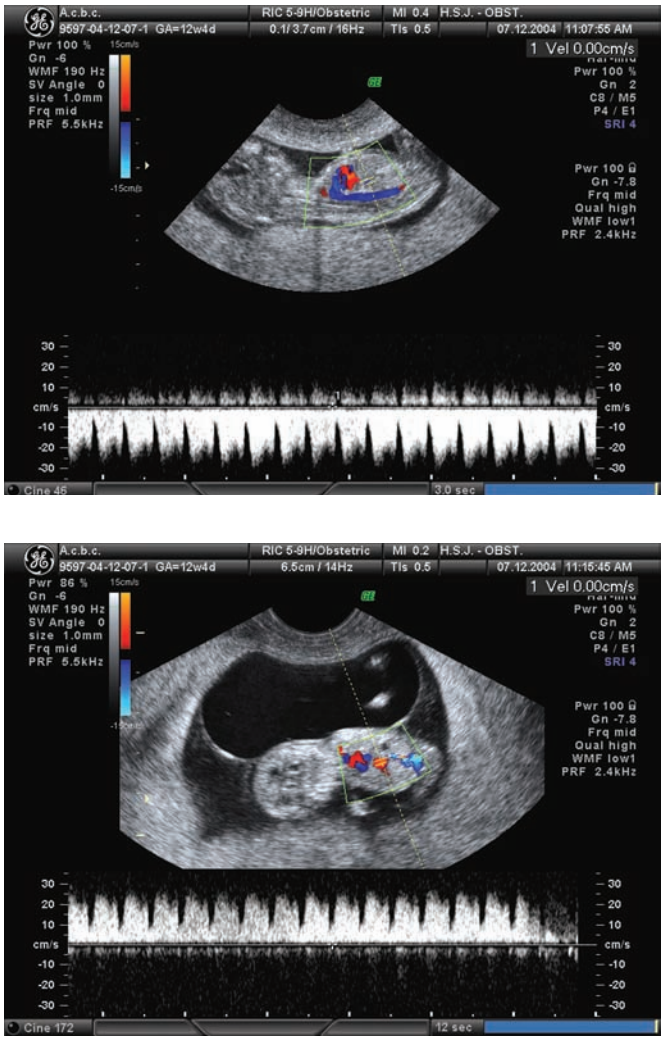

Figure 150.7 Doppler blood flow waveforms in the ductus venosus (DV) obtained in a monochorionic twin pregnancy at 11 weeks of gestation. Both DV waveforms were normal and NT were within normal range and non-discrepant. The pregnancy was uneventful and no TTTS developed.

Figure 150.8 A dichorionic diamniotic twin pregnancy was established at 11 weeks+5 days. The measurements of nuchal translucency (NT) were discrepant (1.1/5.7 mm) and ductus venosus (DV) blood flow was reversed in the fetus with increased nuchal translucency. Amniocentesis revealed a normal karyotype (46,XX) for the fetus with normal NT and DV blood flow; a trisomy 21 was identified in the fetus with increased NT and abnormal flow in the DV.

dichorionic twin pregnancies, since in dichorionic pregnancies the median serum marker level in affected pregnancies will be artificially lowered by the unaffected twin, whereas in monochorionic pregnancies no dilution of the serum markers is expected from an unaffected pregnancy.

Until more data are available from larger studies on the distribution of markers in concordant or discordant twins, NT estimated for each fetuses should be the predominant factor by which women presenting with increased risk should be counseled regarding invasive testing.

Screening and diagnosis of TTTS

TTTS affects about 15% of monochorionic twin pregnancies (1:400 pregnancies) and it accounts for 17% of perinatal mortality. Though clinically identifiable and with expected ominous prognosis, this condition is still far from being effectively anticipated and treated. By definition, it affects *structurally* normal babies, it is a *placenta-based disease*, it is associated with *important perinatal morbidity and mortality* but still is amenable to *curative* therapy.

TTTS reflects primarily a pathological form of circulatory imbalance that develops chronically between hemodynamically connected monochorionic twin fetuses. A vicious cycle of hypervolemia–polyuria–hyperosmolality is established and results in a mid-trimester discordance in amniotic fluid volume and

fetal growth, with signs of hypovolemia and uteroplacental insufficiency in the donor twin and hypervolemia and cardiac dysfunction in the recipient twin.

In the past, diagnosis of the syndrome was made only after delivery of the affected twin pair and careful examination of the placenta. A difference in cord hemoglobin concentrations of 5 g/dl or more and a difference in birth weights of 20% or more established the diagnosis, but both criteria were later found to be inaccurate and non-specific.

Considering the inadequacy of neonatal findings in the diagnosis of TTTS and the more consistent sonographic antenatal criteria,[23–26] ultrasound revealed to be crucial in screening and diagnosing TTTS.

Determination of monochorionicity

TTTS is a syndrome expected to develop in monochorionic pregnancies. Only in the first trimester of pregnancy (10–14 weeks of gestation), type of placentation can be assigned with a 100% certainty. The definition of monochorionicity is based on the presence of the T sign (one placenta with a paper-thin, reflective hair-like septum without chorion between the two amnion) (Figure 150.3a and b).

Discordance in size

In TTTS, the recipient fetus tends to be a bigger and more plethoric baby in contrast with the donor, defined as a smaller and leaner fetus (Figure 150.9). A cut-off value of 20 mm for the difference in abdominal circumference between twins indicated growth discordance of more than 20%.

Discordance in amniotic fluid volume (oligohydramnios sequence)

We understand TTTS as a manifestation of hemodynamic imbalance. Fetal renal perfusion is asymmetric: the congestive heart failure in the recipient will overperfuse the kidneys with consequent polyuria and excess of amniotic fluid; hypovolemia in the donor causes inadequate perfusion of the kidneys with decrease in urinary output and oligohydramnios.

Consequently, differences in the amniotic fluid volume are expected: oligohydramnios if the deepest vertical pool in the donor sac is < 2 cm and polyhydramnios if the deepest vertical pool is >8 cm in the recipient's sac. Not infrequently anhydramnios in the donor sac results in its becoming 'stuck', shrouded by the intertwin membrane, while the recipient's sac becomes severely polyhydramniotic (Figure 150.10). The presence of discordant anomalies in twins that imply differences in amniotic fluid volume, such as one twin with esophageal atresia and consequent polyhydramnios, or with renal agenesis, with consequent oligohydramnios/anhydramnios, is confounding.

Further confirmatory features include a small or nonvisible bladder in the donor, along with a distended urinary bladder with resulting excessive micturition in the recipient.

Figure 150.9 Scan performed at 35 weeks in a dichorionic diamniotic twin pregnancy showing discrepancy > 25% in the abdominal circumference.

Figure 150.10 Image of a stuck twin in a monochorionic twin pregnancy at 20 weeks with TTTS showing a fetus with severe polyhydramnios and the other one shrouded with a thin membrane, with anhydramnios and pushed against the uterine wall.

Abnormal Doppler findings

Alterations in cardiac hemodynamics are indirectly put on evidence by alterations in venous blood flow waveforms. The most striking feature is the reduced or reversed flow during atrial contraction in the DV commonly found in fetuses with congenital heart defects,[27,28] growth retardation (Hecher 1995) and TTTS.[19,20] (Figure 150.6). Hecher and coworkers[29] found umbilical vein pulsations and absent or

reversed flow during atrial contraction in the DV in the recipient with fully established TTTS. Zosmer *et al.*[30] showed that some surviving twins of TTTS had a persistent right ventricular hypertrophic cardiomiopathy with right ventricular tract obstruction (functional pulmonary stenosis) and pulmonary hypertension in the neonatal period.

Recently, diastolic abnormalities were described in the right ventricle, with abnormal filling patterns, prolonged isovolumic relaxation time and abnormal flow patterns in the inferior vena cava and ductus venosus. In addition to hemodynamic remodeling, the role of increased endothelin-1 in the recipient, mainly in the hydropic recipient, as a mitogenic factor to smooth muscle cell in systemic and pulmonary vasculature and for ventricular myocyte proliferation is well recognized.

Abnormalities of vascular distensibility were also described in survivors of TTTS in infancy.[31] The donor fetus shows evidence of chronic hypovolemia causing the activation of the renin–angiotensin system and transfusion of increased concentrations of angiotensin II with increased vascular stiffness in the surviving donor in childhood.

Other ultrasonographic findings

Identification of cord insertion: Velamentous insertion of the cord is more frequent in monochorionic twins.

Funipuncture: Theoretically, it may allow the antenatal evaluation of intertwin hemoglobin difference, the degree of fetal anemia in the donor twin and the twin zygosity through blood group studies. However, middle cerebral artery Doppler studies seem promising in identifying anemia in the surviving twin of a TTTS pair.[32]

Signs of hydrops in the recipient twin: In an advanced stage of TTTS, the recipient twin affected by congestive heart failure may present signs of serosa effusions, such as ascites, pleural effusion and subcutaneous edema.

Difference in color of the placentas: Due to hyperperfusion, the placenta of the recipient tends to be denser in color while the donor tends to show a paler placenta (Figure 150.11).

Figure 150.11 Example of a monochorionic twin pregnancy at 32 weeks with TTTS showing a clear difference in echogenecity between the two parts of the placenta. The placenta from the recipient is more echogenic due to congestion and the one from the donor is less echogenic due to blood depletion. Image courtesy of B. Caspi and I. Blickstein, Kaplan Medical Center.

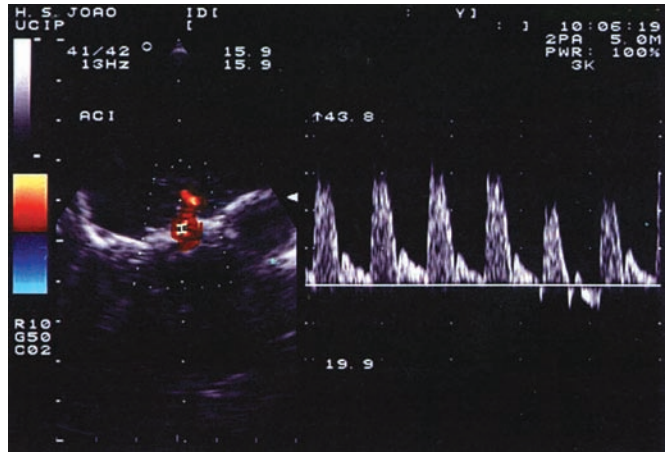

Figure 150.12 Doppler blood flow waveform obtained in the middle cerebral artery. Peak systolic velocity is measured to non-invasively assess the degree of fetal anemia.

Monitoring of anemia in the surviving twin

Intrauterine fetal demise of one fetus in a multiple gestation is a rare event, complicating approximately 0.5–6.8% of twin pregnancies during the second and third trimesters.[33] Demise of both twins has been reported rather infrequently. In higher-order multiples, demise of a single fetus could be more common, ranging from 4.3% to 17% in triplet pregnancies.[34]

The incidence of ominous outcome is dramatically increased in monochorionic twins due to vascular anastomosis. When the death of a co-twin happens, acute hypotension most frequently occurs in the surviving twin with the expected ischemic changes in the spleen, kidney, gastrointestinal tract and skin.[35] More dramatic are the ischemic lesions in the brain of the co-twin, resulting in permanent adverse neurological sequelae (multicystic encephalomalacia, porencephalic cysts).[36,37]

In order to evaluate fetal anemia, invasive techniques such as amniocentesis and cordocentesis are currently used. More recently an alternative noninvasive method, the measurement of middle cerebral artery peak systolic velocity (MCA-PSV), has been proposed to evaluate the level of fetal anemia, namely in pregnancies complicated by rhesus isoimmunization (Figure 150.12).[38] In a study in which a comparison between MCA-PSV and amniotic fluid optical

density at 450 nm was performed, both were useful and reliable in the prediction of fetal anemia, with the former having the advantage of being non-invasive.[39]

In the case of intrauterine death of one twin, in which the surviving twin will endure profound exsanguinations with consequent acute and severe anemia, the measurement of MCA-PSV has been used as a simple and reliable diagnostic tool and may be helpful in counseling and planning invasive assessment.[31] Besides, Senat and coworkers demonstrated that after the correction of the anemia by intrauterine transfusion, MCA-PSV decreased with good correlation between MCA-PSV and hemoglobin concentration.[32,40]

Growth discrepancy in multiple pregnancies: distinguishing between adaptation, promotion and restriction

Discordant growth is a common finding/complication of twin pregnancies. It is commonly accepted regarding this controversial issue that (a) not all discordant pairs are similar; (b) discordant growth does not necessarily represent growth restriction; (c) a discordance level may have a different clinical implication in different gestational ages; (d) the larger the discordance level the greater is the risk for an adverse outcome and (e) the smaller fetuses in severely discordant pairs are at disproportionate risk for perinatal mortality and morbidity.

Intertwin growth discordance may represent a normal variation between sibs working as an adaptive measure to promote gestational age at the same uterine size. Nature seems to favor maturity rather than size: data from large twin and triplet series suggest that significant birth weight discordance result from the inability of the uterine milieu to equally nurture twins.[43] In order to promote maturity – gestational age – mild compensation in the form of size discordance begins after mid-gestation. When the uterine environment competently nurtures multiples, total birth weight increases and discordance decreases. In fact, the entire 'fetal mass' of a multiple pregnancy can exceed the 90th birth weight percentile of a singleton of the same gestational age and the individual fetuses may exhibit growth patterns compatible with adaptation to the limited uterine environment rather than pathological restriction.[41] Adaptation can take the form of relative growth restriction (i.e. discordance in weight or abdominal circumference), whereby not all fetuses show a decelerating growth pattern or hemodynamic compromise.[43]

Further away in this process, when adaptation fails, severely discordant pairs often exhibit patterns of growth restriction. However, even in cases with significant discordance, about 40% of the smaller twins, weigh above the 10th birth weight percentile. Clinically relevant is the fact that recognizing the transition from the physiologic adaptation into the pathologic process of growth restriction. Therefore, the smallest fetus should be evaluated to perceive whether its growth is being promoted (abdominal circumference >P50), adapted (abdominal circumference P5–50) or restricted (abdominal circumference <P5) in conjunction with Doppler blood flow evaluation. From the large series it is recognized that about 75% of twins exhibit <15% discordance (designated concordant), 20% are 15–25% (mildly) discordant, and about 5% are more than 25% (severely) discordant (Figure 150.9).[42,43] Higher frequencies and increased severity are observed among triplets.[44]

Growth curves of twins and triplets do not support the growth restriction pattern seen in singletons. At the same time that individual members of a twin or a triplet set may be smaller than singletons of the same gestational age, only a minority are indeed growth-restricted by singleton standards.[45]

The evaluation of fetal growth depends on stricter sonographic criteria to define normal or abnormal growth. Abdominal circumference rather than head measurements of twins was proposed as the most reproducible and meaningful one. Besides, considering that fetal weight estimations based on singleton growth charts may be inadequate for twins, the abdominal circumference criterion should be definitely used for the sonographic diagnosis of divergent twin growth. A cutoff value of 20 mm for the difference in abdominal circumference between twins indicated growth discordance of more than 25%.

Identification of the genuinely growth-restricted fetuses is an imperative step in the management of birth weight discordance in twin gestations as it has dramatic implications on perinatal morbidity and mortality. Neonatal mortality rates among discordant twins were compared among three groups of discordant twins (> 25%), distinguished by the birth weight of the smaller twin being < 10th, 10th to 50th or > 50th percentile.[45] Among the 10,683 pairs of twins who were studied, the respective proportions of the three groups were 62.4%, 32.9% and 4.7%. The neonatal mortality rate was significantly higher among pairs in which the smaller twin weighed < 10th birth weight percentile (29 vs. 11.1 and 11 per 1000; odds ratio, 2.7; 95% CI, 1.3–5.7). This difference results from the higher mortality rates among the smaller but not among the larger twins. Severely discordant twin pairs in whom the smaller twin is also small for gestational age are at an increased risk of neonatal death.[46]

In order to identify the groups at risk, complimentary to abdominal circumference measurements (Figure 150.9), Doppler blood flow evaluation of the arterial (umbilical artery, middle cerebral artery) and venous (umbilical vein and ductus venosus) compartments should be the next step. Whenever end-diastolic blood flow is absent or reversed in the

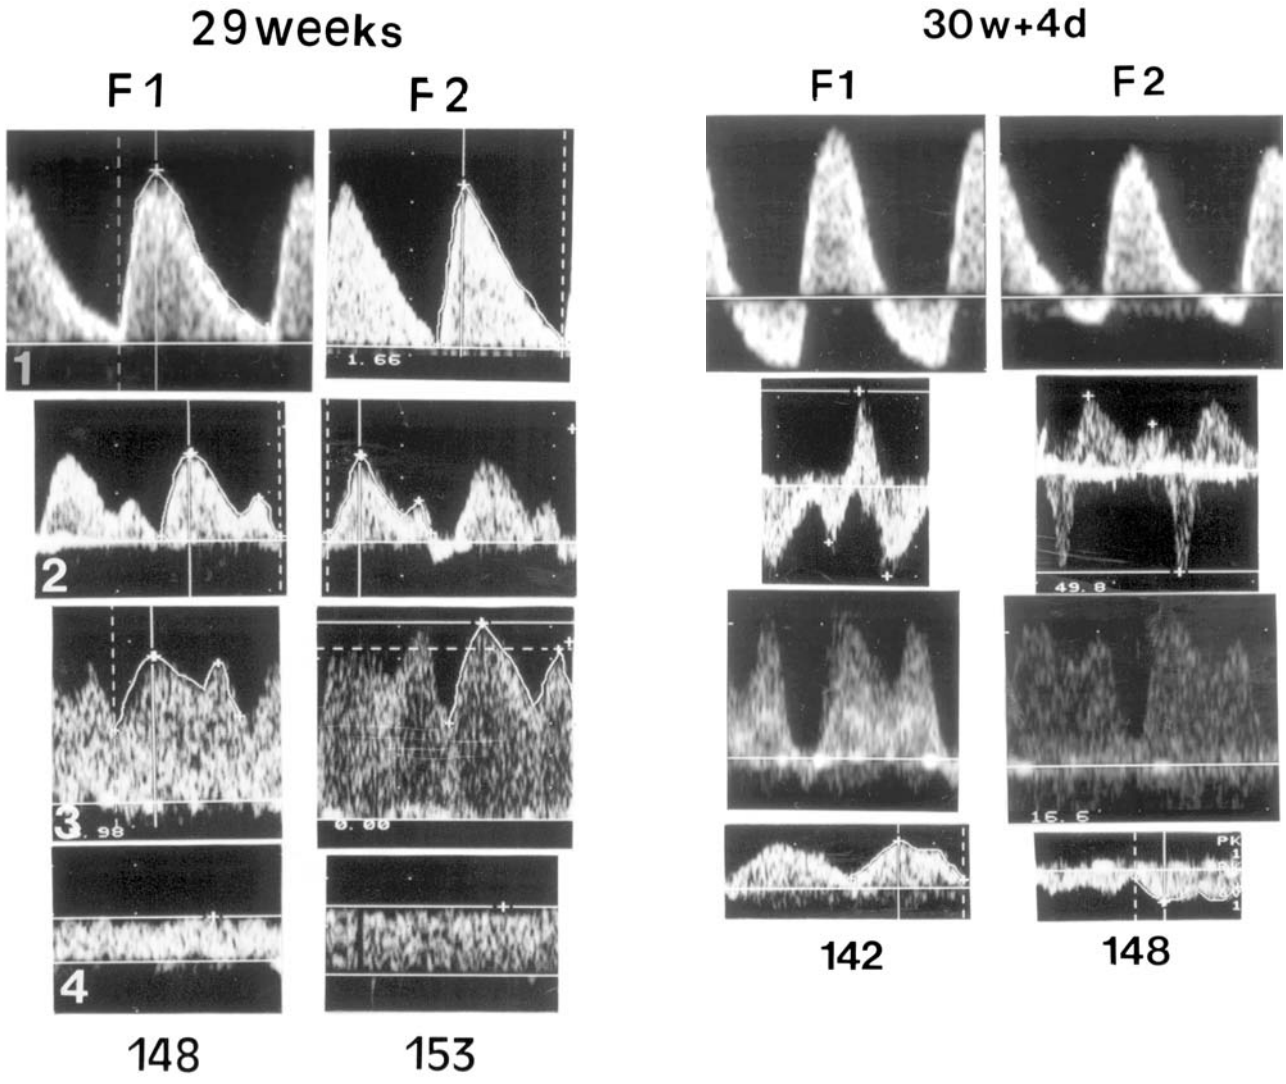

Figure 150.13 Doppler blood flow waveforms from umbilical artery (1), inferior vena cava (2), ductus venosus (3) and umbilical vein (4) obtained in fetuses F1 and F2 of a dichorionic diamniotic twin pregnancy. The first examination was performed at 29 weeks with present end-diastolic flow in the umbilical artery and normal venous flow. The scan performed at 30 weeks +4 days, on the day of the elective delivery, shows reverse end-diastolic flow in the umbilical artery, with a high velocity A-wave in the inferior vena cava, absent flow during the atrial contraction in the ductus venosus and dicrote pulsatile flow in the umbilical vein in both fetuses. Both babies are alive and well, but were born growth-restricted. Reproduced with permission from *Journal of Perinatal Medicine*.

umbilical artery, blood flow in the middle cerebral artery should be assessed looking for adaptive centralization. Venous Doppler waveforms are affected slightly later and depict confidently hemodynamic deterioration and correctly predict acid–base status, mainly when absent or reversed flow appears in the ductus venosus (Figure 150.13).[47–50] The evaluation of amniotic fluid volume as a chronic marker of intrauterine hypoxia may constitute a further differentiating parameter between an adapted or genetically small baby, and a restricted and suffering baby. This hemodynamic deterioration is sequential and can be monitored longitudinally. The timing of delivery has most of its clues in the Doppler flowmetry sequential evaluation both for singletons and multiples, bearing in mind that previously known chorionicity makes a difference when talking about growth discrepancy.

Malformations in multiple gestations

Acardiac twin/TRAP sequence

Acardiac twins were first documented in 1533 and were first diagnosed by ultrasound in 1978.[51] This is a unique complication to monochorionic twinning. Due to a paradoxical retrograde perfusion by a structurally normal ‘pump’ twin there is a disruption of development of the cardiovascular system and a cascade of disruption of organ development in the perfused twin (TRAP sequence – twin reversed arterial perfusion).[52] However, the anomalous twin may have an underlying cytogenetic anomaly or a primary malformed cardiovascular system prior to anastomosis development.

It is a rare condition, occurring with a reported incidence of 1 in 35,000 deliveries, 1% of monozygotic twins and 1 in 30 monozygotic triplets.[53] The

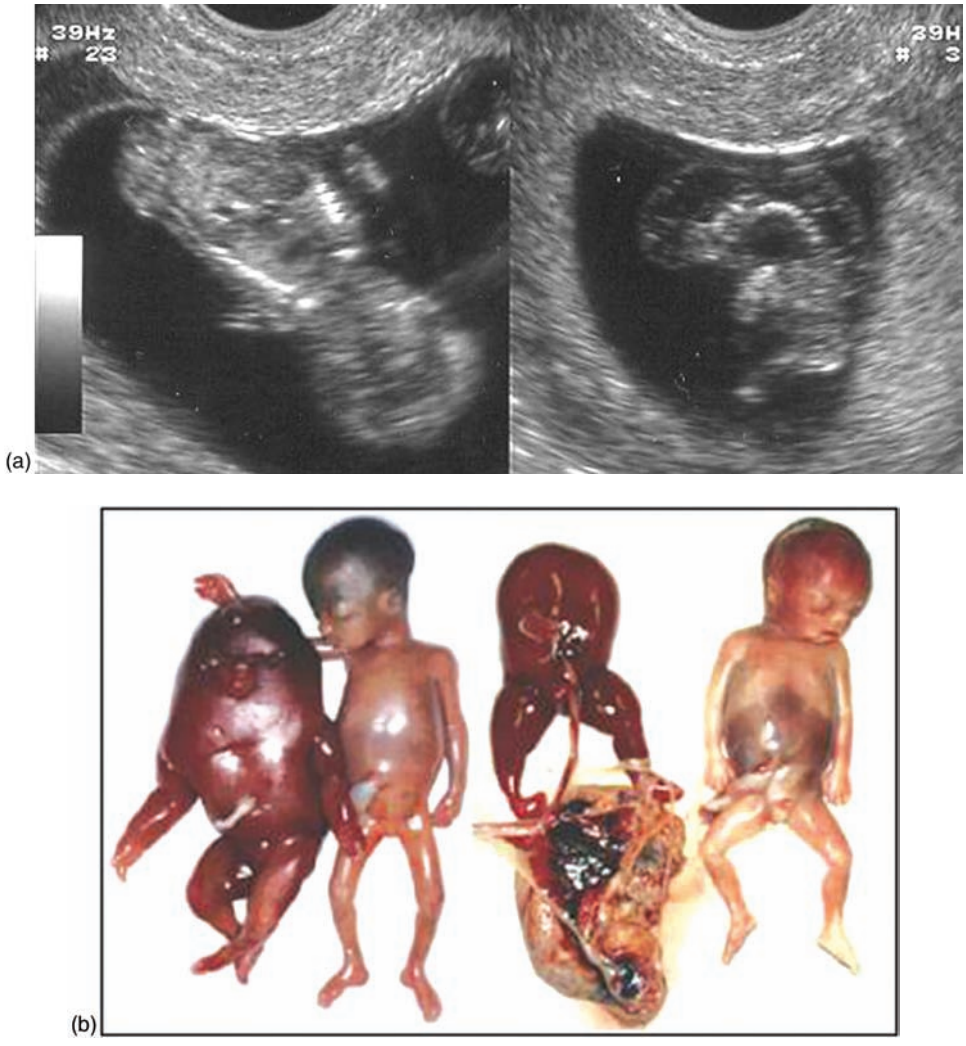

Figure 150.14 (a) Image of an acardiac twin showing a malformed head and trunk and the normal co-twin in the first trimester of pregnancy. (b) Two necropsic specimens of an acardiac twin and the normal co-twin. The one on the right has a rudimentary head ('anceps acardia') and the one on the left represents the most common form of acardiac twin, without head and trunk, with a plethoric appearance. Courtesy of C. Comas.

hemodynamically advantaged or pumping structurally normal twin is at risk for *in utero* cardiac failure and without treatment dies in more than 75% of cases. This risk has three causes: the high cardiovascular demands of the parasitic twin on the pump twin will cause high-output heart failure; an important increase in uterine volume will be caused by the continuing excessive growth of the acardiac twin; and the deoxygenated blood from the pump twin, that will be further deoxygenated by the acardiac twin, will circulate back to the pump twin with a low content of oxygen and will provoke chronic hypoxia and growth restriction.

Acardiac twins can be diagnosed antenatally on the ultrasound by the absence of identifiable cardiac motion. In some cases, due to a rudimentary heart or transmitted pulsation from the pump twin, cardiac pulsation may be suspected. In addition, there is poor definition of the head, trunk and upper extremities, deformed lower extremities, which may show some movements, and usually conspicuous subcutaneous edema and abnormal cystic areas in the upper part of the body of the affected twin[54] (Figure 150.14a and b). In about 70% of the acardiac fetuses, there is polyhydramnios with a functional urinary tract. However, the main clue to the diagnosis seems to be the continued growth of a 'presumed dead' twin on subsequent scans in a monochorionic twin pregnancy.

Color Doppler ultrasound, first used in the prenatal detection as well as documentation of the reversed arterial perfusion, reported by Pretorious *et al.*,[55] is a very useful tool in the definitive diagnosis of an acardiac twin. Those acardiac twins missed in an early pregnancy were those in which color Doppler was not used, namely to put in evidence the two vessel cord (in more than two-thirds of the cases) and the paradoxical direction of arterial blood flow toward rather than away from the acardiac twin, and from caudal to cranial in this twin's abdominal aorta.

Intrauterine diagnosis of acardiac twin has been achieved in some cases in the first trimester of pregnancy,[56,57] suggesting that the pathogenesis in acardia is cardiac dysmorphogenesis secondary to

reversal of blood flow rather than cardiac agenesis, since cardiac beats in the malformed twin were seen until the seventh week and stopped thereafter, along with reversed flow through the umbilical cord into the recipient twin via arterioarterial anastomosis of placental vessels.

Essentially, every single organ system is affected, but the most commonly associated anomalies are cardiac defects: the heart may be completely absent, reduced to tubular or a two-chamber heart. A single umbilical artery is the rule. The lower extremities are usually spared because the femoral arteries contain the most oxygen and nutrients. The abdominal viscera are hardly discernible. The external genitalia may be normal, deficient or absent. The thoracic structures may be present, rudimentary, severely dysplastic or absent. Marked edema and cystic hygroma may be massive. They are typically acephalic with absent upper extremities. When cranial structures are present ('acardius anceps'), or in the rarest form when there are cranial elements but no body structure ('acardius acormus'), anencephaly, holoprosencephaly or facial clefts may be present.

Poor prognostic factors for the pump twin can be assessed by ultrasound: acardiac-to-pump twin weight ratio of $> 70\%$, hydrops in the pump twin, polyhydramnios, acardiac twin with presence of arms or an anceps acardia, a small resistance index < 0.20 in the umbilical artery of both the acardiac and pump twins.[58] Fetal demise will occur unless salvage invasive procedure is performed by disconnecting inter-twin blood circulation. Therefore, TRAP sequence should be monitored on a weekly basis by ultrasound, including size estimation, Doppler flowmetry and echocardiography.

Conjoined twins

Conjoined twins are defined as monochorionic and monoamniotic twins, originating from a single fertilized ovum, fused at any portion of their body as a result of an incomplete division of the embryonic disk, which occurs after the 13th day of conception. The term 'conjoined' is actually a misnomer, since this malformation results from failure of complete separation and not from inadequate fusion. Conjoined twins occur as often as 1 in every 40,000 births but only 1 in every 200,000 live births. The overall survival rate for conjoined twins is between 5% and 25%. Conjoined twins are more likely to be female (70–75%). There are no documented cases of conjoined triplets or quadruplets.

Conjoined twins are usually classified by the point at which they are joined (the Greek word *pagos*, meaning 'that which is fixed'). There have been as many as three-dozen separate types identified in the last century. The most frequent varieties are thoracopagus (40%), omphalopagus (33%), pygopagus (18%), ischiopagus (6%) and craniopagus (2%). The fact of sharing the heart or not makes an important prognostic difference.

Figure 150.15 (a) Scan of thoracopagus conjoined twins at 12 weeks of gestation. Note the parallel, mirror image, head-to-head position of both fetuses, with a shared single heart. (b) Necropsic specimen of the same case, confirming the thoracopagus type of conjoined twins with a single heart.

The first-trimester scan can be very useful to detect and to define the type of conjoined twins.[59] This situation must always be considered whenever a monochorionic monoamniotic twin pregnancy is suspected. Discordant presentation does not exclude conjoined twins.

Basically, the scan must demonstrate fused portion of the bodies of monozygotic–monoamniotic twins (Figure 150.15a and b). Several other sonographic signs can be looked for to avoid misdiagnosis:

- Bifid appearance of the first-trimester fetal pole ('V'- or 'Y'-shaped twin pregnancy)
- Absence of interamniotic membrane between the twins
- Inability to separate fetal bodies and permanent position of the fetus relative to the other, even after maternal abdomen stimulation
- Abnormal number of vessels (more than three) in the umbilical cord

- The heads and bodies of both twins are seen at the same level and a mirror-image can occasionally be seen
- Unusual proximity of the extremities
- Unusual hyperextension of the spines
- Single heart
- Presence of other fetal anomalies.

The timely recognition of this condition enables the parents to consider the possibility of terminating the pregnancy. If not, one should bear in mind that conjoined twins present a higher prevalence of congenital anomalies other than the shared organs of about 50%. Cardiac defects are the most common association (20–30%), and thus echocardiography is recommended in all cases. Neural tube defects and midline fusion defects, orofacial clefts, imperforate anus and diaphragmatic hernia are also frequently seen. Polyhydramnios is observed in more than half of the cases.

Major malformations

It is well established that congenital anomalies are found more frequently in monozygotic twinning than in singleton pregnancies.[60] These anomalies are of different types: some are related to the twinning process itself, others are due to vascular factors, and a few are structural malformations not exclusively found in twins but observed more frequently in monozygotic twinning.[61] The largest study, combining data from nine registries based in European and Latin American countries, analyzed 260,865 twins and 5572 malformations were reported.[61] An expected excess of malformations in twins compared with singletons was found, and all anatomical sites were involved.

Here again, ultrasound has an irreplaceable role in experienced hands and with high-quality equipments in the screening and diagnosis of fetal malformations as early as the first trimester of pregnancy.

151 Genetic diagnosis in multiple pregnancies

Z. Appelman and B. Furman

Introduction

The likelihood of finding chromosomal anomalies and Mendelian diseases is increased in multiple gestations compared to singletons. Prenatal diagnosis may therefore be indicated in multiple pregnancies to a no lesser extent than in the singleton. The most common situations discussed in the context of multiple pregnancies are screening and diagnostic measures to detect aneuploidy, genetic counseling when a structural anomaly is detected and in circumstances with increased risk of specific inherited conditions. The basic rules of genetic counseling in singletons are applicable also in multiples; however, there are specific facets in multiple gestations that need special attention, which makes counseling more complex. Indeed, it is the combination of medical and ethical aspects that makes it so complicated. The basic difference between counseling singletons and multiples is the fact that, as opposed to singletons, any decision in multiples should take into consideration the implication of that decision for the other sib(s). This includes both diagnostic and therapeutic measures. However, genetic counseling is often provided by a general obstetrician, who may benefit from a simplified approach. This chapter describes specific medical situations that require the attention of a genetic counselor.

Prenatal genetic diagnosis – an overview

The incidence of multifetal pregnancies has increased exponentially during the past two decades mostly because of assisted reproduction technologies (ART).[1] Typically, pregnant women after ART are older. Hence, the age-related risk of aneuploidy is often significant. The likelihood of at least one twin having a chromosomal abnormality is five-third times higher than in singleton pregnancy.[2] The decision to undergo prenatal diagnosis in multiple gestations is complex and must take into consideration not only the risk of aneuploidy, but also the procedure-related complications. In addition, abnormal results sometimes require selective termination of an affected sib, a procedure entailing moral, ethical and medical implications. Invasive prenatal diagnosis techniques include chorionic villus sampling (CVS), amniocentesis (AC), cordocentesis, fetal tissue sampling, embrioscopy and fetoscopy (Table 151.1). The indications for prenatal diagnostic genetic testing determined as routine and applicable for singleton and twin gestations are advanced maternal age, familial history of chromosomal abnormalities, previous children with a chromosomal abnormality or neural tube defects (NTDs) and suspected abnormalities identified during sonographic examination.

Advanced maternal age was defined as any expectant mother who will be 35 years old by the time of

Table 151.1 Characteristics of AC and CVS

	AC	CVS
Timing	16–18 weeks	10–12 weeks
Placement	TA	TA and TC
Risk of miscarriage	0.5–1%	TA – 1–2%; TC – 2–6%
Sampling success	99%	99%
Time to diagnosis	3 weeks (FISH available)	2–3 weeks (rapid direct technique may be considered)
Accuracy	High	High
Mosaicism	Rare	Confined placental 1–2%
Open NTD	AFP in amniotic fluid detects 95% of NTDs	Other test required

FISH, fluorescence *in situ* hybridization; TA, transabdominal; TC, transcervical

birth. Nowadays, the age of 35 years still stands as a turning point in prenatal supervision and is recommended as the age at which aggressive screening should be done using AC or CVS. Not everyone accepts categorical age of 35 or even 37 years as an absolute indication for invasive genetic diagnosis. Some would prefer to adjust the risk individually according to the maternal age and some non-invasive risk assessment. In multiple pregnancies, the logical approach would be the combination of maternal age and nuchal translucency (NT) measurement. It is also possible to add to the risk assessment the presence or absence of 'soft' sonographic signs of aneuploidy. It makes sense since chromosomal aneuploidy increases with advanced maternal age. The risk of Down's syndrome in 35-year-old women is 1:365[3] and increases to 1:109 at 40 years and even 1:12 at 49 years. The overall probability that a multiple gestation contains an aneuploid fetus is directly related to zygosity. The risk of both twins being simultaneously abnormal in monozygotic (MZ) twins is the same as the age-related risk in singletons, since one oocyte was fertilized. In contrast, for dizygotic (DZ) twins, each of the fetuses has an independent risk of abnormal chromosomal composition, because at least two different ova were fertilized. Clinically, the risk of only one affected fetus in a dizygotic pregnancy is approximately two times the age-related risk of a singleton. Since the risk of only one affected fetus in MZ twins is basically zero,[4] the overall birth prevalence of Down's syndrome is only 3% greater in twin pregnancies than in singletons.[5] The risk of both the fetuses having a chromosomal abnormality is small. If zygosity is unknown, the risk of one aneuploid fetus can be approximated as five-thirds that of a singleton.[6] This is based on the principle that one-third of twins are MZ. However, this is only an unfulfilled approach because rates of MZ and DZ twins are dependent on maternal age, ethnicity and mainly on the mode of conception.

MZ (twinning from a single egg) twins happen once in 250 pregnancies. This is unaffected by age, race or any other factors except mode of conception. In DZ, or 'fraternal', twins not only maternal age, but also the parity increases the chances of twins. The frequency of twins is three times higher in women over 35 years with at least four other children than in nulliparas under 20 years of age. When parity is considered alone, the chance of twins doubles from the first pregnancy to the fourth pregnancy. African-American women have a 1:79 probability for twins, Caucasians 1:100 and Oriental women 1:155.

Spontaneous twins occur in 1 in 80 births, but in the era of ART and the trend toward delayed childbirth increased dramatically and the incidence of twins is now 1 in 40 births. The increasing use of ART procedures (defined as any procedure that entails the handling of both eggs and sperm or of embryos for the purpose of establishing a pregnancy) and other non-ART fertility treatments (i.e. intrauterine insemination and ovulation-inducing drugs) in the past two decades increased the multiple birth rates.[7,8]

Another factor that increases the twinning rate is the concurrent shift in maternal age distribution as more women delay childbearing into their late 30s and 40s. The extraordinary rise in high-order multiple births over the past two decades, especially in triplet births, has also been associated with the above-mentioned trends: advances in and greater access to ovulation-inducing drugs and ART, and older age at childbirth.[9] Since 1990, the twin birth rate rose 80% among women 40–44 years of age (from 24.7 to 44.5 per 1000), and almost 600% among women aged 45–49 years (from 23.8 to 155.7 per 1000), compared to only a 6% rise for women under age 20 years (14.3–15.2 per 1000). Data are not available, however, for women aged 50–54 years, but in 1999 more than one-third of births (34%) to women in the oldest age group were twin deliveries.[9]

Determination of chorionicity

Determination of chorionicity is crucial in assessing the perinatal risk as well as the risk of aneuploidity and is probably the most important factor in genetic counseling in multiples.[10] In addition, it helps in perinatal risk assessment.[11] The probability of both the DZ twins being chromosomally abnormal is the product of their separate probabilities. For example, the age-related risk for Down's syndrome in a woman is 1:100 for singletons as well as for each twin, thus the probability of having the syndrome for both is $1:100 \times 1:100 = 1:10{,}000$.

First-trimester ultrasound is now accepted as the most accurate for determination of chorionicity (Figure 151.1). Identification of the twin-peak sign in the first trimester provides 100% accuracy for the diagnosis of dichorionic (DC) twins.[12] However, accuracy is reduced when chorionicity assessment is performed later in pregnancy. In midtrimester, after the fusion between the chorion and the amnion, the accuracy of chorionicity determination is about 90%.[13] Other techniques for chorionicity determination like septal thickness measurements and counting the number of intertwin membranes are less popular and seem to depend on the operator's skills and the transducer in use.[14,15] It should be stressed that one-third of MZ twins are DC. However, at present, it is impossible to differentiate DC MZ from DC-like-sex DZ twins on clinical grounds. It follows that assessment of both the twins is inevitable in all DC twins irrespectively of zygosity.

From the genetic point of view, monochorionic (MC) twins imply monozygosity and high genetic resemblance. On the other hand, only unlike-sexed DC twins are 100% DZ, and zygosity is unknown in all like-sexed DC twins. This uncertainty is even greater in iatrogenic conceptions, because the proportion of DZ to MZ twins (about 10:1), as well as the proportion of DC to MC in the subpopulation of MZ twins (proportion

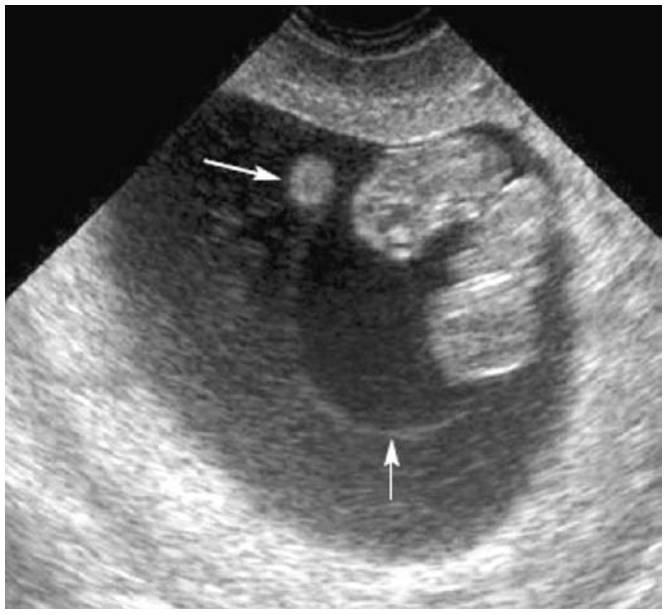

Figure 151.1 A single yolk sac (upper arrow) and two fetuses were observed within a single amniotic sac (lower arrow). This sonographic scan at 9 weeks led to the diagnosis of monoamniotic twins. Image courtesy of B. Caspi, MD, Kaplan Medical Center.

unknown), is different from that of spontaneous conceptions. When chorionicity is unclear and management decisions might be altered by determination of zygosity, prenatal DNA studies should be considered. An example of the difficulty arising from inconclusive chorionicity determination in the later parts of pregnancy is presented in a case of twin pregnancy discordant for hydrocephaly and oligohydramnios in which sonographic evaluation could not exclude MC twinning. Before considering selective feticide, blood samples from both the fetuses were examined by DNA 'fingerprint' analysis. The different banding patterns of the blood samples established dizygosity.[16] Similarly, DNA zygosity studies were performed on amniocytes to guide the management of four such pregnancies.[17] In this series, DNA zygosity analyses provided >99% likelihood of MZ twins in two cases, a fact that altered counseling regarding selective termination options.[17] In the other two cases, DNA studies were used to assess risk to the normal twin in the event of the co-twin's demise, based on the differentiation of twin–twin transfusion syndrome (TTTS) from discordant severe intrauterine growth restriction (IUGR) and oligohydramnios.[17]

Should all MC twin gestations receive genetic counseling?

MZ twins have a two- to threefold increased risk of structural anomalies. When an MC gestation comes to the attention of the genetic counselor, the patient should be informed about this risk, and should be referred for a comprehensive sonographic scan, including detailed echocardiography. When a discordant structural anomaly is found, discussion of management options should consider the vascular anastomoses between the circulations of the twins. This circumstance precludes termination of the anomalous twin by intracardiac KCl injection, which may lead to the so-called 'embolization' syndrome. Selective termination of the malformed twin can be carried out by one of the cord occlusion techniques. Similarly, single fetal demise of a MC twin may indicate appropriate counseling regarding the potential damage to the survivor. When a case of MC twins is referred early enough, there seems to be a clear benefit of NT measurement. Although NT assessment may be indicated in all twins in order to detect chromosomal aberrations and cardiac anomalies, an increased NT in MC twins may also be an early sign of TTTS. It should be noted, however, that the risk of TTTS is mainly associated with MC–diamniotic twins and is rarely seen in MC–monoamniotic twins.

The fact that utility of biochemical screening in twins is limited and practically not available in higher-order multiples only underscores the importance of performing NT measurements in all multiples (Figure 151.2a and b). Sebire *et al.*[18] prospectively screened 448 twins at 10–14 weeks of gestation. Fetal NT thickness was measured by ultrasound examination at 10–14 weeks. Sensitivity and false-positive rates of screening for trisomy 21 by a combination of fetal NT thickness and maternal age were calculated. In the 448 twin pregnancies, the NT thickness was above the 95th centile of the normal range (for crown–rump length in singletons) in 65/896 fetuses (7.3%), including 7/8 (88%) with trisomy 21. Increased translucency was also present in four fetuses with other chromosomal abnormalities. In the chromosomally normal twin pregnancies, the prevalence of increased NT was higher in fetuses from MC (8.4%, 16/190) than in those with DC pregnancies (5.4%, 37/688). The minimum estimated risk of trisomy 21, based on maternal age and fetal NT thickness, was 1 in 300 in 19.5% (175/896) of the twins including all eight of those with trisomy 21. They concluded that in twin pregnancies, the sensitivity of fetal NT thickness in screening for trisomy 21 is similar to that in singleton pregnancies, but the specificity is lower because translucency is also increased in chromosomally normal MC twin pregnancies. In another study,[19] 67 twin pregnancies were identified at the time of an ultrasound scan for determination of fetal NT thickness, where the parents requested karyotyping. The risk of chromosomal defects in each fetus was calculated from the maternal age and the fetal NT thickness at 10–14 weeks of gestation. If the estimated risk of either fetus was 1 in 50 or greater, CVS was the method of choice, whereas if the risk was less than 1 in 50, second-trimester AC was performed. The estimated risk of trisomies was more than 1 in

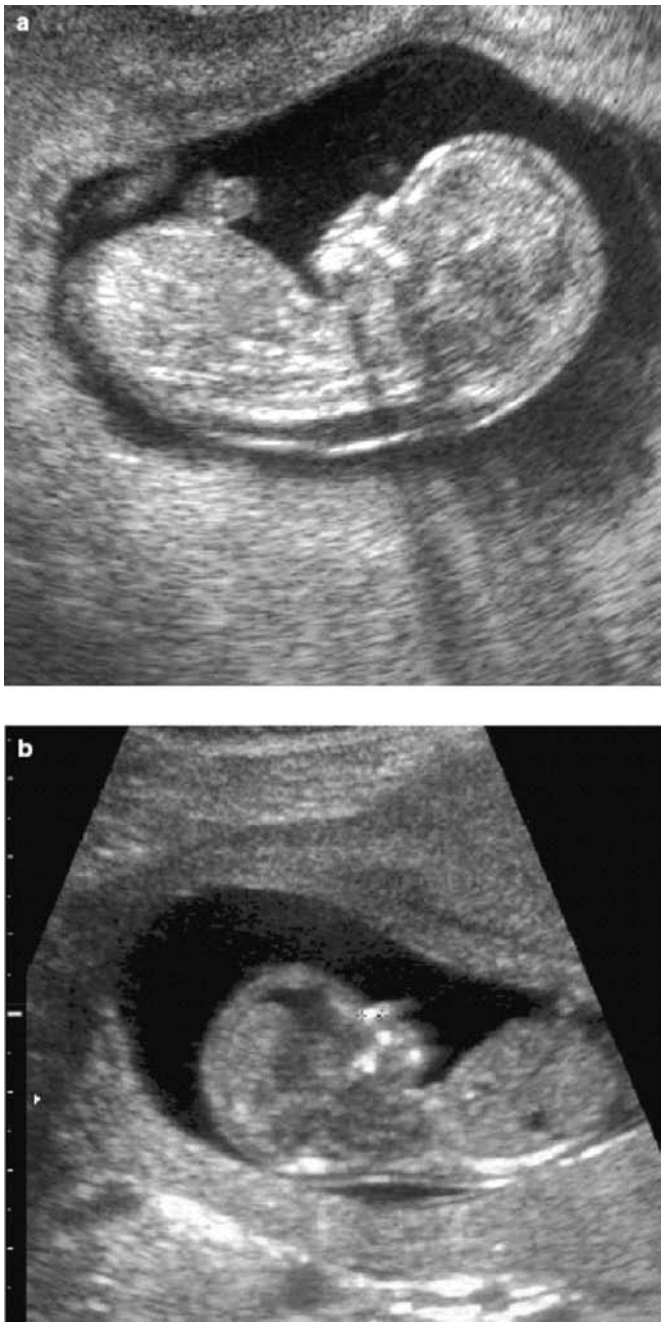

Figure 151.2 Twins screened for NT and the absence of a NB. (a) Image showing an increased NT and absent NB. (b) Image showing a normal NT and presence of a NB (calipers). Images courtesy of B. Caspi, MD, Kaplan Medical Center.

50 in 34 pregnancies and 23.5% of these fetuses were found to be chromosomally abnormal. In contrast, in the 33 low-risk pregnancies, chromosomal abnormalities were found in only 1.5% of the fetuses. The conclusion was that in twin pregnancies, the technique for fetal karyotyping may be selected by calculating the risk of chromosomal abnormality based on maternal age and fetal NT thickness.

The evaluation of screening for fetal trisomy 21 in the first trimester of twin pregnancies by a combination of maternal serum biochemistry and ultrasonography was presented by Spencer *et al.*[20] The population included 230 twin pregnancies in women of all ages presenting with pregnancies between 10 weeks 3 days and 13 weeks 6 days of gestation. Screening using a combination of maternal serum free β-human chorionic gonadotropin (hCG) and pregnancy-associated plasma protein-A (PAPP-A) and fetal NT thickness was offered. Women at increased risk of carrying a fetus with trisomy 21 or trisomy 13/18 ($\geq$1 in 300 at sampling) were offered counseling and an invasive diagnostic procedure. For women who on examination were at 14 weeks of gestation or greater, screening was performed in the same time frame using only maternal serum free β-hCG and alpha fetoprotein (AFP). Overall, 97.4% of the women with twins (224/230) accepted first-trimester screening. The rate of detection of trisomy 21 was 75% (3/4). A risk of trisomy 21 was calculated for each fetus based on the individual fetal NT thickness and the maternal biochemistry. The false-positive rate among those eligible for first-trimester screening was 9.0% (19/206) of pregnancies and 6.9% of fetuses (28/412). Uptake of invasive testing was 59% (10/17) with CVS in eight cases and AC in two. One case of trisomy 21 was identified for every three invasive procedures. First-trimester screening for trisomy 21 in twin pregnancies was both theoretically possible and practically achievable using a combination of NT thickness and maternal serum biochemistry. However, dilemmas for the mother and health professionals when both NT thickness measurements are normal might suggest that greater reliance be placed on the NT thickness risk alone when counseling women about invasive testing.

In a study of 180 twin pregnancies, Spencer[21] has examined the distribution of maternal serum free-βhCG and PAPP-A, in addition to fetal NT thickness, in twins classified as MC or DC, based on ultrasound appearance at 10–14 weeks of gestation. In 45 MC and 135 DC twin pregnancies the multiple of the median (MoM) of free βhCG was not significantly different (1.00 vs. 1.01), while that for PAPP-A was lower (0.89 vs. 1.01), but with no statistical significance. Previous reports of an increased fetal NT in MC twin pregnancies were not confirmed (1.03 vs. 1.00). It was concluded that the existing pseudorisk twin correction algorithm is appropriate for both MC and DC twins in providing accurate first-trimester risks of trisomy 21.

It is currently not definite whether the absence of the fetal nasal bone (NB) (sign for trisomy 21) during NT measurements will significantly increase the screening efficacy of ultrasound in twin pregnancies (Figure 151.2). The absence of NB has been noted in trisomy 21 fetuses at first-trimester ultrasound. In the study of Zoppi *et al.*,[22] the NB was evaluated in relation to fetal karyotype in unselected pregnancies. The fetal facial profile was examined at the 11–14 weeks' scan for screening by NT. NT screening was performed in 5532 fetuses from 5425 pregnancies (85 twins, 8 triplets,

2 quadruplets). The visualization of fetal profile was obtained in 5525 fetuses (99.8%), and in 5491 fetuses (99.4%) the NB was present and in 34 cases (0.6%) it was absent. Fetal karyotype and pregnancy outcome were available in 3503 pregnancies, and 40 chromosomal abnormalities were diagnosed (27 trisomies 21, 5 trisomies 18, 2 trisomies 13, 3 Turner syndromes, 1 partial trisomy 9 and 2 others). The NB was absent in 19 (70%) trisomies 21, 4 trisomies 18 (80%), 2 Turner syndromes (66%), in the partial trisomy 9, in 7 normal karyotype fetuses (0.2%) and in a case with spontaneous first-trimester abortion before prenatal diagnosis. A significant difference was found between NT thickness, expressed as an MoM, in trisomy 21 fetuses with NB present and absent.

Invasive diagnostic procedures

When considering an invasive diagnostic procedure, complications, such as procedure-related fetal loss, are weighed against the probability of an abnormal result. The accuracy of the procedure is of importance as well. The conventional approaches include second-trimester AC or first-trimester CVS. The gestational age at which the procedure is performed should be considered because most patients favor an early diagnosis. Moreover, early diagnosis in multiple pregnancies enables early decision making concerning selective termination of an affected fetus or termination of the entire pregnancy.

AC was first described by Elias *et al.*[23] The procedure is routinely performed between 16 and 20 weeks' gestation. Ultrasound is performed for appropriate fetal measurements, number and location of each placenta and location and characteristics of the dividing membrane. A 22-gauge needle is inserted under continuous ultrasound guidance into one sac and fluid is retrieved, 1–2 ml of inert dye (indigo carmine) is injected and the needle is removed. In the same fashion, a second needle is inserted into the second twin sac under ultrasound guidance and clear, dye-free fluid is retrieved.

With improvement of ultrasound technology and diagnostic skills, another technique for AC sampling was proposed without using the dye.[24,25] In this technique, the initial ultrasound examination visualizes both sacs and the dividing membrane in the same plane. The needle is inserted into the first sac, fluid is retrieved and under direct visualization the needle is pushed through the dividing membrane into the second sac. Using this technique, misdiagnosis may occur due to possible sampling twice the same sac or due to possible cell contamination.

Sampling in MC pregnancy is an additional challenge. Because the fetuses develop from the same zygote, the karyotypes should be exactly the same, and, therefore, sampling of both sacs is not recommended. There are rare cases in which MC twins have discordant chromosomal results. Given that the diagnosis of monochorionicity was accurate, postzygotic non-disjunction can lead to such discordant karyotypes. Because of the rarity of these events, most authors do not recommend sampling of both sacs in cases with characteristic signs of monochorionicity.

Late karyotyping

Karyotyping is possible not only in the first trimester (by CVS) but also in the third trimester by late AC.[26] Late karyotyping after viability carries certain advantages in extremely high-risk pregnancies by avoiding the risk of miscarriage following second-trimester AC. Criteria for late AC include women over 41 years, conception after prolonged infertility and systemic diseases during the period of second-trimester AC.[27] Undoubtedly, this practice is applicable only in countries where the law permits termination of pregnancy after viability. This approach is based on studies of third-trimester AC showing that fetal karyotyping in late gestation provides accurate results with a better fetal outcome in terms of deliveries beyond 30 weeks of gestation.[28] In addition to medicolegal considerations, this practice raises significant ethical dilemmas: which pregnancies are of 'extremely high-risk', should one perform late AC for all pregnant women and avoid procedure-related term birth, should one perform late AC 'per request'.

The loss rates following AC in multiple gestations

There are no randomized control trials documenting the safety of AC in multiple gestations. Figure 151.3 shows the pregnancy loss rates before 20 and 28 weeks in various studies.[25,29–36] Pregnancy loss rates in these studies ranged from 0% to 6% until 20 weeks and from 0% to 8% until 28 weeks. Overall, the mean pregnancy loss until 20 weeks is 1.9% and 3.5% until 28 weeks. The risk of pregnancy loss before 28 weeks in unsampled twins after a normal second-trimester ultrasound is 4.5%–7.2%.[28] Ghidini *et al.*[34] reported similar pregnancy loss rates between twins and their gestational age-matched unsampled controls, (3.0% vs. 2.8%, respectively). The rate of procedure-related pregnancy loss after AC in twin pregnancies is not different from that of singletons and is empirically estimated to be approximately 1%. However, Yukobowich *et al.*[38] in a retrospective study comparing 476 women with DC twins undergoing AC and 477 sampled twin pregnancies found a statistically significant difference between pregnancy loss rates at 4 weeks after AC (2.7% vs. 0.6%, respectively; $P=0.01$). A recent study of Toth-Pal *et al.*[39] compared spontaneous pregnancy losses between 175 women with twins after AC and 300 twin pairs as controls. The authors found that spontaneous losses in multiple pregnancies between 18 and 24 weeks occurred in 2.39%, whereas if AC was performed, the loss rate before the 24th week was 3.87%. Despite the non-significant statistical difference, the investigators

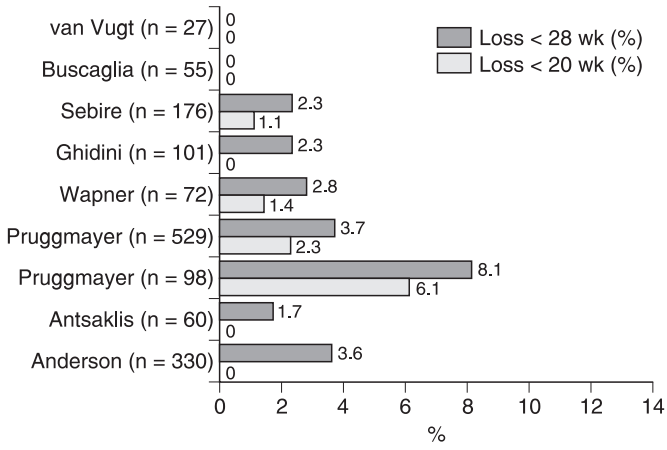

Figure 151.3 Pregnancy loss rates after AC in twins.

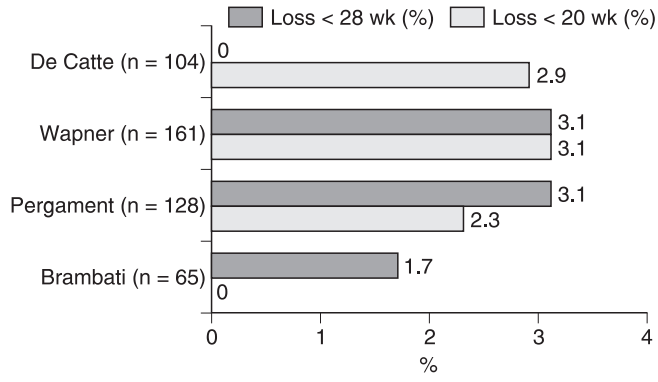

Figure 151.4 Pregnancy loss rates after CVS in twins.

concluded that genetic AC in multiple pregnancies slightly increases the fetal loss rate until the 24th week. Moreover, patients undergoing AC for twins should be informed that there is a greater risk of pregnancy loss than in singletons, although most cases are not related to the procedure.

CVS in twins

CVS has emerged as a safe and efficacious alternative to AC for the identification of genetic abnormalities. The standard of care is to perform CVS after 10 gestational weeks in order to avoid limb reduction defects. A detailed ultrasound examination should be undertaken to determine fetal age, chorionicity, placental location and the presence of major malformation. Performance of CVS in multiple pregnancies demands an accurate assessment of the site of placental implantation for each fetus and zygosity determination. Both transcervical and transabdominal approaches are used for carrying out this procedure.[40] Some pitfalls exist when performing CVS because there is no apparent way to ensure sampling of each frondosum site. Therefore, the same fetus can be inadvertently sampled twice. In some studies, the intertwin villi contamination and sampling errors occurred in about 4% of the samples.[41] Another study compared the diagnostic accuracy of second-trimester AC ($n=297$) and CVS ($n=163$) in twins and triplets.[42] Successful sampling using the two-pass approach was achieved in 99.3% vs. 99.7%, respectively. Uncertain results were present in seven CVS cases (five with placental mosaicism). No uncertain results were found in the AC group. Four of the 15 triplet sets were sampled by CVS and 11 underwent AC; however, one from each group required further AC due to abnormal results. The authors conclude that fetal cell contamination and confined placental mosaicism can be kept to a minimum with CVS and do not lead to critical mistakes.

Loss rates following CVS in multiple gestations

First-trimester CVS in multiple gestations appears to have pregnancy loss rates comparable to that of AC. Figure 151.4 represents pregnancy loss rates after CVS in twins. According to these,[33,40,41,43] the rate of pregnancy loss until 20 weeks following CVS is 2.3–3.1%, and 1.7–3.1% until 28 weeks. In 458 twin pairs, the overall pregnancy loss rates before 20 as well as before 28 weeks were similar (2.8%). Wapner *et al.*[33] compared the procedure-related loss rates between first-trimester CVS and second-trimester AC. Fetal loss rate following the procedure until 28 weeks' gestation was 2.9% following AC and 3.2% following CVS. Altogether, the total fetal loss (corrected for anomalies) was 9.3% following AC and only 4.9% following CVS. It was therefore concluded that CVS is at least as safe and as reliable as AC for prenatal diagnosis of twin pregnancies.

Figure 151.5 shows the reported outcomes of CVS in twin pregnancies by pregnancy losses before 22 weeks of gestation and by total fetal loss.[33,40,41,43] In 614 twin pregnancies, the mean rate of pregnancy loss before 22 weeks was 3.1%, and the mean total pregnancy loss was 4.6%.[44]

Counseling of the older patient

The increased maternal age in multiple pregnancies observed worldwide has led to adapted approaches to these patients. On the one hand, the risk of aneuploidy is age dependent, placing the older mother at increased risk. On the other hand, every invasive diagnostic test entails risks of miscarriage, and very rarely infection and fetal injury. Many of these pregnancies are considered 'premium' because of adverse prior maternal reproductive history; the reluctance for invasive testing in the older patients seems understandable.

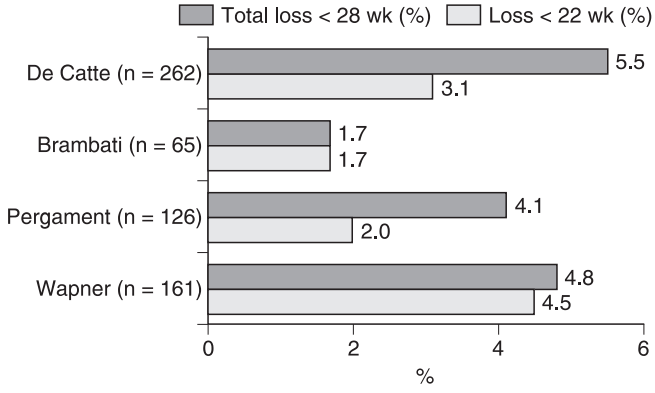

Figure 151.5 Outcome of CVS in twins.

Calculations suggest that the risk of aneuploidy (mainly trisomy 21) in one of the fetuses in DZ twins should lower the maternal age at which AC is recommended in singletons (from 35 to about 32 years). Meyers *et al.*[45] tried to determine the maternal age at which twin gestations have a risk of fetal aneuploidy comparable to that of singleton pregnancies at maternal age 35 years, accounting for variation in DZ twinning rates by maternal age and race. Known aneuploidy risks and rates of DZ twinning by maternal age and race were used to calculate the risk of fetal aneuploidy at term and in the second trimester by maternal age and race in twin gestations. The risk of at least one aneuploid twin at term was 1/193 at maternal age of 31 years for both white and African-American women, which is comparable to the risk of 1/192 for an aneuploid singleton-term pregnancy at maternal age 35 years. The risk of at least one aneuploid twin at AC at maternal age 31 was 1/190 for Caucasian and 1/187 for African-American women, which is slightly lower than the rate in singletons of 1/135. They concluded that invasive prenatal diagnosis for detection of fetal aneuploidy should be offered to all women with twin gestations at age 31, regardless of race. This risk, however, has not been accepted as an indication for invasive genetic testing. A Belgian group recently collected 512 prenatal diagnoses (AC or CVS) from 278 twin pregnancies.[46] The most frequent indications were maternal age ≥35 years (38.8%), assisted reproduction (12.3%) and suspicious ultrasound findings (7.2%). Autosomal chromosome aberrations were found in eight twin sets (2.9%): four inherited balanced rearrangements (two Robertsonian translocations and two paracentric inversions of chromosome 11) and four cases of trisomy 18. Surprisingly, the authors did not detect any trisomy 21 in this population.

A remarkable issue is the case of pregnancies following the use of donor oocytes. Naturally, one may think that the donor's age should be used for aneuploidy risk assessment. However, the donor's age may not always be known or reliable. For example, in a series of established pregnancies from oocyte donation in women aged ≥50 years, the authors found one case of Down's sydrome in 23 infants.[47] Although this single case does not imply an increased risk in pregnancies following oocyte donation, it demands the same attention as all other multiples to markers of aneuploidy.

'Reversed' cytogenetics

Reversed cytogenetics refers to an indication for cytogenetic analysis following a suspected or a pathognomonic ultrasonographic finding. The literature is replete with such signs in singletons, but, regrettably, does not discuss extensively the value of these signs in multiples. It should be remembered that some findings, which indicate further assessment in singletons, are seen more frequently in twins (i.e. major anomalies, such as cardiac malformations, or minor anomalies, such as a single umbilical artery, IUGR, polyhydramnios, oligohydramnios, etc.). Regardless, the approach in such cases should be the same as in singletons with the same presentation.

Ethical consideration

Genetic counseling frequently involves tough ethical issues. In the antepartum period, a conflict may arise in the case of discordant anomalies, when any form of treatment of the anomalous twin may endanger the co-twin. For instance, consider the possibility of a DC twin pregnancy with a suspected discordant chromosomal anomaly. Would it be ethical to perform an invasive procedure to reach the diagnosis, and, at the same time, put the co-twin at risk for potential adverse outcome? Moreover, in the context of multiple pregnancies, these issues are not restricted to prenatal diagnosis only. It may start postpartum with parental requests for zygosity diagnosis of their infants. In the absence of a medical indication, would it be ethical to perform any procedure to satisfy the curiosity of the parents to know if their twins are 'identical'? This may go on to adulthood, when one twin of an MZ set is diagnosed with a late-onset genetic disease. Is there an ethical obligation to reveal the patient's disease state to his/her co-MZ twin? Finally, consider the situation when one twin wishes to know the results of her deceased mother's tests for *BRCA1* mutations (increased risk of breast cancer) and the second twin objects to researchers making this information available.[48] Who is in a position to decide? Obviously, answers are not at hand, and for many cases called into question, the lines of ethic certainty become less clear. Unfortunately, is seems that technical advances will always precede ethical dilemmas, and in this respect, especially in multiple pregnancies, the future does not seem to facilitate the ethical conflicts in genetic counseling.

152 Intrauterine behavior of multiples

B. Arabin and J. van Eyck

Introduction

The phenomenon that two or more children simultaneously grow *in utero*, are borne by the same mother and are characterized by specific similarities in features, behavioral expression and interaction has inspired mythological and religious stories, artists, writers and finally also researchers since ancient times. Hippocrates as well as further Greek and Roman scholars discussed the twinning phenomenon.[1] Prenatal activity and communication of twins was already anticipated in the Bible: Esau and Jacob were supposed to struggle in the womb for the right to breath, to cry or to be welcomed *ex utero* as the first.[2]

In his classical paper *The History of Twins as a Criterion of the Relative Powers of Nature and Nurture* dated 1876 Sir Francis Galton was the first to argue that twins could be of value in the study of the effects of hereditary and environmental influences.[3] Still, not until the 1920s did it become obvious that there are different kinds of twins. The breakthrough of the 'twin method' relating to either mono- or dizygocity being an 'experiment of nature' and a challenge for scientific exploration, dates back to observations of the American psychologist Curtis Merriman and the German dermatologist Hermann Siemens in 1924.[4]

The classic twin method is based on some assumptions: monozygotic (MZ) twins or higher order multiples originate from splitting of the same zygote into two or more embryos during the first 14 days after fertilization and subsequent separate development. Any difference recognized between the MZ co-multiples necessarily is supposed to originate from environmental – which means other than genetic factors – influences. The other mechanism is polyovulation and consequent multiple fertilization resulting in the simultaneous development of dizygotic (DZ) or polyzygotic (PZ) siblings. Both, MZ and DZ twins are of the same age and share prenatally and usually to a large extent also postnatally the same environment. It is assumed that the extent of any characteristics exhibiting a higher within-pair similarity in MZ compared to DZ co-twins reflects the genetic control of a specific variable.

There have been doubts about how far results based on the twin method represent a general population. Bias can arise from antenatal (e.g., different forms of twinning or specific risks of multiple pregnancy) and postnatal (e.g., varieties in the common environment) conditions. Also, the last decades have witnessed tremendous progress in cytogenetics, molecular genetics and chronogenetics. Still, the study of twins remains a precious tool in behavioral genetics, developmental studies, matched-pair designs and epidemiology.

Focusing on prenatal twins and multiples[5,6] and using more sophisticated techniques of supervision and statistical analysis it might be possible to observe still unknown phenomena and achieve new perspectives of human development under normal and pathological conditions.

Methods to describe prenatal behavior of multiples

Brief summary of methods used in singleton pregnancies

Despite over 100 years of interest in prenatal behavior in the medical literature[7] and over 20 years of systematic research initiated by the Prechtl's group,[8–10] the examination of prenatal behavior is still not widely accepted as a potential tool for researchers and clinicians. Difficulties start from its definition, which may be characterized by 'any observable action/reaction towards stimuli'.[11]

Embryonic and fetal movements emerge during the first trimester with 'just discernible movements' at around 7 completed weeks. Subsequently, more complex movement patterns emerge, many of them remaining recognizable throughout life. Prenatal motility is considered to reflect the developing nervous system and involves functional and maturational properties of hemodynamics, muscle or organ tissue.

For the investigation of prenatal behavior various methods have been applied: Fetal body movements *in utero* were first recorded objectively with a kymograph by Haled in 1905 using the displacement of an inverted glass funnel by the distortions of the maternal abdominal wall resulting from movements of the underlying fetus.[12] In 1944 Hooker observed movements and reflexes after cutaneous stimulation of embryos after therapeutic terminations of pregnancy by hysterotomy maintaining them at body temperature in an isotonic fluid bath.[13]

With the introduction of real-time ultrasound, it became possible to observe prenatal motility *in utero*. Reinhold was one of the first to describe fetal activity stressing the spontaneous character of early prenatal movements.[14] Better resolution of ultrasound equipment made it possible to identify qualities of prenatal activity.[9] Cyclic changes of fetal activity accompanied by fetal heart rate (FHR) variability were described at the end of the 1970s[15,16] but were still not linked with sleep–wake states in neonates.[17] By combining FHR-patterns with presence or absence of fetal movements (FMs), it became evident that bandwidth, amplitude and accelerations of FHR are related to the type of FM. FHR and FM patterns were used to classify behavioral states before 36 gestational weeks.[18] Subsequently, Nijhuis *et al.*[10] took advantage of the first prenatal descriptions of fetal eye movements (FEM).[19,20] Thus they were able to detect four behavioral states during the last weeks comparable to those described by Prechtl in neonates.[17] The implication of Doppler velocimetry in addition allowed consumptions that under normal conditions fetal hemodynamics are related to behavioral states.[21]

Independently, prenatal reactions evoked by external stimuli such as sound and vibration,[22] touch,[23] light[24] or merely maternal noise[25] have been investigated.

All methods have meanwhile been integrated into a cohesive whole to describe prenatal behavior in singleton pregnancies.

In twins and higher-order multiples, the same techniques can be applied in principle, though this demands more sophisticated methodological and statistical efforts because of the following reasons:

- two or more different individuals have to be observed simultaneously,
- there might be inter-twin or inter-multiple influences.

Specific conditions of multiple pregnancy such as zygosity, chorionicity, sex and position as well as pathological conditions have to be systematically defined and considered for interpretations.

Methods to document prenatal multiple behavior at early gestation

All types of movements that develop in singleton pregnancies seem to be present up to 15 weeks. This is why we regard the interval between 8 and 16 gestational weeks as an appropriate interval for the study of early twin behavior. In addition, this has a pragmatic background: from 16 weeks onwards it becomes more difficult to visualize both twins completely on one ultrasound monitor.

Though the pioneering work describing the emergence of qualitative movement patterns in singletons was performed with the aid of transabdominal sonography,[9] transvaginal sonography (TVS) has developed as the method of choice during the first 12 weeks of gestation.

Considering individual differences of compliance and abdominal wall thickness of the mothers we switch to transabdominal ultrasound observations from around 12 completed weeks. The type and position of the transducers are selected to optimize accurate simultaneous visualization.

As a compromise between maternal compliance or possible side effects and scientific curiosity our protocol has included weekly ultrasound examinations until at least 30 min of good quality are documented by video registration. Sometimes it might be difficult to visualize two or three members of the multiple pregnancy simultaneously in their full length. Under such conditions it is advisable to change either the position of the mother towards the transducer or to move the transducer to an oblique position.

Selection of study groups

Parents with early diagnosed twin or triplet pregnancy have taken part in our studies of early behavior of multiples. A high percentage of twin and higher-order multiple pregnancies results from fertility treatment such as *in vitro* fertilization, artificial induction of ovulation or artificial insemination. The criteria should be documented and gestational age adapted.

Parents who volunteer to take part in the study, have to be informed that there are still no follow-up studies about bioeffects of long-term ultrasound observations. Our own research protocol had been submitted to the local research ethics committee and approval had been granted. Parents are also informed about possible advantages of the study, such as a more careful evaluation of the development, exclusion of early markers for chromosomal defects between 10 and 14 weeks and the possibility to witness the development of their children. All specific variables which might have an effect on prenatal behavior such as maternal risks, medication or abnormal ultrasound findings have to be documented.

Sonographic determination of placentation and position

Precise analysis of the membranes is of primary importance not only for the classification but also for later management decisions. Already from 5 to 6 weeks onwards chorionicity can be defined by the number of chorionic sacs. In dichorionic (DC) placentation the

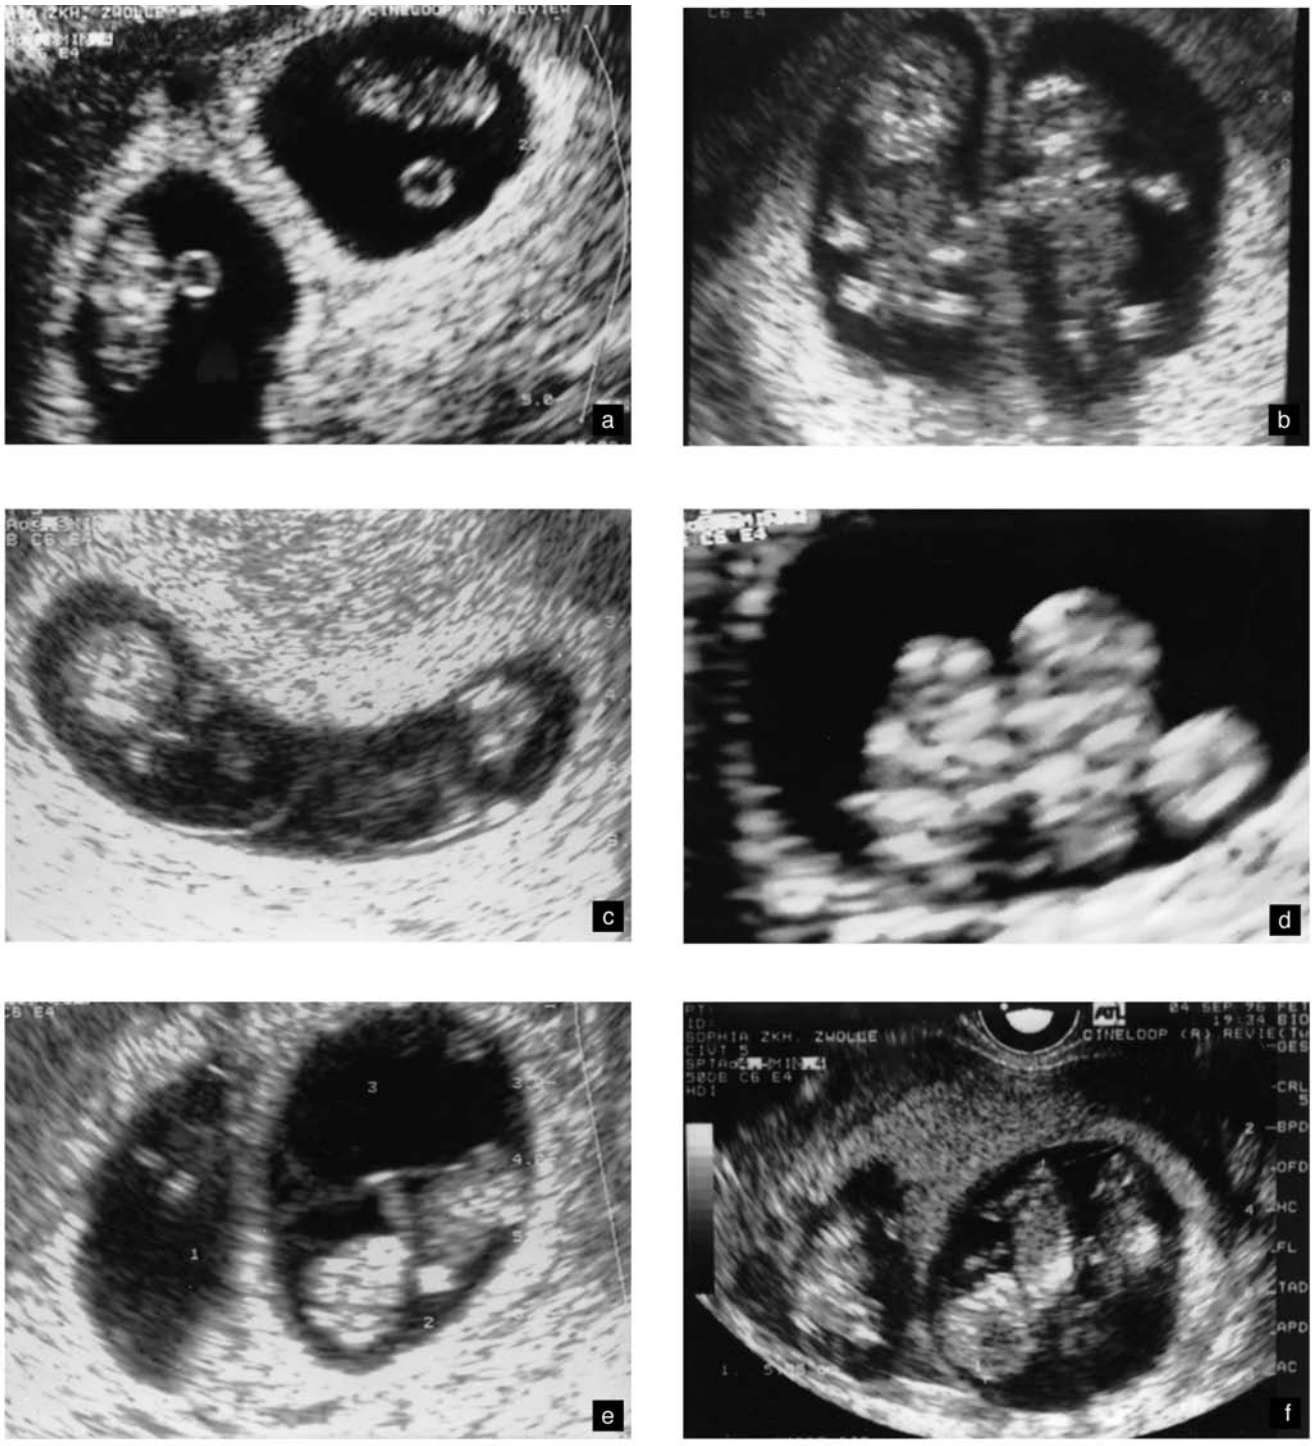

Figure 152.1 Sonographic illustration of chorionicity, impact for inter-twin contact. (a) DC twin pregnancy at 8 weeks still with surrounding villi: no contact possible. (b) DC twin pregnancy at 12 weeks with thick dividing membrane and lambda sign: moment of first inter-twin reaction towards touch. (c) MC DA twin pregnancy at 10 weeks with a single placenta and separate amnions: moment of first inter-twin reaction towards touch. (d) MC MA twin pregnancy at 9 weeks illustrating two adjoining embryos in a single sac: moment of first inter-twin reaction towards touch. (e) DC TA triplet pregnancy at 10 weeks illustrating simultaneous differences of dividing membranes: chorion laeve (left) and thin inter-triplet amnion (right): the two right triplets demonstrated with earlier reactions towards touch. (f) CD DA triplet pregnancy at 10 weeks with one thick inter-triplet membrane (left) and two triplets within one amniotic cavity (right): the two right triplets demonstrated with earlier and more frequent reactions towards touch.

villous stems surround the amniotic cavity (Figure 152.1a) until chorion frondosum and chorion laeve are further differentiated. As in singletons amnion and chorion remain separated by the coelom cavity up to around 12 weeks. The developing dividing membrane consists of two chorions and two amnions and appears echogenic. From around 12 weeks the presence of lambda-shaped structures at the attachment to the placenta is indicative of the dichorial nature (Figure 152.1b).[26] In monochorionic (MC) placentation it is recommended to evaluate whether each multiple is surrounded by an amniotic membrane, so that the

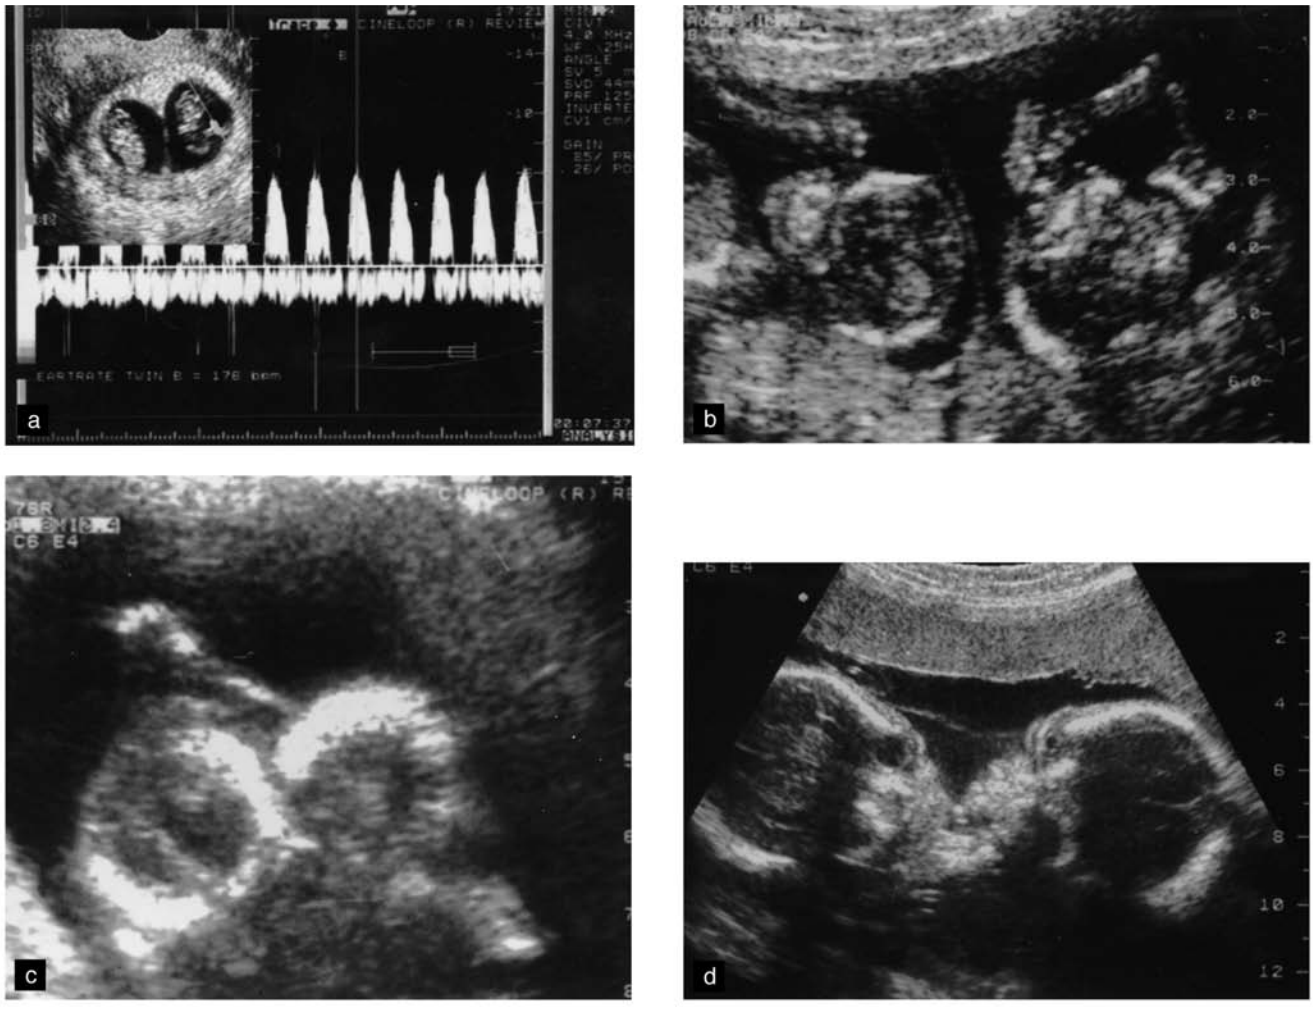

Figure 152.2 Hemodynamics and behavioral patterns at early gestation. (a) Doppler velocity wave forms of umbilical vessels at 10 weeks illustrating pulsatile arterial and venous flow (probe directed on umbilical cord). (b) Simultaneous activities (hand–face contacts) of twins at 12 weeks. (c) Complex contact ('embracement') at 14 weeks. (d) Mouth contact ('kiss') at 16 weeks.

dividing membrane consists of two amnions (Figure 152.1c) or whether there is only one amniotic cavity containing both twins without any dividing membrane (Figure 152.1d). Accordingly, there are six different types of chorionicity in triplet pregnancies, e.g., DC triplets can be triamniotic (TA) (Figure 152.1e) or diamniotic (DA) (Figure 152.1f). All ultrasound findings should be registered.

In utero twins and triplets can also be characterized by their position. Therefore it is important to compare carefully whether transvaginal and transabdominal definitions are in agreement.

In DC twin pregnancies with different sex we have followed the position of twins from 16 weeks onwards and have up to now not recognized a change of position from the primary definitions. We admit that in monoamniotic (MA) twins identification may be a problem.

Longitudinal examination of growth, structure and hemodynamics

It is recommended to document biometry and presentation *in utero* (e.g., vertex/breech) during each session and to notify early growth differences.[27] We have designed early growth charts specific for multiples.[28]

The prevalence of multiple pregnancy, which is related to maternal age and assisted reproduction techniques, has increased and accordingly the number of multiple pregnancies at risk for chromosomal abnormalities. Early ultrasound diagnosis of fetal nuchal translucency thickness, which has been proven to be as sensitive as in singletons in DC multiples, though with a lower specificity in screening for trisomy 21 in MC twins,[29] is recommendable to help the parents to decide for or avoid further invasive techniques. Serial ultrasound examinations of early behavior have the advantage of allowing a careful evaluation of nuchal translucency without further efforts and should therefore be included in all early behavioral studies.

Doppler velocimetry of the umbilical vessels can be theoretically registered from 8 weeks onwards and may allow to detect early heart rate (Figure 152.2a). Subsequently, Doppler velocimetry may be performed in several vessels such as the ductus venosus, the aorta or cerebral vessels.

Longitudinal examination of early activity

Using video documentation of early twin behavior we have defined first qualities of activities of twins

which are analyzed separately for each multiple most of them are comparable to the definitions found by abdominal ultrasound in singletons.[9]

First discernible movements are defined according to their name. Startles are abrupt generalized movements, starting in the limbs and spreading to the trunk and neck including flexion and extension of both arms and legs at the same time. Hiccups are jerky contractions of the diaphragm followed by an abrupt displacement of thorax and abdomen. Hiccups are frequently seen at regular intervals of 2–3 s. Hand–face contacts are characterized by a touch between hands and face (Figure 152.2b). Movements of single fingers and touch of the mouth just with the thumb may be differentiated. Mouth openings without swallowing are differentiated from swallowing movements, which are accompanied by a displacement of the tongue and are often initiated by sucking. During swallowing, fetuses are able to 'drink' amniotic fluid which can be visualized by color imaging and Doppler velocimetry. Breathing movements are paradoxical in nature, accompanied by slow simultaneous movements of the diaphragm (downwards), thorax movements (inwards) and abdominal movements (outwards). They may occur at regular or irregular intervals and may also be accompanied by aspiration and expiration of fluid.

Head movements include retroflexion, anteflexion or rotation of the head. Extremity movements may involve extension, flexion, external or internal rotation or abduction and adduction of arms and/or legs. Jumping appears as a consequence of pushing off the uterine wall with the legs and may occur incidentally and repetitively. Twisting may be defined when the body leans to the left and the right side repetitively. The 'turning point' of the movement may be neck and/or rump. It may appear as 'dancing' and may even initiate a somersault.

Stretching is a complex motor pattern consisting of an extreme extension of the spine, retroflexion of the head, abduction, external rotation and elevation of the arms. The movement may last several seconds. Prenatal yawning is comparable to yawning after birth. Yawning is often accompanied by a retroflexion of the head. After a slow opening, the mouth remains open for several seconds and then quickly closes. Like stretching this movement pattern is nonrepetitive.

In all multiples it is interesting to compare whether the described activities occur independently, 'in turn' or simultaneously (Figure 152.2b).

Longitudinal examination of early contacts

Using video documentation of early twin behavior we have defined first qualities of contacts. 'First reach and touch' is classified when multiples touch without giving evidence of reactions. 'First reaction' was defined as the first movement of the co-twin within 1 s of a touch (Figure 152.1b–d). Thereafter, the part of the body initiating the contact and the speed of the primary contact are classified as 'slow' or 'fast' arm, leg, head or body contact. All short contacts following an action/reaction model are called primary contacts. With advancing gestational age and smaller distance from each other, more complex contacts are observed lasting more than 5 s. Action and reaction might be repetitive so that initiatives cannot be exclusively correlated to only one twin. Thereby both bodies and extremities may be involved (Figure 152.2c). Twins may even touch the head or mouth of the co-twin with the lips followed by a reaction of the co-twin which we classify as 'mouth contact' (Figure 152.2d). Parents often interpreted these contacts as 'embraces' and 'kisses'. With advancing gestation, diffuse interactions, characterized by initiations or reactions, which are difficult to distinguish, are observed.

Using only the speed of initiations and reactions other classifications of contacts can be used such as contacts characterized by slow initiations with a slow reaction, a fast initiative with a slow reaction, a slow initiative followed by a fast reaction and a fast initiative followed by a fast reaction. It is interesting to compare whether contacts are preferably initiated by one of the multiples or whether there are differences in the frequency and sensitivity to react towards touch.

Analysis

Video tapes are retrospectively analyzed documenting gestational age in days, time of the day and meal intake. After a training period we recommend to determine the intra- and interobserver variability of observed qualities. For the observed activities and contacts we have found an interobserver variation coefficient between 88% and 100%. For all activities and contacts the gestational age of the first observation are documented.

The activities can be analyzed separately for each twin or multiple, the contacts can be classified according to described criteria. Throughout the observation period it is possible to calculate the occurrence of activity and contact patterns. In addition, inter-twin variance of activities and dominance can be evaluated. Using a short (1 min) window, rest–activity cycles are analyzed. In our studies all data were coded, collected and analyzed by computer programs.

Methods to document prenatal multiple behavior at advanced gestation

Although fetal activity of twins in the third trimester has been analyzed,[30–32] there are confusing methodological differences relating to whether FM were recorded by mother's perception, real-time ultrasound or electromagnetic devices. Ultrasound observations of fetal activity allow the most precise analysis of the quality of FM. In advanced pregnancy two ultrasound equipments are necessary to document all movements of head, body and extremities of only one child, which then is unrealistic for twins or higher order multiples.

In singleton pregnancy, a Doppler device for simultaneous recording of FM and FHR (actocardiograph MT 320[33]) registers slow and fast FM with a high

sensitivity and specificity.[34–36] We have used a similar equipment designed for multiple pregnancies (actocardiograph MT 430). This portable device captures the signals of FHR and FM with one external Doppler transducer for each twin, the signals are simultaneously recorded on separate channels and designed on one tracing. Thus, FM and FHR patterns can be easily correlated with each other. The simultaneous recording of both FM patterns in combination with FHR patterns on one tracing is the method of choice for acute supervision of advanced multiple pregnancies also in clinical routine. We have published that this method is also a useful tool for research purposes[5,6] and proposed several qualitative criteria to classify prenatal behavior in twin pregnancies roughly summarized as 'concordant' or 'discordant' behavior. The same equipment is useful for simultaneous FHR monitoring of triplets during vaginal delivery.[37]

Selection of study groups

We have performed systematic studies of spontaneous and reactive FHR–FM patterns in normal twin pregnancies from 24 weeks onwards. Mothers who volunteered to take part in the study, were informed about the protocol. For inclusion into the study protocol early ultrasound examinations to confirm gestational age and define chorionicity was a prerequisite. Data from risk pregnancies such as premature labor, pre-eclampsia, diabetes or growth retardation have to be excluded for definition of normal values or analyzed separately.

Sonographic determination of the position, growth and hemodynamics

At the beginning of each session the position of the placenta, presentation (e.g., vertex/breech) and the size of the twins including their estimated weight have to be registered. Using FHR monitoring identification on the tracing is facilitated by different thickness of the FHR-tracings and different height of the FM tracings for each twin. Doppler flow measurements of the umbilical artery (at least) should be performed and the amount of amniotic fluid should be estimated.

Longitudinal examination of spontaneous FHR combined with FM patterns

Usually we have registered behavior of twins over a period of at least 1 h combining spontaneous behavior during the first 30 min and the registration of reactive behavior during the consecutive 30 min. We have used a paper speed of 2 cm/min. It has to be considered that there is no signal loss or disturbances caused by maternal movements. An example of an actocardiographic tracings of spontaneous FHR/FM patterns is presented in Figure 152.3(a).

Longitudinal examination of reactive FHR combined with FM patterns

Studies to examine answers of peripheral sensory receptors face the problem in how far the occurrence of a response is causally related to the stimulus, whether it is accurately measured and reproducible and in how far the present behavioral state has an influence on the occurrence, magnitude and course of the response. Prechtl has described various patterns of responses to external stimuli in relation to different neonatal states.[17]

In contrast to the neonate, the human fetus is surrounded by amniotic fluid, which diminishes technical feasibility to objectify and quantify stimuli as well as responses.

Still various kinds of external stimulations to provoke reactions of a single fetus have been reported and are summarized in detail.[38,39] For all methods of prenatal external stimulation problems have to be overcome due to attenuation and uncertainties of transmission through the maternal abdomen of either touch, sound or light. The possible effect of the attachment alone has to be excluded by touching the abdomen with the instrument without stimulation ('sham stimulation'[40]).

Methodological problems in multiple pregnancies are as follows. Stimulations by light or touch have to be performed for each multiple and still the stimulus might vary dependent on the position of the fetus towards the stimulus (front or back side). The first reaction to light stimulation is often just a short movement of the bulbi, which can only be observed by ultrasound if the fetal face is visualized.

Vibroacoustic stimulations (VAS) using an electronic artificial larynx (EAL) producing a broadband noise at a fundamental frequency of 87 Hz with multiple harmonics up to 15,000 Hz was used in singleton pregnancies.[41] Coupling between the vibrating surface of the instrument and the maternal tissue provides optimal transmission of frequencies of up to 20,000 Hz.[42] When placed between the twins it can be suggested that the stimulus reaches both members in a comparable way. It has been proven that the position of the EAL in relation to the fetus is without influence on the kind of reaction[43] because it is transmitted via the amniotic fluid and the intensity of the sound *in utero* does not vary.[44] It was demonstrated that a stimulus with EAL of 3 s is sufficient to cause a reaction even from quietness to an active state.[45] In our studies we tried to perform a stimulus of around 2 s.

A further problem arises if twins do not demonstrate the same rest-activity state before stimulation. We have only started with sham/final stimulations till at least 10 min of quiet behavior was recorded. Waiting for this condition can extend the duration of the session. An example of an actocardiographic tracing after VAS with various FHR/FM responses is presented in Figure 152.3(b).

Analysis of polygraphic tracings

From each session the tracings are analyzed documenting gestational age in days, time of the day and meal intake. After a training period we recommend

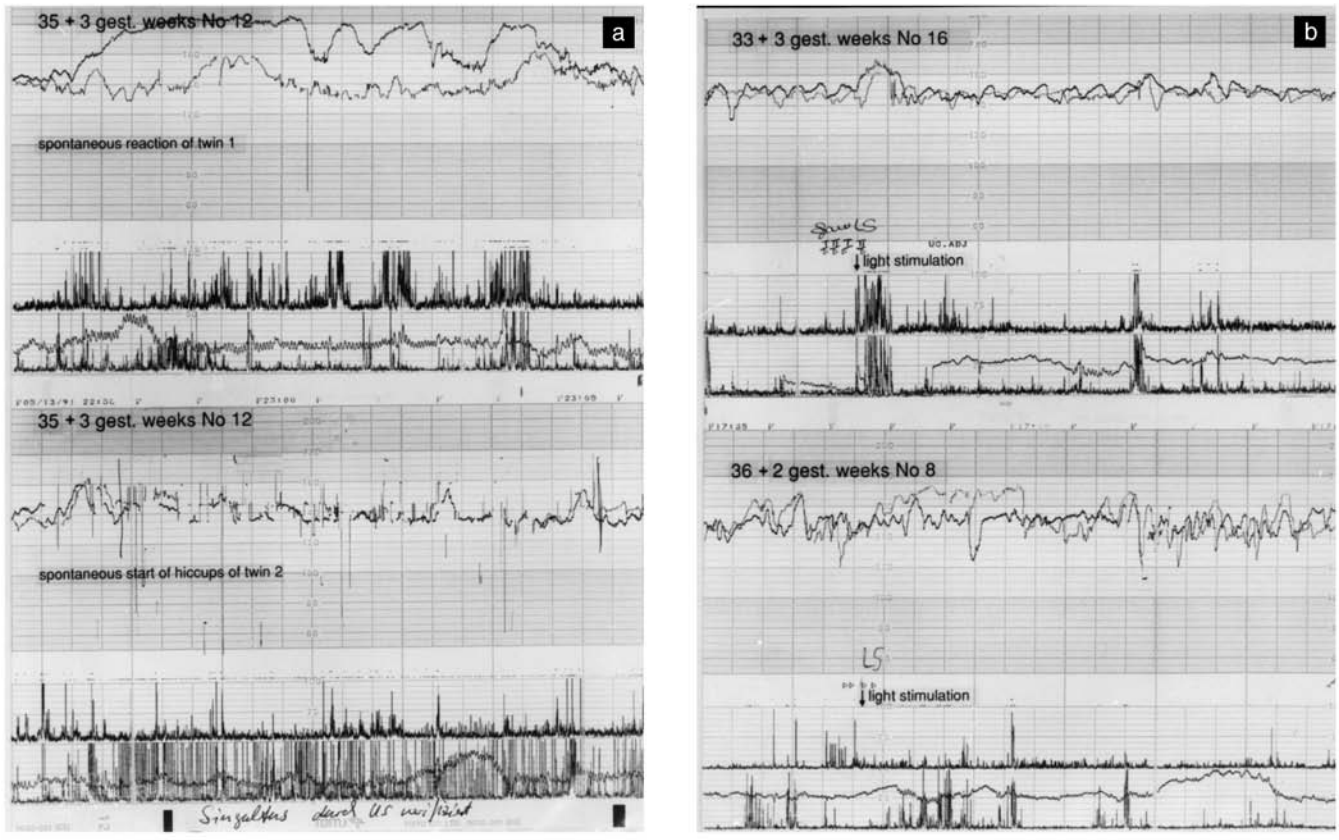

Figure 152.3 Hemodynamics and behavioral patterns at advanced gestation. (a) Actocardiographic patterns demonstrating spontaneous 'discordant'. FHR-FM patterns: spontaneous increase of FHR of twin A (above), spontaneous onset of hiccup of twin B (below). (b) Actocardiographic patterns demonstrating reactive 'concordant' and 'discordant' FHR-FM patterns: both twins react with a FHR-acceleration combined with FM (above), only one twin reacts with a short FM and an increase of FHR-baseline (below).

the determination of the intra- and interobserver variability. For the actocardiographic tracings we have found an interobserver variation coefficient between 80% and 90%. For all reactions towards external stimuli gestational age of the first occurrence can be documented.

For systematic studies we have meanwhile classified FHR/FM patterns according to possible combinations of variability, accelerations and FM (Table 152.1). To classify these periods 3 min consistency is required in a tracing of at least 30 min of good quality. The longest and shortest periods as well as the total distribution as percentage of the registration time can be calculated for the whole study group, subgroups and for each twin pair throughout the observation interval.

FHR/FM patterns after VAS were classified according to possible combinations of FHR accelerations in combination with FM, the duration of the reaction and the change of states. For direct comparison of twin pairs all described criteria can be used. The described parameters can also be combined by semiquantitative scoring systems.[3] Thereby the degree of difference in FHR-variability, baseline, number and synchronicity of FHR accelerations and FM can be compared. The latter are classified as simultaneous if there are less than 10 s difference.[46]

Postnatal assessment

Postnatal assessment of placenta and zygosity

Placentation of multiple pregnancies is influenced by the number of zygotes, blastocysts and the division of the inner cell mass. When two placentas are present, they are always DC, most are dizygotic (DZ), but some are monozygotic (MZ), when division occurs before implantation. Single placentas can be present in DC and MC as well as in DZ and MZ pregnancies.

A proper examination of the membranes allows definite statements concerning the zygosity, which are summarized for twins and triplets.[47]

(1) DZ twins are DC; (2) MZ twins are either DC or MC; (3) MC placenta proves MZ twins

(1) TZ triplets are TC; (2) DZ triplets are either DC or TC; (3) MZ triplets are either TC, DC or MC; (4) DC triplets are MZ or DZ; (5) MC triplets are MZ.

The following placental features should be examined still in the delivery room and used for protocols[47]: the structure of fetal membranes, the unity of the placenta, the site of umbilical cord insertions and the extent of vascular anastomoses in MC placentas. Placental weight, surface area, insertion of the umbilical cord, disturbances of maturation or circulation and signs of infection should be examined.

Table 152.1 Classification of fetal heart rate (FHR) and fetal movement (FM) patterns in twins obtained by the Actocardiograph MT 420

FHR-FM pattern	Variability (amplitude/bpm)	Fetal movements	Accelerations
I	< 10 bpm	NO	NO
II	< 10 bpm	YES	NO
III	> 10 bpm	NO	NO
IV	> 10 bpm	NO	YES
V	> 10 bpm	YES	NO
VI	> 10 bpm	YES	YES

Examination of placentation and gender determines zygosity in around 50% of cases.[48] This ratio varies worldwide. Zygosity remains unclear in cases with the same sex and DC/TC placentation. In these cases sequential blood group testing can be performed considering ABO, Rh, MNSs, Kell and Duffy subgroups. DC twins can be correctly identified if only one (or more) of the subgroups vary. If all subgroups are identical, the probability of MZ twins is around 97%, still 3% are DZ.[49] In uncertain cases, the use of DNA methods to analyze variable numbers of 'tandem' repeat sequences dispersed in the human genome has become the most powerful tool for accurate diagnosis of zygosity. DNA fingerprint can be performed of each twin's leukocytes, umbilical cord tissue or even placental tissue even after being frozen at −20°C.[50,51]

Statistical methods

All data of subgroups of MC vs. DC twin pregnancy or of different gender combinations can be calculated. Our datasets are shown as box–whisker plots using SPSS (Statistical Package for Social Sciences). Thereby the mean, the 75th and 25th centile and the limits of extreme values are plotted so that 50% of the values are collected within the 'box'; the 'whisker' represents all values up to the 1.5-fold distance of the given centiles. Significant differences can be calculated for two or three variables by the Mann–Whitney–Wilcoxon and the Kruskal–Wallis test or by chi-square tests. Multivariate analysis can be used to find parameters with an impact on behavior of multiples.

Possible discussions relating towards long time ultrasonography

Bioeffects of ultrasound have been studied for sixty years now and can be classified as nonthermal and thermal effects. Nonthermal processes are enhanced by gas-body activation occurring when gas filled structures become biologically active when exposed to megahertz frequencies.[52] The 'spatial peak pulse average' (SPPA) represents the average intensity of a pulse. At SPPA values of 10–100 W/cm^2 signs of cavitations were never seen.[53]

Thermal effects of ultrasound depend on the intensity of the ultrasound waves, the duration of exposition and the absorption coefficient of the tissue. Ultrasound waves cause oscillation and heat production. Temperature elevation of less than 1°C is considered to be without any effect for the fetus;[54,55] thermal effects have not been reported in mammals below 39°C.[56] The critical temperature for fetal tissue is 41°C and its exposition limit at this temperature is 16 min.[54] However, in animal experiments a temperature of 41°C is only reached with intensities of > 300 mW/cm^2 and an exposure duration of > 60 min.[57] The SPTA (spatial peak temporal average) values have to be considered.

Mutagenic effects of ultrasound are only described in *in vitro* cell lines.[58,59] Epidemiological research has been performed in children, who were exposed to ultrasound during pregnancy and no increased risk for malignancy was found.[60,61]

Recently, it has been suggested that there is an association between routine ultrasonography and subsequent non-right-handedness[62] and growth restriction if ultrasound is performed frequently.[63] However, no other differences in intelligence, neuromuscular or psychological development were found. However, there were critics on methodological aspects of these studies.[64] Side-effects of long-term ultrasound have not yet been noticed. In any case, it is important to discuss these subjects with parents openly and not to use ultrasound in an unreflected way.

Development of activities, hemodynamics, reactions towards touch and external stimuli

Onset of twin activities

The first increase in axodendritic and axosomatic synapses occurs between 8 and 10 weeks.[65] In this period movement patterns differentiate rapidly. Another striking increase in the number of axosomatic synapses is described between 12 and 15 weeks.[66] In these weeks simple general movements of body, head and extremities as well as more complex activity patterns such as swallowing, stretching and yawning emerge. Besides the study of Samueloff *et al.*[67] and our own reports, prenatal twin behavior has not been studied in early pregnancy.

First appearance of the described activities can be correlated to the gestational age; however, it has to be considered that all phenomena could have emerged already during the interval of the sessions. During the first weeks of gestation movements become more frequent and appear faster. The cascade of developing activities in twins is demonstrated in Figure 152.4(a).

The clinical importance of qualitative observations was stressed from replays of video recordings of neonatal movements. It was possible to distinguish between

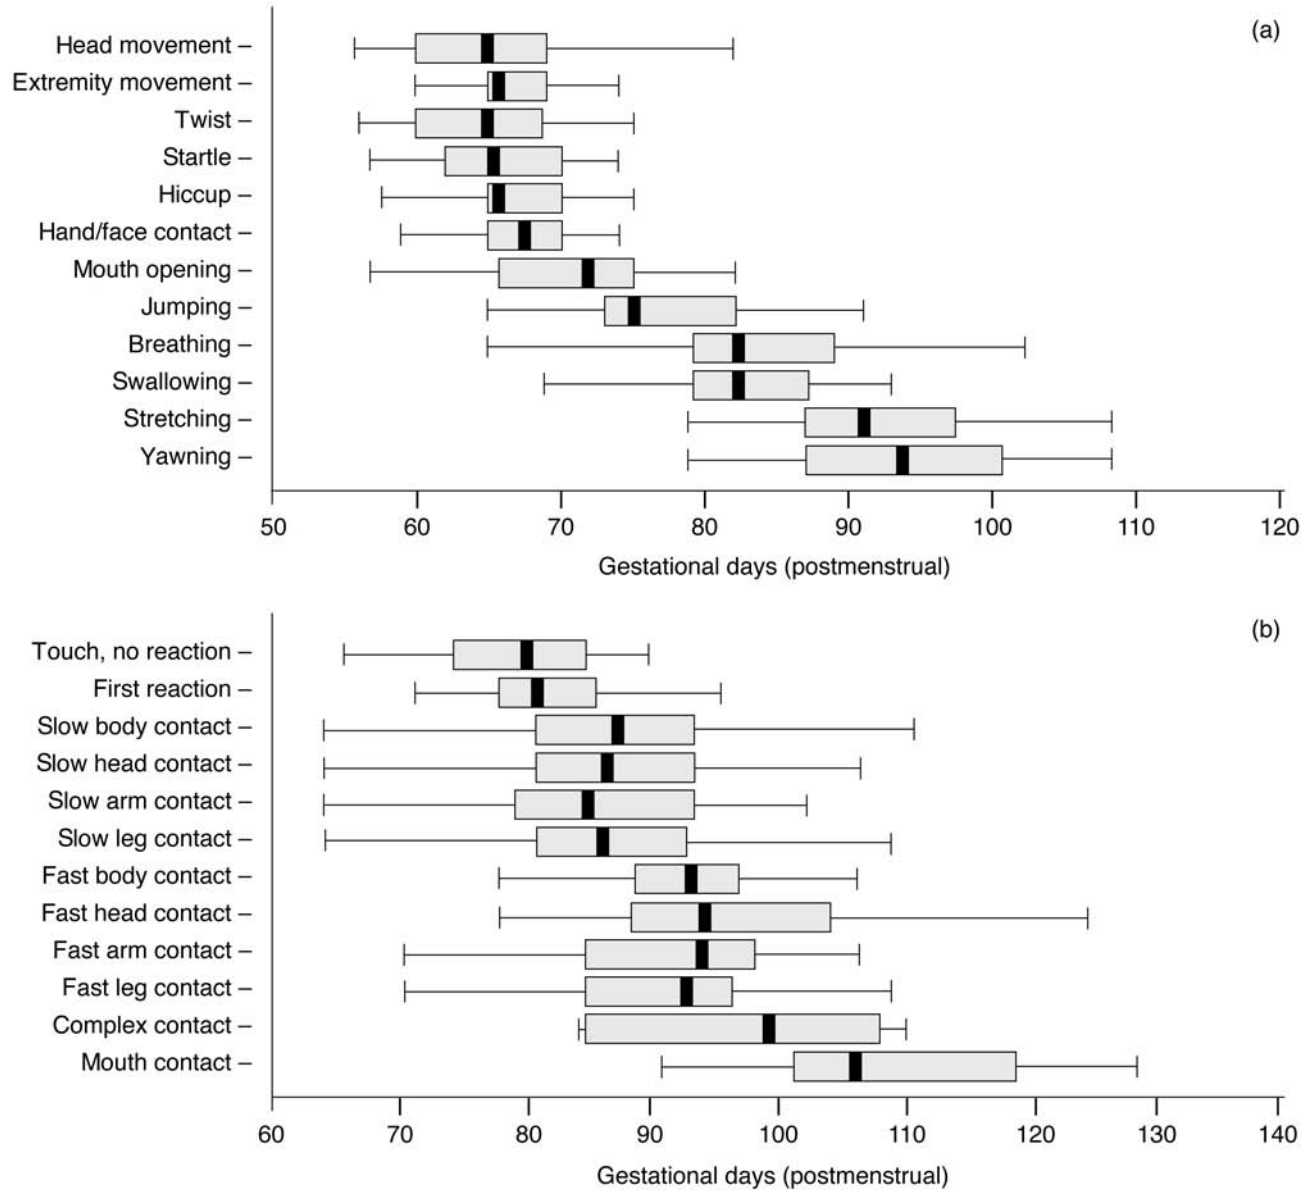

Figure 152.4 Onset of behavioral patterns in box–whisker plots, ultrasound observations at 1-week intervals, $n = 25$ (20 DC and 5 MC) twin pairs. (a) Onset of activities. (b) Onset of inter-twin contacts.

infants with intact nervous system and brain lesions, though there was no difference in the quantity of movements. Neonates with brain lesions seemed to demonstrate with abnormal movements lacking elegance, fluency and rotations superimposed to limb movements.[68] These 'subjective' observations had a high interobserver agreement of around 90%,[69] which is comparable to our own correlation coefficients.

Onset of intertwin contacts

To study reactions of singletons towards touch *in utero* would be combined with ethical and practical restraints. However, twins are naturally exposed to sensory stimulations of the co-twin and thus ideal models to study the onset of reactions towards touch *in vivo*. As it was supposed for motor activities of singletons[70] the primacy of contact patterns may also indicate that contacts develop before being 'useful' responses to biological or psychological relevant sensory input.

Studying movements in twins in the last trimester Sadovsky stated[31]: 'The possibility that movements of one twin stimulate the other to move was rejected by the fact that in no instant did one fetus move immediately after the second started to move'. Looking at our video tapes we arrived at different conclusions.[71] Similarly, inter-twin contacts have been supposed to cause increased rates of simultaneous twin activities in early pregnancy.[68]

As described for activities, primary contacts can be correlated to the gestational age, still it has to be

considered, that all phenomena could have emerged during the interval before the session. Both, the first interhuman contacts without and with reaction were primarily observed in a MC MA twin pair of two boys at 57 and 65 postmenstrual days, respectively. The cascade of developing contacts from simple to more complicated patterns in twins is demonstrated in Figure 152.4(b).

Prenatal contacts start with slow initiatives followed by slow reactions, giving the appearance of a 'tender' contact. This may be due to the still poorly developed muscular and sensory system. As described *in vitro*[3] we found *in vivo* that embryos respond to tactile stimulation as early as at 8–9 weeks. Yet at this age the receptors to perceive tactile stimuli have not yet penetrated the basement layer of the skin.[72] It is speculated that the developing neural system is responsive prior to the formation of specific receptor cells.[73] In MC twins contacts occur earlier, which might be interpreted with the smaller distance and the thinner intertwin membranes.

Continuity of early twin activities

A change in motility has been reported from 'rather jerky' around 12 weeks to 'slow and harmonious' at 16 weeks[74] for singletons. Interindividual differences in the quantity of FM have been described for singletons.[75] In twin pregnancies the question is whether they depend on systematic variables such as gender, zygosity, position *in utero* or possibly on 'early individuality', so that activity *in utero* might already be an early expression of temperament. Particular movements, for example, twisting and jumping, showing large ranges and unsystematic differences might be representative of individual differences. In contrast, some movements might be considered merely as reflexes (startles, hiccups) or seem to be essential for fetal development of organs (breathing movements and swallowing). These activity patterns show smaller inter-twin differences.

The number of most exhibited patterns increases throughout early gestation, except for twisting, which seems to be an early pattern that disappears after 13 weeks. Startles and hiccups decline after 13 weeks. Breathing and swallowing display a constant rise up to 16 weeks. Frequencies of hand–face contacts remain stable throughout. In Figure 152.5(a), the course of breathing movements, given as number per hour is plotted separately for twin A and B. In Figure 152.5(b), the course of twisting is demonstrated. There are large unsystematic differences between the two twins reflecting the incidental and possibly individual character, after 14 weeks twisting movements seem to disappear.

Continuity of early inter-twin contacts

The described change from 'rather jerky' activity around 12 weeks to 'slow and harmonious' activity at 16 weeks[74] correlates with our observations of the development of diffuse contact patterns during these weeks. Contacts may be explained by the onset of movements whereby incidental touches cannot be avoided *in utero* or are responded by early reflexes. Both, the part of the body that initiates the contacts as well as the reacting part may be randomly involved. Some reactions may be just incidental endogenously evoked movements or passive answers towards touch. Early contacts of MC twins are also more in number. Our classification of early contacts might be a subjective one. We tried to establish 'normal values' of the described qualities which cannot be demonstrated in detail. We just show two examples of our normal values classified according to the speed of either initiative or reaction (Figure 152.5c and d).

Hemodynamics during early multiple gestation

It is well known that normal values of FHR fall during the first 10 weeks of pregnancy.[76,77] This also holds true for twins and triplets. Due to the decrease of vascular resistance within the placental bed there is also a fall in pulsatility index (PI) of the umbilical artery in twins and triplets.

As an example we demonstrate our normal PI values and the FHR of twins in Figure 152.6(a) and (b) possibly of use for further research of the influence between early activity and hemodynamics.

Spontaneous FHR/FM patterns after 26 weeks

Observations of spontaneous FHR–FM patterns have been published in twin pregnancies before,[30,31,32,46,78] however, no normal values were established which is a prerequisite for further scientific and clinical evaluation.

As described we have tried to classify periods according to FM and FHR patterns (Table 152.1). If a 3 min window was used, the distribution of all periods varied per week, but there were no systematic changes throughout the observation period of 26–36 weeks. The distribution of periods with or without FM demonstrates the high percentage of active periods (mean around 80%) compared with singletons,[6] which might be caused by intertwin stimulations. Accordingly periods with a variability of >10 bpm were present in around 80% of the registration time (Figure 152.7a).

The question of whether or how often spontaneous FHR–FM patterns of co-twins are comparable, has been investigated in small samples. Sadovsky observed 10 normal twin pregnancies between 33 and 39 weeks looking whether the twins moved simultaneously or independently. Of all observed fetal movements around 75% were independent of the movements of the co-twin.[31] Similarly completely similar patterns were found in 26% of the observation time.[32] Still it could be demonstrated that FHR accelerations are more often associated (in 57%) than

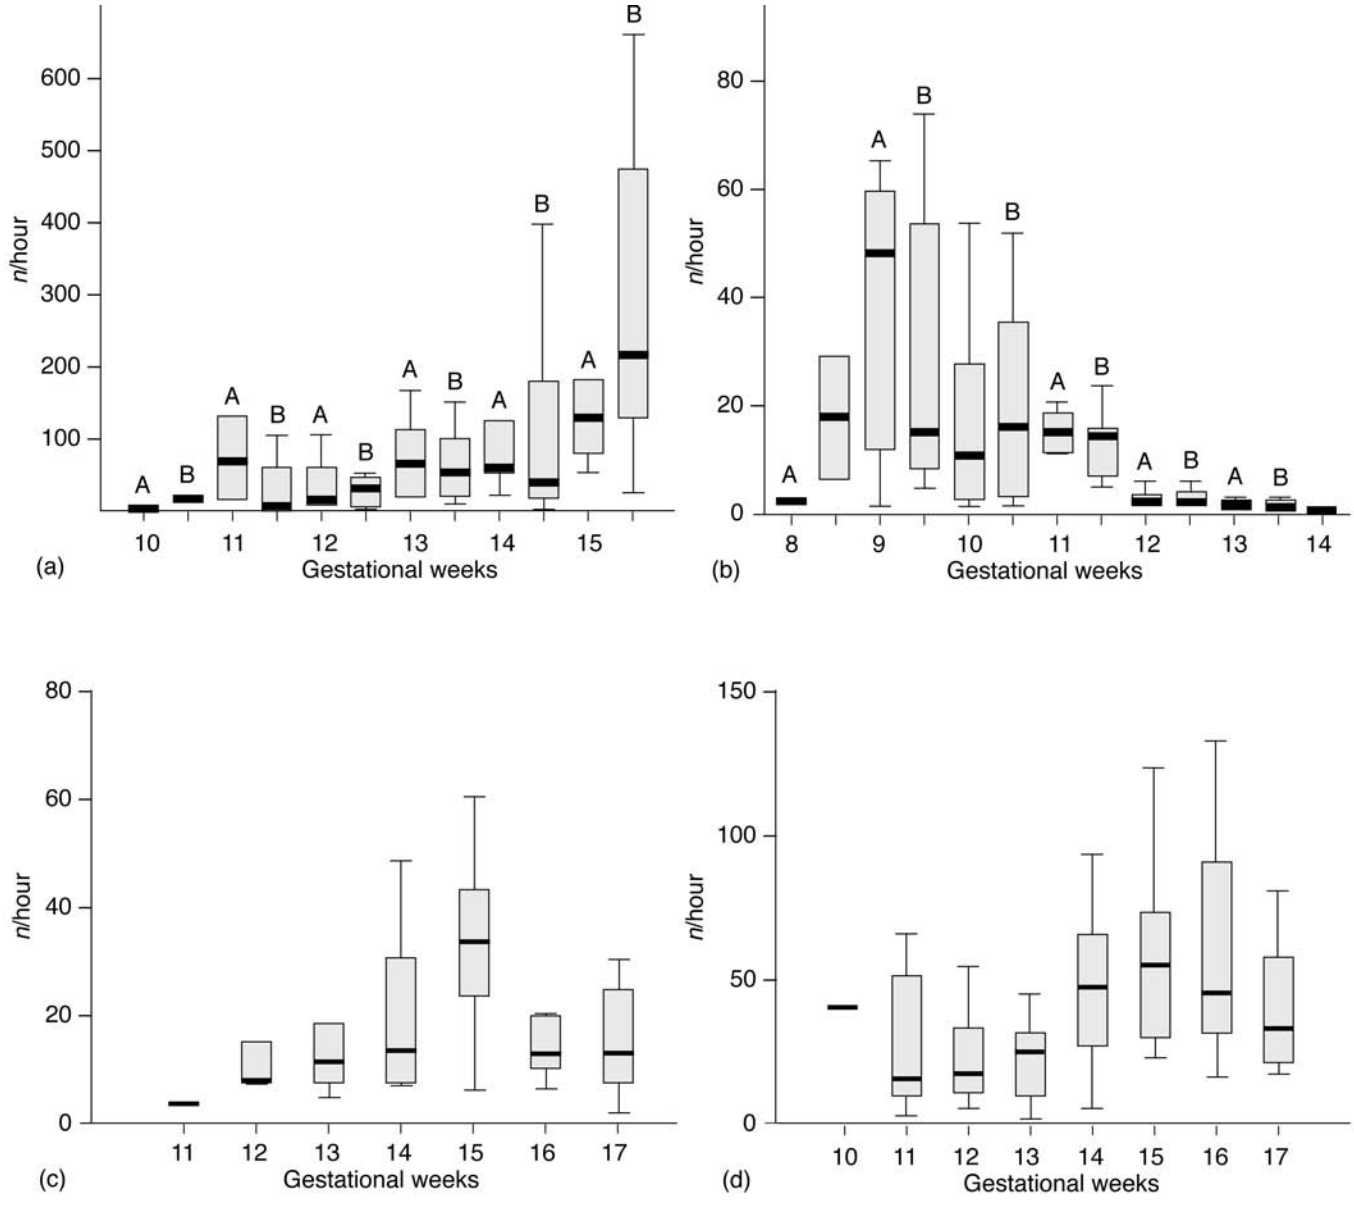

Figure 152.5 Continuity of early behavioral patterns in box–whisker plots, ultrasound observations at 1-week intervals, $n = 25$ (20 DC and 5 MC) twin pairs. (a) Breathing movements (number per hour) separate for twin A and B. (b) Twisting movements (number per hour) separate for twin A and B. (c) Slow initiations with slow reactions between corresponding twins. (d) Fast initiations with fast reactions between corresponding twins.

statistically expected within the members of a twin pair.[78] Whether this proves the similarity of endogeneous behavioral patterns or just 'inter-twin stimulations' must remain open.

In our group of longitudinally investigated twins we have analyzed how far oscillation amplitude and fetal activity can be compared. Two members of a twin pair showed the same pattern of either FHR-variability < 10 bpm (patterns I and II), respectively, > 10 bpm (pattern III–IV) in around 50%. Similarly two members of a twin pair demonstrated simultaneously with an inactive pattern (I, II, IV) in 49% and with comparable active patterns in 43%.

Onset of reactions towards external stimuli

A measurable response of the fetus towards external stimuli depends on developmental differentiation of sensory receptors, adequate stimulation and fetal state. Emphasis in this section is put on two further sensory routes through which the fetus may be stimulated: vision and hearing.

Vision

After 18 weeks synapses appear on the eye rods. Between 20 and 24 weeks fetal eyelids may open, later followed by the development of the maculae

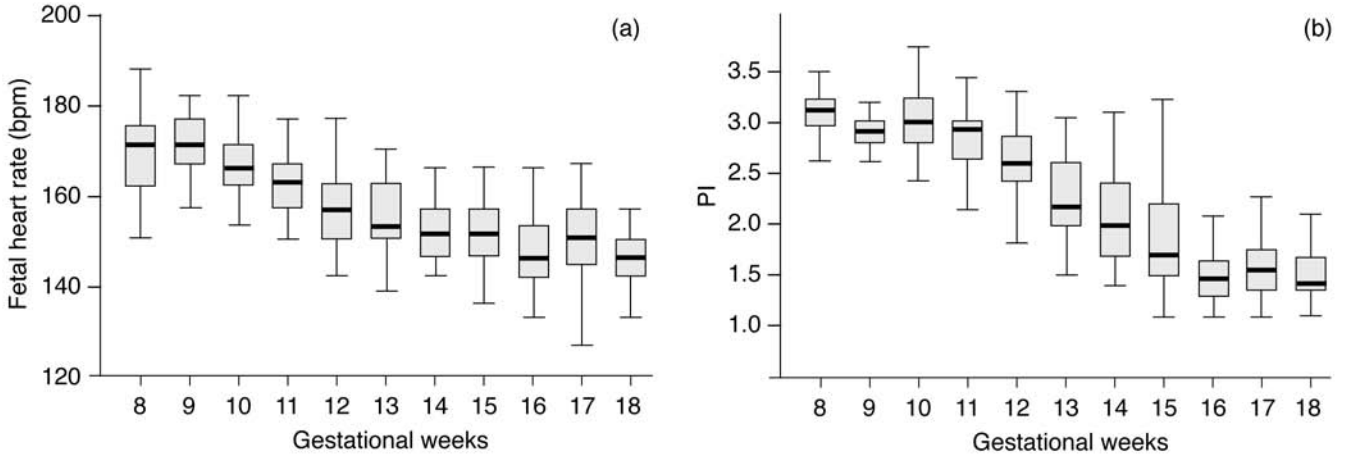

Figure 152.6 Development of early hemodynamics (box–whisker plots, ultrasound observations at 1-week intervals, $n = 31$ twin pairs). (a) Course of fetal heart rate ($p < 0.001$, Kruskal–Wallis test). (b) Course of pulsatility index in the umbilical artery ($p < 0.001$, Kruskal–Wallis test).

and photoreceptors.[38] There are only few studies of stimulations in singletons and up to now none in multiples.

As explained we have incidentally observed movements of the bulbi ('twinkling') by ultrasound towards stimulation with flash light from 28 weeks onwards. Reactions of FHR and FM in twins were observed by our team from 28 weeks onwards, at 30 weeks we even observed simultaneous reactions of two twins. However, probably due to the described methodological problems reactions of FHR–FM patterns were only registered in 29/390 light stimulations (around 8%) in our series. Therefore, we did not collect further systematic data for normal values or inter-twin comparison.

Audition

In the 4–5-week-old embryo the otocyst divides into two parts for cochlea and labyrinth. At 6 months, peripheral vibration-sensitive endings include Meissner's and Pacinian corpuscles, which transmit vibrotactile stimuli. The cochlea and peripheral sensory end organs have reached normal development at around 24–25 weeks.[39] Still, auditory brain stem response in the premature newborn have not been registered before 26 completed weeks.[79]

Auditory stimuli are the most documented and are even used clinically. External stimuli have to overrule intrauterine background noise *in utero* as well as attenuation by the maternal tissue. After the first suggestion to use FHR-monitoring in combination with external pure tone stimulation[80] a wide variety of acoustic stimuli have been introduced. The most 'reliable' responses were registered after stimulation with the EAL.[39]

Whether the FHR-response is a direct one or concomitant with muscular activity cannot always be differentiated. In singletons, first reactions to acoustic stimulations were observed as a 'aurepalpebral reflex' at 28 weeks[81] on a regular basis. Using FHR–FM monitoring responses in the form of FM and/or FHR-accelerations, reactions were observed as early as from 26 gestational weeks.[82,83]

Up to now, there are only a few studies on reactive behavioral patterns in multiples.[6,31,84,85] We have studied reactions of twins, though we still withheld it from clinical routine. Only by using the actocardiograph, we could observe a first fetal reaction in twins at a gestational age of 26 weeks + 4 days characterized by a short FM in combination with a change from FHR–FM pattern I to II. First simultaneous reactions of two members of a twin pair were observed at 27 weeks and 2 days.

Reactive FHR/FM patterns after 26 weeks

After stimulation with the EAL we have investigated twin reactions throughout pregnancy. The distribution of the number and type of reactions changes significantly during the observation period.

After VAS short reactions describing a rapid FM possibly combined with FHR accelerations and reactions with a longer duration of more than 60 s can be differentiated in singletons and twins. Throughout the observation period we have observed significant increases of short reactions consisting predominantly of FM and FHR-accelerations (Figure 152.7b) as well as in the number of reactions of longer durations of more than 60 s characterized by changes of the baseline and/or FHR-variability (Figure 152.7c). In addition, we have investigated changes of the described FHR–FM patterns after VAS.

Before 30 weeks, the mean duration of a long reaction of twins is 184 (1–990) s and after 34 weeks it is 237 (3–690) s. Before 30 weeks the mean increase of the baseline after VAS is 3.5 bpm, after 34 weeks the mean increase is 11.9 bpm, the mean increase of the oscillation amplitude is 1.3 and 2.4 bpm, respectively, in a group of 32 longitudinally investigated twins.

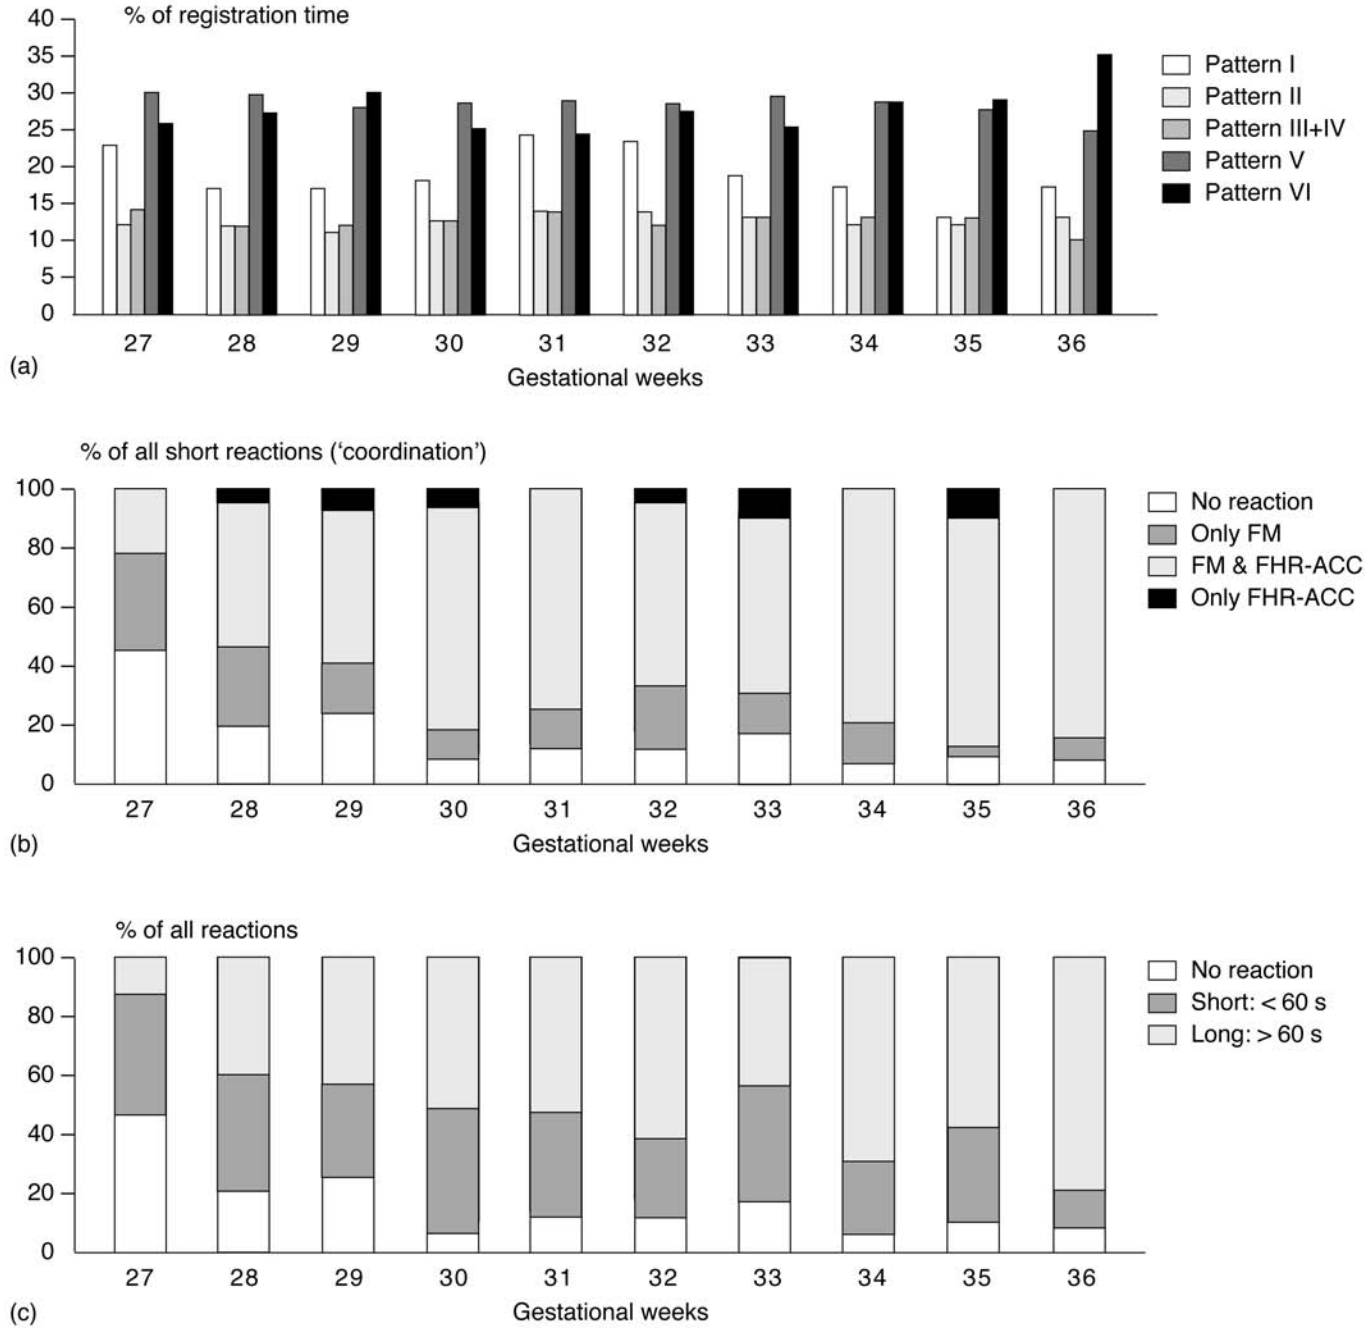

Figure 152.7 Continuity of behavioral patterns at advanced gestation (actocardiographic monitoring, $n = 32$ twin pairs). (a) Distribution of spontaneous FHR-FM patterns (mean, $n = 320$ tracings, ns). (b) Distribution of combinations of short reactive FHR-FM patterns (mean, $n = 320$ tracings, $p < 0.001$, Kruskal–Wallis test). (c) Distribution of combinations of short reactive FHR-FM patterns (mean, $n = 320$ tracings, $p < 0.001$, Kruskal–Wallis test).

Multivariate analysis demonstrates that the influence of gestational age on both variables is significant with even a higher impact on the baseline in all twins independent of their sex, zygosity or position. Stimulations without any alteration of either baseline or oscillation amplitude decrease in the group of twins from 98% at 27 weeks to around 55% at 36 gestational weeks. The described phenomena were observed in all twin groups independent of their zygosity, their sex and their presentation, though the degree of alterations shows significant differences.

Simultaneous FHR and FM-alterations after VAS were already described.[81] Investigating variables such as the duration of the reaction, the kind of the combined reaction and change of combined FHR–FM pattern synchronous reactions are demonstrated in around 70–80% of 'normal' co-twins. This again is a model for proving the effect of a stimulus.

Table 152.2 Comparison of the onset of contacts 8–16 weeks: Male vs. female vs. mixed pairs and monochorionic (MC) vs. dichorionic (DC) pairs: earlier onset in male and MC pairs (n = 340 video tracings/25 twin pairs, Kruskal–Wallis & Mann–Whitney test)

First contact	Different gender (male vs. female vs. mixed)	Different chorionicity (MC vs. DC)
First reaction	p = 0.29 (NS)	p = 0.005
Slow body contact	p = 0.29 (NS)	p = 0.001
Fast body contact	p = 79 (NS)	p = 0.02
Complex contacts	p = 0.01	p = 0.009
Mouth contact	p = 0.46 (NS)	p = 0.79 (NS)

Influences on prenatal behavior under normal conditions

Prenatal twin studies offer the opportunity to observe two fetuses developing in the same environment. Apart from spontaneous activities and functions, inter-twin reactions towards touch as well as reactions towards external stimuli have a developmental aspect. One of the challenges is to examine inter-twin differences in specific subgroups relating to onset, qualities and quantities of behavioral variables.

Some simple questions are: Is there a difference in subgroups with different zygosity, gender, chorionicity and position? What is the influence of gestational age? Is there a dominant twin *in utero*? If the hypothesis holds true, that the character and incidence of activities, contacts and reactions is determined by individual genetics or by gender-specific variances, intermultiple differences are expected to be smaller within MZ or sex-alike compared to DZ or sex-unlike multiples. If the hypothesis holds true, that activities, reactions towards touch or external stimuli are determined by what we call 'environmental influences *in utero*', behavioral differences would be smaller in MC compared to DC multiples or in multiples lying in the same position.

It has to be considered that all these models are simplifications since there are interactions between intrinsic and extrinsic variables.

Influences on behavioral variables in early multiple pregnancy

From adult life we know that there are individual characteristics of behavioral patterns – also in the way how people move and communicate. In our series we up to now found a trend that the onset of activities is more similar between MZ than between DZ twins. The frequency of activities did not reveal significant inter-twin differences with a few exceptions: MZ and MC twins demonstrate with a higher incidence of 'jumping' compared to DZ or DC twins. No significant differences were found between pairs with different gender combinations except for yawning and mouth opening; however, the results may be biased by the low incidence of these patterns.

Contact patterns offer more obvious differences in their onset and incidence depending on chorionicity, zygosity and sex.

Analyzing the onset of early contacts we found that in the total group of MC twins ($n = 5$), including one MC MA twin, mean and minimum of nearly all forms of contacts are observed significantly earlier than in the 20 DC twins (Table 152.2). This might be interpreted with the smaller distance and the thinner inter-twin membranes.

Analyzing the subgroups according to different gender combinations we did not yet detect systematic differences in the onset of primary contacts except for complex contacts which seem to occur significantly earlier in the group of only female twins (Table 152.2).

Analyzing the course of early contacts we found that within the first 16 gestational weeks all contacts in MC twins are more numerous (Table 152.3). It is not surprising and even known from adult life, that long interhuman distances and interhuman 'walls' make physical contacts impossible. The question of how far the observed contacts only occur because – here the multiples – are forced to move in a limited space remains open.

Surprisingly, we found significant differences in the speed of initiatives and reactions within subgroups of different gender combination as early as during the observation period of 8–16 weeks. In the group of only male twins, fast initiatives combined with fast or slow reactions were significantly increased compared to only female or mixed twin pairs (Table 152.3). Also the number of complex contacts within same-sex male pairs were significantly increased. It is suggested from animal experiments that differences of testosterone levels, being recognizable from around 12–14 weeks might even have an impact on early development *in utero*. Sex differences in adult human behavior have been reported for a

Table 152.3 Comparison of the number of contacts 8-16 weeks: Male vs. female vs. mixed pairs and monochorionic (MC) vs. dichorionic (DC) pairs: higher incidence in male and MC pairs (n = 340 video tracings/25 twin pairs, Kruskal–Wallis & Mann–Whitney test)

First contact	Different gender (male vs. female vs. mixed)	Different chorionicity (MC vs. DC)
Extremity contact	p = 0.01	p = 0.00001
Fast initiative/slow reaction	p = 0.0007	p = 0.00001
Fast initiative/fast reaction	p = 0.0058	p = 0.00001
Complex contact	p = 0.01	p = 0.0014
Mouth contact	p = 0.45 (NS)	p = 0.001

number of dimensions of cognition, aggression, sensation seeking, affiliation and sociability and biological explanations have focused on the organizational or sensitizing influences of pre- and perinatal exposure to steroid hormones as well as neuroanatomic differences. The fact that hormones may have an impact on the anatomical development *in utero* leaves us with the following question. How far either females or males will be influenced by their opposite-sex co-twin?

Influences on behavioral variables in advanced normal pregnancy

Investigation of spontaneous FHR–FM patterns up to now have not shown a 'dominant' twin.[78] Gallagher *et al.* compared FHR patterns of five MC pairs with 10 DC pairs and found that simultaneous patterns occurred in 100% of all MC but only 92% of all DC pairs. The group found a 98% vs. 92% rate of simultaneous patterns in twin pairs with the same sex compared to twin pairs of different sex.[46] The differences were calculated as significant. As opposed to these results, Zimmer *et al.* did not find an influence of gender on FHR patterns of twins, however he could prove that twins who were lying on the right side of the uterus were significantly more active.[32]

In twin pairs with a DC fused placenta it was described that the rate of similar FHR-patterns regarding the amplitude of accelerations or the baseline was significantly higher (70%) as compared to twins with DC-separate placenta (30%).[86]

Accordingly, we have used the described distribution of active and passive periods as well as periods with variability of above or below 10 bpm to investigate whether different subgroups of twins demonstrate with more or less comparable patterns. Using chi-square tests, we could prove that female twin pairs demonstrate significantly more often with periods of the same variability (60%) as compared to mixed and male groups (50% and 38%, respectively). No influence could be proven by zygosity or position. MZ twins demonstrated more often with active periods compared to DZ twins, which might be attributed to the thinner inter-twin membrane.

FHR–FM patterns after VAS were examined between different subgroups. The mean increase of the baseline was found to be higher in twin pairs with vertex compared to breech position ($p < 0.01$, Kruskal–Wallis test). Multivariate analysis demonstrated a dominant influence of the gestational age, the presentation, and gender. Before 30 weeks, the state before VAS had an influence. An increase of the oscillation amplitude was more frequent in male as compared to female or mixed pairs ($p < 0.01$, Kruskal–Wallis test) and in pairs with both in vertex position ($p < 0.05$, Kruskal–Wallis test). No differences were found in MZ vs. DZ or left compared to right twins. Multivariate analysis demonstrated a significant influence of the state before the stimulation, presentation, gender and gestational age on the oscillation amplitude.

The kind of the first short reaction characterized by either no reaction, only FM or FM with FHR-accelerations is more frequently comparable among twins of the same sex (79% vs. 61%, $p < 0.05$, chi-square test), multivariate analysis demonstrates in addition a significant influence of zygosity after 30 weeks and of the presentation before 34 weeks.

The distribution of reactions of either short or long duration mainly depends, as expected, on the gestational age, the state before VAS and the chorionicity. The presentation only had an influence after 33 weeks. No differences could be found between right and left twins by multivariate analysis. By direct combination, 81% of twins with the same sex demonstrated with reactions of the same duration compared to only 68% of twins with different sex ($p < 0.05$, chi-square test).

The degree of changes of FHR–FM patterns is significantly more similar in MZ than in DZ twin couples (72% vs. 59%, $p < 0.05$, chi-square test). Multivariate analysis demonstrates that the state before VAS, gestational age, presentation and zygosity have significant influences on the degree of state changes between 26 and 36 weeks.

Also, the score by which we considered several FHR–FM variables was significantly more 'similar' in twins with the same presentation, with the same sex and between 31 and 33 weeks in MZ twins.

Table 152.4 Comparison of possibilities to describe fetal reactions towards vibroacoustic stimulation (left column): The parameters listed according to gestational age groups have a significant influence on the corresponding reactive behavioral pattern (n = 390 video tracings/32 twin pairs, multivariate analysis)

Kind of reaction	< 30 weeks	30–33 weeks	33–36 weeks
First reaction		state/zygosity	position
Change of state	state	state/sex	state
Kind of reaction	state	state/sex/position	state/position
Duration of reaction	state	position	position
Score of concordance	position	zygosity	sex

To summarize results from multivariate analysis we list the significant variables according to tracings of age intervals (Table 152.4). With more sophisticated variables and advancing gestational age the influence of gender, zygosity and position increases.

Influences on prenatal behavior under pathologic conditions

The rate of malformations is increased in MZ twins, concordance of malformations is only seen in around 10–20% even within MZ twin pairs.[87] Postulated theories explaining the increased rate of malformations are 'crowding' causing mostly concordant musculoskeletal malformations, early defects in the splitting process with the ultimate example of conjoined twins and vascular compromise secondary to a shared placenta leading to early organ embolization (e.g., disruption).[88]

Differences in the location of the nidation, connective mechanisms between embryonic and trophoblast circulation resulting in variances of umbilical insertion and differences in vasculatory support from the uterine vessels may be a reason for the development of circulative inter-twin differences and A–B asymmetry. Twins represent a unique model to study adaptive changes resulting from unequal placental nourishment. Hereditary difference in growth potential for each infant could be proposed as an alternative mechanism in DZ but not in MZ twins. Differences of fetal behavior in cases with A–B asymmetry – mainly if also detected by Doppler examinations – might be classified as 'environmental' ('nurture').

It is interesting that twins exposed *in utero* to the same 'environmental' influences may react with different degree of abnormality. This indicates that differences in fetal susceptibility or in the speed of their development may be of importance for the expression of syndromes caused by 'environmental' or teratogenic influences ('nature and nurture').

Influences on behavioral variables in early gestation

Individual growth of multiples is comparable with growth of singletons during the first and second trimester. Early growth differences between twins demand further evaluation. Weissman *et al.* reported retrospectively on five cases with discordant growth of > 5 days' difference during the first trimester. In all cases major anomalies were identified.[89]

Up to now in 3/80 multiple pregnancies with intermultiple growth differences of > 7days between 8 and 10 gestational weeks we prospectively performed early behavioral studies including Doppler examinations at 1-week intervals. Behavioral parameters were analyzed from the video tapes and karyotyping was performed.

In the first case (Figure 152.8a), a DC twin pregnancy, a triploidy xxx was diagnosed in the smaller twin next to a healthy boy. The sick twin demonstrated a significantly later onset of activities and contact initiations; some complex patterns such as swallowing and yawning were not observed at all. This twin died *in utero* at a gestational age of 26 weeks. Pregnancy continued until 35 weeks.

In the second case, a TC TA triplet pregnancy, one embryo appeared as a 'vanishing triplet' at 11 weeks. The most striking behavioral difference was a reduced number of movements and lower heart rate until intrauterine death.

In the third case, a TC TA triplet pregnancy after ovulation stimulation, a normal karyotype in all triplets (3x xy) was diagnosed and superfecundation was suspected. Behavioral patterns did not differ throughout the observation period. The mother developed premature rupture of membranes (PROM) 1 week after amniocentesis. All triplets died due to amnioninfection and prematurity.

The analysis of these cases might suggest that detailed analysis of early behavioral patterns including early Doppler parameters as suggested recently[90] might improve non-invasive diagnosis mainly in cases when other symptoms of risk are present.

Twin-to-twin transfusion syndrome (TTTS) may also develop as early as from 10 weeks onwards. The earliest case we have observed presented with extreme hydops of the recipient with tricuspid and mitral valve regurgitation of the recipient at 16 weeks. Laser treatment was performed at Kings College Hospital in London.[91] Though the condition of the twins stayed

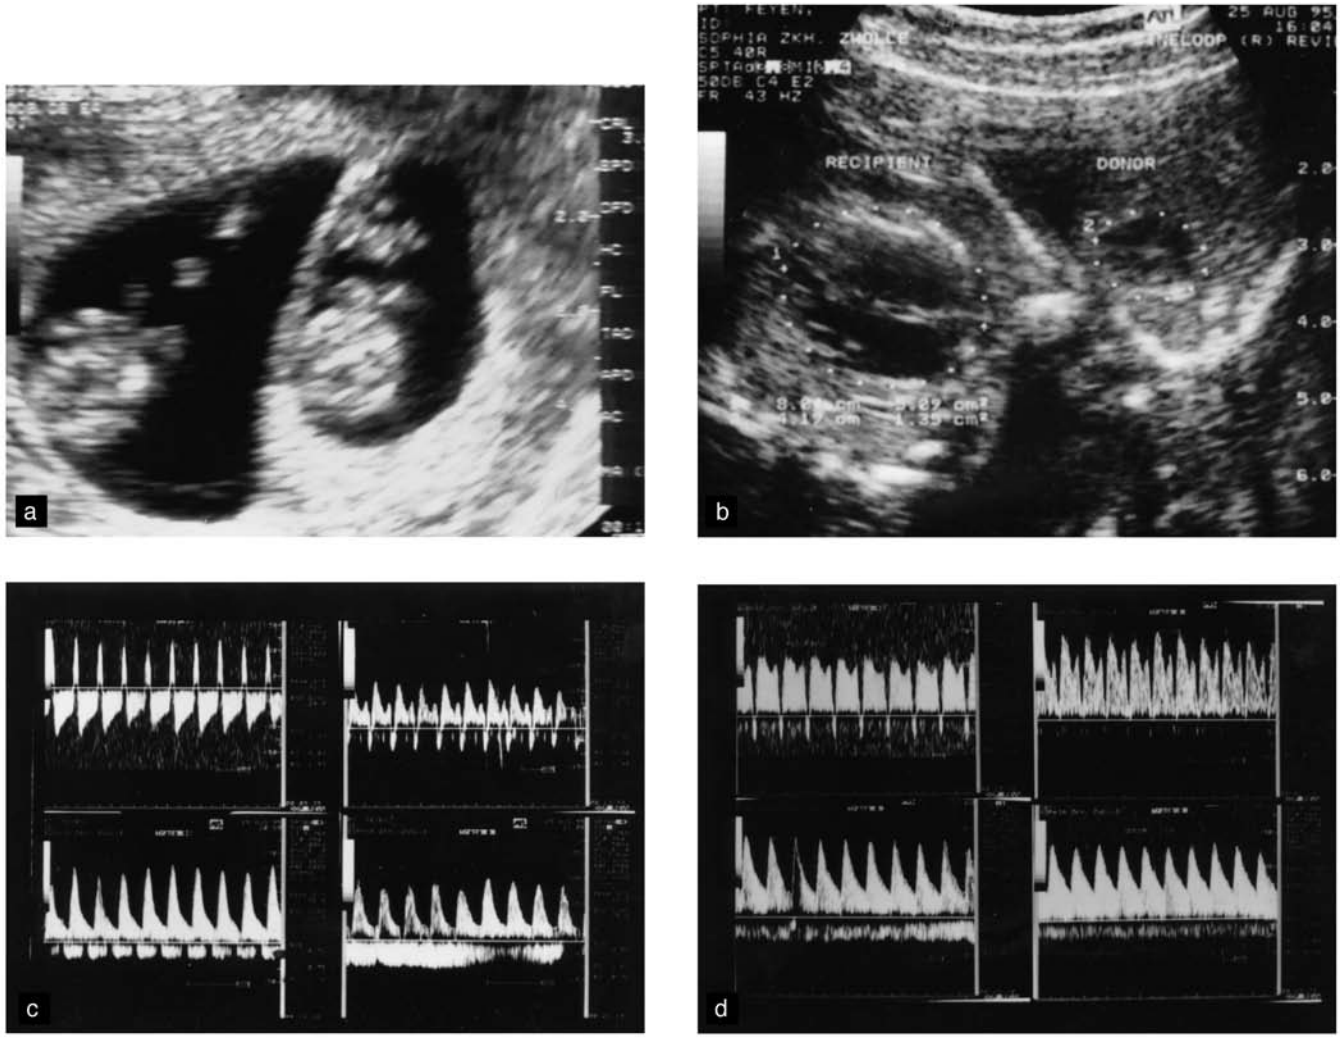

Figure 152.8 Ultrasound pictures of pathologic early twin gestation. (a) Early growth difference in a dichorionic twin pregnancy at 10 weeks (triploidy xxx). (b) Early TTTS at 16 weeks with hydrops of the recipient twin (left), there is evident inter-twin difference in cardiac dilatation. (c) Doppler flow velocity wave forms of the ductus venosus (above) and the umbilical vessels (below) of recipient (left) and donor twin (right) before treatment. (d) Doppler flow velocity wave forms of the ductus venosus (above) and the umbilical vessels (below) of recipient (left) and donor twin (right) after treatment.

stable, the hydrops did not disappear until we started with digitalization of the mother. Before treatment the ductus venosus velocity waveforms of the recipient showed a significant reverse flow as described[92] and umbilical flow demonstrated with venous pulsations (Figure 152.8c, left). Only some days after digitalization the hydrops disappeared and behavioral patterns of both twins switched towards more active periods (Figure 152.9a). The donor twin presented with increased activity (Figure 152.9b). Doppler velocity waveforms improved (Figure 152.8d, left). Placental evaluation by computer-angiography revealed that there were no communications between the two placental parts.

Doppler examination is regarded as an important tool in the diagnosis of MA twinning visualizing common tangle at the cord insertion[93] or later in gestation the occurrence of notches.[94] In the two cases with MC MA placentations (Figure 152.1c and f) that we have followed up to now we observed two arterial patterns with different heart rhythm reflected from the entangled umbilical cords already at 10 weeks. Though we were skeptical about the prognosis we could continue even the DC DA triplet pregnancy until lung maturity was proven at 34 weeks. Growth and FHR–FM patterns were not at all affected during the whole course of pregnancy, though excessive entanglement was diagnosed during caesarean section. Close monitoring including behavioral patterns and circulation helps clinical decision making, but can also give confidence to parents and doctors in charge.

Influences on behavioral variables in advanced gestation

Interesting aspects of behavioral studies can be drawn from twin gestations discordant for fetal anomalies also in advanced gestation. In a case report of a DC

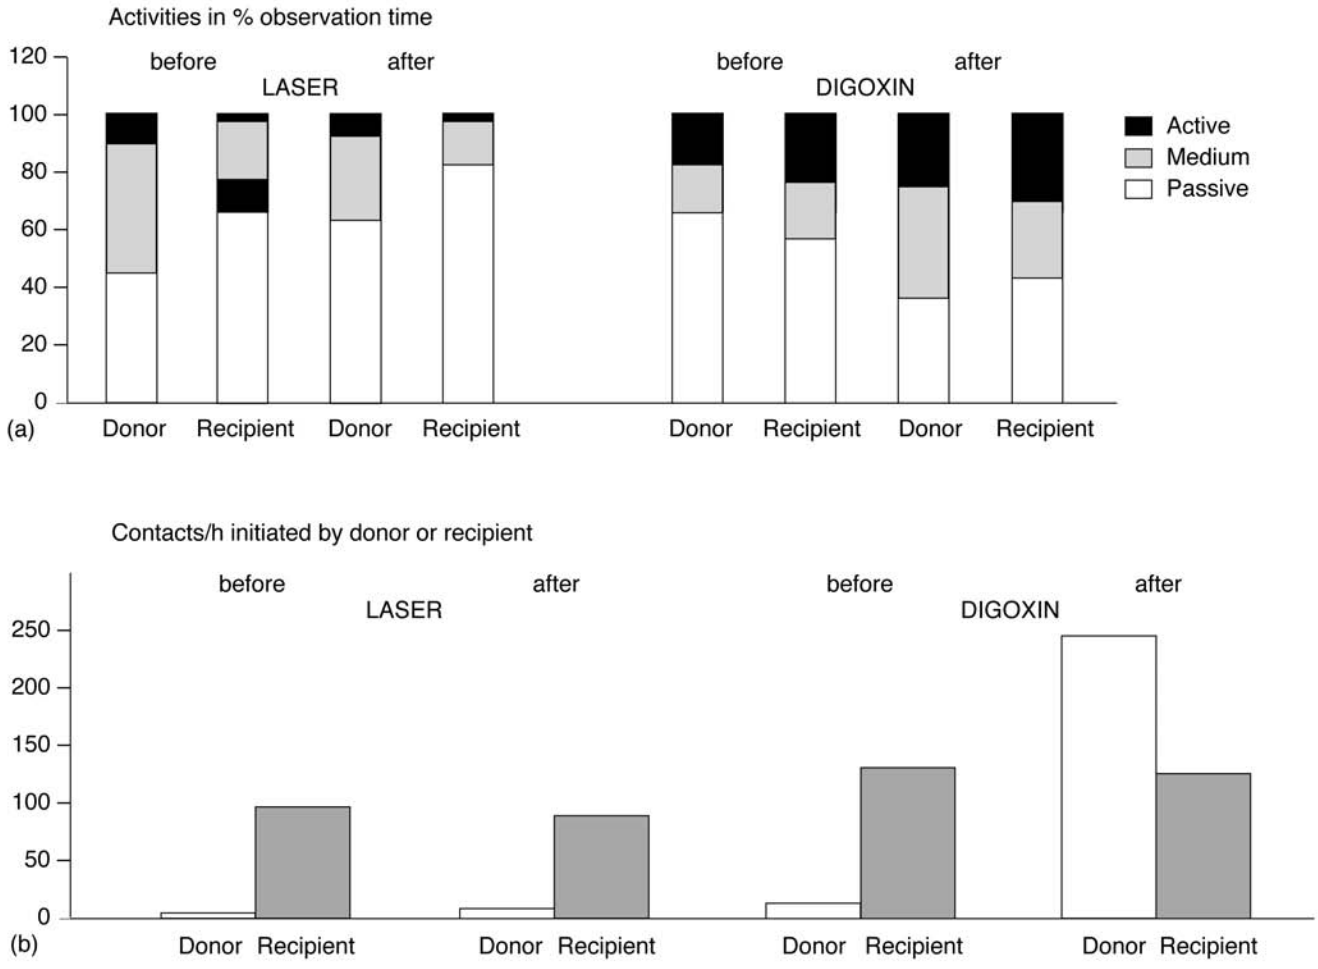

Figure 152.9 Behavioral patterns before and after treatment of early TTTS between 16 and 20 gestational weeks. (a) Activities given as active (fast FM), medium (slow FM) and passive (no FM). (b) Contacts with reactions of the co-twin.

twin pregnancy discordant for anencephaly significant inter-twin differences could be found.[95] Data analysis of ultrasound observations revealed that the incidence of startles and jumping, decreasing in the normal fetus, remained high in the anencephalic one. It is suggested that these movements are due to spinal cord stimulations and their elimination is usually controlled by the brain above the medulla oblongata. In contrast, breathing movements and hiccups were limited or nearly absent in the anencephalic twin indicating that at least an intact medulla oblongata and pons are required for preparatory movements.

In a similar case that we have documented from 30 to 34 weeks of gestation, we have additionally observed that FHR-variability was significantly decreased in the anencephalic fetus whereas FMs were increased, maybe due to the polyhydramnios. Reactions towards VAS did not occur in the anecaphalic fetus (unpublished).

The clinical significance of FHR–FM patterns in advanced pregnancy of twins or higher-order multiples, in general, does not differ significantly from those in singleton pregnancy. Still, probably due to inter-twin stimulation or difficulties in interpretations of two simultaneous FHR tracings, FHR–FM patterns might not be as an early indicator of threatening fetal hypoxia as in singletons.

As already known from singleton pregnancy, Doppler flow velocity wave forms of umbilical, arterial cerebral and venous vessels are now prerequisite for the control of pathologic multiple pregnancies to differentiate the underlying pathologic processes. In TTTS umbilical arterial Doppler is of no obvious value and is meanwhile replaced by venous Doppler measurements[92] as already described at early gestation. Predictive sensitivity of Doppler examination in the internal carotid and the umbilical artery preceded diagnosis of growth retardation in twins by a mean of 3.7 weeks, combining ultrasound improves the sensitivity to 84%[96] and interpair differences also improve prediction of discordant growth of twins[96] and triplets.[97] It would be interesting to examine, whether intrauterine stress may cause accelerated maturation measurable by behavioral variables.

It has to be considered that with advancing gestational age behavioral states might have an influence

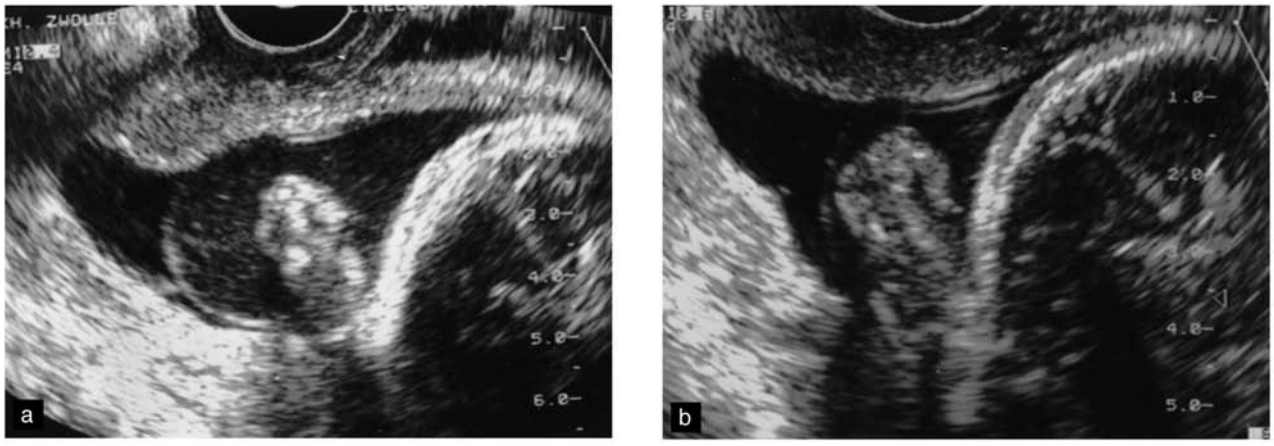

Figure 152.10 Future aspects of twin behavior: 'the self examining twin'. (a) Funneling with spiriting amnion and chorion. (b) Examining hand of the first twin.

on Doppler velocity waveforms as proven for singletons.[21,98,99] We have up to now not yet repeated these studies for twins, since the simultaneous registration of FEM would demand to use two Doppler equipments and separate ultrasound equipments. To investigate multiple behavior during advanced gestation under pathologic conditions is awaited for, but would definitely imply, that all data from Doppler examinations have to be included in the protocols.

Though we have used VAS as a tool for research under described conditions, we have up to now consciously withheld it from clinical routine and therefore no experience with systematic clinical testing besides from controlled trials. Warning hints from the literature not to use VAS in cases with low variability and possible hypoxia to avoid unnecessary stresses for the fetus[100] may be taken even more seriously in twins.

An interesting aspect of multiple gestation are pregnancies in which both twins are exposed to the same pathologic influences such as drugs, alcohol or nicotine. In a set of DC twins of a frankly alcoholic mother, one twin presented with the stigmata of fetal alcohol syndrome, whereas the other just displayed mild fetal alcohol effects.[101] Whether different susceptibility to ethanol dysmorphogenesis or exposure to different concentrations due to different circulation of the corresponding placenta is of primary etiology remains an open question. At present we are investigating the influence of nicotine and caffeine on behavior and hemodynamics of multiples.

Implications for future research

Methodological improvements

Realizing that skepticism often arises toward pioneering work, we are aware that many readers will have doubts on the described phenomena at early gestational age. This might hopefully stimulate them to improve the methods by more intense research efforts.

Methodological self-criticism is realized: Proposing time-intervals and durations of ultrasound sessions we have to compromise with the patients compliance, e.g., discomfort when proposing longer or more frequent ultrasound sessions or anxieties about bioeffects of serial ultrasound studies. Still we realize that within 30–60 min of documentation the whole pattern of possible contacts may not be reflected and that within a week new contacts may emerge without being realized. We still do not know the impact of the time of the day, health or emotion of the mother, food intake or even of ethnic differences on the onset and early development of activities and contacts. Though we have documented these data, larger series are needed.

Methodological criticism also relates to the present form of presentation of this article. Books are being replaced or accompanied by database systems combined with addresses of researchers in charge of the most recent information or meta-analysis.[102] Processes by which moving images are predominant can be presented on CD-ROM and thus improve our understanding tremendously.[103] For several ultrasound features including behavioral patterns and hemodynamics, as well as for delivery management, 'multimedia documentations' would be of enormous advantage.

Computer analysis of behavioral FHR and FM patterns has been described, mostly for singleton pregnancies.[104] In twins, the advantage is that the high number of data can be compromised. There are still a lot of disadvantages: most computer programs only concentrate on just one of two parameters such as FHR-variability and incidence of movements. The tremendous advantage of behavioral observations are, however, primarily to describe and analyze qualities of activities or phenomena that have to be carefully described in order not to lose precious information.

Reaction of the family toward ultrasound visualization of multiples' 'bonding'

The first steps *in utero* are observed with enthusiasm by parents and siblings. Visualization of prenatal twin life seems to evoke even more surprising reactions than in singletons. The existence of inter-twin contacts

in utero is perceived with great amazement. The early tender touches are moving, the more forceful hitting and kicking at a later stage may sometimes cause laughter. It is impressive that the fetuses are touching and reacting without seeing each other. Following the expression of parents, they 'embrace' and 'kiss' without having had teachers. Questions arise about the inborn aspect of contacts in humans.

Parent–infant bonding is defined as a one-way concern and affection of adults towards children they care for during the first days of life was systematically described only as late as 1972.[105] As soon as the contact is reciprocal, even if it is only by crying or smiling, we speak of attachment. In mothers who experience extra contact with their infants at the time of delivery and during the first days of life, maternal–infant bonding is facilitated.[106] It is also suggested that emotional attachment to the fetus starts shortly after conception and deepens as pregnancy progresses. This is also true in high-risk pregnancies[106] – as multiple pregnancies often are. Early affectionate relationships may also develop towards two newborns[107] though initial bonding difficulties were seen more frequently due to medical problems, prematurity and maternal feelings of inadequacy. Early ultrasound examination might prepare parents of their future task and allow space for talks and dreams.

The impact of ultrasound on expectant parents in singletons has been found to be a reassuring experience[107] inducing a positive attitude towards the growing baby.[108] After a single ultrasound examination between 12 and 20 weeks[109] the baby was perceived as being more active, more beautiful and familiar as well as the woman's own body as more pleasant, relaxed and less fearful. Integrating other family members might facilitate that all members of the new family will be welcomed more easily. We always ask that besides the husbands, older young brothers and sisters also take part in the ultrasound sessions and stimulate them to paint the future family in order to avoid later jealousy.

Prospective studies of the effect of frequent and early ultrasound examinations on bonding or attachment in multiple pregnancy have not yet been performed. Unfortunately, it is only recently that we became increasingly aware of the impact of our examinations on bonding and on the doctor–patient relationship and therefore have only performed retrospective questionnaires. Prospective research and sampling procedures might demand professional efforts of psychologists and large sample sizes.

Follow-up

Follow-up examinations are the best control – yet this is far from reality. Many perinatologiosts only hear incidentally of the further development of their prenatal patients and are sometimes surprised to hear of either positive or negative outcomes. Unfortunately, health systems do not care sufficiently to promote direct 'bonding' between pediatricians and perinatologists which makes it difficult to get systematic data on specific risk groups. This also holds true for twins and higher-order multiples and even more, if comparison of prenatal and postnatal behavior is concerned. We admit that prospective studies would be time-consuming for both sides.

Activity itself promotes growth and dendritic branching of individual neurons. Sensation from receptor cells promotes the development of the neural system.[110] The fact that twins experience more tactile stimuli than singletons might improve their development. This was speculated by early follow-up examinations,[111] showing accelerated functional maturation in multiples born between 32 and 37 weeks[112] and by long-term follow-up studies at the age of 6 where multiples scored better than singletons.[113] It can be speculated that intrauterine neurological development is accelerated by increased rates of intrauterine stress of multiples as proven for lung maturation processes.[114] Simultaneous assessment of functional and metabolic maturation of the central nervous system and the lungs at birth of growth-discordant MZ (ideally DC) multiples not due to TTTS or of MZ multiples discordant for PROM would be an interesting topic for a multicenter trial.

Prenatal learning, habituation or adaptation toward touch of the co-twin, as described for repetitive auditory stimuli,[110,115,116] deserves further evaluation. Yet in early gestation nothing is known about the phenomenon of habituation. Again, twin pregnancies would be a perfect model to study eventual 'learning' which is defined as any change resulting from past experience.[117]

Follow-up studies in opposite-sex twins are fascinating: We found a study[118] based on the findings of Zuckerman *et al.*[119] that aspects of sensation seeking are consistently increased in males relative to females. In comparing age-adjusted data for opposite- and same-sex twins, it was shown that there is a predicted increase of sensation seeking in female members of opposite-sex pairs. Though psychosocial explanations cannot be excluded, the findings are consistent with hypothesized *in utero* hormonal influences of prenatal androgen exposure on later behavioral development of females. Influences of estrogen in opposite-sex males could not be proved. This might suggest that it is not sufficient to just analyze all females or all males of all twin pregnancies, but to differentiate as it was performed in our studies, between mixed or pure male and pure female twin pairs. Further comparisons of prenatal and postnatal series are required.

Similarly surprising are follow-up studies in MZ DC vs. MZ MC twins. Intrapair differences in personality and cognitive ability among MZ distinguished by MC or DC placentation were calculated. Absolute differences of individualized personality inventory scores for children between MC MZ co-twins were smaller than between DC MZ twins.[120] The findings are interpreted as follows. Variation in timing of embryological division and possible effects on MZ twins' placental vasculature may have consequences

for some dimensions of their behavioral development as well.

Controlled follow-up studies concentrating on side effects of frequent early ultrasound examinations should be recommended. These studies could be combined with other study proposals and be collected in an international 'behavioral register'. Still, manpower, limited international communication and statistical evaluation play a limiting role.

How far increased intelligence scoring of postnatal twins as compared to singletons,[113] matched for gestational age and birth weight, suits the intrauterine multiples is an open question. In a prospective study to detect the diagnostic value to predict prematurity, we could describe that separation of amnion and chorion included in funneling of the cervix was diagnosed as a new risk factor (Figure 152.10a and b).[121]

Conclusions

Multiple pregnancies do not only represent sorrows and problems as indicated in the obstetric literature. They also represent challenges mainly for their parents and perinatologists. Therefore, we would like to add the statement supported by more than 1000 publications during the last decade: 'It is tough to be a twin: The risk of disorder, disease and death are greater for all members of a plural set from the moment of conception to the end of their life span and encompass physical, psychological and social threats'[122] …by a new statement: 'It is also great to be a twin: The stimulating pleasure of close company, contact, competitive challenges and interaction are unique for all members of a plural set from the moment of conception to the end of their life span and encompass physical, psychological and research chances'. Do not forget: No pleasure without risk!

153 Invasive antenatal interventions in complicated multiple pregnancies

L. Lewi, E. Gratacos and J. Deprest

Abstract

Multiple pregnancies still pose challenging problems in modern obstetrics. Monochorionic (MC) multiple pregnancies have received much interest recently as they indeed are at much higher risk than dichorionic multiplets. Some complications can be treated today by sonoendoscopic interventions on the placenta and umbilical cord. Fetoscopic laser coagulation of vascular anastomoses has recently been shown to be the best first-line treatment for severe twin-to-twin transfusion syndrome. In selected indications, fetoscopic or ultrasound-guided cord coagulation can be offered and is an effective technique for selective feticide in MC twins, albeit with still considerably higher fetal loss rates as compared to selective feticide by KCl injection in dichorionic twins. Long-term outcome of these procedures seems good. The place of surgical interventions for other indications, such as some forms of selective intrauterine growth restrictions in MC twins, has not been established yet.

Twins have a more complicated *in utero* stay than singletons. Also, management is complicated by the fact that more than one fetus has to be taken into account and varies according to chorionicity. About 30% of twins are monozygotic and 70% dizygotic. Dizygotic twins result from the fertilization of two different eggs. By definition, dizygotic twins are therefore dichorionic and diamniotic (Figure 153.1). Monozygotic twins result from the fertilization of a single egg followed by early division into two cell masses, which further develop separately. In 30%, cleavage occurs prior to the third day postfertilization resulting in dichorionic diamniotic twins, whereas in 70% splitting takes place after the third day, resulting in MC twins in its different manifestations.

Correct and timely determination of chorionicity is paramount to appreciate the risks and correctly manage multiple pregnancies. Ultrasound is highly accurate when performed in the first trimester (Figure 153.2).[1] MC multiplets run the highest risk of complications and the well-being of one fetus crucially depends on that of the other(s) because of the almost ever-present vascular anastomoses in the common placenta (Figure 153.3).[2] These vascular anastomoses can cause significant blood volume shifts between the fetuses, leading to complications such as twin-to-twin transfusion syndrome (TTTS), acute exsanguination of the survivor in the fetoplacental unit at the time of demise of its co-twin, as well as in the presence of large intertwin arterio-arterial (AA) anastomoses, for instance, in case of selective intrauterine growth restriction (sIUGR), or in its extreme form, the twin reversed arterial perfusion (TRAP). Sonoendoscopic surgery on the placenta and the umbilical cord today plays an important role in the treatment of certain complicated MC multiple pregnancies and has acquired an established place in modern fetal medicine.[3] TTTS affects about 10–15% of MC twins and fetoscopic laser treatment of the vascular anastomoses is currently the best treatment available.[4] For selective feticide in MC multiple pregnancies, the conventional method of potassium chloride injection into the target fetus' circulation is unsuitable because the toxic drug may embolize to the healthy fetus(es). Furthermore, patent anastomoses can trigger acute exsanguination of the surviving fetus into the demised fetus' circulation[5] Therefore, minimally invasive techniques have been developed to separate and occlude the sacrificed fetus' circulation completely and permanently.[6] The presence of vascular anastomoses in the single placenta seems to be the basis of many complications, and it seems logical to apply experience with the above techniques in other complicated MC twins. At this moment, however, such therapies remain experimental and should be restricted to expert centers and within strict protocols.

Fetoscopic laser treatment for twin-to-twin transfusion syndrome

Introduction

In most MC multiple pregnancies, interfetal transfusion is a constant but usually balanced phenomenon. However, in about 10–15%, a chronic imbalance in net flow develops, resulting in TTTS. The donor twin becomes hypovolemic, resulting in oliguria and oligohydramnios, which leads to the typical 'stuck twin' sequence on ultrasound. Hypervolemia, polyuria and polyhydramnios evolve in the recipient twin, who can develop circulatory overload and hydrops. TTTS typically occurs between 15 and 26 weeks and is a sonographic diagnosis based on the following criteria (www.eurofoetus.org):

- Polyhydramnios in the sac of the recipient twin (defined as the deepest vertical pocket of ≥ 8 cm prior to 20 weeks and ≥ 10 cm between 20 and 26 weeks) with signs of polyuria (distended bladder).

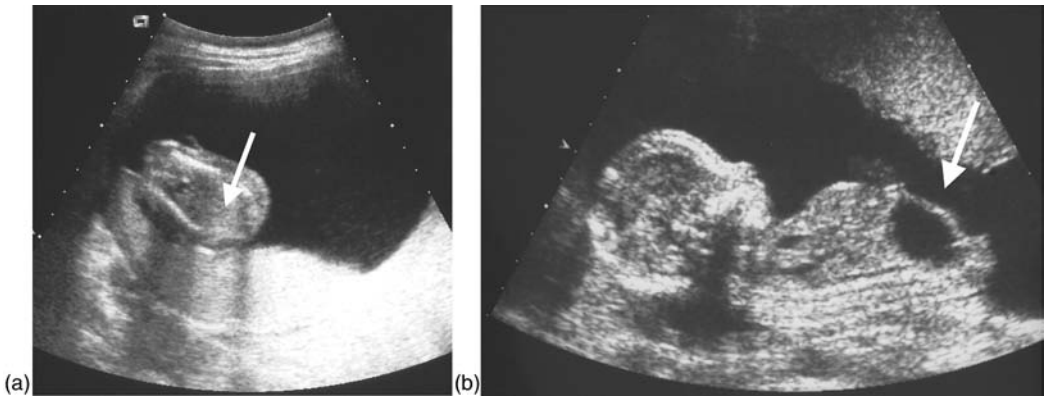

Figure 153.4 Ultrasound image of TTTS. (a) The donor is stuck to the uterine wall without bladder filling. (b) There is polyhydramnios in the sac of the recipient, who has a distended bladder.

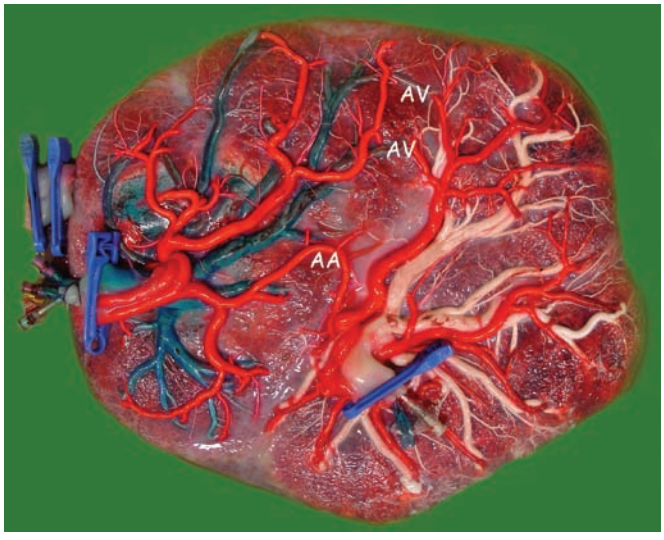

Figure 153.5 Macroscopic image after dye injection of a monochorionic placenta. (a) Superficial AA and deep AV anastomosis. (b) AV and oppositely directed VA anastomosis.

- Oligohydramnios in the donor's sac (the deepest vertical pocket ≤ 2 cm) with signs of oliguria (small or empty bladder) (Figure 153.4).

The diagnosis is made by ultrasound only; discordant growth may be present, but is not a prerequisite.

The pathophysiology of TTTS is usually explained on an angioarchitectural basis. Placental anastomoses can be AA, arterio-venous (AV or VA) and veno-venous (VV) or a combination of these types.[7] AA and VV anastomoses are typically superficial, bidirectional anastomoses on the surface of the chorionic plate, forming direct communications between the arteries and veins of the two fetal circulations. AV anastomoses occur at the capillary level, deep within a shared cotyledon, receiving arterial supply from one twin and providing venous drainage to the other twin. The supplying artery and draining vein of the AV anastomosis can be visualized on the placental surface, piercing the chorionic plate at close proximity to each other to supply the shared cotyledon, which may receive other vessels too (Figure 153.5). AV anastomoses allow flow in one direction only, and hence can create an imbalance in the interfetal transfusion leading to TTTS, unless balanced by an oppositely directed transfusion through other (superficial or deep) anastomoses.

Untreated, severe mid-gestational TTTS has a mortality rate of nearly 100%. Polyhydramnios may lead to spontaneous abortion, rupture of the membranes and/or extreme preterm delivery. It may also have a direct effect on fetal hemodynamics and placental function. *In utero* fetal death (IUFD) may result from cardiac failure in the recipient or poor perfusion in the donor, which may lead to acute, agonal or postmorten intertwin transfusion into the dead fetus. Additionally, there are substantial risks of cerebral and cardiac sequelae in survivors due to the chronic or acute hemodynamic imbalance. Initially, only serial amnioreduction was available as a treatment option to reduce the polyhydramnios and intrauterine pressure, thus alleviating symptoms and prolonging pregnancy. Repeated amnioreduction is a simple and widely available technique, but it does not address the vascular basis of TTTS. The anastomoses remain patent maintaining the pathologic chronic transfusion process or, in the event of single IUFD, allow acute interfetal transfusion, putting the surviving twin at high risk of IUFD, anemia and neurological damage. Vascular anastomoses can in most cases be visualized on the chorionic surface during fetoscopy, and their coagulation would therefore be a causative treatment. A recent randomized trial set up by the Eurofoetus research consortium comparing serial amnioreduction vs. laser coagulation for severe TTTS prior to 26 weeks showed that laser had significantly better outcome in terms of survival of at least one twin (76% vs. 51%), gestational age (GA) at delivery (33.3 vs. 29.0 weeks) and neurological damage (6% vs. 14%),).[4] Laser, therefore, appears to be a better first-line treatment than amnioreduction.

Technique of laser coagulation

Hardware

Today good-quality videoendoscopic hardware is a given, including a high-quality light fountain, lightweight video camera and monitor. For fetoscopic operations, some extra investments are needed, such as a range of purpose-designed fetoscopes and adapted sheaths, long light cables and a twin camera system mixing ultrasound and endoscopic images may be helpful. Further, appropriate energy sources are needed to coagulate the vessels of interest. Laser energy sources with specific absorbance in the red are preferred, such as Nd:YAG (minimal power requirements 60–100 W) or diode (minimal power requirements 30–60 W), which typically comes with bare fibers of 400–600 μm. For intrafetal or cord electro-coagulation, a conventional electrosurgical generator can be used.

Fetoscopic endoscopes differ from their hysteroscopic or laparoscopic counterparts but are delivered by the same suppliers. At present, there is no evidence that one particular brand or even type of endoscope performs better than another. Intuitively, one strives for a combination of minimal diameter, appropriate length and maximal light transmission and resolution. Personal preference, local factors such as after sales-service and compatibility with other operation room equipment will influence the choice of the manufacturer. In Europe, considerable investments have been made by the European Commission in its 'Biomed 2 Programme' for instrument development by a partner of the Eurofoetus research consortium (Karl Storz Endoskope).[8] Thanks to this project, a range of 20–30 cm fetoscopes with diameters of 1.0–2.3 mm are now available (Figure 153.6).[9] The majority are semiflexible 0° fiberoptic scopes, which can be curved, e.g. to direct the scope toward an anterior located placenta.[10] Rod lens telescopes have also been fabricated, with angles of inclination up to 30°, with an associated deflecting mechanism for the laser fiber. Steerable fiberscopes have also been used for an anterior placenta;[11,12] however, image quality is not optimal because of poor light transmission (unpublished observations). A double-access method with side firing fibers has also been reported in that case. All scopes are used within a sheath, housing the endoscope and any additional instrument such as a laser fiber or other. Fibers are usually inserted through an additional working channel, which keep the fiber in a stable position. Luer lock connections allow irrigation or drainage of fluid.

To gain entry, the sheath can either be introduced directly or through a cannula. For direct introduction, the sheath is loaded with its accompanying trocar. The sheath is inserted into the amniotic cavity under ultrasound guidance and once inside, the trocar is removed and replaced by the fetoscope. During the procedure, the sheath can be moved back and forward – causing friction at the membrane–myometrium interface, but cannot be withdrawn without losing access to the amniotic cavity. The use of formal cannulas obviates this problem, as the port remains during the entire procedure and instruments and scopes can be interchanged numerous times. We ourselves use teflon cannulas, which are thin-walled and therefore add only 0.3 mm to the external diameter of the sheath, are semiflexible to accommodate curved instruments and come in a variety of diameters with purpose-developed fitting trocars.[9] There are currently no data available to support either the direct or cannula access method to the amniotic cavity. Further technical details on endoscopes and ancillary equipment are available in more recent handbooks on fetal therapy.[13–15]

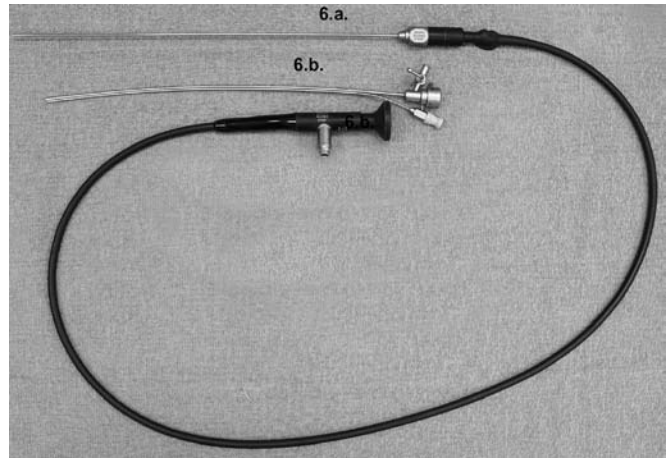

Figure 153.6 Example of fetoscopic instruments as used for laser coagulation of the vascular anastomoses in TTTS. (a) Straight forward telescope, diameter 2 mm, length 30 cm, with remote eyepiece (Karl Storz, Tuttlingen, Germany). (b) Fetoscopic sheath with channel for laser fibers up to 600 μm with one stopcock and one luer-lock adaptor (Karl Storz).

Procedure

Preoperatively, in our institution, all patients receive 2 g cefazolin i.v. and 20 mg slow release nifedipin postoperatively (PO), which will be continued for 48 h. Laser coagulation is performed by percutaneous approach (Figure 153.7) through a 3-mm incision under local or locoregional anesthesia and under strict aseptic conditions. The position of the fetuses, umbilical cord insertions and placenta is mapped by ultrasound scan. A skin incision is made the size of the sheath, and under ultrasound guidance the cannula or fetoscopic sheath is inserted into the hydramniotic sac (Figure 153.8). At all times, the placenta, fetal parts, maternal vessels and bowel are avoided. We personally use, in addition, transplacental sedation of the fetus while administering remifentanyl to the mother, which is a short-acting agent.[16]

In TTTS, fetoscopic detection of the anastomoses is improved by the presence of polyhydramnios. The amniotic fluid is normally clear by dilution and its volume flattens the placenta. Occasionally though vision may be hampered by blood (from previous procedures or bleeding) or debris. In these instances, amnioexchange with warmed Hartmann's solution heated by a blood warmer or a special amnioirrigator[17] can improve visibility. Three fixed landmarks are used to identify any anastomosing vessels: the intertwin membrane, the recipient's and the donor's cord insertion. The intertwin septum and its placental insertion are easily identified as a white line (Figure 153.9). From there, blood vessels leaving the donor usually cross under the septum in the direction of the recipient. These blood vessels are followed to identify any anastomosing vessels. Importantly, the vascular equator does usually not coincide with the intertwin septum and cannot be predicted by simple determination of the cord insertions. Alternatively, vessels can also be followed starting from the recipient's or donor's cord insertion. The purpose of the procedure is to visualize the entire vascular equator and to coagulate *all* anastomoses. A 'hyperselective' approach, as discussed by Machin *et al.*[18] – coagulating only the causative AV anastomosis – is probably wishful thinking and not at all used in the European centers practicing laser coagulation. Any residual anastomoses put the remaining fetuses at risk of hypovolemic events in case of single IUFD and may even lead to persistence or reversal of transfusion. Arteries are distinguishable from veins, as they have a darker color due to the deoxygenated blood. Also, arteries usually cross over the veins.

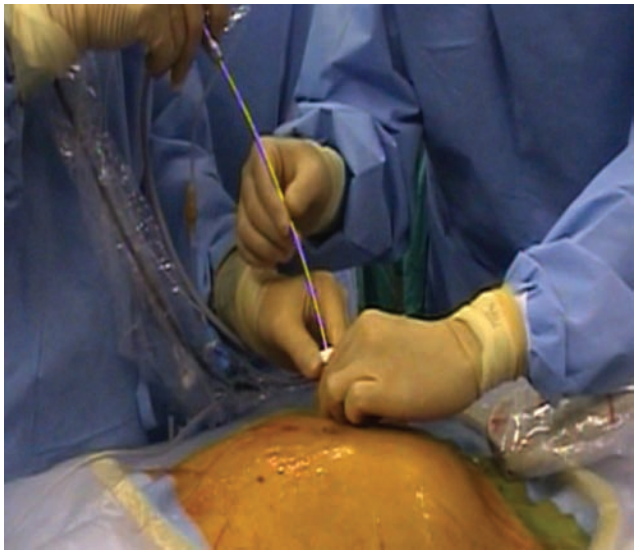

Figure 153.7 Image of the operative setup and percutaneous access used for fetoscopic interventions.

Occasionally, it may be impossible to determine whether vessels anastomose or not, due to the position of the intertwin septum, placenta, fetus or other physical limitations. In these instances, the vessels with uncertain course are coagulated as well. Also, with an anterior placenta, the amniotic sac as well as the vessels on the placenta may be more difficult to access. As mentioned above, instruments for anterior placentas have been purpose-developed, but it is yet unclear whether this improves performance. So far, similar outcomes have been reported for anterior and posterior located placentas.

Coagulation is performed at a distance of approximately 1 cm and ideally at a 90° angle, using a non-touch technique (Figure 153.10). Sections of about 1 cm are coagulated with shots of about 3–4 s, according to tissue response. Laser energy is adapted to the source used, the diameter of the vessels and the tissue response. Typically, a Nd:YAG laser is set at 50–70 W

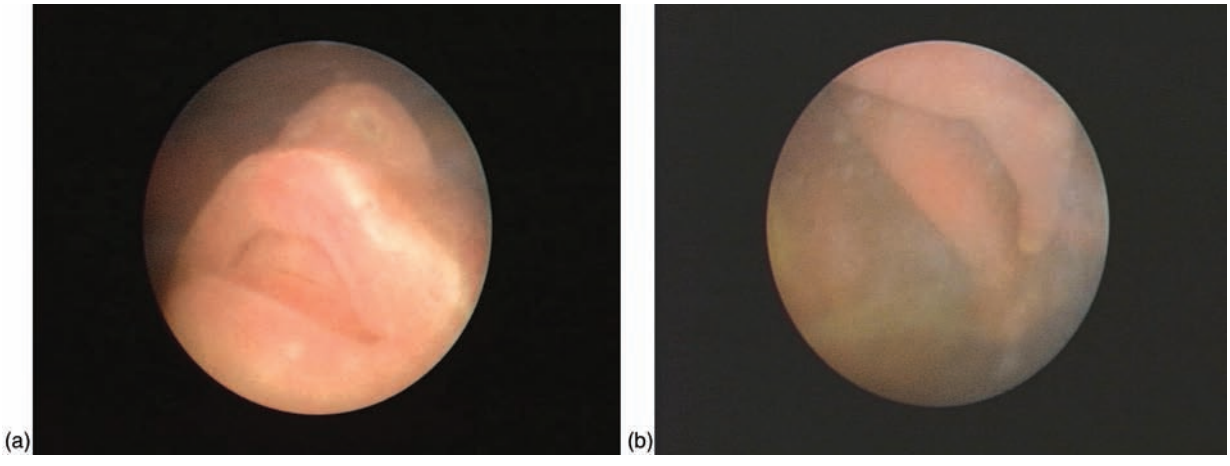

Figure 153.8 (a) Fetoscopic image of the face of the recipient, who moves freely in the hydramniotic sac. (b) Fetoscopic image of the feet of the donor, who is stuck behind the intertwin septum.

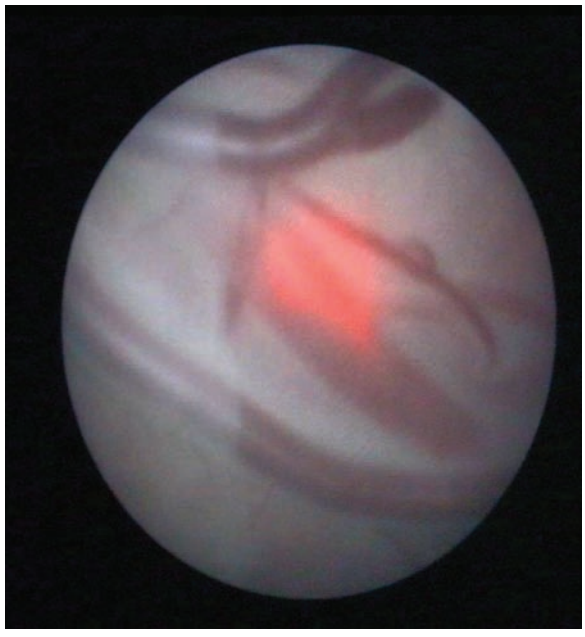

Figure 153.9 Fetoscopic image of the intertwin septum inserting on the chorionic surface with the donor's vessels crossing underneath.

Figure 153.10 (a) Fetoscopic image of a coagulated AV anastosomosis.

and a diode laser at 30–40 W. Large vessels can be coagulated from various angles to obtain progressive narrowing and eventual coagulation. The use of excessive laser power levels should be avoided, as this may cause vessel perforation and fetal hemorrhage. Once all vessels are coagulated, the vascular equator is followed once more to ascertain that all anastomoses have indeed been fully coagulated and that flow has not resumed.

The procedure is completed by amnioreduction until normal amniotic fluid pockets are seen on ultrasound scan. The cannula or sheath is removed under ultrasound guidance to detect any significant bleeding from the uterine wall. In continental Europe, the patient remains as an in-patient for 48 h. Blood pressure, pulse, temperature and fluid balance are monitored. Ultrasound scan is repeated the first and second days to document fetal viability, Dopplers, amniotic fluid volume and bladder filling. Cefazolin is repeated every 8 h for 24 h and the patient stays on nifedepin PO 12-hourly for 48 h.

Hecher *et al.* demonstrated a learning curve, with improving results in terms of survival as well as neurologic outcome over time. We have seen the number of patients developing preterm prelabor rupture of the membranes (PPROM), a strong predictor of preterm delivery, and hence morbidity, dropping with experience. This argues against scattering the experience over too many centers.[19]

Risks and outcome of the procedure

In contrast to amnioreduction, where IUFD of one or both fetuses often occurs remotely from the procedure, most IUFD with laser are diagnosed within 48 h. In our experience with our first 100 cases, this happens in 18% and affects the donor as often as the recipient. The cause of these deaths remains largely unexplained, although it is generally assumed that too little placental mass may remain after laser for both fetuses to survive.[20] However, preliminary data suggest that preoperative MRI accurately predicts placental distribution in TTTS and that postoperative IUFD is not restricted to the fetus with the smallest placental mass.[21] Further research is therefore needed into the exact cause of these losses yet attempting to prevent these. Nonetheless, the surviving twin appears far less likely to be anemic after laser[22] or to sustain neurological sequelae[23,24] compared to survivors after amnioreduction where the anastomoses remain patent.

Another important fetal risk is preterm delivery. In the Eurofoetus research consortium trial (RCT), median GA at delivery was higher in the laser than in the amnioreduction group (33.3 vs. 29.0 weeks' gestation), with 42% and 69% women, respectively, delivering prior to 32 weeks. However, PPROM remains the most important complication of invasive antenatal procedures, accounting for a high morbidity and mortality if the membranes rupture prior to viability. In our own experience of the first 100 cases, PPROM within 5 weeks of the procedure occurred in 16%. The overall incidence of PPROM (<37 weeks) was 45% with median GA at delivery of 30 weeks in

cases with PPROM as compared to 35 weeks in those without PPROM group. Amniotic fluid volume drained, cervical shortening or prior procedures may be contributing to that risk. The intra-amniotic injection of platelets and clotting factors may be a successful technique to treat cases of early postoperative PPROM.[25,26] Other rare fetal complications include congenital skin loss, gangrenous limb lesions, microphthalmia and intestinal atresia.[27,28] These anomalies have been described in TTTS not treated by laser[29] and can therefore also originate from the disease process itself.

The neurological infant outcome in laser for TTTS may be determined by the severity of the disease, the GA at delivery and the procedure. In the Eurofoetus RCT, infants in the amnioreduction group had higher incidences of cystic periventricular leukomalacia (laser: 6% vs. amniodrainage: 14%), in particular the recipients. Presently, the children are being followed until 2 years of age and these results are eagerly awaited. A recent long-term follow-up study of children surviving an uncontrolled series managed by laser (age between 14 and 44 months of age) observed major neurological problems in 11% of survivors.[30]

Maternal safety remains a priority, and serious maternal complications should be registered carefully in a registry, such as the one set up by Eurofoetus.[3] Transient maternal mirror or Ballantyne syndrome with pulmonary edema, placental abruption, chorioamnionitis and bleeding requiring transfusion are reported, but none yet leading to maternal death. In the Eurofoetus RCT, there was no severe maternal morbidity (no woman required ICU admission or blood transfusion), although three placental abruptions occurred at the end of the amnioreduction (two in the drainage and one in the laser group); all requiring immediate delivery. Infection is another potential problem. In our study on fertility and pregnancy outcome in a consecutive series of 100 patients, fetoscopic interventions did not appear to influence future fertility and pregnancy outcome.[31]

Selective feticide in multiple pregnancies

Introduction

The indications, technique and outcome of selective feticide in complicated multiple pregnancies crucially depend on an exact chorionicity determination in the first trimester. In MC multiple pregnancies, selective feticide may be contemplated for several indications: (1) a severe discordant structural or chromosomal anomaly, (2) severe discordant growth with high risk of IUFD, (3) TRAP and (4) severe TTTS with associated discordant anomaly or where inspection of the chorionic plate was precluded by the position of the fetus and placenta. In contrast, in dichorionic twins, selective feticide is restricted to the management of discordant structural or chromosomal anomalies.

Structural anomalies are more common in twins. Unfortunately, most studies have not related their incidence to zygosity or chorionicity. Nonetheless, it seems that in dizygotic twins the rate per fetus is the same as in singletons, whereas in the monozygotic twins the rate is two to three times higher.[32] Even in MC twins, in more than 80% of cases, only one fetus is affected.[33] The exact mechanism of this increased prevalence remains unknown.

In dizygotic twins, the age-related risk of chromosomal abnormalities for one twin is independent of the risk for the other and should be the same as in singletons. Therefore, the risk of at least one fetus, e.g. having Down's syndrome should theoretically be double that in singletons. In contrast, all MC twins are monozygotic and the risk for chromosomal abnormalities should therefore be the same as for singletons and in the vast majority both fetuses are equally affected. Nonetheless, discordance in MC twins for nearly all common human aneuploidies (trisomy 13,[34] trisomy 21,[35] monosomy 45,X[35]) has been reported, most cases involving one twin with Turner syndrome and the other with either a female or male phenotype but usually a mozaic karyotype. This rare phenomenon is called heterokaryotypic monozygotism; going into its exact genetics mechanisms would lead us to far. Our series of selective feticide includes five such cases of discordant chromosomes in MC twins (46,XY/47,XY,+21; 46,XX/47,XX,+13; 46,XY/45,X; two cases of 46,XX/45,X).[36] Heterokaryotic MC twins can only be diagnosed prenatally if an amniocentesis is performed of both amniotic sacs, which is recommended in the event of discordant anomalies in MC twins.[35]

There are essentially three management options for discordant structural and chromosomal anomalies: conservative management, selective feticide or termination of the entire pregnancy. For anomalies that are non-lethal but may well result in serious handicap, parents must thus decide whether the burden of a handicapped child is enough to risk the loss of the healthy twin from feticide-related complications. For lethal anomalies in dichorionic twins, it may be best to avoid such risk and conservative management is preferable, unless the condition threatens the well-being of the healthy co-twin. Such a dilemma is illustrated by twins discordant for anencephaly, which is always lethal but due to associated polyhydramnios places the healthy co-twin at risk of severe preterm delivery. While in dichorionic twins expectant management may be preferable for anomalies with a high risk of *in utero* demise, in MC twins this specifically warrants selective feticide. In dichorionic twins, single IUFD is associated with perinatal death or handicap of the surviving twin in 5–10%, and that is largely

due to extreme preterm delivery. In contrast, single IUFD in MC twins has a co-twin IUFD rate of 10–25% and antenatal cerebral lesions in 25–45% of surviving twins, due to acute exsanguination in the fetoplacental unit of the dead twin, which adds to the effects of extreme preterm delivery.[37,38]

An extreme manifestation of TTTS is TRAP, which complicates about 1% of MC twin pregnancies. In TRAP, blood flows from an umbilical artery of the pump twin in a reverse direction into the umbilical artery of the perfused twin, via an AA anastomosis. The perfused twin's blood supply is by definition deoxygenated and results in variable degrees of deficient development of the head, heart and upper limb structures. Two criteria seem to be necessary for the development of a TRAP sequence. The first is an AA anastomosis and the second a discordant development[39] or an IUFD[40] in one of the MC twins, allowing for reversal of blood flow. The increased burden to perfuse the parasitic twin puts the pump twin at risk for congestive heart failure and hydrops.[41] Because of the rarity of the disorder, the natural history of antenatally diagnosed cases is still poorly documented with reported survival rates for the pump twin varying between 14%[42] and 90%.[43] Data on long-term outcome are not available, although the risk of cardiac and neurodevelopmental sequelae may be high due to hemodynamic imbalances *in utero*.[44,45] Prediction of outcome of TRAP diagnosed is challenging, particularly early in pregnancy. Several parameters have been suggested to indicate poor prognosis such as a high acardiac/pump weight ratio,[46] a rapid increase in the acardiac mass[47] and small differences in the umbilical artery Doppler values.[48,49] These parameters were mostly studied in late second and third trimesters, and do not necessary apply in the early second trimester, where spontaneous resolution as well as sudden, yet unpredictable death of the pump twin have been observed. Early intervention is an issue, as the diagnosis is now usually made at an early stage in pregnancy and the techniques are available. Early prophylactic intervention may preclude the technical difficulties of achieving arrest of flow in larger and often hydropic acardiac masses, as well as cardiac failure. Some may therefore prefer to offer prophylactic, minimally invasive intervention if no spontaneous arrest of flow has occurred by 16 weeks, recognizing the pump twin may survive without any intervention in at least half of cases. It is unlikely whether a more expectant rather than an aggressive prophylactic attitude will ever be shown to be superior, given the rarity of the condition.

For the treatment of TTTS, selective feticide has been proposed, merely to try to salvage one twin.[50,51] The rationale is that laser coagulation has such a high risk of IUFD of one twin that it acts as a selective feticide. Therefore, cord occlusion may appear an alternative, as it is technically easier to perform and may better protect the surviving twin. This approach is at least open for debate, as this will by definition at best yield a 50% survival rate, given no complications occur. It necessarily leads to some difficult decisions. Not only does it pose a tremendous strain on the parents to give up a structurally normal fetus, but also it may not always be easy to determine which fetus will have the worst prognosis. Initially, it was thought to be the donor, especially if abnormal umbilical artery Dopplers were present, but these can normalize after occlusion of the recipient's cord. Access to the donor is also technically more challenging and recipients appear to be at higher risk of neurological[4] and cardiac sequelae.[52] As laser can salvage fetuses at all stages of the disease, advanced disease is not an indication.[20] In our opinion therefore, fetoscopic laser coagulation remains the preferred first-line treatment available in Europe, and selective feticide should be restricted to highly selected and exceptional cases. The place of selective feticide in sIUGR will be discussed further on.

Technique and outcome of selective feticide in dichorionic twins

Selective feticide in dichorionic twins is performed by intracardiac or intrafunicular injection of potassium chloride under ultrasound guidance. It is of utmost importance to ascertain that the correct fetus is terminated by identification of gender differences, obvious structural anomalies, placental localizations and cord insertions. The risks of selective termination are loss of the entire pregnancy and premature delivery. The overall loss rate reported by the international selective feticide registry of 402 multiple pregnancies including some higher-order multiple pregnancies is 7.5%. Preterm delivery before 33 weeks occurred in 22%, with 6% delivering between 25 and 28 weeks.[53] One center with 200 selective feticides reported an overall loss rate of only 4%, with 16% of patients delivering before 32 weeks.[54] This underscores the importance of the procedure being performed by experienced hands, just as for any other invasive procedure. In order to reduce loss rates, it has also been proposed to defer selective feticide to 28–32 weeks, which is obviously only an option in countries where late termination is legal and may be emotionally more difficult to accept for both parents and doctors. In a series on 23 dichorionic twins with non-lethal anomaly, there were no fetal losses and all patients delivered beyond 35 weeks.[55]

Technique and outcome of selective feticide in MC twins

As mentioned above, for selective feticide in MC multiple pregnancies, the conventional techniques of potassium chloride injection cannot be used. Therefore, minimally invasive techniques have been proposed to arrest and isolate the target twin's circulation

completely and permanently,[6] although all have considerably higher risks for fetal loss as compared to the injection of potassium chloride.

Currently, the preferred method for selective feticide in MC multiple pregnancies is cord occlusion by either laser/bipolar coagulation. The initially reported method of umbilical cord embolization using a variety of agents is no longer recommended because of failure rates of > 60%,[6,56] probably due to incomplete vascular obliteration or migration of the toxic products to the co-twin. Fetoscopic cord ligation is already a historical technique, although it does cause immediate, complete and permanent interruption of both arterial and venous flow. Despite the fact that co-twin survival rates are over 70% when done fetoscopically, it is a quite cumbersome technique with a high risk for PPROM.[57] In contrast, fetoscopic laser coagulation of the umbilical cord is a simple technique, which is similar to fetoscopic coagulation of the vascular anastomoses in TTTS. It has been performed as early as 16 weeks, using a double-needle loaded with a 1 millimeter fetoscope and a 400 μm laser fiber.[58] The procedure allows optimal visual control but may fail beyond 20 weeks because of increasing size of the umbilical cord vessels.[59] Ultrasound-guided bipolar cord coagulation was therefore introduced for selective feticide at later gestational ages. In our institution, we primarily use laser coagulation prior to 21 weeks GA. Later on, we may attempt laser coagulation, but in over 75% of bipolar cases will be needed between 21 and 26 weeks, which can be used even later on.[60]

The pre- and postoperative care and access method are similar to those described for laser coagulation of the vascular anastomoses in TTTS. At all times, a double setup for fetoscopic laser and ultrasound-guided bipolar coagulation is prepared. The site of port insertion is chosen according to the position of the placenta, the amniotic sac of the target fetus and its umbilical cord. Preferentially, entry is in the sac of the target fetus to avoid direct interference with the other sac in case of PPROM. Whenever necessary, amniodrainage or amnioinfusion with warmed Hartmann's solution at 38°C is performed to reduce or expand the working space around the target cord and/or to improve endoscopic vision.

Laser coagulation is performed by an Nd:YAG laser or diode laser with bare fibers of 600 μm. The cord is coagulated over a distance of 5–10 cm, using a non-touch technique in continuous mode (Figure 153.11). Absence of flow is interrogated by color Doppler. Septostomy can be performed by laser when direct access to the target sac is not possible and laser coagulation through the intertwin septum fails (Figure 153.12). Bipolar coagulation is performed with a 3.0 or 2.4 mm forceps, according to the cord diameter (Karl Storz). Under ultrasound guidance, a portion of the umbilical cord is grasped at the abdominal wall, at its placental insertion or any other appropriate place as to ensure correct identification and enhance stability (Figure 153.13). Direct contact with the placenta, fetus or membranes is avoided. To improve visual control, a new 'optical' forceps is being evaluated within the Eurofoetus project that combines the advantages of bipolar coagulation and fetoscopy. Coagulation starts at power settings of 15 W applied for approximately 15 s with progressive increments of 2–5 W until the appearance of turbulence and steam bubbles indicative of local heat production and hence eventual tissue coagulation between the forceps' blades (usually between 25 and 45 W). Higher initial energy settings are avoided to prevent tissue

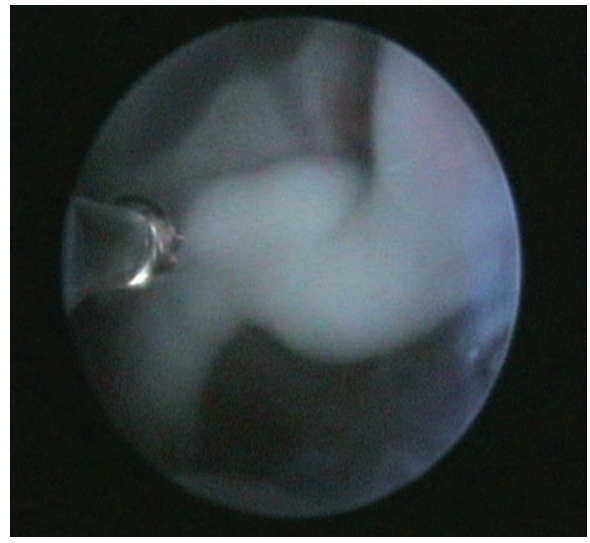

Figure 153.11 Fetoscopic image of laser cord coagulation.

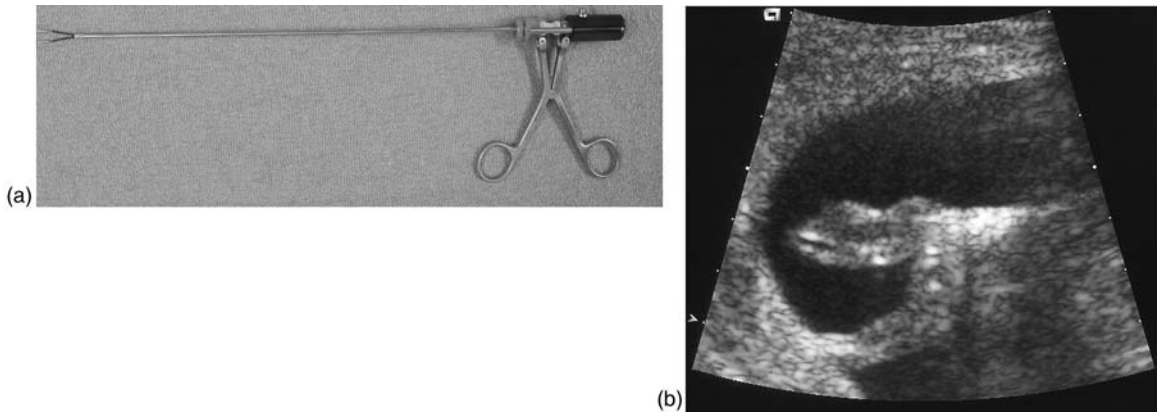

Figure 153.13 (a) Reusable 2.4-mm bipolar forceps (Karl Storz). (b) Ultrasound image of the bipolar forceps grasping the umbilical cord at its placental inertion.

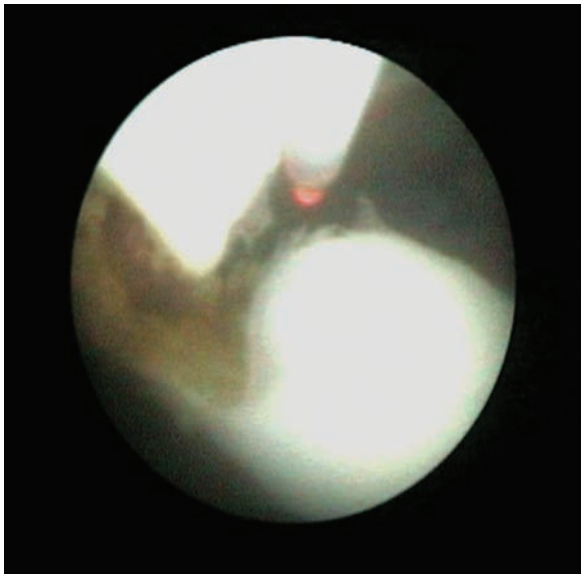

Figure 153.14 Fetoscopic image of a cord transection by laser in contact mode after selective feticide in monoamniotic twins.

carbonization, which may lead to the cord becoming stuck to the forceps' blades and eventual cord perforation. Confirmation of arrest of flow is performed after the forceps is freed from the umbilical cord by gentle manipulation. Even if there is no longer any visible flow, two additional cord segments (preferentially at a site more proximal toward the target fetus) are coagulated. This is an additional safety precaution, because absence of Doppler flow may be caused by temporary vasospasm rather than by true vascular obliteration. In monoamniotic twins, to avoid later cord entanglement, the cord is first coagulated and then transected with laser in contact mode (Figure 153.14). After completion of the procedure, amniodrainage of excessive fluid is carried out before removal of the cannula. Middle cerebral artery Dopplers are performed postoperatively to detect fetal anemia.

In our initial 10 cases, two patients had PPROM and underwent a termination. The other eight patients delivered at a mean gestation age of 35 weeks, i.e. more than 15 weeks after the procedure.[56] Later Nicolini *et al.* reported their experience with 17 cases.[61] The survival rate was 81% (13/16 survivors; one patient had TOP because of an abnormality diagnosed later on). There was one fetal hemorrhage caused by cord perforation, which may be avoided by not applying too much energy. We reported the outcome of 50 consecutive cord coagulations in complicated MC multiplets (including four triplets) by laser and/or bipolar coagulation performed between 16 and 28 weeks (mean 21 weeks).[62] Indications were TRAP (38%), discordant anomaly (38%), severe TTTS (20%) and selective IUGR (4%). In 75%, laser was used as the primary energy, but additional bipolar was necessary in about half of the cases. Overall survival was 75% with normal outcome (range: 1–36 months, 63% follow-up), except for one child with mild developmental delay born after PPROM < 28 weeks GA. Persistent PPROM < 30 weeks occurred in 25%, and if < 25 weeks, was associated with a mortality of 80%. There were no serious maternal complications, except for one mild transient mirror or Ballantyne syndrome. To avoid the risks of early PPROM for the healthy co-twin, there is a strong argument to defer selective feticide until after 24 weeks in highly selected cases of discordant anomaly where the risk of IUFD is small (such as in severe discordant central nervous system, genitourinary, skeletal anomaly), at least in countries where this is legally possible, and when ethically acceptable. Bipolar coagulation can then be performed using the 3.0-mm forceps by overstretching the blades whereupon the forceps opens more widely to accommodate for the larger cord diameter, as we showed in a consecutive series of five cases performed between 26 and 30 weeks

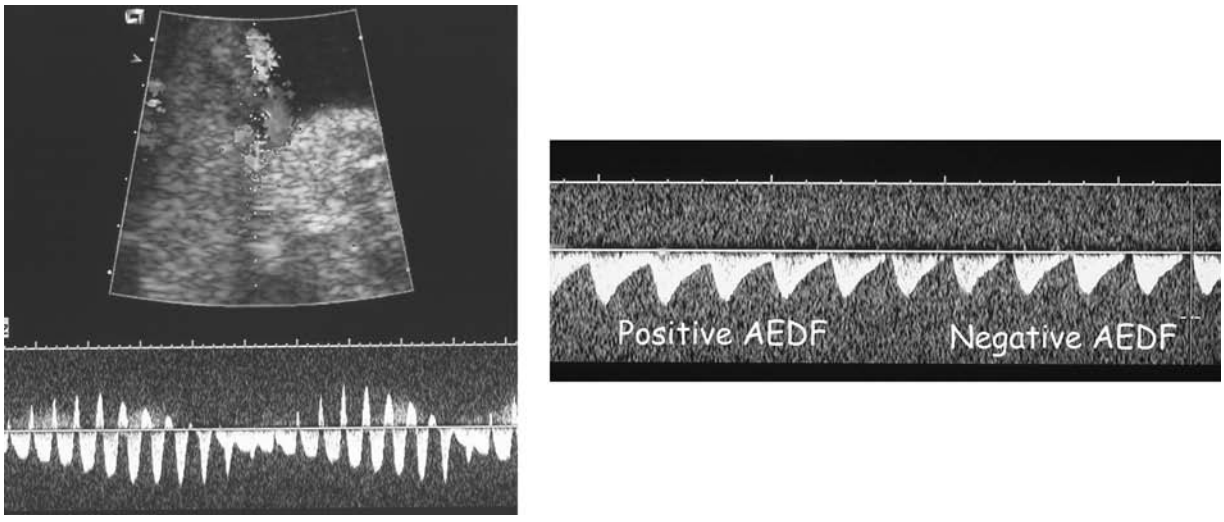

Figure 153.15 iA/REDF: Abnormal Doppler findings in umbilical artery with intermittently a positive, and negative flow (right) and reversed flow (left), a sign of retrograde transmission of an AA wave from in the umbilical artery.

GA. All deliveries occurred beyond 31 weeks (range: 31–37 weeks). All infants survived, except for one unrelated neonatal death of a child born at 36 weeks due to a complication of balloon dilatation for pulmonary stenosis.[63]

Selective growth retardation in MC twins

sIUGR complicates approximately 7% of all MC twin pregnancies.[64] sIUGR is usually defined as fetal growth below the P_{10} for GA together with an intertwin weight discordance of $>25\%$, calculated as [(larger twin – smaller twin)/larger twin]. It is usually associated with an unequal distribution of the placental vascular territory. While the incidence is similar in dichorionic and MC twins, the nature and incidence of risks is not. Neurological damage is much more frequent in MC with sIUGR, mainly due to the existence of intertwin placental anastomoses.[65] Intrauterine demise of the IUGR twin may result in agonal postmortem acute feto-fetal transfusion, with concomitant death of the larger twin (occurring in 25–30% of cases) and neurological damage in 30% of survivors.[66] Recent clinical studies indicate a substantial risk for neurological damage in the absence of single IUFD of the small twin.[67,68] In one series ($n=13$),[67] abnormal neurodevelopment was observed in 42% of children and cerebral palsy rates were 19%. There were four instances of IUFD; three children survived and all had cerebral palsy. The other series ($n=42$)[68†] showed an IUFD rate of 10% with 12% parenchymal brain damage in surviving infants. This clearly demonstrates that MC twins with discordant growth are at especially high risk of adverse outcome.

Up to 50% of MC twins with sIUGR present with a pattern of intermittent absent or reversed end-diastolic flow (iA/REDF) on umbilical artery Doppler velocimetry.[66,69] iA/REDF, a sign unique to MC twins, is characterized by the presence of absent and/or reversed end-diastolic flow in the umbilical artery, alternating over seconds or minutes with positive diastolic flow (Figure 153.15). This pattern reflects retrograde transmission of an AA waveform in the umbilical artery. It is strongly associated with sIUGR coexisting with the presence of large-diameter intertwin placental AA anastomoses.[70] The presence or absence of this sign predisposes to a different pregnancy course and outcome, and therefore the clinical management will be discussed separately.

MC twins with sIUGR and iA/REDF in the umbilical artery

Twins with iA/REDF have an atypical clinical course and do not show the Doppler and biophysical profile changes observed in most fetuses with severe IUGR secondary to placental restriction. Umbilical artery waveform patterns indeed reflect downstream vascular resistance, but in MC twins this is determined not only by the adequacy of spiral artery invasion but also by the direction and degree of shunting across the anastomoses. This makes interpretation of Doppler findings problematic, since absent end-diastolic flow and reversed flow in the sIUGR twin, a sign known to

† Small, but important case series on the finding of cyclic changes in umbilical artery waveforms in the smaller of growth discordant MC twins

be associated with fetal distress in singletons, may rather indicate the presence of (a) large AA anastomose(s). Despite the apparently benign nature of this situation, sudden intrauterine death in the small twin occurs in up to 25% of the cases[66] and neurological damage of the appropriately grown twin may develop in up to 30% of the cases.[71] This clinical course is thought to be caused by acute intertwin blood transfer episodes through the large AA anastomoses, necessary to allow this pattern and which might interfere with the natural history of the growth-retarded twin.

The clinical management of these cases constitutes at present a dilemma. The smaller twin will not show any sign of fetal deterioration, but conservative management may result in serious complications as discussed above, without typical alarm signs. In theory, laser coagulation of placental anastomoses, including the predisposing AA anastomosis, would be a potential and causative therapy. Delinking the two fetal circulations would protect the appropriately grown fetus in the event of IUFD of the growth-retarded fetus and may render the use of Doppler for fetal well-being theoretically more reliable. Quintero *et al.*[71] reported his early experience in a small and more heterogeneous series and compared it to 17 cases managed expectantly. However, there was no significant difference in survival or neurological morbidity[70] between treated and expectantly managed patients. In our own experience in a small clinical series of MC with growth discrepancy and iA/REDF in the umbilical artery, we observed more and different technical limitations as compared to laser therapy for TTTS (unpublished data).

Selective termination does not appear as an immediate option, as it implies selective termination of a fetus, which in up to 75% of cases would survive in good conditions. Finally, considering that in our clinical series neurological damage occurred in most pregnancies beyond 32 weeks, a policy of elective delivery at 30–31 weeks could reduce, in part, the incidence of complications. The best management option for sIUGR with iA/REDF remains to be formally evaluated in future clinical trials, their nature and design still being undefined.

MC twins with IUGR and without iA/REDF

In these cases, the IUGR twin may have a normal or pathologic umbilical blood flow pattern, but it is 'constant' or unchanged during the course of the Doppler interrogation. As opposite to those with iA/REDF, MC sIUGR fetuses with absent or reverse 'constant' diastolic flow will show a clinical evolution similar to what has been described for single fetuses or dichorionic twins with growth restriction, and the typical cascade of fetal hypoxic deterioration can be assessed by means of Doppler and/or fetal heart rate patterns.[4] The observation of significant fetal deterioration indicating a high risk of intrauterine demise of the IUGR twin is a clear indication for active management in order to prevent the typical risks of monochorionicity to the normally grown fetus. Selective termination is considered as a first option in previable cases. Later in pregnancy, and particularly before 32 weeks, the decision whether to perform selective termination vs. elective delivery must be carefully discussed with parents, certainly between 24 and 28 weeks, where complications of cord occlusion, such as PPROM, may compromise the outcome of the appropriately grown twin.[62] This is ethically a very challenging dilemma.[72]

Conclusion

Complications unique to MC twins and the shared circulation have stimulated a revival of fetoscopy as a means to operate on the placenta and umbilical cord. At present, fetoscopic laser coagulation of the vascular anastomoses is the preferred first-line treatment for TTTS, complicating 10–15% of MC multiple pregnancies. Minimally invasive cord coagulation appears to be an effective technique for selective feticide in MC twins complicated with discordant anomaly, severe early discordant growth, TRAP and selected cases of TTTS. However, these procedures still have considerably higher fetal loss rates (20%) as compared to selective feticide in dichorionic twins (7.5%).

154 Route of delivery

J. W. Dudenhausen and J. A. S. Dimer

The principal issues for neonatal morbidity and mortality in multiples are intrauterine growth restriction and prematurity.[1] Nevertheless, the route of delivery of multiples affects the perinatal morbidity and mortality rates.[2] There is no general consensus regarding the optimal route of delivery in multiple gestations. We must clearly separate the mode of delivery of higher-order gestations and triplets from that of twins.

Triplets and higher-order pregnancies

The route of delivery of triplets and higher-order gestations is widely variable and is controversial. In North America, the planned cesarean section is widely accepted as standard care; in South Africa, on the other hand, a cesarean section rate of 14% was reported by Pheiffer and Golan in 1979[3] as well as by Deale and Cronje in 1984.[4] In the African experience, the majority of cases that were described are those where a higher-order gestation was first discovered during the birth. Thus, few conclusions should be made from isolated birth statistics without regard to the obstetrical environment in which those statistics were gleaned.

In 1989, Lipitz *et al.*[5] reported the outcome of 78 sets of triplets; the cesarean section rate was 78% in this collective. Triplets born vaginally had a higher rate of low Apgar scores and respiratory distress. In 1988, Feingold *et al.*[6] published their experience with a group of 15 triplet pregnancies undergoing vaginal birth; the mortality and morbidity of the initial infant was 21%, of the second infant 31% and of the third infant 43%. These observations were not seen by Ron-El *et al.*[7] In comparison, in 1990, Olofsson[8] reported the experience of 14 triplets and quadruplets. In this group, vaginal birth was initiated in the 34th week of gestation, even when the presenting fetus was breech. In three cases, the vaginal birth was interrupted and an emergency cesarean section was performed for intrapartum fetal indications. During 1989, the obstetrical experience in a large group of 198 triplet pregnancies delivered at 24 different hospitals was reported by Newman *et al.*,[9] where 94% of the infants were delivered abdominally and 12% were delivered solely vaginally. In 2004, Alran *et al.*[10] investigated a series of 93 triplet pregnancies in a single perinatal department. Of these, 66 (84%) had a successful vaginal delivery, 12 delivered by emergency cesarean section and 15 by elective cesarean section. The perinatal mortality was 48/1000.

In a review of the literature in 1989, Petrikovsky and Vintzileos[11] evaluated the route of delivery of higher-order gestations. Although malpresentations were common, a broad spectrum of complications were seen such as placental abruption, intrauterine oxygen deprivation, umbilical cord prolapse and vaginal bleeding. An elective cesarean section avoided the majority of these complications and allowed for the antepartum organization of the obstetric and neonatology personnel. The importance of this interdisciplinary cooperation and the availability of neonatal beds should not be underestimated. When the decision has been made to proceed with a vaginal trial of labor, the attending obstetrician should plan to have the assistance of another well-trained obstetrician who is capable of diagnosing an anomalous fetal presentation with ultrasound, and who is able to be a competent operative assistant if a malpresentation is seen. Furthermore, during the second stage of labor, there must be adequate obstetric personnel at hand, who are able to monitor the fetal movement ultrasonographically.

The potential safety of the vaginal delivery of triplets has been studied in recent years in a few European centers. In 1995, Dommergues *et al.*[12] reported for a group in Paris about a case–control study of 69 consecutive triplet pregnancies delivered at the same institution. He found the neonatal mortality was not significantly increased by vaginal birth and concluded that vaginal delivery of triplets may be safe in carefully selected cases. Also, in 1995, Wildschut *et al.*[13] in the Netherlands reported the results of a retrospective study comparing planned abdominal with planned vaginal birth in triplet pregnancies. He found two centers in the Netherlands with two distinctly different primary modes of delivery: in Leiden 80% of women were delivered by cesarean section and in Amsterdam 87% favored vaginal birth. Similar reports of planned vaginal delivery of triplets have emphasized that the greater maturity of the infants delivered vaginally

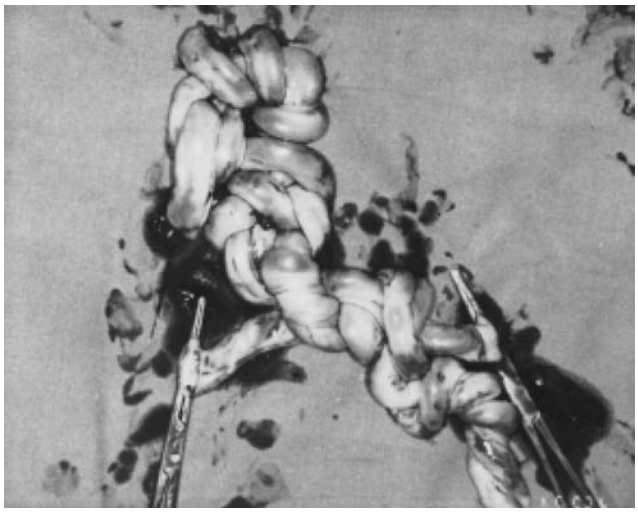

Figure 154.1 Complex umbilical cord knot from monoamniotic twins. Courtesy of Dr D. Berg, Amberg/Germany.

appeared to be the major factor for the lower neonatal morbidity and mortality seen in such a review.[14]

Multifetal reduction of triplets to twins yields an improved perinatal outcome compared with non-reduced triplets and a similar outcome compared with non-reduced twins.[15] Probably, the best means of reducing the perinatal morbidity of higher-order multiple gestations is to prevent multiple pregnancies in *in vitro* fertilization programs by reducing the number of embryos transferred per cycle.[16]

As a rule, today, obstetricians choose to deliver triplets and higher-order multiples with a planned cesarean section. This operative procedure should be performed by obstetricians who are experienced in the delivery of multiple gestations from malpresentations and who are also experienced in the treatment of intractable postpartum hemorrhage and possible hysterectomy. A comparison of the maternal and neonatal outcomes in patients following transverse and longitudinal uterine incisions has concluded that a transverse lower segment uterine incision should be used to increase the chances of a normal vaginal delivery in the future.[17] The anesthesia team should also be well experienced and prepared to manage a potentially life-threatening circulatory collapse. It deserves to be emphasized that a generous dose of oxytocin should be given following the delivery of the infants to prevent the development of uterine atony.

In a study from the USA in 1995, the total cost involved in the delivery, prenatal and neonatal care for triplet pregnancies was estimated to be $64,347 per family. Neonates averaged 13.7 hospital days and mothers averaged 16.7 in-patient hospital days.[18] Improvement in the neonatal resuscitation and care as well as delivery by cesarean section are felt to be responsible for lower mortality rates and overall better outcomes.[19]

Antepartum intrauterine death of one fetus in a multiple gestation may be associated with significant morbidity and mortality in the surviving infants, and it may be a factor in deciding the time and route of delivery. Neurological damage is recognized to be higher in the surviving infants, especially when intrauterine fetal death is associated with monochorionic placentation.[20]

Delayed interval delivery in triplet pregnancies has been reported in the literature.[21,22] In the rare circumstance that the presenting fetus is expelled, conservative management of the remaining viable fetuses has resulted in 34 and 49 days of interval time before the birth of the remaining three or two infants, respectively.

Twins

The prerequisites involved in the decision of the optimal mode of delivery in twins are manifold because one must always consider the different fetal presentation constellations. Chervenak[23] reported the following fetal presentations: vertex/vertex 42.5%, vertex/non-vertex 38.4%, non-vertex/vertex or non-vertex 19.1%. These findings take into consideration the clinically important factors necessary to make a decision regarding mode of delivery.

In the case of monoamniotic twins, regardless of fetal lie and presentation, the literature frequently recommends primary cesarean section to reduce the risks of umbilical cord complications and locked fetal heads[24] (Figure 154.1). Umbilical cord entanglement is the most common complication and often results in intrauterine fetal demise. These umbilical cord complications may be seen when one twin suddenly descends in labor.

Locked twins is a rare intrapartum complication; it is seen once in 1000 twins births.[25] The risk of locked twins is clearly higher in monochorionic–monoamniotic twins than in dichorionic–diamniotic twins. Both oligohydramnios and low birth weight increase the risk of locked twins.

Conjoined twins are a uniquely demanding situation for the obstetrician. The twins should be systematically evaluated ultrasonographically antepartum to determine if the anatomical findings are compatible with extrauterine life. To avoid the maternal risks resulting from an obstruction of labor, an elective cesarean section should be recommended.

Vertex/vertex

Vaginal delivery is appropriate for vertex/vertex twins. A thorough review of the literature on this constellation supports an attempt at vaginal birth.[26] Some authoritative sources have reported that 75% of all vertex/vertex twins may be delivered vaginally without difficulty.[27] On the other hand, other authors propose that cesarean delivery should be indicated for

preterm birth or estimated fetal weight under a given value.[28] The weight cutoff and gestational age restriction are variable. In a consensus article,[29] this estimated fetal weight cutoff was recommended to be 1800 g.

There are exceptions to this rule that only vertex/vertex twins estimated to weigh over 1800 g should be encouraged to attempt a vaginal trial of labor. If there is an estimated fetal weight on ultrasound indicating that the weight of the second twin is 15–25% higher[30] than the first, an elective cesarean section is indicated to avoid complications during the birth of the second twin.

Course of labor following the birth of the first vertex twin

Following the birth of the first twin, a brief physiologic pause between uterine contractions usually ensues. An intravenous oxytocin infusion is appropriate to shorten this pause. Before initiating the oxytocin infusion, ultrasound and/or external abdominal palpation to discern the fetal lie should be performed. Furthermore, the heart rate of the second twin (just as was indicated before the birth of the presenting twin) should be continuously monitored. A vaginal examination will determine if the amniotic membranes are intact and what fetal part is presenting. Following the return of uterine contractions and the descent of the fetal presenting part, an amniotomy may be performed and the fetal heart rate can be obtained via the direct mode.[31] The fetal heart pattern should remain reassuring throughout this procedure. In the presence of a non-reassuring fetal heart rate tracing, an operative delivery is indicated.

The time interval between deliveries has been a topic of discussion in the literature for decades. During the 1960s in Europe, the approach was rather conservative and non-interventional for adopting strict norms regarding this time interval. In comparison, the Anglo-Saxon language literature of the times seemed to support a 30-min cutoff to avoid the risk of intrapartum hypoxia of the second twin that could result from umbilical cord prolapse, placental abruption and the clamping down of the cervix. There was no controversy, however, on the fact that there is a clear correlation between the difference in the umbilical artery pH values (twin I minus twin II) and the time interval between deliveries regardless of the fetal heart tracings.[32] Current obstetrical practice mandates that the fetal heart rate be continuously monitored and taken into consideration in the management scheme. A relationship exists between the frequency of fetal hypoxia in the second twin and the time interval between deliveries, especially in those where a fetal heart rate pattern is non-reassuring. In these cases, it is recommended that a timely completion of the delivery be accomplished; this frequently requires an operative delivery of the second twin.

When the fetal heart pattern of the second twin is within normal limits following the birth of the first twin, this correlation with time interval between deliveries does not apply. Although expectant management in view of reassuring fetal heart pattern may be indicated, this should not imply that the attending obstetrician should wait until the cervix has clamped down.[33]

There are three modes of delivery of twins: both are delivered by cesarean section (C–C), both are delivered vaginally (V–V) and the first twin is delivered vaginally but the second one is delivered by cesarean section (V–C). The higher neonatal morbidity of the V–C-mode is caused by labor and delivery complications after the delivery of the first twin.[34,35] The increase of neonatal morbidity and mortality in the second twin is more evident in term births than in preterm births.[36]

Vertex/non-vertex

Intrapartum management of vertex/non-vertex and vertex/transverse twins has been debated in the literature. In the American literature, support can be found for a general indication for elective cesarean section in such cases.[37] This opinion is not generally seen by European authors and practicing obstetricians.[38]

In the case of a malpresentation of the second twin, intrapartum management includes an attempt at external cephalic version of the second twin. An internal version combined with extraction from a non-vertex presentation should be handled the same way as a vaginal breech delivery.

External version of the second twin

Reports of external version of the second twin conflict markedly. Although a few authors recommend the external cephalic version of the second twin and have analyzed their own extensive experience,[39] other authors criticize this maneuver because it increases the risk of umbilical cord compromise and wastes time.

Alternatively, the breech presentation of the second twin is less controversial. There is no increased rate of neonatal compromise following the unremarkable vaginal breech birth.[40,41] One report presented experience with 39 vertex/breech twins following vaginal birth. The author found no difference in the outcome of the study and control groups when the second twin had converted to a vertex presentation. Another prospective study compared elective cesarean section, external version and breech extraction.[42] This study included only fetuses with an ultrasound estimating fetal weight over 1500 g. The best outcome was present following vaginal delivery; there was no increased neonatal or maternal morbidity. An external version was successful in 20 of 41 cases. An emergency cesarean section was necessary in a single case. Manual breech extraction of the second twin is a rather uncomplicated procedure, as cited in the literature on twins over 1800 g in weight. The combination of the version of a second twin in transverse lie

to breech and delivery via total breech extraction is usually possible for the experienced obstetrician. With certain risk factors such as oligohydramnios, dorsoposterior transverse lie and macrosomia, this version–extraction combination may be difficult. In these cases, a cesarean section may be indicated instead of the difficult operative vaginal manipulations.

Non-vertex/vertex or non-vertex/non-vertex

It is generally accepted that an elective cesarean section is indicated in these cases.[43] The locking of the fetal heads is a potentially lethal complication of the vaginal birth when the first twin is breech. It must be said that these statements have not been extensively validated by clinical studies in this area.

155 Delayed interval delivery in multiple pregnancy

J. van Eyck, B. Arabin and R. A. van Lingen

Introduction

In the recent decades, the number of multiple pregnancies has increased rapidly, primarily due to the use of assisted reproduction techniques (ART) and increased maternal age. Multiple pregnancy is frequently complicated by premature delivery, which is a major cause of perinatal mortality and morbidity. Luke *et al.* reported relative risks of mortality in twin pregnancies and triplet pregnancies of 6.6 and 19.4, respectively, whereas among survivors the relative risks of severe handicap were 1.7 for twins and 2.9 for triplets.[1] After premature vaginal delivery of the first baby of a multiple pregnancy, arrest of labor may occur. Traditionally, only a few attempts were undertaken to postpone delivery of the remaining fetus(es), and thus increase their chance of survival. Since 1957, several case reports and small series have been published reporting on delayed interval delivery in multiple pregnancies. In 1998, we published the largest series ($n=17$) of that moment on delayed interval delivery in twins originating from one single center.[2] In our series, a fixed treatment protocol was used and the 'success rate' was 53%. This was in contrast to a review of the literature, which showed a large variation in the treatment protocols and a very high success rate (93%), suggesting that mainly cases with successful outcomes were reported. Because of this selection bias, it was only possible to speculate on both prognosis and recommendations concerning treatment protocols. In this chapter, we report on data from our department, which provides again the largest series of delayed interval deliveries in twins and triplets originating from one single center, including neonatal follow-up.

In our chapter published in 1998, we reviewed the literature between 1957 and 1996.[2] In this chapter, a review of the literature between 1996 and 2004 is performed and compared with the former review.

Population and techniques

Between 1991 and 2004, a total of 78 twin pregnancies and 21 triplet pregnancies were complicated by vaginal delivery of the first fetus between 16 and 31 weeks of gestation. After exclusion of pregnancies in which a cesarean section had to be performed for the second twin, labor progressed or patients with specific contraindications to postpone delivery, such as ongoing infection, 33 women with twin pregnancy and 8 women with triplet pregnancy could be included in our final study. Mean maternal age in the group with twins was 30.8 years (range: 23–39 years) and in the group with triplets 33 years (range: 25–41 years). In twin pregnancies, 67% of women conceived spontaneously, whereas all women with triplets conceived after ART. When preterm delivery was anticipated, women were asked to give informed consent and were treated according to a fixed protocol, in which four phases can be distinguished: phase 1: preparation, phase 2: delivery of the first baby, phase 3: period between the birth of the first and the remaining fetus(es) and phase 4: delivery of the last multiple including the evaluation of the placenta. Each phase is characterized by specific measures that have to be taken.

Phase 1

The procedure starts with ruling out contraindications and obtaining informed consent. Contraindications include fetal distress or severe congenital abnormalities of the remaining fetus, chorioamnionitis, severe vaginal blood loss and other situations in which the maternal condition is compromised (e.g. preeclampsia, suspicion of placental abruption, infection). Membranes of the remaining fetus(es) must be intact, since early-onset long-term oligohydramnios is associated with pulmonary hypoplasia.[3] Considering the potential risks of the procedure vs. the risks of perinatal mortality and morbidity, it is not appropriate to pursue delayed interval delivery after 31 weeks of gestation, especially when corticosteroids have been administered to stimulate fetal lung maturation.

Informed consent consists of thorough explanation of the procedure to both future parents, its limited success rate and the potential risks for mother and her

unborn child(ren), such as chorioamnionitis, placental abruption and, although rare, maternal coagulation disorder. Side effects of anticipated medication, such as tocolytics, should also be discussed.

In the Netherlands, immature delivery before 25 weeks is practically always associated with neonatal death. However, parents should be made aware that if delivery of the remaining fetus takes place between 25 and 28 weeks, neonatal mortality may be reduced, but neonatal morbidity remains high. The latter may be considered an even greater and costly burden for the future parents and society. Motivation of the parents is an absolute prerequisite for starting a delayed interval delivery procedure.

For tocolytic treatment, we administered ritodrine and more recently atosiban intravenously or nifedipine orally and, if necessary, indometacin suppositories. Fetal lung maturation is stimulated by giving two doses of 12 mg betametasone intramuscularly with an interval of 24 h to the patient between 25 and 32 weeks of gestation. After cervical and urinary culture was obtained, antibiotics are administered intravenously for at least 1 week.

Phase 2

The birth of the first baby deserves special consideration. Expulsion forces should be kept limited. During delivery of the first baby, administration of tocolytics and antibiotics are usually continued. As episiotomy is a source of infection; it should be avoided mainly since there is no proof of better outcome after episiotomy. After delivery of the first baby, no efforts should be undertaken to deliver the placenta. A culture is taken from the cervix and the vagina is intensively disinfected. The umbilical cord has to be ligated as high as possible near the cervix. We do not recommend cervical cerclage. In rhesus-negative women, 1000 IU of anti-D globulin is injected intramuscularly immediately after the first delivery.

Phase 3

After delivery of the first baby, digital examination is avoided. Cervical length, dilatation and funneling are monitored, preferably by transvaginal sonography, applying the transducer only into the proximal part of the vagina. Monitoring the maternal condition focuses on (early) detection of chorioamnionitis, recurrent preterm labor, placental abruption and coagulation disorders. Body temperature is measured four times daily. Cervical cultures are taken weekly and antibiotics are administered according to their results. Laboratory tests (infection and coagulation) are performed periodically. Fetal monitoring consisted of very frequent biophysical assessment, including cardiotocography, Doppler flow velocimetry and real-time ultrasound. Fetal biometry and the amount of amniotic fluid are examined by ultrasound at regular intervals. The patient remains hospitalized as long as contractions and/or cervical dilatations are present. Peridural analgesia is frequently given during the first three phases of the procedure and offers good relief of pain and discomfort.

Phase 4

After delivery of the remaining fetus(es), the placenta must be carefully examined in order to prevent retention of the placenta, and also of the first baby. All placentas were histologically examined for signs of infection and chorionicity. During the whole procedure, parents are counseled regularly by our social worker and special attention is paid to their emotional state, which is frequently ambiguous in the situation when one baby is dead and the other may survive.

Results

Within our series of 99 multiple pregnancies with vaginal delivery of the first baby before 32 gestational weeks, we have treated 33 twin and 8 triplet pregnancies according to our protocol.

Data of all 33 twin pregnancies are shown in Table 155.1. The mean gestational age at delivery of the first baby was 24.8 weeks (range: 16–31 weeks). The mean birth weight was 751 g (range: 140–1660 g). Perinatal mortality of all first-born twins was 70%. All 18 first babies born before 26 weeks died and had a mean birth weight of 481 g (range 140–1000 g). Survival rate of 10 first-born babies, born between 26 and 29 weeks, was 50%. From 29 weeks onward, all five first-born babies survived, but needed artificial ventilation in contrast to their later-born sibs. On average, delivery of the remaining fetus could be postponed for 20.6 days (range: 0.5–106 days). Mean birth weight of the 33 remaining second-born fetuses was 1163 g (range: 250–2995 g). Perinatal mortality of these children was 30%. Six of the remaining fetuses were delivered by cesarean section because of partial placental abruption ($n=1$), cord prolaps ($n=1$), fetal distress ($n=1$) and in three women because of chorioamnionitis, in one case associated with prolapse of the umbilical cord. One woman had a relaparotomy because of a postoperative intra-abdominal hemorrhage. This woman developed pulmonary embolism postpartum despite prophylactic use of anticoagulants. In 18 twin pregnancies, in which the first baby was born before 26 weeks, it was possible to delay the second delivery until at least 26 weeks in 9 of 18 cases (50%), resulting in a perinatal mortality of the second baby of only one of nine cases (13%). In 80% of all women, it was possible to administer complete betamethasone treatment. Histological examination of the placenta showed 29 dichorionic (DC) and

extraction was performed because there was full dilatation and gestational age was below 25 weeks. Two women had a partial placental abruption, one of them delivered by breech extraction because there was fully dilatation. One woman had an isolated transient elevation of liver enzymes, but serological tests for viral infections were negative. One woman had a transient atrium fibrillation, which was successfully treated with digitalis and heparin. In one woman, appendectomy was performed in the puerperium.

Data of all eight triplet pregnancies are shown in Table 155.2. The mean gestational age at delivery of the first baby was 23.8 weeks (range: 18–26 weeks). The mean birth weight was 513 g (range: 220–830 g). Perinatal mortality of all first-born triplets was 75%. All five first-born babies born before 26 weeks died and had a mean birth weight of 355 g (range: 220–645 g). Mean interval between delivery of the first baby and the second baby was 9.6 days (range: 1–34 days). Three women delivered on three separate days. Mean interval between the second and the third delivery was 1.3 days (range: 1–2 days). Perinatal mortality of all 16 remaining fetuses was 81%. Perinatal mortality of the eight remaining fetuses that were delivered after 26 weeks was 63%. In two women a cesarean section was performed on a remaining multiplet because of fetal distress and chorioamnionitis, respectively. The latter had a relaparotomy because of a hemorrhage in the abdominal wall and she also developed urosepsis. She recovered completely. In one woman, the placenta that had to be removed manually, postpartum hemorrhage was more than 1 L. Two women developed clinical signs of chorioamnionitis. Histological examination of the placenta showed that all placentas were trichorionic. Four placentas showed histological signs of chorioamnionitis.

Short- and long-term neonatal follow-up was evaluated in our series.[4] Long-term follow-up at the corrected age of 1 and/or 2 years is not yet known in children born after 2002 and was not available for those born before 1997, and was therefore only analyzed in 17 sets of twins and 3 sets of triplets. As expected, mean birth weight and gestational age was significantly higher in the second born infants. Nine of 11 surviving first-born infants and 16 of 23 second-born infants needed assisted ventilation for an average period of 17 days and 14 days, respectively. This difference in the need for and duration of assisted ventilation was not significantly different. Idiopathic respiratory distress syndrome (RDS) and patent ductus arteriosus were more prevalent in first-borns, whereas second-born infants developed sepsis and bronchopulmonary disease more often. However, these differences are not significant either. For long-term outcome, we evaluated neuromotor development at the corrected age of 9 months, the developmental outcome at the ages of 1 and 2 years post-term using a Bayley score and adverse outcomes, defined as either mortality or a suspect (score between –1 SD and –2 SD) or an abnormal Bayley test (score $< -$ 2SD), at the corrected age of 2 years. At the corrected age of 9 months, neuromotor development of seven first-borns was normal in 71%, suspect in 14% and abnormal in 14%. In the group of infants ($n=17$) born after delayed interval delivery, neuromotor development was normal in 76%, suspect in 18% and abnormal in 6%, which was comparable to a reference group. One first-born and four children who were born later were lost to long-term follow-up. We obtained a Bayley score on four

first-borns (group 1) and nine infants (group 2) who were born after delayed interval delivery. The differences were not statistically significant. In group 1, the results after 1 year were that two children had normal developmental outcome, whereas one child was scored abnormal. At the age of 2 years, the score of these children had not changed. In group 2, after 1 year there were three children with normal developmental outcome, whereas two children were scored as having a suspect developmental outcome. At the age of 2 years, of the latter two children, one appeared to have a normal developmental outcome and the other an abnormal outcome. Adverse outcome was 74% in group 1 and 30% in group 2.

Review of the literature

In 1957, Abrams was the first to report on a woman with uterus simplex and twin pregnancy, who gave birth to two children with an interval of 35 days between the deliveries and were both alive at time of birth.[5] At 23.3 weeks of gestation, the mother delivered a girl of 396 g, who died 3 h after birth at home. Five weeks later, she delivered a living boy weighing 1033 g. Unfortunately, neonatal outcome and further development were not stated. Since 1957, several well-documented case reports were published on delayed interval delivery from women, in which the first baby was born before 32 weeks of gestation. In 1998, we reviewed data published between 1957 and 1996, consisting of 21 small series including 30 cases with delayed interval deliveries in twins, 11 single case reports in triplets and 3 single case reports in quadruplets.[2] At that moment, there were only two larger series: Arias *et al.* had presented a series of delayed interval procedures in eight twin and three triplet pregnancies,[6] whereas Van Eyck *et al.* had reported a series of 13 twin and 4 triplet pregnancies.[2] As already mentioned, the success rate of the smaller series was almost twice as high as in the two larger series, suggesting that in the smaller series mainly cases with successful outcomes were reported. Furthermore, in the smaller series and case reports there was a great variety in the treatment protocols and a lack of neonatal follow-up.

Since 1996, several small studies have been published on delayed interval delivery in twins (12), triplets (10), two studies on quadruplets and quintuplets and one study on very high-order multiplets (more than five fetuses). Furthermore, three larger series of more than six cases were published originating from a single center and three studies reporting on results of multicenter databases.

Small series (six or fewer cases) on twin pregnancies originating from a single center

Table 155.3 shows 12 studies including 30 cases of delayed interval delivery in twins published in the period between 1996 and 2004.[7–18] The most important variation in treatment protocols implied the use of cervical cerclage, which was performed in 53% of the cases. Tocolytics were administered in 93%, antibiotics in 100%, whereas corticosteroids were administered in 100% of the cases when a gestational age of more than 24 weeks was reached. Mean gestational age at delivery of the first-born baby was 22 weeks (range: 15–27 weeks). Mean interval between the two deliveries was 55 days (range: 1–153 days). The survival rate of the first-borns was 23%. Survival rate of the second twins was 87%. Neonatal follow-up was reported in six studies. Maternal complications consisted of placental abruptions ($n=2$), sepsis ($n=2$), chorioamnionitis ($n=7$) and thrombophlebitis of the left ovarian vein ($n=1$).

Small series (six or fewer cases) on triplet pregnancies originating from a single center

Table 155.4 summarizes 10 studies reporting on 12 cases of delayed interval delivery in triplets, which were published in the period between 1996 and 2004.[8,9,11,14,16,19,20–23] Besides the use of antibiotics (100%), treatment protocols varied largely with respect to the use of cervical cerclage (25%) and administration of tocolytics (58%). Corticosteroids were given in 75% of pregnancies in which a gestational age of more than 24 weeks was reached.

Mean gestational age at delivery of the first-born was 22 weeks (range: 17–31 weeks). Mean interval between the birth of the first and the remaining fetuses was 30 days (range: 3–70 days). Only one delivery took place on three separate days. The survival rate for 12 first-borns was 25% and that of the 24 remaining fetuses was 67%. Neonatal follow-up was reported in one study. Maternal complications consisted of placental abruption ($n=1$), chorioamnionitis ($n=2$) and sepsis with multiorgan failure ($n=1$).

Quadruplet pregnancies originating from a single center

Table 155.5 shows two studies reporting on two cases of delayed interval delivery in quadruplets, which were published in the period between 1996 and 2004.[24,25] In both series, tocolytics, antibiotics and corticosteroids were given and no cervical cerclage was performed. Gestational age at delivery of the first-born was 19 and 26 weeks, respectively. The interval between the birth of the first and the remaining fetuses was 92 and 12 days. Only one of the two first-borns survived, whereas five out of six (=83%) of the remaining fetuses survived. In both series deliveries took place on two separate dates.

Quintuplet pregnancies originating from a single center

Table 155.6 shows two studies reporting on two cases of delayed interval delivery in quintuplets, which

were published in the period between 1996 and 2004.[26,27] In both studies, no cervical cerclage was performed. In both studies antibiotics were given. When a gestational age of 24 weeks was reached tocolytics and corticosteroids were administered. Gestational age at delivery of the first-born was 19 and 24 weeks. The interval between the birth of the first fetus and the last fetuses was 14 and 61 days. No first-borns and only one of the remaining fetuses survived. This infant had normal development after 1 year. No maternal complications were reported.

Very high-order (more than five fetuses) multiple pregnancies originating from a single center

Table 155.7 shows one study of two cases of delayed interval delivery in very high-order (more than five fetuses) multiple pregnancies.[25] Kirshon reported on delayed interval delivery in a woman with a sextuplet pregnancy, who already had a cerclage placed at the end of the first trimester.[25] Despite tocolytics, the first baby was born at 22 weeks and 4 days through the anterior cervix. At 26 weeks, she had vaginal blood loss and full dilatation. A cesarean section was performed. Five neonates were born with birth weights between 580 and 760 g. One of the five surviving infants had intraventricular hemorrhage grade III, with resultant hydrocephalus. The other four had no significant long-term sequelae. Kirshon also reported on delayed interval delivery in a woman with octuplet pregnancy. Despite tocolytics, the first baby was born at 25 weeks after removal of the cervical cerclage. A girl of 690-g weight was born and developed uneventfully. At 26 weeks and 5 days a cesarean section was performed because of fetal distress of one multiplet. Seven neonates were born with birth weights between 320 and 810 g. Postoperative course was complicated by intra-abdominal bleeding, relaparotomy and the necessity to apply a large amount of blood products. At the age of 1 year, all seven surviving infants were neurologically intact and met all their milestones.

Larger series (more than six cases) originating from a single center

Since 1996, a total of three larger series originating from a single center were reported. In 1998, Porreco *et al.* reported on nine cases (six twin and three triplet pregnancies).[28] Monochorionicity was considered as an exclusion criterion. The treatment protocol consisted of cervical cerclage and administration of tocolytics and antibiotics. Mean gestational age at delivery of the first baby was 23.9 weeks (range: 19.4–27.9 weeks). Mean latency interval was 34 days (range: 3–76 days). Perinatal mortality was 70% for first-borns and 18% for the neonates born after delayed interval. No information is given on birth weights, neonatal follow-up or maternal complications.

Van Doorn *et al.* reported in 1999 on 15 cases (10 twins and 5 triplets).[29] The treatment protocol

consisted of administration of tocolytics and antibiotics. In one case, a cervical cerclage was performed. Mean gestational age at delivery of the first baby was 26 weeks (range: 19.7–30.4 weeks). In five women, the attempted interval delivery resulted in a delay of less than 3 h between separate deliveries. The mean latency interval within the 10 remaining pregnancies was 12 days (range: 1–53 days). Five of 15 first-borns survived. Survival rate of the 20 neonates born after delayed interval was 50%. In all triplet pregnancies, the second and the third child were born on the same day. Long-term follow-up revealed one child with axial hypotonia and strabismus and one child with rachitis. Maternal morbidity consisted of chorioamnionitis in three women and one woman with postpartum hemorrhage necessitating blood cell transfusion.

Farkouh *et al.* reported in 2000 on 24 cases (20 twin and 4 triplet pregnancies).[30] The treatment protocol consisted of cerclage and administration of tocolytics and antibiotics. Administration of corticosteroids was not mentioned. Mean gestational age at delivery of the first baby was 22.7 weeks (range: 16.4–28.6 weeks). Mean latency interval was 36 days (range: 3–123 days). Patients with a previous cervical cerclage during the index pregnancy had significantly shorter mean latency intervals than patients without previous cerclage. There were no survivors among first-born infants when the gestational age at presentation was 24 weeks or less. Perinatal mortality of the first-born infants was 84%, whereas perinatal mortality of the infants who were retained after the birth of the first-borns was 37%. The duration of hospital stay of the survivors was used to express the short-term neonatal morbidity. Hospitalization of the surviving first-born infants ($n=4$) lasted on average 86 days (range: 72–106 days). In the surviving siblings who were retained after delayed interval delivery ($n=17$), hospitalization lasted on average 47 days (range: 2–126 days). The duration of hospitalization was significantly shorter for the 'retained' group. Long-term neonatal morbidity was not studied. Seven women developed postpartum endometritis and one woman, septic pelvic endometritis.

Multicenter studies

Three larger series originating from a multicenter database were published.[31–33] Zhang *et al.* studied the US 1995–1998 Matched Multiple Birth File.[31] Two hundred twin pregnancies were identified in which the first twin was delivered between 17 and 29 weeks and the second twin two ore more days later. These 200 delayed interval deliveries were individually matched with 347 twin pregnancies in which the second twin was delivered on the same or the next calendar day. Among the 200 pregnancies with delayed delivery, the mean gestational age at first delivery was 23 weeks and the median duration of delay was 6 days (range: 2–107 days). One week of delay in delivery was associated with a mean increase in infant birth weight of 131 g. Furthermore, 56% of the delayed second twins survived to 1 year of age, whereas only 24% of the non-delayed second twins survived to 1 year of age ($P<0.001$). However, 11% of the second twins in delayed delivery (95% CI: 6–16%) experienced fetal death before 24 weeks. There was no information on treatment protocols, maternal and neonatal morbidity.

Fayad *et al.* published a series of 35 cases (28 twin and 7 triplet pregnancies) of delayed interval delivery originating from 12 tertiary care centers over 10 years.[32] Treatment protocols varied and consisted of a high ligation of the cord (in 78%), cervical cerclage (in 32%), administration of antibiotics (in 100%), tocolytics (in 82%) and hospitalization (in 93%). In relation to the 'success' expressed by the duration of the interval, there was no statistical difference whether or not a cerclage was performed; antibiotics or tocolytics were administered or whether the patient was admitted or not. Mean gestational age of the first twin deliveries was 20.8 ± 5.5 weeks and the mean birth weight of first twins was 497 ± 239 g. Only 7% of the first-borns survived. The mean interval between deliveries was 47 days (range: 3–140 days). The mean birth weight of the second twin was 1217 ± 602 g. The survival rate of these second twins was 79%. In each of the seven triplet pregnancies, only one delayed interval delivery procedure was performed. The mean interval between deliveries was 23 days. Survival rate of the first, second and third triplets was 9.5%, 19% and 14.2%, respectively. No data were presented with

respect to maternal and neonatal morbidity or neonatal follow-up.

Livingston *et al.* published a series of 14 cases (nine twin and five triplet pregnancies) of delayed interval delivery originating from two tertiary care centers over 12 years.[33] The mean gestational age of delivery of the first multiplets was 21 weeks. All women received tocolytics and intravenous antibiotics. Two of three attempts to place a cerclage were successful. The mean latency was 2 days (range: 1–70 days). There was one survival of a first-born multiplet. Of the 19 retained fetuses, 2 died *in utero*, 10 died between birth and day 57 of life and 7 (37%) survived until hospital discharge. Six of he seven survivors had major sequelae from prematurity. One of 19 fetuses (5%) was discharged without major sequelae. Maternal morbidity included two pregnancies with placental abruption and eight pregnancies with infectious morbidity including one septic shock.

Discussion

Even the review of the recent literature shows a large variety of treatment protocols and relatively higher success rates in smaller compared to larger series. However, compared to our review of the literature, which was published in 1998,[2] a larger number of studies were published reporting also on procedures that were not favorable. Only few studies include long-term neonatal follow-up. With respect to treatment protocols, the use of cervical cerclage for delayed interval delivery is still controversial. In the smaller series, there is no consistency with respect to performing a cervical cerclage. Even if this were the case, it would be impossible to draw conclusions because of the selection bias. Retrospective multicenter studies report on large series, but have the disadvantage that there is a large variety in treatment protocols, especially with respect to the use of cervical cerclage. Zhang *et al.* examined whether cervical cerclage after the first delivery prolonged the interdelivery interval in reports on delayed interval delivery published between 1880 and 2002.[34] Seven larger series (81 cases) were selected that identified all cases of delayed interval delivery in their institutions during a specified period. Studies in which a cerclage was infrequently used reported a shorter interdelivery interval compared to studies where cerclage was used (median: 9 vs. 26 days, respectively, $P < 0.001$) despite similar gestational age at the first delivery, similar use of antibiotics, tocolytics and incidence of infection. After controlling for other factors, the use of cerclage did not significantly increase the risk of intrauterine infection. Zhang *et al.* suggest that cervical cerclage after the first delivery is associated with a longer interdelivery interval without increasing the risk of intrauterine infection. In contrast, we never performed cervical cerclage in our series of 41 cases, which resulted in a mean interval of 21 days (range: 0.5–106 days) in twin and 10 days (range: 1–34 days) in triplet pregnancies. There is still a debate not only on whether to perform but also on when to perform a cerclage. Some authors perform a cervical cerclage immediately after delivery of the first twin,[6,35–37] and others perform a cerclage only if cervical dilatation persists.[32,38,39]

There is meanwhile more information on maternal complications and morbidity in relation to cervical cerclage.[9,23,30,33,34] Hoffman *et al.*[23] reported on a procedure in a triplet pregnancy, resulting in chorioamnionitis, septic shock, multiorgan failure and artificial ventilation because of RDS and even dialysis for the treatment of acute renal tubular necrosis. Kalchbrenner *et al.*[9] reported on four cases of chorioamnionitis, including two cases of sepsis and one of placental abruption. In a series of 24 cases, Farkouh *et al.*[30] observed eight cases of endometritis, including one case of septic pelvic thrombophlebitis. In a series of 14 cases, Livingston *et al.*[33] reported on two pregnancies with placental abruption, eight cases of infectious morbidity, including one case of septic shock. In a review of 66 case reports and case series published between 1880 and 2002, Zhang *et al.*[34] stated that despite prophylactic routine use of broad-spectrum antibiotics, the average incidence of clinical intrauterine infection after the first delivery was 36% and the incidence of maternal sepsis was 4.9%. A remarkable complication in a special kind of interval delivery was reported by Porreco *et al.*[40] At 28 weeks and 4 days of gestation a cesarean section was performed in a woman with twin pregnancy because of growth retardation of one fetus. A neonate of 619 g was born and the other fetus was kept *in utero*, which was closed in two layers with fibrin glue interposed. The woman was discharged on home uterine activity monitoring and modified bed rest. The mother complained of left lower uterine pain and increasing uterine activity at 31 weeks and 6 days of gestation. Ultrasonic evaluation showed anhydramnios and the fetal heart tracing showed variable and prolonged decelerations. The retained sibling (a boy of 1738 g) was delivered by laparotomy and had normal Apgar scores and umbilical cord blood gases. A complete uterine scar dehiscence was noted with prolapse of a loop of umbilical cord into the peritoneal cavity. The infant was delivered through the dehiscence, the edges were debrided and the uterus was closed in layers. The mother was discharged on her fourth postoperative day.

Our study describes a large series originating from a single center. In this series, the survival rate of at least one remaining baby is comparable with other large series.[28–30] In contrast to these series, we never performed cervical cerclage. Success rate depends on numerous criteria, including the length of postponement or merely whether time was obtained to give

corticosteroids for lung maturation of the remaining fetus or whether there was a reduction of mortality or morbidity. With respect to viability of the remaining baby, the goal of our series was to postpone the second delivery until a gestational age of at least 26 weeks, resulting in a reduction of perinatal mortality to 13%. All remaining babies born after at least 29 weeks survived. Due to the small number of infants available for follow-up, we could not find a significant difference between the two groups. If, however, we bear in mind that the reason for postponing the delivery of the second sib is the birth of a viable baby and adverse outcome is defined as death or abnormal development, there was a significant difference. Nonetheless, it is important to recognize that delayed interval delivery may be associated with a relatively high degree of maternal morbidity. Besides the technical aspects of this procedure, it is important to consider psychosocial and emotional support to the patient and her partner.

Conclusion

If twin pregnancies are complicated by immature or very premature delivery of the first baby, delayed interval delivery results in a significant reduction of perinatal mortality of the second infant. Single case reports and small series have a higher success rate than larger series, suggesting selection bias, based on the fact that only successful results were published. The significant reduction of adverse neonatal outcome has to be considered in relation to the degree of complications and maternal morbidity. For further recommendations, randomized studies performed for all multiple pregnancies with a vaginal delivery of the first multiplet before 26 weeks might be an option to differentiate whether a cervical cerclage improves the outcome. In any case, for an adequate counseling of future parents about the described procedure including pros and cons, it is important to document protocols and outcome of all cases (also the failures) of each single center.

156 Cerebral palsy in multiple pregnancy

P. O. D. Pharoah

Introduction

Cerebral palsy (CP) is not a single disease entity, rather it is a syndrome, the manifestations of which vary in severity and topographical involvement of the extremities and the site, type and timing of cerebral impairment.

The earliest clinical description is usually attributed to Little and the syndrome eponymously bears his name.[1] Inherent in the title of Little's paper is that difficulties in labor, preterm delivery and neonatal asphyxia placed the child at risk for cerebral impairment.

Variation in the manner by which CP is manifested and the overlap of presenting symptoms and signs with many other conditions has promulgated several attempts to classify and to formulate a definition of the syndrome. Suggested classifications have been based on timing of the impairment (intrauterine, birth or intrapartum palsies and postnatal or acquired palsies),[2] limb topography (hemiplegia, paraplegia – now regarded as diplegia to distinguish it from a paralysis attributable to a spinal cord lesion that is not considered to be CP, quadriplegia and disordered movements without rigidity),[1,3] muscle tonicity and clinical features (spasticity, hypotonia, dystonia, ataxia choreoathetosis and mixed forms).[4] Epidemiological description demands a definition of the syndrome that is being studied and there have been several definitions of CP.[4–10] Such plurality of definition is testament to the variability of what is or is not CP. Common to these definitions is that CP is a disorder of movement or posture due to a cerebral impairment that is non-progressive though not unchanging, i.e. it is not due to progressive lesions such as cerebral tumors or the lipoidoses but the symptoms and signs may alter as the child develops. It is also mentioned in the definition that the timing of the impairment is during early development although this begs the question as to what is meant by 'early' development.

Epidemiology of CP

The descriptive epidemiology of CP has been dependent on special surveys or on specific CP disease registers. Early studies reported population prevalence rates that ranged from 0.76 to 5.8 per 1000.[11] The development of specific CP disease registers, with an emphasis on the definition of the syndrome and efforts to ensure complete ascertainment of cases, has narrowed the range of CP prevalence to 2–2.5 per 1000 live births.[12–14]

It has been customary in the past to distinguish CP as those that are 'congenital', i.e. infants whose cerebral impairment occurred before birth, and those that are 'acquired', i.e. cerebral impairment that occurred postnatally. However, this distinction is unsatisfactory because of the difficulty, particularly in very preterm infants, of determining the precise timing of the cerebral insult. The alternative classification of 'early' impairment that has been sustained during fetal development or in the perinatal period and 'late' impairment sustained after the seventh postnatal day has been suggested.[15,16]

Late impairment (acquired) CP

Late impairment CP is usually attributable to head injury, both accidental and non-accidental and infections of the central nervous system such as encephalitis and meningitis.[17] These contribute about 10% of all CP,[11] are of marginal relevance to perinatal medicine and will not be considered further.

Early impairment (congenital) CP

Two risk factors dominate the epidemiology of early impairment CP. These are preterm delivery or low birth weight and multiple births. There is also the confounding of these risk factors in that an inverse association exists between the degree of plurality at birth and birth weight.

Prevalence and incidence in CP

It is essential, when examining the epidemiology of CP, to acknowledge the difference between incidence and prevalence of the condition. The incidence is a measure of the number of new cases entering a population and a changing incidence is primarily a pointer to what may be of etiological significance. The point

Table 156.1 Birth weight specific prevalence of CP

*Prevalence per 1000 live births
**Prevalence per 1000 neonatal survivors

prevalence is a measure of the number of cases in a population at a point in time and is affected by both the incidence and the duration of the disease. The arithmetic relationship is:

$$\text{Prevalence} \propto \text{Incidence} \times \text{Duration}$$

and, at a given point in time, Prevalence = Incidence × Duration, if the incidence and the mean duration of the disease are unchanging. This relationship merits emphasis in perinatal medicine and, in particular, in conditions such as CP and the congenital anomalies when the impairment may occur prepartum. There are two caveats that must be borne in mind when examining population prevalence of CP:

(1) It is unusual to make a firm diagnosis of CP before the age of 3 months and often it is not made until much later. In early impairment CP, the impairment may be of such severity that the child succumbs before a diagnosis can be made. The true incidence cannot be established and only the prevalence at a point in time is possible. If the cerebral impairment occurs during fetal development, contrary to expectation, improvements in fetal and neonatal medicine will lead to an *increasing* prevalence of CP. The impaired infant that would otherwise have died now survives with an increase in duration leading to an increase in prevalence. The corollary to this is that, when the impairment occurs during the perinatal period as may occur with hypoxic-ischemic injury in very preterm infants, improvements in medical management thereby preventing such injury will be associated with a *decrease* in the prevalence of CP.
(2) The population denominator for the prevalence must be stated. This assumes significance when birth weight specific prevalence of CP is considered. Very low birth weight infants have a much-increased neonatal mortality and the denominator used in calculating the CP prevalence will reflect this. The CP prevalence per 1000 live births may differ significantly from that per 1000 neonatal survivors.

Risk factors in CP

Birth weight and gestational age show a strong inverse association with the prevalence of CP. Indeed, Little's seminal description of CP in 1862 noted the relevance of prematurity.[1] Table 156.1, compiled from different population registers of CP, illustrates the inverse association of birth weight with CP prevalence.

Birth asphyxia and CP

Birth or perinatal asphyxia is usually taken to mean asphyxia sustained intrapartum or in the immediate postpartum period. Particularly in very preterm infants, the difficulty in maintaining normality of physiological variables, with the attendant risks of hypoxic-ischemic cerebral impairment manifest as periventricular leucomalacia or hemorrhage, is well recognized. Undoubtedly, peripartum asphyxia may lead to CP, usually of the dyskinetic hypertonic type. Also, CP in some very preterm infants, irrespective of whether they are multiple or singleton births, is attributable to hypoxic-ischemic damage sustained soon after birth, i.e. postnatal asphyxial damage.

Particularly in very preterm infants, distinguishing between intrapartum and immediate postpartum asphyxial damage is fraught with uncertainty. Abnormal ultrasound appearances, not present at birth but appearing shortly thereafter, are discriminant for CP.[20] Nevertheless, there is an increasingly prevalent view that this is less of a problem than had been previously assumed.[21] White matter damage in preterm infants shown by neonatal echoencephalography, even in those of birth weight < 1000 g, was more likely to have been sustained antenatally.[22]

The contribution of intrapartum asphyxia to the genesis of CP has also been downgraded in importance.[23] In a case–control study, although an association was observed between clinical signs of birth asphyxia and subsequent CP, it was estimated that in only about 8% was intrapartum asphyxia the possible cause of the brain damage.[24] In one cohort study, the proportion of CP in infants with complicated deliveries,

low Apgar scores and neonatal hypoxemic-ischemic encephalopathy was only 13%.[25,26] In another cohort study, 10% of CP was attributable to birth asphyxia.[27]

Thus, CP of perinatal or postperinatal origin accounts for about 20% of all CP, and the remaining 80% is considered attributable to an insult occurring during fetal development.

Multiple births and CP

Over a century ago, Freud recognized that multiple births are at increased risk of CP compared with singleton births.[3] Several studies have confirmed this observation[28–34] with twins having about a fivefold increase in risk compared to singletons. Table 156.2, compiled from two population-based CP registers, shows birth weight specific CP prevalence per 1000 neonatal survivors.[18,33] From Table 156.2, compared with singletons, the relative risk for twins is 5.2 and for triplet and higher-order multiple births it is 12.6. Both values are highly statistically significant.

However, the inverse association of birth weight and CP prevalence means that birth weight is an important confounding variable when comparing crude relative risks. In Table 156.2, the prevalence of CP in twins and higher-order multiple births compared to singletons is not significantly different for the birth weight groups < 1500 and 1500–2499 g. Therefore, there are two components to the increased crude relative risk of CP associated with multiple births. One component is attributable to the high proportion of very low birth weight infants. The second component, evident as a striking feature of Table 156.2, is that for normal birth weight infants, i.e. ≥ 2500 g, the relative risk for twins compared to singletons is 2.5 (95% confidence interval 2.2–4.8; $P < 0.00001$). The increased risk in normal birth weight infants must be attributable to something other than problems of neonatal management of very immature infants. (The number of triplet and higher-order multiple births weighing ≥ 2500 g is too small for a meaningful estimation of relative risk.)

The higher the order of multiplicity at birth, the greater is the proportion that is preterm or of low birth weight. The birth weight frequency distributions for singleton and multiple births shown in Figure 156.1, have been compiled from the national birth registration statistics for England and Wales, 1993–2000. Applying Weinberg's rule to the data, the birth weight frequency distribution of twins was subdivided into dizygous (DZ) and monozygous (MZ) components.[35] The rule assumes that opposite-sex twins are DZ and that an equal number of same-sex twins are DZ. The remainder, obtained by subtracting twice the number of opposite-sex from the total, gives the number of MZ twins.

Of particular note, the birth weight frequency distribution of MZ is shifted to the left of DZ twins. The lower the birth weight of twins, the greater is the likelihood that they are MZ. Among Caucasian populations, MZ comprise about one-third of all twins. However, among twins of birth weight < 1000 g, 40%

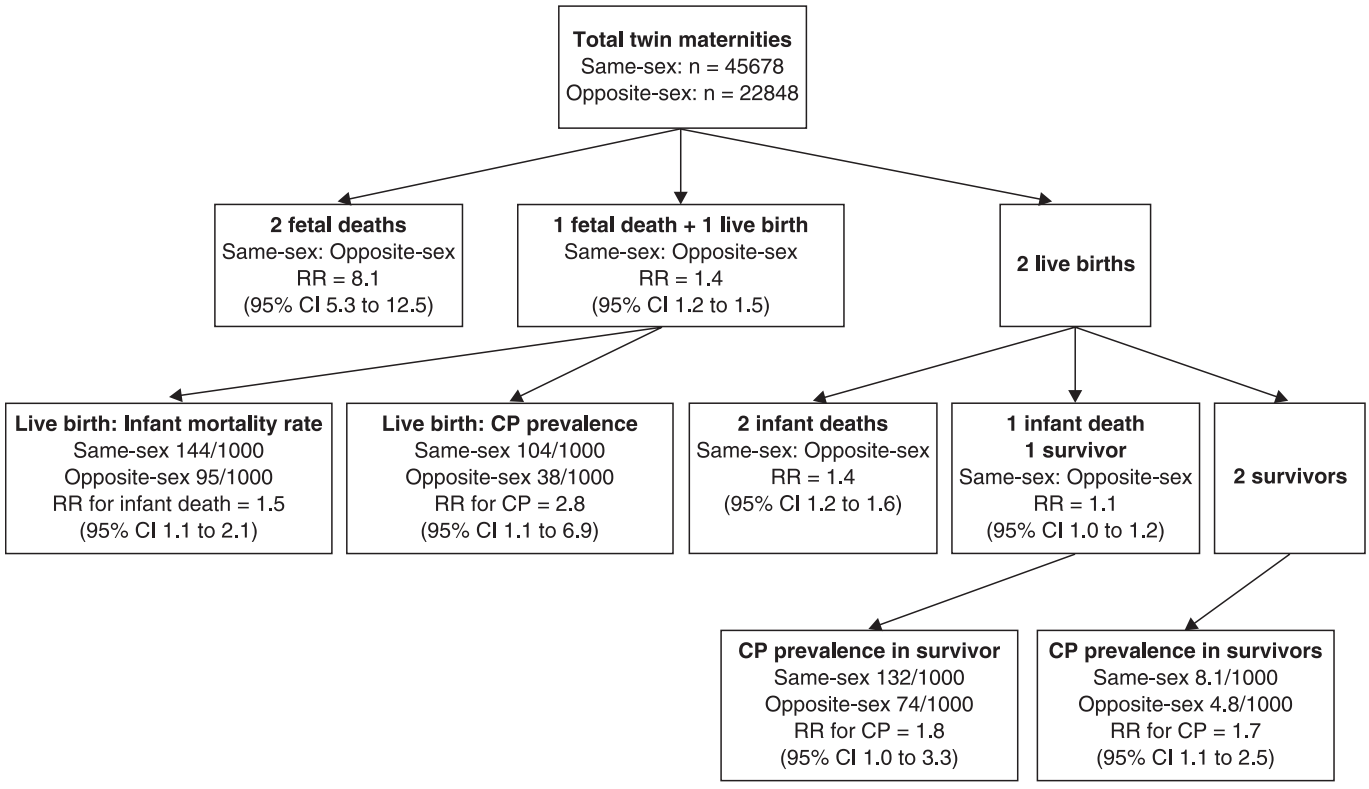

Figure 156.2 Mortality and CP risks in same- and opposite-sex twins.

are MZ, but in those of birth weight ≥3000 g, about 25% are MZ. This difference in birth weight distribution will place MZ at greater risk of CP than DZ twins.

Mortality and CP risk associated with zygosity

CP, whether in singleton or multiple births, needs to be considered as part of a spectrum of severity of cerebral impairment. This spectrum may range from early or late fetal death through a live birth that results in death in infancy to a survivor that presents with CP. The severity of the disabilities that comprise CP also varies extensively from a child with severe motor, cognitive and sensory abnormalities to one having minimal cerebral dysfunction.

In the context of multiple births, zygosity is a major determinant of fetal death and subsequent morbidity, particularly CP. In national birth and death registrations, zygosity in multiple gestations is not recorded, nevertheless, as a partial substitute, same-sex and opposite-sex comparisons may be used as an indicator for DZ and MZ risks.

There is a significantly greater risk for same-sex compared with opposite-sex at all points of the spectrum of severity as shown in Figure 156.2.

When both twins suffer fetal death, the same-sex:opposite-sex relative risk is 8.1. When one twin dies *in utero*, infant mortality in the surviving co-twin is very high irrespective of zygosity, but within this group, it is significantly higher at 144 per 1000 in same-sex compared with 96 per 1000 live births in opposite-sex twins. An analysis of multiple births in the United States found that same-sex twins were two times more likely than opposite-sex twins to die after intrauterine demise of one fetus at 25–32 weeks and more than three times more likely to die after a death at 33 + weeks.[36]

When both twins are live births, same-sex compared with opposite-sex twins are at a 40% increased risk for both to die in infancy. There is a high preponderance of very preterm infants when both twins die in infancy. Therefore, in part the excess risk is attributable to the shift to the left in the birth weight frequency distribution of same-sex twins. However, even after adjusting for birth weight in 500 g groups, the same-sex:opposite-sex relative risk is 1.21 (95% CI 1.12–1.32; $P < 0.00001$). The excess fetal and infant mortality in same-sex compared with opposite-sex twins is associated with the zygosity of the pregnancy.

Further along the spectrum of severity, not only is there an increased risk of fetal and infant death in same-sex compared with opposite-sex twins, but there is also a significantly increased risk of CP in a survivor whose co-twin died *in utero* (Figure 156.2). There are numerous case reports of a variety of congenital anomalies in the surviving co-twin. Predominantly, cerebral impairments such as multicystic encephalopathy, ventriculomegaly, porencephaly, polymicrogyria, cerebral atrophy and hydranencephaly have been described. These impairments are frequently, though

not necessarily, clinically manifest as CP, and almost invariably with MZ and, specifically, monochorionic twinning.[37–43] Population registers of CP confirm the high risk associated with fetal demise of a co-twin. The Californian Registry noted that, in children who survived fetal death of a co-twin, CP was 108 times more prevalent than in singletons and 13 times more prevalent than in twins whose co-twin was born alive.[44] The Mersey registry observed a 1 in 10 probability of CP in the surviving twin whose co-twin died *in utero*.[33] Further evidence of the vulnerability of the surviving co-twin to serious morbidity has been reported in cohort studies. The CP prevalence data shown in Figure 156.2 are from a national[45,46] and a regional[47] survey and confirms the very high risk of CP in the surviving co-twin of a fetal death. The risk is significantly greater in same-sex than in opposite-sex twins. However, it is pertinent that, when both twins are live born and one dies in infancy, the risk of CP in the surviving twin also is extremely high with the risk being greater in same-sex compared with opposite-sex twins.

Because birth weight is an important confounding variable, birth weight specific comparison of CP prevalence between same- and opposite-sex twins should be examined (Table 156.3).

The weighted relative risk of CP in same-sex compared with opposite-sex twins is significant for the surviving twin whose co-twin either died *in utero* or was liveborn but died in infancy (Table 156.3a and b). This observation is confirmed in a collaborative study combining the data from five population-based registers and the difference in the prevalence of CP persists after adjusting for birth weight and gestational age.[49]

When both twins survive infancy (Table 156.3c), the relative risk, though not statistically significant, is nevertheless greater in same-sex than in opposite-sex twins. In the collaborative study, only a marginal difference in CP prevalence was observed between same- and opposite-sex twins.

Problems associated with birth registration in multiple births

When determining the prevalence of CP, population denominators are obtained from birth registrations. The very high prevalence of CP associated with fetal or infant death of a co-twin emphasizes the importance that should be given to ensure that birth registrations in multiple gestations, particularly of fetal

deaths, are complete and, for the purpose of comparison of same- with opposite-sex, the correct sex of the fetus is registered.

The World Health Organization defines a fetal death for registration purposes as 'death prior to the complete expulsion or extraction from its mother of a product of conception, irrespective of the duration of the pregnancy'. It is inherent in this definition that it is the gestational age at expulsion or extraction from the mother and not the gestational age at death of the fetus that determines whether such a fetus from a multiple pregnancy is registered. This applies particularly to a fetal death in the midtrimester that is clinically manifest as a fetus papyraceous at birth. Usually, it is the legal requirement of the parents to register a birth. However, obstetricians differ as to whether or not the parents should be informed that a fetus papyraceous has been delivered or, if the parents are informed, that the fetus should be registered.[50] Furthermore, the sex of a fetus papyraceous is not usually known but, in England and Wales, the parents who register the fetus papyraceous may be allowed the choice as to whether the fetus is registered as male or female. As fetal death is more common in MZ gestations, arbitrary allocation of sex to a fetal death, comparisons of same- and opposite-sex will underestimate the contribution of monozygosity to the prevalence of CP.

In the United States, the 1992 Revision of the Model State Vital Statistics Act and Regulations recommends reporting of fetal deaths of 350 g or more, or if the weight is unknown, of 20 completed weeks gestation or more. However, there are regional variations, some using birth weight or gestational age as the primary determinant, while others require all fetal deaths to be reported. There is, therefore, variation in the registration of those fetal deaths weighing less than 350 g or of gestational age less than 20 weeks.

In an analysis of 18 cases of CP in the twin survivor of a fetal death and where the fetal death had been recorded in the obstetric case records, in only 12 instances had both twins been registered and six cases of CP had been registered as singletons.[51] This accentuates the importance of completeness of registration of all births not only for elucidating the pathogenesis of CP but also in counseling and advising parents who have suffered fetal loss in a multiple pregnancy.

Initially, it was considered that only late fetal death was associated with neurological impairment in the surviving co-twin.[52–54] Subsequently, second-trimester demise of one fetus was also reported to have neurological consequences for the survivor.[40,55]

Since the initial report of the loss of one fetus early in a multiple gestation,[56] the phenomenon of the 'vanishing' twin is now well recognized.[57] Such first-trimester loss of a twin has been reported in association with neurological polymicrogyria in the surviving co-twin[37] and report of a further four cases of CP in the surviving co-twin led to the hypothesis that CP in an apparently singleton child may be attributable to first-trimester loss of a fetus as the vanishing twin.[58] Fetal death of one twin may be associated with cerebral impairment in the surviving co-twin irrespective of the gestational age at which the fetal death occurs.

Mechanisms of neurological impairment in multiple births

Hypoxic-ischemic impairment sustained peripartum in a vulnerable preterm infant may occur irrespective of the multiplicity or zygosity of the gestation. In addition to the increased risk associated with preterm delivery of multiple gestations, there is the risk associated with monozygosity and, specifically, monochorionicity. While MZ gestations are of the same genotype, they may differ significantly in their phenotype and these differences hinge predominantly on the placentation that the fetuses share and the vascular anastomoses within the placenta. The chorionicity of MZ gestations is dependent on the stage of splitting of the fertilized ovum as depicted in Figure 156.3. Fertilization of two ova produces dichorionic, dizygotic twins with either separate placentas or a fused placenta but without vascular anastomoses. Early splitting of a single fertilized ovum may also lead to dichorionic placentation without vascular anastomoses. Later splitting produces monochorionic MZ twins with intraplacental anastomoses and late incomplete splitting presents as conjoint twins.

Case reports that have observed cerebral impairment in association with fetal death of a co-twin note that monochorionicity is invariably present. The crucial role of monochorionicity lies in the vascular anastomoses within the placenta that provide a shared circulation between the fetuses.

Initially, it was hypothesized that thromboplastin or thromboemboli from the dead fetus passing to the co-twin led to cerebral damage from disseminated intravascular coagulation or embolization.[42,59–61] This proposed mechanism considered the dead fetus to be the donor and the surviving fetus to be the receptor. However, in the majority of cases neither disseminated intravascular coagulation nor thromboli has been demonstrated in the surviving twin.

Subsequently an alternative explanation proposed that the dead fetus acted as the receptor with the surviving fetus as the donor. Ischemic damage to the surviving fetus was attributed to an acute twin–twin transfusion with exsanguination into the dead fetus that acted as a low-resistance vascular sump.[41,62]

In both mechanisms the dead fetus, either the donor or the receptor, is the cause of the cerebral impairment in the surviving co-twin. However, fetal death of a twin is not a necessary component as the prevalence of CP is significantly in excess among same-sex compared with opposite-sex twin when both twins are live births and one dies in infancy or when both survive (Table 156.3).

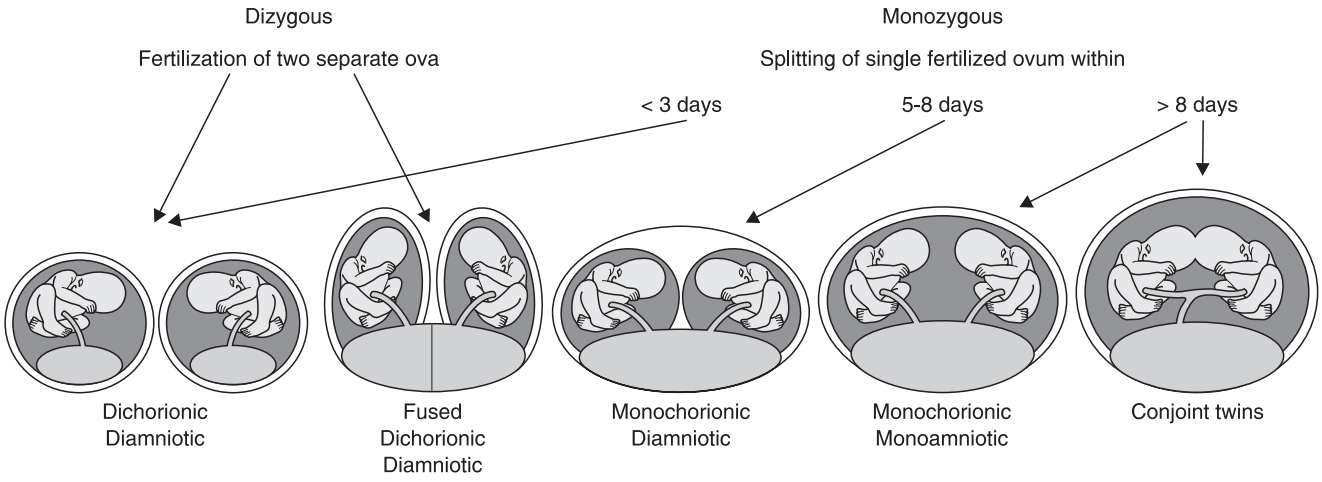

Figure 156.3 Zygosity and chorionicity in twin gestations. Reprinted from: Pharoah POD. *Semin Neonatol* 2002;7:223–30 with permission from Elsevier.

A third proposed mechanism is that the fetal death of one twin and the cerebral impairment in the co-twin are both the result of vascular instability with acute episodes of bidirectional shunting and that either twin may be donor or receptor.[63–66] This mechanism is sufficient to account for the extreme range of mortality and morbidity that may be observed in both fetuses of a monochorionic gestation. Early fetal death of both fetuses will present as a spontaneous abortion, an outcome recognized as being more common in monochorionic than dichorionic gestations.[67,68] Later fetal death will present as two stillbirths also significantly more common in monochorionic than dichorionic gestations (Figure 156.2). When both twins are live births, same-sex compared with opposite-sex twins are at greater risk of infant death and CP (Figure 156.2 and Table 156.3).

If monochorionicity with acute episodes of feto-fetal transfusion leading to cerebral impairment is an important cause of CP of antenatal origin, explanation is needed for those cases of CP observed in the twins of opposite sex. The hypothesis that CP in a singleton infant may be attributable to loss of a twin, either as a 'vanishing' twin or as a recognized but non-registered twin such as a fetus papyraceus[58] is applicable to higher-order multiple gestations. Loss of one of an MZ pair within a triplet gestation may result in twin births of opposite sex. Therefore, it cannot be assumed that twin births of opposite sex are *both* from a DZ gestation. Also, placental vascular communications, albeit rarely, have been observed in dichorionic placentas.[69,70] Additionally, the arbitrary allocation of gender to a fetus papyraceus at the time of registration of the births will introduce further misclassification over whether twins are of the same or opposite sex.

Assisted reproductive technology (ART) and CP

The increased prevalence of CP among multiple gestations has inevitably posed questions over the possible effect of ART on CP prevalence. Over the past quarter century, there has been a striking increase in rates of multiple births, predominantly as a result of ART.[71–73] The possible effect of this increase in multiple births on the prevalence of CP needs to consider the two major components that affect CP prevalence, low birth weight or immaturity and chorionicity.

Multiple births, whether spontaneously conceived or by ART, are at increased risk of low birth weight. However, cohort and matched control studies have shown that ART singleton births are at increased risk of being born preterm or of very low birth weight.[74,75] An adverse birth weight distribution will predispose to a higher prevalence of CP in ART conceptions. Based on published data, CP prevalence was estimated at 2.7, 8.8, 10.3 and 16.9 per 1000 neonates in spontaneous conceptions, two transferred embryos, three transferred embryos reduced to twins and three transferred embryos, respectively.[76] The estimates suggest that iatrogenic reduction from three to two embryos can be expected to decrease the prevalence of CP. In a study of trichorionic triplet pregnancies, iatrogenic reduction to twins increased the gestational age at delivery and there were three cases of CP among 183 survivors, a prevalence of 16.4 per 1000. As the gestations were trichorionic, monochorionicity was not a risk factor and all three cases of CP were of birth weight < 1500 g.[77]

The increased risk of CP attributable to monochorionicity may be relevant because MZ division occurs more commonly in ART than in spontaneous conceptions.[78,79] About 1 in 10–15 ART gestations undergo MZ division.[80] It is not known why MZ division is more frequent than expected in ART conceptions but the specific method of assisted reproduction may be important. Embryos from intracytoplasmic sperm injection were found to be at lesser risk of MZ division than those from other techniques of *in vitro* fertilization[81] and there was no difference in neurodevelopmental scores in children conceived following *in vitro* fertilization by intracytoplasmic sperm injection and their matched controls.[82] The extent to which ART

gestations may be at risk of CP will depend on the proportion that are of very low birth weight, the proportion that undergo MZ division and within the latter group, the number that are monochorionic.

Summary

CP is 5–10 times more common in multiple compared with singleton gestations. There are two components to this increased risk. The shift to the left in the birthweight-frequency distribution of multiple compared with singleton births places them at risk of cerebral impairment of peripartum origin. The second component is MC placentation when the risk of CP is very high in a surviving twin if the co-twin dies *in utero* or is a liveborn who dies in infancy.

The increased risk associated with MC placentation has been variously ascribed to transfer of thromboplastin or thromboemboli from the dead to the surviving fetus, exsanguination of the surviving fetus into the low-pressure reservoir of the dead fetus or hemodynamic instability with bidirectional shunting of blood between the two fetuses.

The risk of CP in multiple gestations may be considerably underestimated owing to failure to register or record early loss of a vanishing twin or later fetal demise as a fetus papyraceus.

An increase in risk of CP in ART gestations is likely because of the higher proportion of very preterm births. Because ART gestations are predominantly DZ, the risk of CP attributable to MC placentation will be limited to the minority that undergoes MZ division.

157 Infectious disease in pregnancy

J. G. Schenker

Introduction

Infection may be defined as multiplication of microbes (viruses, bacteria, fungi and protozoa) or multicellular parasites in the tissue. The host may or may not be symptomatic. In the evolution of any infectious disease, the virulence of the organism, the susceptibility of the host as well as the inoculums of the infectious agent are determinants of the clinical course. Infection during pregnancy poses a unique situation, since two patients become potentially involved – the mother and the fetus. Fetal and neonatal infections can occur at different stages of gestation from conception to birth. The mother is at risk because of certain changes induced by pregnancy, such as depression of immunity, urinary tract infection, genital tract infection due to premature rupture of membranes or prolonged labor, injuries to the genital tract during birth or retained products of conception.

Infections that occur at fertilization or during the early stages of conception often destroy the zygote or pre-embryo, and only rarely leave definite evidence. The inability of most agents to infect the pre-embryo probably depends largely on the local barriers to the infectious agent. Some viruses can infect only embryos of certain developmental stages. After implantation, most infectious agents reach the fetus hematogenously by transplacental infection. The fetus is at risk as a result of ascending infection from the birth canal or during passage down the birth canal. Viruses can infect the embryo and the fetus, and this kind of infection, which is often trivial in the adult, can be devastating to the newborn. Fetal infections during the organogenetic period can cause major malformations, and the most serious are those affecting the central nervous system. Bacterial infections increase perinatal wastage, mainly due to premature labor. Postnatal infections may be acquired from the mother via secretions, blood, milk or from attending medical personnel or the hospital environment.

Major advances have been made in the later part of the present century in the development of new antibiotic preparations. In spite of this, infections continue to be of great concern in obstetric practice.

We have tried in this section on infectious diseases to introduce the various clinical aspects of infections that affect the mother and her fetus. Sexually transmitted diseases (STD) are a special threat to population. They may adversely affect pregnancy, causing pregnancy losses, and the disease may be transmitted to the offspring *in utero* or during delivery. Because STD in women is often asymptomatic, screening for the most common infections is an important component of prenatal care, particularly in highly predisposed women. Although more than 20 infectious diseases may be sexually acquired, the chapter on STD deals with syphilis, gonorrhea, chlamydia, herpes, trichomoniasis, human papilloma virus, chancroid and donovanosis. Since human immunodeficiency virus (HIV) infection is a global threat in the developed and developing world, and poses a special threat to pregnant women and their fetuses, special attention is given to acquired immunodeficiency syndrome (AIDS).

The traditional bacterial infection by Group A β-hemolytic streptococcus is at present a minor clinical problem, but infections by β-hemolytic streptococcus can cause a serious or even fatal infection in the newborn infant.

Group B streptococcus (GBS) is an extremely important human pathogen causing thousands of maternal and neonatal infections yearly. In the last 5 years clinical research has put much effort into understanding the risk factors for GBS and strategies for its early detection and prevention. Future studies will determine whether GBS infections can be prevented by administration of vaccine in high-risk women. Pregnant women who are in an immunodeficient state are at risk for pneumonia infection due to agents such as *Pneumocystis carinii*, *Mycobacterium avium* and *Mycobacterium tuberculosis*. Recently, pneumococcal infections have become partly or completely resistant to penicillin or its synthetic components. Varicella pneumonia requires special attention in pregnant women.

Obstetrical interventions are associated with increased incidence of infectious morbidity, especially the common procedure of cesarean section. The prevention of infection may be accomplished by applying aseptic techniques, but is mainly achieved today by prophylactic antibiotics.

Septicemia and septic shock are dramatic clinical syndromes that result from acute invasion of the bloodstream by certain microorganisms or their toxic products. Even with the appropriate antimicrobial and supportive care, many patients die of septic shock, making strategies for prevention and more effective treatment of this critical condition of primary importance.

Infections of the gastrointestinal tract may have an impact on the course of pregnancy and its outcome. Several pathogens such as *Salmonella* and *Campylobacter* cause bacteremia with secondary infection of the placenta and the fetus. Other microorganisms cause severe circulatory compromise due to dehydration and electrolyte imbalance, and may bring about fetal hypoxia. Several aspects of gastrointestinal infections during pregnancy and the neonatal period are discussed.

Central nervous system (CNS) infections in pregnant women are divided into different clinical syndromes according to the principle site of the infection within the CNS (meningitis, encephalitis and myelitis). CNS infections may be caused by a wide variety of infectious agents: bacteria (including rickettiae, spirochets and mycobacteria), viruses, fungi and protozoa. The clinical course of CNS systemic infections in pregnancy, the diagnostic tools and the effects of the disease and the therapy on the fetus and the newborn are reported.

Puerperal pelvic infections are usually caused by anaerobic flora resistant to common antibacterial drugs. There is increasing evidence that infections ascending from the lower genital tract, which may be caused by an anaerobic organism, are risk factors for chorioamnionitis, postabortion septicemia, and septic shock and postcesarean infection. The treatment of anaerobic infections in pregnancy follows the usual rule of antimicrobial treatment, which includes the following agents: metronidazole, clindamycin, some penicillins, chloramphenicol and impipenem–cilistatin. By applying these treatment modalities one should balance the benefits of the treatment with their potential side effects.

Parasitic infections are common throughout the world, but most clinicians have no experience in the diagnosis and treatment of these diseases. Clinicians are increasingly confronted with parasitic infections such as malaria, schistosomiasis and leishmaniasis because of the increase in international travel and emigrations. Malaria is one of the most prevalent and serious infectious disease problems throughout the tropical and subtropical areas of the world. Intrauterine transmission of malaria from mother to fetus frequently occurs, although the mechanism of transplacental passage of the parasite is unknown. In the endemic areas, prophylaxis for pregnant women is recommended.

Pregnant women are more prone than non-pregnant women to have vaginal colonization with fungal infectious agents such as candida. Rarely, the infection can ascend and involve the uterine content, producing chorioamnionitis and congenital candidiasis. Viral infections can cause damage to the fetus through passage across the placenta. Approximately 5% of pregnancies will be complicated by one or more viral infections, excluding the common cold. Vaccines are at present being successfully developed in order to prevent these viral infections. Measles can be severe during pregnancy and has been associated with spontaneous abortion and premature delivery. However, in contrast to rubella, the measles virus is not known to cause congenital anomalies of the fetus. Mumps is generally a benign condition during pregnancy, but it affects the fetus by increasing the rate of abortion, prematurity and congenital malformations. Vaccination against mumps is available, but it should not be administered to pregnant women. The treatment of the disease is only symptomatic, and there is no antiviral agent available yet.

Only a few antimicrobial agents have been shown to be completely non-toxic when given to pregnant women, and some of them have teratogenic potential. Thus, the administration of an antimicrobial drug during pregnancy should always be a carefully considered action in which a balance between the need of the mother and the possible adverse effect of the drug on the fetus should be taken into consideration. The Food and Drug Administration of the United States has established a fetal risk summary, which divides drugs into categories, based on accumulated safety data from animal and human studies. Therefore, a physician, when administering any antimicrobial or antiviral agent, should find out to which category the drug belongs.

158 Sexually transmitted infections in women with special reference to pregnancy

M. Dan

Introduction

Sexually transmitted infections (STIs) represent a special threat to the feminine population. Many STIs are transmitted more efficiently from men to women than from women to men. STIs are often asymptomatic in women; thus, treatment is not sought, and the disease remains uncontrolled, often leading to pelvic inflammatory disease, which in turn can damage the fallopian tubes irreversibly. Tubal scarring is a major cause of mechanical sterility and ectopic pregnancy. STIs may adversely affect pregnancy, causing spontaneous abortion, stillbirth and premature delivery. The infected pregnant women can transmit the disease to her offspring *in utero* or at delivery. Venereal infection present on delivery can be responsible for postpartum endometritis. Risk factors identified for most STIs include young age, multiple sex partners, early onset of sexual activity, being single, substance abuse and Black race. Consequently, when all STIs are considered together, they may represent one of the most common medical complications in pregnancy, especially in high-risk groups, such as indigent urban populations plagued with drug abuse and promiscuity. Because STIs in women are often asymptomatic, screening for the most common infections is considered by some authors as an important component of prenatal care, particularly in highly predisposed women. Although more than 20 infectious diseases may be sexually acquired, only those transmitted primarily by sexual contact and causing genital disease will be discussed in this chapter.

Syphilis

Syphilis is a chronic spirochetal infection with many diverse clinical manifestations that occur in distinct stages. It holds a special place in the history of medicine as the 'great imitator' or 'great imposter'.

The Pathogen

Treponema pallidum subspecies *pallidum*, the causative agent of syphilis, is a slender, tightly coiled, motile organism. Belonging to the family Sperochaetaceae, the genus *Treponema* includes several other members, some of which are human pathogens; *T. pallidum* subsp. *pallidum* is the only one that can be transmitted by sexual contact. The pathogenic treponemes cannot be cultivated *in vitro*, and the distinction between them is based primarily on the clinical presentation.

Pathogenesis

Syphilis is most often acquired through sexual contact. Venereal transmission of *T. pallidum* is possible only when mucocutaneous syphilitic lesions are present. Immediately after *T. pallidum* penetrates the intact mucosa or gains access through disrupted skin, it enters the lymphatic and blood stream and disseminates throughout the body. Virtually any organ can be invaded including the central nervous system. Once established, the natural history of the disease is divided into several stages: primary, secondary, latent and tertiary (late) syphilis. The primary stage is characterized by the development of a chancre at the site of inoculation, which consists of an intense infiltration of plasma cells, scattered histocytes and the typical obliterative endarteritis. The secondary stage reflects the dissemination of the infection to the entire body and is characterized by a variety of diffuse mucocutaneous lesions and constitutional symptoms. Secondary syphilis can recur up to 4 years after acquisition of infection in about 25% of the patients, the

risk of recurrence being higher in patients with suppressed cellular immunity, e.g., third-trimester pregnancy; most relapses (90%) occur within the first year. During the latent period, the only evidence for the presence of infection is the positive serologic response after the lesions of primary and secondary disease have vanished. The Centers for Disease Control and Prevention (CDC) define an infection of less than 1 year as early latent syphilis (recurrence of secondary disease possible, high infectivity), and infection of more than 1 year as late latent syphilis (recurrence unlikely). Tertiary syphilis develops in about one-third of untreated patients after a variable interval of latency. Two types of lesions can develop during this stage of the disease: the most common variety is the obliterative endarteritis of the vasa vasorum of the aorta and the arteries of the central nervous system as seen in cardiovascular syphilis and meningovascular neurosyphilis and where *T. pallidum* can be demonstrated by appropriate staining. The other type is the gumma which is a granulomatous-like lesion consisting of a necrotic, coagulated center surrounded by an inflammatory zone and fibrosis. The lesions, which may contain spirochetes, can be found anywhere in the body, most often in the liver, skin, bones and spleen.[1]

In the infected woman, syphilis is not associated with impairment of subsequent ability to conceive.[1] The pathologic consequences of *T. pallidum* infection are less prominent during pregnancy.[2] Since many of the manifestations of adult and congenital syphilis are thought to have an immunologic basis, the milder form of syphilis in the pregnant female is consistent with the relative state of immunosuppression which accompanies pregnancy. At least two-thirds of fetuses of women with early (infectious) syphilis during pregnancy are affected. Once the infection reaches the placenta during maternal spirochetemia, fetal infection usually follows. The infected placenta becomes large and pale. Microscopically, the villi appear to have lost their characteristic arborescent appearance and to have become thicker and club shaped. The blood vessels may decrease in number or almost disappear as a result of endarteritis. Vascular resistance in uterine and umbilical arteries may be increased.[3] Evidence of fetal involvement is more likely to be documented after the 18th gestational week, although spirochetes were detected as early as 9 weeks' gestation.[2] Thus, syphilis is not associated with early abortion. It has been proposed that the lesions of congenital syphilis do not become evident until the fetus becomes immunologically competent at about the 16th gestational week.[2] The consequences of congenital syphilis depend on the severity of the infection: late abortion, stillbirth, neonatal death, premature labor, delayed intrauterine growth, neonatal disease, or latent infection may be seen. These appear to be largely due to the dysfunction of the maternal–fetal endocrine axis, resulting from decreased levels of dehydroepiandrosterone produced by the fetal adrenal glands.[4]

Epidemiology

Although the vast majority of cases of syphilis result from transmission by sexual intercourse, the infection can also be acquired by passage of the organism through the placenta (congenital syphilis), by kissing or touching a person who has active lesions, by transfusion of fresh blood (*T. pallidum* cannot survive longer than 24–48 h in stored blood units), or by accidental direct inoculation (syphilis of the fingers in medical personnel). Sexual transmission is highest during the primary and secondary stages: one-third of contacts will acquire the infection.

In the United States, the incidence of syphilis declined sharply after the introduction of penicillin therapy and broad based public health programs, attaining its lowest levels in the 1950s (annual rate of primary and secondary syphilis, ~5 cases per 100,000 population).[5] An increase in the rate of primary and secondary syphilis was observed during the late 1980s with an incidence of 20 cases per 100,000 population in 1990. More recently, the rate decreased again, and in 2000 it was the lowest (2.1 cases per 100,000) since reporting began, although a slight increase was observed thereafter (2.5 cases per 100,000 in 2003). This increase was due to the rise of the rate of primary and secondary syphilis among men (4.2 cases per 100,000 in 2003), while in women the incidence continued to decline (0.8 cases per 100,000 in 2003).[6] In 2003, almost 40% of cases of primary and secondary syphilis reported to the CDC occurred among African-Americans, with a rate 5.2 times higher than the rate among Whites.[6]

Women usually have had lower rates of disease than men although most recently the male-to-female rate ration in White Americans was 1.0. Women cycled at low levels until the epidemic of the 1980s, when rates, primarily in Black women, increased rapidly (Figure 158.1), a trend that also led to a dramatic increase in congenital syphilis. This change is probably related to the development of a new highly promiscuous life style which is marked by exchange of sexual favors for drugs, especially crack cocaine.[7] A sharp decrease of primary and secondary syphilis among women was observed during the 1990s and the early 2000s, with an incidence of 0.8 case per 100,000 in 2003.[6] The vast majority of cases occur as expected in the most sexually active age group (15–29-year-olds).

In other industrialized countries, the incidence of syphilis has generally been lower than in the United States even before the recent epidemic. In Western Europe and Canada, a sharp decline in the rates had been observed after the advent of penicillin. A further decrease in incidence has occurred in the 1980s with rates of ≤ 2 cases per 100,000 since 1983, probably as a consequence of changes in sexual behavior imposed by the AIDS epidemic.[5] During the 1990s, until 1998, the number of cases of infectious syphilis diagnosed in England remained stable among both sexes, but then more than doubled between 1998 and 2000 in

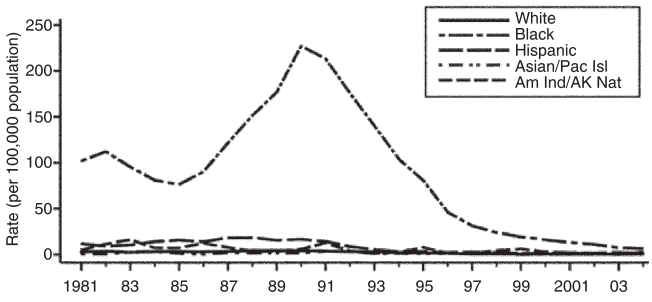

Figure 158.1 Primary and secondary syphilis. Rates among 15- to 19-year-old females by race and ethnicity: United States, 1981–2004 (from Centers for Disease Control and Prevention[6]).

men and rose by 53% in women. In 2000, 48% of syphilis infections in men were homosexually acquired, rates being highest in London (men 2.9/100,000; women 0.8/100,000) and in northwest England (men 2.0/100,000; women 0.2/100,000) regions.[8] A similar trend has been observed in Israel with a significant decline in the incidence of syphilis since the 1970s (less than 0.5 per 100,000 in 1990). Since the mid-1990s, however, an increase in the incidence was documented (3 cases of primary and secondary syphilis per 100,000 in 2001), mostly due to morbidity among newly arrived immigrants.[9] In Eastern Europe, on the other hand, a brisk increase in the incidence of primary and secondary syphilis was observed in countries formerly belonging to the USSR (32 cases per 100,000 in Russia).[10] Very limited information is available on the prevalence of syphilis in non-industrialized countries. The estimates for parts of Africa are 360 cases per 100,000 in 1990.[11]

In pregnant women, the prevalence of positive serologic tests for syphilis in the penicillin era in Northern Europe and the United States has been roughly 0.1–0.6%.[1] More recently, 1.5% of women who delivered in a large tertiary care urban hospital in Detroit, Michigan, USA, had reactive serologic tests. Seropositive mothers were primarily Black, multigravida with a mean age of 25 years and had a history of crack heroine use.[12] Women with untreated syphilis apparently may remain infectious to their fetuses for many years, although the proportion of affected fetuses and the severity of fetal disease decrease with longer duration of untreated maternal infection. According to World Health Organization (WHO) estimates, a million pregnancies each year are adversely affected by syphilis due to maternal infection, and about 270,000 infants are born with congenital diseases. Primary or secondary syphilis during pregnancy affects virtually 100% of fetuses with 50% of such pregnancies resulting in premature delivery or perinatal death. Pregnancy during early latent syphilis results in a 40% rate of prematurity or perinatal death, whereas late syphilis causes congenital infection in 10% of infants and 10-fold risk of perinatal death.[2] According to the 1988 Centers of Disease Control Surveillance case definition, a presumptive case of congenital syphilis includes any infant whose mother had untreated of inadequately treated syphilis at delivery, regardless of findings in the infant, as well as symptomatic infants.[13] Trends in congenital syphilis occurrence closely parallel trends in rates of primary and secondary syphilis in women in the peak childbearing age group (15–29 years) which is also the peak age group in which early syphilis occurs. Peaks in congenital syphilis usually occur 1 year after peaks in primary and secondary syphilis among women. At present, syphilis is an uncommon cause of stillbirth in industrialized countries: the incidence of congenital syphilis has steadily declined in recent decades reaching an all time low of 2–3 cases per 100,000 births in the late 1970s.[1] However, since the early 1980s, an increase in congenital syphilis was noted in the United States.[1,6] In 1987, the incidence of reported congenital syphilis in infants less than 1 year of age was about 12 cases per 100,000 live births, and it continued to increase steeply until 1991 when 107 cases per 100,000 live births were reported. A sharp decline was observed thereafter with 10.3 cases per 100,000 live births in 2003.[6] In 2003, Blacks accounted for the majority of congenital syphilis cases with a rate of 33.9 cases per 100,000 live births, followed by Hispanics (18.1 per 100,000 live births) and non-Hispanic Whites (1.3 cases per 100,000 live births).[6] In the United Kingdom, each year around two infants are born with congenital syphilis. Similar low rates are reported in other West European countries such as France and Switzerland.[14] In Israel, congenital syphilis is also rare: during the period 1991–2000, a mean of 2.4 cases were reported annually to the Ministry of Health (range, 0–4 cases per year). The annual incidence during this period was $\leq$0.08 cases per 100,000 live births.[9] On the other hand, a 50-fold increase in the incidence of congenital syphilis was documented in the former Soviet Union during the decade 1990–1999.[14]

Maternal and congenital syphilis still remain a major problem in developing countries, especially in sub-Saharan Africa. Prevalences of syphilis seropositivity in pregnant women attending antenatal clinics in Africa range from 10% to 15% in most reports.[1] In Zambia, congenital syphilis was documented in 1% of the babies delivered at a Lusaka hospital, and seropositivity rates ranging from 2.9% to 6.5% was noted among infants under 6 months of age.[1] In another study from Zambia, serologic tests for syphilis were positive in 43% of women who delivered stillborn babies, 19% of those who aborted and in 13% of women attending their first antenatal visit; 19% of miscarriages in this country were attributed to syphilis.[1] In Durban, South Africa, congenital syphilis is the fourth, and in Addis Ababa, Ethiopia, the fifth leading cause of perinatal death.[2] Also, in the latter city, syphilis is responsible for as many as 10% of all perinatal deaths.[15] According to other sources the impact of congenital syphilis

on perinatal mortality in sub-Saharan Africa is even higher.[14] In most of the North African, Latin American and Asian countries the rates of syphilis among pregnant women range between 2% and 5%.[14]

Clinical manifestations

Treponema pallidum infection may remain asymptomatic in many cases: 11% of infected women develop signs of primary syphilis, 41% develop signs of secondary disease, and 48% remain asymptomatic. The classical primary chancre appears at the site of inoculation (labia, the posterior fourchette, cervix, vagina, anus, etc.) as a single painless papule after an average 21-day incubation period (range, 3–90 days). It quickly erodes to form an indurated ulcer with a smooth, clean base, and firm, raised borders. Multiple chancres can occur, however, especially in the person infected with HIV. Other variations in presentation are possible; thus any genital lesion should raise the suspicion of syphilis ('any anogenital ulcer is syphilis until proven otherwise'). The cervical location is more common in pregnant women, probably because of inoculation of the friable cervix.[3] In some instances, the lesion may be somewhat larger than usual, presumably because of increased genital vascularity. On other occasions, it may be of such a small size or be located as to go unnoticed.[3] The chancre is often accompanies by non-tender, non-suppurative enlarged inguinal lymph nodes. Primary syphilis must be differentiated principally from herpes virus infections, chancroid and traumatic superinfected genital lesions. The chancre heals spontaneously within 3–6 weeks (range, 1–12 weeks), while the lymphadenopathy usually persists for a longer duration.

Secondary syphilis usually appears approximately 6 weeks (range, 2–8 weeks) after the appearance of the chancre, and up to 6 months after exposure, in the form of highly variable mucocutaneous lesions and constitutional symptoms. In about 15% of women, the chancre may still be present. Skin lesions occur in 80% of patients in form of macular, papular, maculpapular and/or pustular rash that may persist from a few days to 8 weeks. Any surface area of the body can be affected with all of the different rashes being present at one time; the involvement of palms and soles strongly suggests the diagnosis. Temporary patchy alopecia and loss of eyebrow may be seen. In warm, moist intertriginous areas (perianal area, vulva, etc.) highly infectious plaques, called condyloma lata, may develop. Mucous patches, in form of silvery gray superficial erosions, may also be noted on the mucous membranes of the vagina, cervix, mouth, pharynx, etc. The constitutional symptoms include low-grade fever, malaise, anorexia, weight loss and generalized painless lymphadenopathy. The cerebrospinal fluid may be inflamed in up to 40% of the patients, but most of them do not develop neurosyphilis after treatment with one of the currently recommended regimens. Virtually any organ can be affected: kidney (glomerulonephritis, nephrotic syndrome), liver (high serum alkaline phosphatase levels), spleen (splenomegaly), eyes (iritis, uveitis), the osteoarticular system (synovitis, osteitis) and cranial nerves (palsies).

Tertiary syphilis is a slowly progressive inflammatory disease that can touch any organ in the body and can produce clinical illness years after the initial infection. It is generally referred to as cardiovascular syphilis (syphilitic aortitis), gummatous syphilis (can affect any organ), or neurosyphilis (asymptomatic, meningovascular or parenchymatous). Neurosyphilis encompasses a heterogeneous collection of neurologic syndromes and psychiatric manifestations with tabes dorsalis and Argyll Robertson pupil being the most specific for syphilis. The parenchymatous neurologic lesions are usually irreversible and respond only slightly to therapy.

Most syphilitic infants lack manifestations at birth.[1] Neonates who are born with manifest syphilis are usually severely affected and carry a worse prognosis. In symptomatic patients the earliest sign (appearing usually on the third to eighth week of life) is a rhinitis (snuffles) followed by a diffuse maculopapular desquamative rash with skin sloughing particularly on the palms, soles and about the anus and mouth. In contrast to acquired syphilis, a vesicular rash and bullae may be seen. Necrotizing funisitis (swollen and discolored umbilical cord) is pathognomonic. Osteochondritis and perichondritis can affect all bones of the osteoarticular system, most prominently the nose (saddle nose) and the metaphyses of the lower extremities ('saber shin'). The liver is often heavily involved with accompanying splenomegaly, anemia, thrombocytopenia and jaundice. Immune-complex glomerulonephritis can develop at about the fourth month of life. Neonatal congenital syphilis must be differentiated from other generalized congenital infections (TORCH). Late congenital syphilis (beyond 24 months of life) is characterized by the frequency of interstitial keratitis and neurosyphilis, while cardiovascular syphilis is rare. Other typical lesions include recurrent arthropathy, deformed upper central incisors (Hutchinson's teeth), frontal bossing and other craniofacial malformations.[1]

Laboratory diagnosis

Demonstration of the pathogen

Since *T. pallidum* is not culturable on artificial medium, the organism can be diagnosed only by direct demonstration in an appropriate specimen. Dark-field examination of a serous exudate from a moist lesion is the quickest and most productive technique. *Treponema pallidum* will have a corkscrew appearance and will move in a characteristic spiraling

motion which is not seen in non-pathogenic treponemes. An alternative technique, which can be used also in biopsy specimens, is the direct or indirect immunofluorescence or immunoperoxydase staining.[16] Promising results were recently obtained with the polymerase chain reaction (PCR) technique which can be applied also on paraffin-embedded tissue. The PCR technique could be extremely valuable in diagnosing infection in congenital syphilis (in amniotic fluid, neonate's serum and cerebrospinal fluid, CSF) and neurosyphilis.[17]

Serologic tests

Serology remains the most useful diagnostic tool in women. These tests cannot distinguish, however, between syphilis and other treponemal infections. Hence, the interpretation of reactive serologic tests can be difficult in patients who live in or come from areas where non-venereal treponematoses are common. Two different types of tests are used in concert.[1] *The non-treponemal tests:* inexpensive, rapid and convenient means for screening large numbers of sera, and when used quantitatively, can give an indication of disease activity. Limitations of the non-treponemal tests include their lack of sensitivity in early primary cases (less than 5 weeks) and in late syphilis (negative in up to 30% of cases); the possibility of *prozone reaction* (false-negative reaction in undiluted serum because of antibody excess); or false-positive results which can occur in association with advanced age, pregnancy, drug addiction, connective tissue diseases, chronic liver disease, cancer, multiple myeloma and a variety of infectious diseases including early HIV infection.[11] These tests detect antibodies directed against a lipoidal antigen that is the result of the interaction of host tissue with *T. pallidum*. The standard antitreponemal test is the VDRL (Venereal Diseases Research Laboratory). The rapid plasma reagin (RPR) card test and the automated reagin test (ART) are two modifications of the standard test used for routine screening. A positive screening test should be further evaluated with a confirmatory treponemal test and a non-treponemal quantitative test. Following adequate therapy early syphilis, the titers of the quantitative test should decline until little or no reaction is detected after the first year.[18] A persisting positive test with insufficient decline of the titer in a treated patient suggests: (a) persistent infection, (b) reinfection, or (c) biologically false-positive reaction. However, after an appropriate clinical response to treatment, non-treponemal titers persist at low levels in some individuals for a long time (sometimes for life), a response referred to as a 'serofast' state. Up to 15% of HIV-negative patients with early syphilis who received therapy at recommended or greater dosages do not demonstrate a 2-dilution decline in RPR/VDRL titers at 12 months following therapy, without evidence of clinically defined treatment failure. No further therapy is required in serofast states if titers are not increasing, clinical disease resolves (primary and secondary syphilis), clinical disease does not recur (primary and secondary disease) or develop (early latent syphilis), and the patient is HIV-negative. HIV-positive patients with a serofast reaction to treatment of latent syphilis may need a lumbar puncture for further evaluation.[19]

Treponemal tests

Treponemal tests are used primarily to verify the reactivity of the non-treponemal tests. In primary syphilis, they may become reactive before the non-treponemal tests.[17] Three tests are currently considered the standard: the fluorescent traponemal antibody absorption test (FTA-ABS), the *T. pallidum* hemagglutination (TPHA), and the microhemagglutination assay for antibodies to *T. pallidum* (MHA-TP). All these tests use *T. pallidum* as the antigen to detect antibodies. The treponemal tests are technically more difficult and costly to perform than the non-treponemal tests and cannot be used to monitor therapy. For most infected persons, test results may remain positive for life-time even after successful therapy. About 1% of the general population have false-positive results: these are also associated with systemic lupus erythematosus and some other spirochetal and non-spirochetal infections.[2,11] A reactive treponemal test result on a sample that is also reactive in a non-treponemal test is, however, highly specific.[17] If late latent syphilis is suspected, serologic testing of the CSF should be considered to rule out neurosyphilis. A definitive diagnosis is made on the basis of a reactive VDRL-CSF test[17] or the intrathecal *T. pallidum* antibody (ITPA) index.[16] All patients with diagnosed syphilis should be tested for HIV.

Treatment

Experience has shown that a single benzathine penicillin G dose had a success of 95% or higher in early syphilis in patients with intact immune system. In late syphilis, because spirochetes are thought to divide more slowly, the suggested duration of therapy is longer.[11] Recommended choice and dosages of antimicrobial agents for the various clinical forms of syphilis are shown in Table 158.1. During pregnancy, syphilis therapy must be guided not only by its ability to cure the mother, but also by its ability to prevent or cure fetal infection. Treatment in the pregnant woman is generally the same as that of the non-pregnant patient and depends on the duration of infection, the presence or absence of central nervous system involvement and the competence of the patient's immune system. Some experts recommend, however, additional therapy (e.g., a second dose of benzathine penicillin G 2.4 million units IM) 1 week after the initial dose, particularly for those women in the third

Table 158.1 Recommended therapeutic regimens for syphilis[20]

Stage	Treatment of choice	Alternative regimens*
Primary, secondary early latent (≤1 year)	Benzathine penicillin G, 2.4 million units IM in a single dose	Doxycycline 100 mg po bid ×14 days or Tetracycline 500 mg po qid ×14 days or Erythromycin 500 mg po qid ×14 days or Cefriaxone (dosage not established; see Schafer *et al.*[22])
Late (or of unknown duration) latent tertiary (cardiovascular, gummatous)	Benzathine penicillin G, 3 doses of 2.4 million units, IM each at 1 week intervals	Doxycycline 100 mg po bid ×14 days or Tetracycline 500 mg po qid ×14 days
Neurosyphilis	Aqueous crystalline penicillin G, 2–4 million units IV every 4 h for 10–14 days or Procaine penicillin 2.4 million units IM daily, plus probenecid 500 mg po qid, both for 10–14 days	
Congenital	Aqueous crystalline penicillin G, 50,000 units/kg IV every 12 h during the first 7 days, and every 8 h thereafter, for 10–14 days or Procaine penicillin G, 50,000 units/kg IM daily for 10–14 days	

*For patients allergic to penicillin; not recommended for use in pregnant women

trimester and for women who have secondary syphilis during pregnancy.

In patients with a history of penicillin allergy, skin testing with penicillin G minor determinant mixture and penicylloyl polylysine is recommended. If skin tests are reactive, penicillin desensitization should be performed using the technique described by Wendel *et al.*[20] Alternative therapy during pregnancy with one of the non-penicillin regimens is discouraged by the CDC because of reported treatment failures in preventing congenital syphilis, especially with erythromycin, and potential adverse effects on the mother and the fetus.[16] Initial reports on treatment of early syphilis with cefriaxone are promising.[21,22]

The Jarisch–Herxheimer reaction is a well described phenomenon often occurring in pregnant patients treated for primary or (more particularly) secondary syphilis. Symptoms usually occur within 24 h after any therapy for syphilis. Approximately 1–2 h after therapy has been initiated, systemic manifestations of fever, rigors, tachycardia, hyperventilation, vasodilatation, hypotension, profuse sweating headache, myalgia and arthralgia. Uterine contractions frequently develop during the reaction, and they may be followed by evidence for fetal distress manifested as late fetal heart decelerations.[3] The reaction is self limited and can be treated with aspirin or prednisone if manifestations are severe.

All patients treated for early syphilis should have repeat quantitative non-treponemal tests at 3, 6 and 12 months post-therapy. In pregnant women, serologic tests should be performed monthly until adequacy of treatment has been assured. All patients with syphilis of more than 1 year duration should also be tested 24 months after treatment. Patients with documented neurosyphilis should be carefully followed serologically and have a CSF examination for at least 5 years unless all abnormal parameters normalize before.

The risk of infection for the infant is minimal (less than 2%) if the mother has received adequate

penicillin therapy during pregnancy. However, the child must be examined monthly after delivery and until the non-treponemal test or PCR analysis become negative. Treatment of the infant should be considered in the following circumstances: (a) mother had received inadequate penicillin therapy or was treated with antibiotics other than penicillin, (b) the treatment status of the mother is not well documented, (c) the mother was treated appropriately, but a significant decrease in non-treponemal antibody (≥ fourfold) has not been achieved or documented after therapy to indicate adequate response, and (d) the infant could be difficult to follow. Additionally, any infant with physical, radiologic or serologic (quantitative titer ≥ fourfold greater than the mother's titer) evidence of active diseases should be fully treated.[23] Since neurosyphilis is difficult to exclude in newborns, treatment regimens similar to those recommended for neurosyphilis should be used in infants. If the mother was appropriately treated *during* pregnancy (more than 4 weeks before delivery), mother's titers decreased fourfold, and the infant was normal on physical exam and serologically (titers <fourfold the maternal's), no evaluation is required; yet, it is recommended to give the infant a single dose of IM benzathine penicillin G 50,000 units/kg.[23]

Syphilis in HIV-infected patients often presents with a more protracted and malignant course, greater constitutional symptoms, organ involvement, atypical and florid skin rashes and a significant predisposition to develop neurosyphilis.[16] HIV-infected patients are more likely to show an aberrant serologic response.[16] Therapeutic recommendations vary: some authors recommend more vigorous and prolonged regimens, while others suggest that regimens used for non-HIV patients are satisfactory.[23] Failure of even high dose intravenous therapy to cure symptomatic neurosyphilis in HIV infected patient has been reported.[24] Penicillin should always be administered and careful follow-up is essential. Since syphilis increases the risk for the acquisition and transmission of HIV,[11] testing for HIV is recommended for all persons in whom syphilis is diagnosed.[23]

Case detection and prevention

Any person sexually exposed to a patient with syphilis in any stage should be evaluated clinically and serologically.[23]

Congenital syphilis is entirely preventable in an appropriate case detection program. Most congenital syphilis today is the result of failure to detect and treat syphilis in pregnant women. In the recent epidemic of congenital syphilis in the United States, half of the infected infants were born to women who received prenatal care, but in whom serological screening was not done and thus maternal syphilis was not treated.

Prenatal first-trimester serologic screen is cost-beneficial even in countries with prevalence of maternal syphilis as low as 1:20,000.[2,14] The CDC recommend serologic testing at the beginning of prenatal care and, for high-risk women, at the beginning of the third trimester and at delivery. Any woman who delivers a stillborn infant after 20 weeks' gestation should also be tested.[23] To improve early detection in pregnant women, particularly in developing countries and in poor and minority women in industrialized countries, the following practical measures are suggested: on-site pregnancy testing of women in STI clinics and drug addiction programs whose menstrual periods are late; routine PRP testing whenever a positive pregnancy test is reported in all pregnancy testing programs; and early testing by prenatal programs before the regularly scheduled prenatal visit when the waiting time for their first scheduled visit is long.[2] No infant or mother should leave the hospital unless the maternal serologic status has been documented at least once during pregnancy and preferably again at delivery.[23] All infants born to mothers seropositive to syphilis should have a quantitative non-treponemal serologic test performed on infant serum (treponemal tests are not necessary). These infants should also be examined for signs of congenital syphilis: non-immune hydrops, jaundice, hepatosplenomegaly, rhinitis, skin rash and/or pseudoparalysis of an extremity. Pathologic examination of the placenta or the umbilical cord is suggested, and microscopic examination of suspicious lesions or body fluids for tremonema is recommended. Laboratory tests should include CSF analysis for VDRL, cell count and protein, complete blood count and differential, platelet count. Other tests if clinically indicated: radiographs, liver function tests, ophthalmologic examination, etc.[23]

Gonorrhea

Gonorrhea may present as a localized infection of the lower genital tract, an invasive infection of the upper genital tract or disseminated disease with systemic manifestations. Ascending genital infection in women is responsible for salpingitis, one of the leading causes of infertility in the world.

The Pathogen and pathogenesis

Neisseria gonorrhoeae is a non-motile, non spore-forming, gram-negative coccus that typically grows in pairs (diplococci). The bacterial cell surface is an important determinant in the pathogenesis of the gonococcal infection, and specific surface components have been related to adhesion, tissue and intracellular penetration, cytotoxicity and invasion of host defenses both systemically and at the mucosal level. These include protein structures such as pili, porins and opacity proteins, lipoligosaccharids and phospholipids. Some of the gonococcal serovars are associated with resistance to the bactericidal effect of normal human serum and with enhanced propensity to cause bacteremia.[25]

Gonococci primarily infect columnar and cuboidal epithelium. Attachment to mucosal epithelium,

mediated in part by pili and opacity proteins, is followed within 24–48 h by penetration of the bacterium into the submucosal tissue.[25] The primary site of gonococcal infection in women is the endocervix, although the organism can also invade the urethra and occasionally the periurethral and Bartholin's glands. In 10–20% of women with gonorrhea, the infection can extend to the upper genital organs and involve the endometrium, fallopian tubes and the ovaries. *Neisseria gonorrhoeae* can invade the upper genital tract as a solitary pathogen or as part of a polymicrobial infection. From the fallopian tubes the infection can extend further to the liver capsule and the overlying peritoneum to give acute perihepatitis. However, the most serious complications of pelvic inflammatory disease (PID) are infertility and ectopic pregnancy due to fallopian tube scarring.[26] Infertility occurs in 15–20% of women after a single episode and up to 80% of those with three or more episodes. Evidence for prior salpingitis can be found in 50–80% of women with ectopic pregnancies.[27]

Extragenital sites of infection include the rectum, the pharynx (following anogenital and orogenital sexual exposure, respectively), the conjunctiva (resulting from autoinoculation in the adult, or acquired through contact with the infected birth canal in the newborn), or disseminated gonococcal infection. Gonococcal dissemination is associated with some host factors, such as complement deficiency, female sex, menstruation and perhaps pharyngeal gonococcal infection and pregnancy.[25] Disseminated gonococcal infection, occurring in 0.5–3% of patients with gonorrhea, results from bacteremic spread of *N. gonorrhoeae* to the skin and articular or periarticular tissues; various immunologic mechanisms are also involved in some cases.[25]

In most pregnant women, gonococcal infection is limited to the lower genital tract. Acute salpingitis is rare, but can develop if cervical infection ascends before obliteration of uterine cavity through fusion of the chorion and decidua at 12 weeks. Rarely, preexisting infection can cause a tubo-ovarian abscess. Local cervical factors also decrease the risk for ascending gonococcal infection. Serum progesterone concentrations are greatly increased in pregnancy; high concentrations of this hormone are known to inhibit the growth of *N. gonorrhoeae in vitro*. Cervical mucus becomes impermeable to motile sperm and perhaps to microorganisms under the influence of progesterone.[2] Although PID during pregnancy is quite rare, it can be particularly virulent resulting in severe morbidity and in higher rates of pregnancy loss. The prevalence of pharyngitis as the sole gonococcal infection may be higher during pregnancy (15–30% of infected women) reflecting perhaps an increase in the frequency of fellatio as pregnancy progresses.[2] There are conflicting reports as to whether pregnancy is a risk factor for disseminated gonococcal infection.[25]

Gonococcal infection may have a deleterious effect on the pregnancy outcome at any stage, although the consequences on late pregnancy have been better studied. Antenatal gonorrhea is associated with increased risks of chorioamnionitis, spontaneous abortions, premature labor, early rupture of membranes, perinatal infant mortality and postpartum upper genital tract infections.[28–35] It is not clear, however, whether gonococcal infection is always directly responsible for all of these complications or is merely a marker for high risk due to concomitant pathogens. A threefold increased relative risk for endometritis was observed in patients who had untreated gonococcal infection when compared with uninfected control subjects.[31] Elliot *et al.* found that the attributable risk for preterm birth was 14%.[33] Stoll and colleagues showed that treatment of gonococcal carriage reduced the increased risk for adverse pregnancy outcome.[34] Infected mothers can transmit *N. gonorrhoeae* to the newborn *in utero*, during delivery or in the postpartum period.[25] Conjunctivitis (ophthalmia neonatarum) is the most common postnatal complication, occurring in 30–42% of infants born to infected women,[35] although septicemia and arthritis can also be rarely seen. Gonococcal conjunctivitis of the newborn is still a common cause of blindness in some developing countries.

Epidemiology

The risk of transmission of gonorrhea from an infected male to a female partner is approximately 50% per contact. The risk of female to male transmission is approximately 20% per intercourse.[25,36] Transmission by rectal intercourse appears to be similarly efficient, while spread by oral–genital contact is believed to be lower.[25] Gonorrhea is usually a short-lived infection, even when not treated. Therefore, high rates of partner change are required to maintain the spread of infection. Individuals at high risk of acquiring and transmitting gonorrhea – the core transmitters – are characterized by young age (20–24 years), low educational and socioeconomic level, urban residence, being single, prostitution activity, illicit drug use and reduced access to health care.[25,36] The role of anovulary contraceptives as a predisposing factor for contracting gonorrhea has remained controversial. High rates of gonorrhea have recently been observed also in rural communities in the southeastern United States, surpassing those in urban counties.[37] Risk factors are generally similar in pregnancy as in the non-pregnant state. More cases of gonorrhea are reported in men than in women, reflecting a greater ease of diagnosis in men; in the United States the male:female case ratio was 1.3:1 in 1992.[25]

Gonorrhea is most common in developing countries. In a survey conducted by the WHO in Senegal and Uganda in 1990–1991, the prevalence of gonorrhea was 0.6% among military men and 13.1% among commercial sex workers.[38] The prevalence of gonorrhea in unselected populations of pregnant women has been estimated to be 10% in Africa, 5% in Latin America and 4% in Asia.[39] Gonococcal conjunctivitis

of the newborn was diagnosed in about 4% of all live births in Kenya in 1987.[39] According to a survey performed in 1990–1991[38] the prevalence of gonorrhea among pregnant women in Senegal and Uganda was 1.4%. The prevalence rates in the United States have been generally higher than those in other industrialized countries. The annual incidence in the United States had reached a peak in 1975 with 468 cases per 100,000. It declined thereafter, attaining a rate of 116 cases per 100,000 in 2003.[6] Since 1997, the rates of gonorrhea among men and women are almost identical. The highest rates of gonorrhea among women in the United States are in the age group of 15–29 years. When analyzed by ethnic groups, incidence rates (in 2003) were highest among the Black population (655.8 per 100,000), followed by Native Americans and Hispanics (103.5 and 71.7 cases per 100,000, respectively), and was lowest in the White population (32.7 cases per 100,000).[6] Not unexpectedly, the difference between the Black and White populations in the prevalence of gonorrhea was also documented among pregnant women.[40] The incidence of gonorrhea has been substantially lower in most European countries, and indigenous gonorrhea was virtually eliminated in Sweden. More recently, however, a trend toward the resurgence of gonorrhea is being observed in several West European countries, such as Sweden, Denmark, United Kingdom and France.[41] In Israel, following a period very low reported rates during most of the 1990s (0.7 cases per 100,000 in 1994–1995),[9,42,43] a sharp increase in the incidence of the disease was documented in the late 1990s and early 2000s (13.8 cases per 100,000 in 2001).[44] The reasons for this change in the epidemiology of gonorrhea are not evident, however, the role of sex tourism and immigration of sex workers originating from countries with high gonorrhea prevalence (eastern Europe) was evoked.[41,44] After attaining a peak incidence of 16/100,000 in 2002, a trend toward a decrease in the incidence was observed more recently (8.5/100,000 in 2004) (Department of Epidemiology, Ministry of Health, Israel; unpublished data). In a survey conducted among young female soldiers, gonococcal infection was detected by PCR in 1.0%.[45]

Risk factors for PID include teenage, use of intrauterine device, prior PID and vaginal douching.[25] In the United States 20–40% of PID in most urban areas were associated in the 1980s with *N. gonorrhoeae*, whereas in Sweden and Israel, where gonorrhea has become very rare, the organism is seldom isolated from patients with PID.[43] It has been estimated that in a cohort of 100 women with gonorrhea, of whom 25 were pregnant, effective treatment would prevent 25 cases of PID, one of ectopic pregnancy, six instances of infertility, and seven cases of neonatal ophthalmia.

Clinical manifestations

Many infected women remain asymptomatic or develop only minor symptoms. In surveys in which infections are detected through screening, up to 90% of women with gonorrhea may be asymptomatic. The incubation period is variable: symptoms appear within 10 days in most cases. The dominant symptoms of lower genital tract infection include increased vaginal discharge, dysuria, usually without urgency or frequency, and intermenstrual bleeding.[25] Abdominal pain usually indicates infection of the upper genital tract. On examination, purulent or mucopurulent cervical exudate, cervical edema and bleeding, and purulent urethritis can be seen. Gonococcal Bartholin's abscesses associated with gonorrhea most often are unilateral, acutely suppurative and painful.

Rectal infection, seen in up to 40% of women with gonorrhea, is most often asymptomatic, although acute proctitis can develop in some patients, manifested by anal pruritus, tenesmus, purulent discharge or rectal bleeding.[25] Pharyngeal gonorrhea can be found in 10–25% of heterosexual women with genital infection. The infection is most often asymptomatic and resolves spontaneously.[25]

Gonococcal PID often follows the onset of menses by a few days. It usually presents acutely: abdominal pain usually bilateral and often associated with manifestations of cervicitis, is the most common symptom. High fever, chills, nausea and vomiting can be seen in a minority of the patients.[25] On examination, pelvic adnexal and uterine fundal tenderness is often noted and pain can be produced on moving the cervix; mucopurulent cervicitis is usually present. The lower abdomen is tender on palpation and signs of peritoneal inflammation are common in severe cases. Abscess formation is uncommon. Leukocytosis, accelerated erythrocyte sedimentation and elevated C-reactive protein levels are present in about two-thirds of patients with PID. The minimal criteria for diagnosis of PID include uterine-adnexal tenderness or cervical-motion tenderness.[23] The differential diagnosis includes appendicitis, septic abortion, adnexal torsion, and ectopic pregnancy. Chronic pelvic pain that may be very disabling can be a complication in up to 20% of women with PID and is often difficult to distinguish from recurrent PID. Perihepatitis (Fitz–Hugh–Curtis syndrome) manifests with abdominal pain and hepatic tenderness; in many cases pelvic symptoms and signs are lacking. The definitive diagnosis is made by laporoscopy which can visualize the 'violin string' adhesions between the liver capsule and the parietal peritoneum.[25]

Disseminated gonococcal infection is characterized by the 'arthritis–dermatitis syndrome'. The initial manifestations consist of additive and sometimes migratory polyarthritis; physical signs of arthritis and synovitis are present.[25] Typically, a few joints are involved in an asymmetric manner. A characteristic dermatitis can be seen in about 75% of patients and consists of lightly scattered discrete papular and pustular lesions (occasionally hemorrhagic, bullous or necrotic), localized predominantly on the extremities. Subsequently, septic arthritis develops in one or two

joints and can occasionally be the sole manifestation of disseminated gonococcal infection. Fever, systemic toxicity and leukocytosis are usually mild when present. Infective endocarditis, meningitis, osteomyelitis and fulminant septicemia are rare yet severe manifestations of disseminated gonococcal infection.[3]

Gonococcal conjunctivitis in the adult is usually severe and can be complicated by corneal ulcerations. In the newborn, purulent conjunctivitis develops within 1 week of delivery. It can result in perforation of the globe and blindness if inadequately treated.

Laboratory diagnosis

Isolation of *N. gonorrhoeae* by culture is the preferred method for diagnosing gonococcal infection. Endocervical specimens are obtained after wiping exudate from the endocervix, while avoiding contact with the vaginal mucosa or secretions.[25] Rectal specimens are best obtained by collecting purulent secretions or swabbing in an inflamed area under direct visualization by anoscopy.

For direct identification of diplococci with their typical morphology, smears of discharge are stained with Gram stain or methylene blue. This technique is very specific (95–100%) when performed by highly trained personnel, although its sensitivity is low when used for endocervical or rectal specimens (40–60%).[25] A definitively positive urethral or cervical smear (showing intracellular gram-negative of blue stained diplococci within neutrophils) is diagnostic.

Specimens should be transferred to the laboratory in a non-nutrient transport medium without refrigeration and inoculated onto growth medium within 6 h.[25] Immediate inoculation onto growth medium (e.g., Thayer–Martin medium or New York City medium) at room temperature with prompt incubation is preferable.

All gonococcal isolates should undergo antimicrobial susceptibility testing and be tested for β-lactamase (penicillinase) production. Penicillinase producing strains were first discovered almost simultaneously in 1975–1976 in the United States, western Europe, The Philippines and western Africa.[25] In 1990, penicillinase producing strains accounted for about 10% of isolates in the United States and western Europe and 30–60% in most developing countries. More recently, strains of *N. gonorrhoeae* with high level resistance to tetracycline have been detected and increasingly noted, particularly in Africa.[46] Resistance to quinolones is now being reported from several areas around the world.[47] Resistance to third generation cephalosporins has been rarely reported.

Nucleic acid amplification tests (NAATs) such as polymerase chain reaction (PCR) or ligase chain reaction (LCR), are highly specific and sensitive techniques,[25] and often perform better than culture. These tests, which are designed to amplify nucleic acid sequences that are specific for the pathogen being detected, do not require viable organisms. Another advantage consists of the possibility to use urine samples for the testing. On the other hand, if diagnosis is based on these tests solely, antimicrobial susceptibility tests cannot be done. All other non-culture tests are less sensitive than culture, especially for endocervical specimens, and are little better than Gram stain.

The possibility of concurrent sexually transmitted infections should be taken into consideration when diagnosing and treating gonorrhea. Up to 35–50% of women with gonorrhea are also infected with *C. trachomatis*.[25]

Treatment

Because of public health implications, an acceptable regimen for the treatment of gonorrhea should have efficacies that approach 100% and not less than 95%. Antibiotic treatment of gonorrhea is most often empiric, and should follow local guidelines which take into consideration the local antimicrobial resistance patterns. Thus, penicillin and tetracyclines should not be used any more in most cases for the empiric treatment of gonococcal infections. More recently, resistance to fluroquinolones has emerged and is spreading worldwide, particularly in the Far East, Australia, Hawaii, California, Israel, and in some countries in Europe.[47] Fluoroquinolones should not be used empirically anymore in patients infected in these areas.

Uncomplicated gonorrhea in adults

The regimens recommended by the U.S. Public Health Services[23] are presented in Table 158.2. Ceftriaxone cures genital, pharyngeal, rectal and conjunctival gonococcal infection, probably aborts incubatory syphilis, and is safe and effective in pregnant women. Ceftriaxone in a single dose of 125–150 mg IM is in fact the only regimen recommended for pregnant women. However, in areas where penicillin resistant strains represent less than 1% of all isolates, an acceptable alternative is aqueous procaine penicillin 2.8 million units injected IM at two sites with 1.0 g probenecid given by mouth. The efficacy of cefixime against incubating syphilis is uncertain. Quinolones should be avoided in pregnant women, and they will not abort incubatory syphilis. Spectinomycin 2 g IM is highly effective for genital and rectal, but not for pharyngeal gonorrhea, and it does not affect *T. pallidum*. Its main indication is the treatment of pregnant women with history of immediate allergy to penicillin or documented cephalosporin allergy. Cephalosporins can be given to patients with history of delayed reaction to penicillins.

The treatment of gonorrhea should be accompanied with a regimen active against *C. trachomatis* if coinfection by this organism has not been ruled out, and serologic testing for HIV and syphilis should be done. Since tetracyclines are contraindicated during pregnancy, most authorities recommend following ceftriaxone administration with 7–10-day course of erythromycin.[23,25] Azithromycin, 1 g orally, single dose is an acceptable alternative to erythromycin, although

Table 158.2 Recommended regimens for the empiric treatment of uncomplicated gonococcal urethritis/cervicitis/proctitis (from Centers for Disease Control and Prevention[23])

Target	Agent	Dosage
Gonorrhea	Cefixime	400 mg orally, single dose
	or	
	Ceftriaxone	125–250 mg intramuscularly, single dose
	or	
	Ciprofloxacin*	500 mg orally, single dose
	or	
	Ofloxacin*	400 mg orally, single dose
	or	
	Levofloxacin*	250 mg orally, single dose
	or	
	Spectinomycin	2.0 g intramuscularly, single dose
	plus	
Chlamydia**	Azithromycin	1.0 g orally, single dose
	or	
	Doxycycline	100 mg orally twice a day for 7 days

*Quinolones should not be used for infections acquired in areas with increased prevalence of quinolone resitance
**If chlamydia infection is not ruled out

it should be used with caution in pregnant women. HIV carriers with gonococcal infection should receive the same treatment as patients not carrying the virus.[23] Retesting to document cure is not recommended by most authorities if one of the suggested treatment regimens is used, unless therapeutic compliance is in question or symptoms persist.[23,25]

Disseminated gonococcal infection

Hospitalization is recommended for initial therapy which consists of ceftriaxone 1.0 g once daily IM or IV. Other third generation cephalosporins and spectinomycin 2.0 g IM twice daily are probably as effective. After clinical improvement, and in absence of complications, such as septic arthritis, treatment may be switched to oral cefixime 400 mg twice daily (or a quinolone in a non-pregnant patient) to complete 7–10 days of total therapy.[23] Meningitis should be treated with a 10–14-day course of ceftriaxone 1–2 g IV every 12 h, and patients with gonococcal endocarditis should receive at least 4 weeks of parenteral therapy.

Neonates and children

The advised regimen for neonates and children, weighing 45 kg or less, is ceftriaxone 25–30 mg per kg body weight, not to exceed 125 mg. It should be given as single dose for uncomplicated gonorrhea and conjunctivitis, or as a daily dose for 7 days in disseminated infection, and for 10–14 days if meningitis is documented. For conjunctivitis, topical antibiotic therapy alone is inadequate and is unnecessary if systemic treatment is administered; local care of the eyes by an expert is also important. Test for chlamydial infection should be done, and specific therapy should be withheld unless infection is diagnosed.[23]

PID

Close observation and aggressive antibiotic therapy are advised. Therapeutic regimens must provide empiric, broad spectrum coverage of likely pathogens because the specific organisms responsible for the infection usually are not known. Antimicrobial coverage should include *N. gonorrhoeae*, *C. trachomatis*, gram-negative facultative bacteria, anaerobes and streptococci.[23] For outpatients, the recommended regimen consists of ofloxacin, 400 mg orally twice a day for 14 days, or levofloxacin, once a day for 14 days, with or without metronidazole, 500 mg orally twice a day for 14 days; this regimen is not suitable for infections caused by quinolone-resistant gonococci. An alternative regimen, effective against quinolone-resistant gonococci, consists of ceftriaxone 250 mg intramuscularly as a single dose, or cefoxitin 2 g intramuscularly as a single dose, plus probenecid, 1 g orally, plus doxycycline, 100 mg twice a day for 14 days, with or without metronidazole, 500 mg twice a day for 14 days. The inpatient regimen includes cefotetan, 2 g intravenously every 12 h, or cefoxitin, 2 g intravenously every 6 h, plus doxycycline 100 mg orally or intravenously every 12 h. An alternative inpatient regimen includes clindamycin, 900 mg intravenously every 8 h, plus gentamicin 2 mg per kg of body weight (loading dose), followed by 1.5 mg per kg every 8 h (this regimen is less suitable for gonococcal infections). The parenteral therapy for PID should be continued for 24–48 h after clinical improvement occurs and should be followed by oral therapy with doxycycline, 100 mg twice a day, or clindamycin, 450 mg four times a day, for a total of 14 days.[23] For the management of PID during pregnancy the recommendations of the CDC are very brief and consist of the suggestion that 'pregnant women with suspected PID should be hospitalized and treated with parenteral antibiotics'.[23] Some of the regimens recommended for the treatment of PID in non-pregnant women include agents such as doxycycline, ofloxacin, levofloxacin or gentamicin, which should be avoided during pregnancy (these agents belong to categories C and D of the Food and Drug Administration Fetal Risk Drug Classification[48]). The following empirical regimens probably provide an effective and safe coverage of salpingitis in pregnant women: cefoxitin 1–2 g IV every 6 h or cefotetan 1–2 g IV every 12 h, plus erythromycin 500 mg IV or orally every 6 h. Ceftriaxone 1 g IV or IM every 24 h is

probably also effective, although it is less active than the former cephalosporins against anaerobic bacteria. The alternative regimen recommended by the CDC for non-pregnant patients, clindamycin 900 mg IV every 8 h, plus gentamicin 1.5 mg/kg every 8 h (following a loading dose of 2 mg/kg), should be avoided in pregnancy because of the aminoglycoside component, and should be used only when essential. Therapy should continue for a total of 14 days. Recommendations for continued oral therapy are difficult to formulate, particularly for an adequate coverage of gram-negative facultative bacteria.

Prevention and control

Use of a condom provides a high degree of protection for the non-infected partner. Because gonococcal infection, which is often subclinical in women, may have deleterious effects on pregnancy outcome, a screening cervical culture is recommended by most authorities at the first prenatal visit or prior to an induced abortion. In high-risk populations (young, non-White, single, primigravada, low socioeconomic status, IV drug use, current or past STI), some authorities recommend that a repeat culture be obtained during the third trimester.[23] Sexual partners of infected patients and parents of infected infants should be examined and treated for *N. gonorrhoeae* and *C. trachomatis* infection regardless of whether clinical evidence of gonorrhea is found. Patients should be instructed to avoid intercourse until patient and partner(s) are cured.

An endocervical swab for Gram stain and culture for *N. gonorrhoeae* should also be obtained in women with premature rupture of membranes, intrapartum fever or septic abortion.[2]

Treatment of gonococcal and chlamydial infection in pregnant women is the method for preventing neonatal infection. However, ocular prophylaxis in newborn infants is useful in areas where the prevalence of maternal gonococcal infection is greater than 1% and is required by law in many countries. Infants should receive ocular prophylaxis as soon as possible after delivery whether delivery is vaginal or cesarean. The preparations recommended by the CDC are: silver nitrate (1%) aqueous solution in a single application; or erythromycin (0.5%) ophthalmic ointment in a single application; or tetracycline ophthalmic ointment (1%) in a single application.[23] Silver nitrate aqueous solution and tetracycline ointment were found equally efficient in reducing the incidence of gonococcal conjunctivitis when compared with a historical control group who did not receive prophylaxis.[2] It should be noted that prophylaxis with 1% silver nitrate is not effective against *C. trachomatis*. Recently, povidone-iodine administered as a 2.5% solution was found to be as effective as silver nitrate or erythromycin against *N. gonorrhoeae* and more effective than the two other agents against *C. trachomatis*[49]; its use has not been approved yet by the CDC. Some authorities recommend that neonates born to mothers with documented untreated antepartum or intrapartum gonococcal infection should receive parenteral antibiotics in the standard curative dosage in addition to topical ocular prophylaxis.[2]

Chlamydial infections

Chlamydia trachomatis is responsible for two distinct genital infections which are caused by different serovars and differ in their clinical presentation and potential sequelae: the urethritis–cervicitis entity which is by far the most common form, especially in developed countries, and lymphogranuloma venereum which is endemic in the tropics and will be discussed separately. The most important impact of genital chlamydial infection concerns the reproductive health sequelae of upper genital tract infections in women: ectopic pregnancy and tubal infertility.[50]

The Pathogen

Chlamydia trachomatis is a true parasite closely resembling gram-negative bacteria with a biphasic life cycle. The extracellular infectious form, the elementary body, attaches to a susceptible epithelial cell, penetrates it by endocytosis and transforms to a reticulate body which is the replicative form. The reticulate body uses the host cell energy resources and amino acids to replicate and retransform to elementary bodies which are released to reinfect new cells. Of the 15 serovars, serovars A–C are associated with ocular trachoma, D–K with genital tract infection and inclusion conjunctivitis, and serovars L_1–L_3 cause lymphogranuloma venereum.[51]

Pathogenesis

The genital serovars of *C. trachomatis* (D–K) attack the squamocolumnar epithelial cells of the endocervix and upper genital tract in women, and the urethra, rectum and conjunctiva in both men and women. In infants, the pathogen can infect the columnar epithelium of the respiratory tract.[51] The acute inflammatory stage is succeeded by formation of lymphoid follicles which consist of aggregates of lymphocytes and macrophages in the submucosa, seen in both ocular and genital disease.[51] Papillae can form as result of epithelial proliferation. Finally, fibrosis and scarring occur as inflammation resolves. The inflammatory and fibrotic process intensifies with each additional episode of recurrent infection, leading to the development of substantial scarring and deformation of the fallopian tubes when the upper genital tract is involved. It has been suggested that the pathogenesis of chlamydial disease is due at least partly to the host immune response to a chlamydial sensitizing antigen (the 60-kDa heat shock protein). The presence of serum antibodies reactive with the chlamydial heat-shock protein was associated with ectopic pregnancy and infertility.[51]

The immune response to chlamydial genital infection is only partially protective. Although recurrent chlamydial infections are quite common in sexually active individuals with genital tract infections, patients with a prior history of a sexually transmitted disease are at lower risk for acquiring a new chlamydial infection than those without such history.[51]

Little is known about the natural history of endocervical infection with *C. trachomatis*. Some data suggest that chlamydial can persist for a prolonged period of time in the female genital tract.[51] Thus, untreated infections among women often persist for months; during this period complications may develop and infection transmitted to others.

Chlamydia trachomatis is an important cause of PID with sequelae including infertility, ectopic pregnancy and chronic pelvic pain. Up to two-thirds of cases of tubal infertility and one-third of cases of ectopic pregnancy have been attributed to *C. trachomatis* infection. These conclusions derive mainly from studies that have demonstrated higher rates of antibodies to *C. trachomatis* in women with the above complications than in normally pregnant women.[2,52,53] Moreover, colonization of the fallopian tubes by *C. trachomatis* has been demonstrated in infertile women without symptoms and in the absence of laparoscopic signs of active pelvic infection.[50] The mechanism that accounts for tubal occlusion after chlamydial infection is not fully known, although an immune-mediated process might be involved. Chlamydia apparently causes more severe subclinical tubal inflammation and tubal damage than other pathogens despite its more benign appearing symptomatology.[52]

It has been suggested that pregnancy may influence shedding of *C. trachomatis* from the cervix since the rate of isolation of the organism was found to be higher during the third than the first or second trimester.[2] Shedding of chlamydia in pregnancy may be influenced by the development of ectopy which is positively correlated with *C. trachomatis* isolation and/or by the depressed cellular immunity observed during pregnancy.

Endocrinologic changes associated with pregnancy may increase the virulence of both symptomatic and asymptomatic chlamydial infection. Animal studies have demonstrated that treatment with estradiol resulted in florid endometritis, salpingitis and cystitis while in control animals infection was limited to vagina and the cervix. Moreover, direct *C. trachomatis* infection may occur more commonly in trophoblastic tissue and the conceptus than is generally recognized.[54]

Chlamydial infection during pregnancy has been incriminated in causing ectopic pregnancy, pregnancy loss, inadequate fetal development, bleeding, premature labor or premature rupture of membranes. Whether *C. trachomatis* infection can cause abortion is unknown. It is though, however, that chlamydial infection of endometrial or decidual cells or fetal trophoblast cells may alter maternal–fetal tolerance mechanisms that are integral to successful pregnancy. The increased local production of cytokines caused by chlamydial infection may decrease cell-mediated tolerance at maternal fetus interfaces.[54]

Studies on the role of genital *C. trachomatis* infection in prematurity and perinatal mortality have given conflicting results. While a series of studies have all shown a correlation of antenatal chlamydial infection with prematurity, no such association could be found by others.[54] Some of the 'negative' studies have suggested, however, that women with either recent or more extensive and invasive chlamydial infection (associated with the presence of IgM antibodies) are at increased risk for premature rupture of membranes, premature birth and low birth weight.[54] In two studies, but not in a third, women successfully treated for chlamydial infection and uninfected control women had significantly less adverse pregnancy outcomes compared with untreated women.[55] Correlation of antenatal *C. trachomatis* infection with perinatal mortality was observed in only one study and has not been confirmed in others.[2] Antepartum chlamydial infection may also have a role in amnionitis and postpartum infection. Studies have found that intrapartum fever and/or postpartum endometritis were significantly associated with antepartum *C. trachomatis* infection. Other studies, however, have failed to document a significant association between cervical chlamydial infection and postpartum or postcesarean endometritis.[2,54] A delayed postpartum uterine infection with *C. trachomatis* 2–3 weeks after delivery, causing vaginal bleeding or discharge, low-grade fever, lower abdominal pain and uterine tenderness, has been described.[3] An excess rate of postabortal PID has been observed among women with chlamydial infection at the time of the procedure.[55]

Vertical transmission of *C. trachomatis* during vaginal delivery occurs in about two-thirds of infants born to infected women[54]; however, not all infected infants develop clinically overt disease. Colonization or infection may take weeks to months to become detectable and can involve multiple sites including the conjunctiva, nasopharynx, rectum and vagina. The nasopharynx is the most common site of organism recovery after birth.[54] Although chlamydial pneumonia is usually not progressive, affected infants may be subjected to a prolonged respiratory disease, with impaired lung function tests later in childhood and perhaps chronic lung disease.[50] Perinatally acquired *C. trachomatis* infection may persist in the nasopharynx, urogenital tract or rectum for more than 2 years.[51]

Epidemiology

Chlamydia seems to be more difficult to transmit than *N. gonorrhoeae*. Among couples, men apparently transmit the organism to their female partners 40% of the time, while women transmit the infection to their male partners, 32% of the time.[50] Transmission during

Table 158.3 Risk factors for chlamydial genital infection (from Cates and Wasserheit[52] and Centers for Disease Control and Prevention[55])

Less than 20 years of age
Intercourse at an early age
Unmarried status
Lower socioeconomic status
Living in the inner-city
Nulliparity
Black race
Cervical ectopy
Multiple sexual partners/more than one sexual partner
New sexual partner
Concomitant or past other STIs
Oral contraception
Inconsistent use of barrier contraception

a single coitus is probably much lower. Symptomatic individuals are more infectious than asymptomatic carriers of the pathogen.[51] Among the risk markers for chlamydial genital infection (Table 158.3), young age (less than 25 years and, in particular less than 20 years) has been the factor most strongly and consistently associated with the infection. This association is largely due to the more intense sexual activity among younger women, and the larger area of ectopic columnar epithelium surrounding the ectocervix; this ectopy provides a larger target area for chlamydial infection than is present in older women. Although barrier contraception (condom, diaphragm) protects from chlamydial infection, evidence that oral contraception increases the risk for infection is inconsistent.[46,50]

Genital chlamydial infection is not a reportable disease in most countries, and the actual incidence of the entity is not known. However, a large number of studies have examined its prevalence. In the United States, surveys published in the 1980s and 1990s have reported a prevalence of 6–13% among sexually active women attending family planning clinics, 15–19% among female patients of STI clinics, 5–10% among women attending university clinics and 2–4% among female patients seen in private clinics.[50] In North America, genital infections caused by *C. trachomatis* were probably three times more frequent than those caused by *N. gonorrhoeae* during the same period.[52] Chlamydia infection is more common than gonorrhea among Whites, pregnant women, oral contraceptive users and asymptomatic individuals.[52] Recently, a decline in the prevalence of chlamydial infection has been noted among girls (age 13–19 years) attending adolescent health clinics in Indianapolis, Indiana, between 1985 (rate 25.9%) and 1994 (rate 9.7%). Behavioral data showed decreases in the frequency of sexual intercourse and in lifetime years of sexual activity, as well as an increase in condom use.[56] Reporting of chlamydia infection became mandatory in all U.S. states in 2000. In 2003, the incidence of reported infections was 304.3 cases per 100,000 population, which constitutes a slight increase compared with the preceding year. The incidence in women (466.9/100,000) was over three times higher than the rate among men, and seven times higher among African-American women (1633.1/100,000) than among White females.[6]

In Sweden (Uppsala county), the prevalence of genital chlamydial infection among women had been 6% in the 1980s, and it has declined to 3.2% in the early 1990s.[57] However, an increase in the incidence of the infection was noted in the Nordic countries in the second half of the 1990s.[58] In the United Kingdom, recent data suggest that the rate of infection among young women exceeds 10%. In a survey conducted in Israel in 1995, endocervical cultures yielded *C. trachomatis* in 2.0% of sexually active women presenting to a gynecologic clinic; none had evidence of mucopurulent cervicitis.[59] More recently *C. trachomatis* infection was detected by PCR in urine samples of 3.2% of young Israeli female soldiers.[45] These rates are markedly lower from those reported by surveys conducted in the 1970s and 1980s.[60]

In contrast with other STIs, chlamydial infection rates in developing countries often have been comparable to or even lower than rates in Western countries. Prevalence of chlamydial antigen has been reported to be between 8% and 14% in most studies conducted in Africa.[61–65] It has been suggested that the low rates of chlamydial infection among highly exposed women in Africa may be caused by relative immunity, although other factors such as technical diagnostic problems or indiscriminate use of tetracycline cannot be excluded.[46]

The prevalence of genital chlamydial infections in pregnant women is generally similar to that of nonpregnant women with comparable demographic and epidemiologic characteristics. *Chlamydia trachomatis* was isolated or its antigen detected in genital specimens in 5–10% of low income Hispanic and White women in the United States,[66,67] 15% of unmarried and 5.6% married women in Japan,[68] 15–24% of young inner-city women attending public clinics in the United States[23,67] and 26.7% of pregnant women in Martinique.[69] In Africa, on the other hand, the prevalence of genital chlamydial infection among pregnant women varies between 2% and 15% in most studies.[46,62,70]

It is estimated that about 8% of women with endocervical *C. trachomatis* infection develop acute salpingitis.[52] The proportion of women with PID from whom chlamydia can be isolated from the urogenital tract ranges between 5% and 51% depending on the population studied and the techniques of detection used.[44,52] Up to two-thirds of cases of tubal-factor infertility and one-third of cases of ectopic pregnancy

may be attributable to *C. trachomatis* infection.[71] Among pregnant women, endometritis may develop during late postpartum period in 19–34% of infected women who deliver vaginally and at term.[2] Similarly, endometritis, and possibly salpingitis, developed among 10–28% of pregnant women who underwent induced abortion.[55]

Approximately two-thirds of infants born to infected women have serologic evidence of chlamydial infection.[54,55] *Chlamydia trachomatis* is the most common cause of neonatal conjunctivitis and is one of the most common causes of pneumonia during the first few months of life.[48] Chlamydial conjunctivitis is seen in 22–44% of infants born to women with infected cervix, while 11–22% of such infants develop chlamydial pneumonia.[55]

Clinical manifestations

The vast majority of chlamydial genital infections in women (and men) do not cause symptoms: as many as 85–90% of women harboring *C. trachomatis* are symptomless, and asymptomatic infections can persist for several months.[50,71] The spectrum of clinical manifestations of *C. trachomatis* infections includes cervicitis, urethritis, bartholinitis, endometritis, salpingo-oophoritis, PID, perihepatitis and reactive arthritis. The endocervix is the organ most often infected. Infection of the cervix and urethra may cause dysuria, abnormal vaginal discharge, and postcoital bleeding. The most frequent symptoms are vaginal discharge and dysuria. Despite the frequent absence of symptoms, at least one-third of infected women have local signs of infection.[71] On examination, the cervix may appear normal or exhibit signs of mucopurulent cervicitis: edema, erythema and hypertrophy with mucopurulent discharge. The presence of green or yellow mucus in the cervical os, or cervical friability (bleeding upon introduction of a cotton swab), or ≥ 10 polymorphonuclear leukocytes per oil immersion field of a gram-stained smear of cervical secretions, have been strongly associated with chlamydial infection.[50] The specificity and sensitivity of these parameters are, however, poor in predicting *C. trachomatis* infection in pregnant women.[72] Chlamydial urethritis should be considered in women with acute urethral syndrome and 'culture negative' pyuria.[72] *Chlamydia trachomatis* has been isolated from the Bartholin's gland in women with bartholinitis.

Endometritis and salpinigitis may cause lower abdominal pain, which may be constant or intermittent, irregular uterine bleeding and menstrual abnormalities. Increased vaginal discharge or fever may or may not be present. Commonly symptoms begin at the time of menstruation. On examination, uterine tenderness or cervical pain on motion can be noted. Women with chlamydial salpingitis are more likely to experience a chronic, subacute course with longer duration of abdominal pain insidious onset and prolonged course than those with gonococcoccal PID. Yet they have as much or more tubal inflammation at laparoscopy.[49]

Rectal infection with the genital serovars of *C. trachomatis*, resulting usually from anal intercourse, generally produces a mild disease ranging from asymptomatic carriage to variable degree of acute proctitis with rectal pain, mucopurulent discharge, abdominal pain, diarrhea and rectal bleeding.[49]

Inclusion conjunctivitis in the adult results from autoinoculation with infected genital secretions or direct inoculation from an infected partner during oral–genital sexual contact. The presentation is that of an acute follicular conjunctivitis often with a foreign body sensation in the eye. Untreated the condition can persist for many months and scarring may occur. Chlamydial infection appears to be the most common triggering event for sexually reactive arthritis, which is seen less often in women than in men.[49]

An infant born to a mother with active chlamydial infection has a risk of acquiring infection at any anatomical site of 50–75%. Approximately 30–50% of infants born to chlamydia-positive mothers will have conjunctivitis, and at least 50% of infants with chlamydial conjunctivitis will also have nasopharyngeal infection. Chlamydia pneumonia develops in about 30% of infants with nasopharyngeal infection.[71] Neonatal chlamydial conjunctivitis usually develops within 5–14 days of delivery and presents with ocular discharge, swollen eyelids and erythematous conjunctiva.[2] Significant corneal scarring develops in a minority of cases. A mucopurulent rhinitis and vulvovaginitis are often associated with conjunctivitis.[51] Infant chlamydial pneumonia usually develops 4–17 weeks following delivery. Onset is usually mild and subacute, although the initial respiratory manifestations may, especially in very young infants, be more severe and include prolonged spells of apnea or respiratory failure. Physical findings are often nonspecific, and the infant is often afebrile. The chest radiograph shows diffuse interstitial or patchy alveolar infiltrates with hyperinflation. Peripheral eosinophilia, arterial hypoxemia and elevated serum immunoglobulins are characteristic. Untreated, the course is prolonged, lasting weeks to months.[51]

Laboratory diagnosis

Because most genital chlamydial infections are asymptomatic or have mild and non-specific presentation, they require laboratory confirmation for definitive diagnosis. Although typical intracytoplasmic inclusion can be identified in conjunctival or endocervical scrapings, this finding is not sensitive enough for diagnostic purposes, especially in adult infection.

Isolation of the pathogen

Cell culture has remained the gold standard for the diagnosis of chlamydial infection. It is particularly

preferred for specimens with low numbers of organisms which is often the case in low-prevalence population and asymptomatic infection. Although *C. trachomatis* grows well in a variety of cell lines, the most commonly used are the cycloheximide-treated McCoy cells. Three to seven days are required to obtain a result. The sensitivity of culture is between 70% and 90%, while the specificity is 100%.[51] For best results the specimen should contain columnar epithelial cells from the endocervix or the urethra. Culturing both the endocervix and the urethra can increase the rate of positive culture by 23%.[51] Secretions and discharge should be removed from the cervical os before obtaining a specimen. The swab should be inserted 1–2 cm into the endocervical canal and rotated against its wall for 10–30 s. The swab should then be withdrawn without touching any vaginal surface and be placed in an appropriate transport medium. Urethral swabs should be obtained 2 h after the patient has voided. The swab should be inserted 1–2 cm into the urethra and rotated for 5 s.[55] Swabs used for specimen collection (Dacron or rayon material is preferred) should be free from substances that may be toxic to the organism; wooden shafts should not be used. The specimen must be kept refrigerated, but for no longer than 24 h before inoculation. Alternatively, the sample can be stored at –80°C until it is processed at a later date, but this may result in loss of some organisms. Specimens should never be stored at –20°C.

Non-culture tests

These tests are based on the detection of the chlamydial antigen or its nucleic acids. In general, non-culture tests are more reliable in symptomatic patients who shed large numbers of organisms, than in asymptomatic individuals who usually shed fewer organisms.[55] The presence of the chlamydial antigen in the clinical specimen can be demonstrated by direct fluorescent antibody (DFA) staining which detects the elementary bodies using a fluorescent-labeled monoclonal antibody. This test allows also assessment of the quality of the specimen, but requires a highly skilled microscopist for proper interpretation.[51] Another technique, the enzyme-linked immunosorbent assay (EIA), employs polyclonal or monoclonal antibodies conjugated with an enzyme that reacts with the substrate which produces a colored product if chlamydial organisms are present. The EIA requires less skilled personnel but generally takes longer to perform. Nucleic and hybridization tests use a chemiluminescent-type DNA probe that is complementary to a sequence of ribosomal RNA in the chlamydial genome of the patient's sample. The assay is relatively easy to perform and interpret, is species specific for *C. trachomatis* and does not cross-react with other bacteria. Specimens can be stored at room temperature in a special transport material up to 7 days before being processed. The accuracy of the three diagnostic techniques is similar, with sensitivities greater than 70% and specificities of 97–99% in populations of men and women with a prevalence of infection of $\geq$5%.[55] In low-prevalence populations (< 5%), a significant proportion of positive test will be falsely positive. Verification of a positive test is therefore desirable by culture (which should be preferred in medicolegal situations) or a second non-culture test targeting a different antigen or nucleic acid.[55] The most newly developed nucleic acid assays are the amplification tests based on the detection of chlamydial DNA using polymerase or ligase chain reactions. These tests are species specific and appear to be more sensitive and as specific as cultures.[51,73] Moreover, they can be performed on urine specimens from both symptomatic and asymptomatic men and women; however, their sensitivity is slightly lower compared with endocervical specimens.[51,73] Recently, specimens obtained form the vaginal introitus were found highly effective for *C. trachomatis* testing by polymerase chain reaction.[74,75]

Serology

Serologic tests have little value in routine clinical evaluation of patients suspected of having chlamydial genital infection.[55] The specificity of serology is low because antibodies generated against chlamydiae can persist for years. The microimmunofluorescence test is highly sensitive and detects antichlamydial IgG in $\geq$99% of women with cervicitis, adults with inclusion conjunctivitis and infants with pneumonia. Antichlamydial IgM is present in 100% of infants with pneumonia, but is uncommon in adults with genital tract infection.[51] The complement fixation test measures antibodies against genus-specific antigens. It is less specific and less sensitive than the microimmunofluorescence test.

Treatment

The main purpose of treating chlamydial infection would be to decrease the likelihood of sequelae in women with cervical infection, to prevent transmission to infants during delivery, and to prevent transmission to sexual partners. Several studies have provided evidence that treatment of *C. trachomatis* in the antenatal period decreases the incidence of poor pregnancy.[76] The active antichlamydial agents are tetracyclines, macrolides, rifampin and some fluoroquinolones. Penicillin has limited activity because its intracellular concentration is low and chlamydiae lack peptidoglycan.

Doxycycline, 100 mg orally, twice daily for 7 days, has been the standard regimen used for the treatment of uncomplicated urethral, cervical or rectal *C. trachomatis* infections in non-pregnant women.[55] Failure rates have ranged from 0% to 8% among women with cervicitis.[50] However, tetracyclines, including doxycycline, are contraindicated in pregnant women because of possible adverse effects on the

Table 158.4 Regimens recommended by Centers for Disease Control and Prevention[55] for the treatment of chlamydial infections during pregnancy

Regimen	Options
First choice	Erythromycin base, 500 mg orally 4 times a day for 7 days
	or
	Amoxicillin, 500 mg orally 3 times a day for 7–10 days
Alternatives	Erythromycin base, 250 mg orally 4 times a day for 14 days
	or
	Erythromycin ethylsuccinate, 800 mg orally 4 times a day for 7 days
	or
	Erythromycin ethylsuccinate, 400 mg orally 4 times a day for 14 days
	or
	Azithromycin, 1 g orally, single dose

fetus such as discoloration of deciduous teeth. Erythromycin base, 500 mg orally four times a day for 7 days, has been the first alternative and the drug of choice in pregnant women and infants (Table 158.4). Women unable to tolerate erythromycin at the standard dose can be treated with 250 mg four times a day for 14 days. Erythromycin estolate should be avoided in pregnant women since 10% of those receiving the drug develop liver enzyme impairment. Other alternative regimens include amoxycillin and clindamycin. Eradication rates of 86–98% were reported in studies of amoxycillin treatment for *C. trachomatis* infection in pregnant women.[77] Clindamycin appears to be as efficacious as erythromycin in both pregnant (92.7% vs. 83.8% cure rate) and non-pregnant women.[78] It is recommended by the American College of Obstetricians and gynecologists, but not by the CDC, as an alternative regimen in pregnancy.[76] However, caution is advised because of the possible occurrence of pseudomembranous celitis. Recently, azithromycin given as a single 1 g dose has been found to be as effective as a seven day course of doxycycline.[79] This is the only antimicrobial agent effective against *C. trachomatis* infection as a single dose therapy. Moreover, azithromycin is well tolerated and is associated with significantly lower rate of gastrointestinal adverse effects than erythromycin. It is now considered by the CDC as an equivalent regimen to doxycycline for the treatment of chlamydial infections in non-pregnant women.[55] In pregnant women the success rates with the same regimen of azithromycin were between 91% and 100%.[80,81] Azithromycin is classified as a pregnancy category B agent, and its use in pregnancy is indicated only if clearly needed.[78] Although comparable to doxycycline in the treatment of uncomplicated chlamydial genital tract infection, ofloxacin at a dose of 300 mg twice daily for 7–10 days, offers no advantage over the standard regimen and is contraindicated in patients under the age of 18 years, pregnant women and lactating mothers.[50] Retesting for chlamydia may be considered 3 weeks after completion of treatment with erythromycin (because of low compliance), amoxycillin or clindamycin (because of limited clinical experience). This is usually unnecessary if the patient was treated with doxycycline, azithromycin or ofloxacin, unless symptoms persist or reinfection is suspected.[55]

Because of the risks of infertility and other sequelae of PID, clinicians should have a low threshold for the prompt institution of treatment in women who are at risk for chlamydial infection. The delay of antibiotic therapy is associated with an increased risk of adverse outcome (The regimens recommended for the therapy of PID are detailed in the section on gonorrhea.)

The timely treatment of the patient's sexual partner is also essential in order to reduce the risk of reinfection. The sexual partners should be evaluated, tested, and treated if they have had sexual contact with the patient during the 60 days preceding the diagnosis.[71]

For the treatment of infant chlamydial infection, oral erythromycin 50 mg/kg of body weight per day in four divided doses for 10–14 days, is the treatment of choice for both inclusion conjunctivitis and pneumonia. The efficacy of this regimen in both indications is approximately 80%, and a second course may be required.[23] Topical treatment of inclusion conjunctivitis is not recommended. Mothers of infants with chlamydial infection should be evaluated and treated.

Case detection and prevention

The main objective of chlamydial prevention strategies is to prevent chlamydial salpingitis and its sequelae, as well as perinatal and postpartum infection. For this purpose, both primary and secondary prevention strategies should be applied.[55]

Primary prevention of chlamydial infection consists of two approaches: (1) behavioral changes that reduce the risk of acquiring or transmitting chlamydial infection as well as other STDs: delaying age at first intercourse, decreasing the number of sex partners, partner selection and use of barrier contraception; and (2) identifying and treating persons with genital chlamydial infection before they infect their sex partners, and for pregnant women, before they infect their babies. Because chlamydial infections are usually asymptomatic, active screening and referral of sex partners of infected persons are required. A recent study that sought to identify criteria for selective screening concluded that a combination of young age and attending an urban clinic was highly predictive of chlamydial infection and identified a minimum of 85% of infected women in all public clinic settings.[82] In

countries where an extensive educational and control program has been applied, there has been a dramatic decline in chlamydial infection over the last decade.[58,79]

Secondary prevalence strategies include efforts to prevent complications (such as salpingitis and its sequelae) among persons infected with chlamydial: (1) screening women, mainly sexually active adolescent and young females, to identify and treat asymptomatic infections; (2) treating sex partners of infected men; and (3) recognizing clinical conditions, such as mucopurulent cervicitis or urethral syndrome, which are often caused by chlamydia and applying appropriate diagnostic tests and treatment.[55] In a large randomized trial of screening and treatment of women at high risk of chlamydial infection, the incidence of PID was significantly lower in the screened group compared with the usual care group.[83] However, it is not clear yet who should be screened and how often. Screening on the basis of age (less than 25 years) appears to be effective in areas where the prevalence of chlamydial infection is low to moderate (3–6%); women with other risk factors for chlamydial infection (Table 158.3) should also be considered for screening. In high-risk women screening should be done every 6 months; otherwise, annual screening is reasonable.[71]

There is some evidence that screening high-risk women for *C. trachomatis* during pregnancy can reduce the rate of adverse outcomes of pregnancy.[71] The American College of Obstetricians and Gynecologists recommends screening high risk pregnant women in their first prenatal visit and again in the third trimester. The CDC recommends screening high-risk pregnant women preferably during the third trimester.[55] High-risk factors for chlamydial infection in pregnant women are the same as in non-pregnant women (Table 158.3).

Prevention of neonatal *C. trachomatis* infection should consist of detection and treatment of chlamydial infection during pregnancy together with ocular prophylaxis. Recently, povidone-iodine administered as a 2.5% solution was found more effective than silver nitrate solution or erythromycin ointment in preventing ocular *C. trachomatis* infection.[49] It should be borne in mind that topical prophylaxis of conjunctivitis does not prevent pneumonia.

Lymphogranuloma venereum

Lymphogranuloma venereum (LGV) is a sexually transmitted disease caused by L_1, L_2 and L_3, serovars of *C. trachomatis* and characterized by acute inguinal lymphadenitis (bubo) and other local and systemic manifestations. We are not aware of any report on the adverse effect of LGV on pregnancy or the newborn.

The LVG strains are more virulent and more invasive than the A–K serovars, and may cause disseminated infection. The pathogen gains entrance into the body through breaks in the skin or infects epithelial cells of the genital tract and rectal mucosa.[84] It is then carried by lymphatic drainage to the regional lymph nodes where it multiplies inside mononuclear phagocytes. Histologically, granuloma are formed, and small abscesses develop that may coalesce to form diamond-shaped suppurative foci which are progressively replaced by fibrosis. This histopathologic picture is suggestive although not specific to LGV.

The infection is endemic in tropical and subtropical countries: areas of Africa (Ethiopia, Nigeria, Swaziland), India, Southeast Asia, South America and the Caribbean.[85] Clinic-based series of patients with genital ulcers suggest that LVG is an uncommon cause of genital ulceration in Africa.[86] It occurs only sporadically in developed countries, where it is usually found in promiscuous persons (homosexual men and prostitutes) and individuals returning from endemic areas (sailors, travelers, military personnel). Clinical disease is sixfold more common in men than in women.

The clinical course of LGV can be divided into three stages: the primary stage involves the site of inoculation; the secondary stage involves the regional lymph nodes and sometimes the anorectum; the tertiary stage consists of late sequelae affecting the genitals and/or the rectum. A total of 3–30 days after infection occurs, a primary lesion appears in the form of a small papule, vesicle or ulcer on the genital mucosa or the adjacent skin.[51] The lesion may not always occur, and when present it is often not noticed because symptoms are few or absent and healing is rapid without leaving a scar. Symptomatic urethritis can occur if the lesion develops in the urethra. Days to weeks later and up to 6 months after exposure, regional lymphadenopathy and systemic symptoms develop. Inguinal lymphadenopathy is less common in women than in men, since lymphatic drainage of the vagina and the cervix is to the retroperitoneal rather than the inguinal lymph nodes. Lymphadenopathy is initially discrete and tender, and is unilateral in two-thirds of the cases.[84] The localization of enlarged lymph nodes above and below the groin gives a groove appearance ('groove sign') which is regarded as pathognomonic for LGV although it is seen in only 10–20% of cases. The inflammatory process spreads from the affected lymph nodes into the surrounding tissue forming an inflammatory mass consisting of abscesses that coalesce to give a bubo. The bubo can rupture spontaneously in one-third of the cases, with development of fistulae or a sinus tract. Otherwise the bubo hardens and forms an inguinal mass which gradually evolves over time. The untreated lesion may, however, persist in an active form for years.[87] Proctitis, characterized by a bloody mucopurulent anal discharge and tenesmus, is seen mainly in women and homosexual men, and is often accompanied by pronounced systemic symptoms. Cervical lymphadenopathy has been reported following inoculation during oral sex, while ocular inoculation can give rise to

follicular conjunctivitis accompanied by preauricular lymphadenopathy.[86] Systemic symptoms, noted during the acute stage of lymphadenitis, include fever, chills, sweats, malaise, headache, myalgia, anorexia, nausea and vomiting. A variety of skin manifestations, such as erythema nodosum and erythema multiforme, can be seen. Other rare manifestations include conjunctivitis, arthritis, hepatitis and meningitis. Lymphatic obstruction, secondary to fibrotic changes, may lead to elephantiasis of the genitalia. Other local complications consist of fistulae formation involving the rectum, perineum, vulva and vagina; esthiomene, a chronic, granulomatous enlargement with ulcerations of the external genitalia; and rectal strictures resulting from the replacement of inflamed muscle layer by fibrous tissue.[51] Mild leukocytosis with an increase in monocyte and eosinophil counts is frequent in the early bubonic stage.

Diagnosis is based on serology or isolation of the pathogen. Complement fixing antibodies usually appear within 4 weeks after infection starts. The test is genus specific, and therefore does not distinguish between infections with different chlamydiae (trachomatis, psittaci, pneumoniae). Because of its increased invasiveness, LGV is associated with higher serum antibody titers than is *C. trachomatis* infection.[86] Virtually 100% of individuals with LGV will have complement fixing antibody titers greater than 1:16.[51] In an appropriate clinical setting a complement fixation titer of $\geq$1:256 is strongly supportive of a diagnosis of LGV, although confirmation requires a fourfold titer rise between acute and convalescent sera.[51] The microimmunofluorescence test is invariably positive, the titer being usually higher than 1:512 during the acute phase. The test can distinguish between infections with different chlamydial species, but its use in clinical practice has been limited because it requires a fluorescent microscope and a skilled technologist.[86] Isolation of *C. trachomatis* from bubo aspirates, genital or rectal tissue is possible in only about one-third of cases.[84] The organism can also be identified by direct fluorescent microscope using a commercially available conjugated monoclonal antibody on a smear of bubo or ulcer material. Histopathology, although non-specific, can lead to a presumptive diagnosis when combined with serologic tests in an appropriate clinical setting. A skin test (Frei test) has been used in the past, but is not currently available. The differential diagnosis includes genital herpes, chancroid, donovanosis, syphilis and occasionally, lymphoma.

Treatment of LVG consists of doxycycline, 100 mg twice daily for 14–21 days. Alternatively, erythromycin, 500 mg four times daily, or sulfisoxazole can be used.[23] Fluctuant bubos should be aspirated to prevent rupture, using a lateral approach through normal skin. Antibiotic therapy results in rapid decline of systemic symptoms, but has limited effect on bubo resolution. The general rules of STI prevention are also applicable to the management of LGV patients.

Herpes simplex infections

Herpes simplex infection is life long and is characterized by recurrences that are either symptomatic or not. Genital herpes is caused by herpes simplex virus type 1 (HSV-1) or herpes simplex virus type 2 (HSV-2). While usually annoying and troublesome for the infected woman,[88] the virus can have devastating effect on the newborn.[89] Women with genital herpes who are pregnant should be identified so that preventive measures can be applied.

The pathogen

Herpes simplex virus (HSV) has an internal core containing double-stranded DNA, an icosahedral capsid composed of 162 polypeptide capsomers and a lipid containing envelope. HSV can be distinguished from other members of the herpes virus group by its cytopathogenic affects and by its antigenic and DNA base composition. The two subtypes of HSV differ primarily by their clinical and epidemiologic characteristics and can also be separated by a variety of biochemical and biologic properties. HSV type 1 is transmitted essentially by a non-genital route and causes mainly non-genital infections, such as labial blisters, keratitis and adult encephalitis; however, in many developed countries it has become the leading cause of genital herpes. HSV type 2 is transmitted by genital contact and is responsible for most of the herpetic genital and neonatal infections.[88]

Pathogenesis

Inoculation occurs following exposure of mucosal surfaces or abraded skin to secretions or mucosa containing the virus. After penetration, HSV replicates locally in parabasal and intermediate epithelial cells. Virus replication results in lysis of infected cells and development of local inflammatory reaction. In individuals with depressed immune mechanisms (particularly cell-mediated immunity), infection can disseminate resulting in viremia and visceral involvement (liver, lungs, central nervous system). From the primary site of infection, HSV is transported along the axon to the nerve cell bodies in the sensory and autonomic ganglia, where the virus becomes latent. During latency, viral replication almost ceases, and the viral genome is maintained in a repressed state. Several nonspecific stimuli, e.g., bacterial or other viral infection, ultraviolet radiation, nervous stimuli, or hormonal changes can trigger reactivation of HSV. Reactivation and replication of the virus in the ganglia does not result in cell lysis. The virus then migrates back to the skin by peripheral sensory nerve fibers that share the infected ganglia. Viral reactivations occur periodically, characterized by viral shedding that may be symptomatic or subclinical. The vast majority of recurrent episodes are due to viral reactivation not reinfection.[90] Most recurrences of genital herpes

infection are caused by HSV-2 which readily establishes latency in the sacral ganglia, while HSV-1 is less prone to do so. Autoinoculation from genital areas to other sites, including hands, thighs and buttocks, is not uncommon.

A complex immune response is involved in the natural history of HSV infection. Cell-mediated immunity is essential for recovery from both primary infection and recurrences. The presence of high titers of neutralizing HSV antibodies may limit recurrences. High levels of antibodies transferred by the mother to the fetus may have a protective effect on the neonate from contracting the virus during passage through an infected birth canal.

Primary genital herpes infection occurring in a pregnant woman before 20–23 weeks of gestation may cause spontaneous abortion in up to a half of the cases and low birth weight in one-third.[91,92] Primary infection during pregnancy may also lead to premature labor and congenital infection causing microencephaly, chorioretinitis and large skin scars.[92,93] Infection of the neonate during passage through the birth canal is common and can have devastating effects including encephalitis with high rates of mortality and residual morbidity.[88] On the other hand, recurrent episodes of genital herpes during pregnancy are no worse than recurrences in non-pregnant women, and they are not associated with prematurity or other obstetrical adverse events. Neonatal infection is uncommon and less devastating, not only because of the protective effect of transplacentally acquired maternal antibodies, but also due to a smaller viral inoculum and lower rates of cervical virus shedding associated with recurrent infection.[94,95] The increased neonatal susceptibility to HSV infection which persists for several months following delivery is presumably related to the poor cellular immune response during this period of life.[2]

Genital ulcer disease, including that caused by HSV-2, is a well-recognized risk factor for the transmission of human immunodeficiency virus (HIV). High titers of HIV are found in genital herpes ulcerations, and the plasma HIV viral load increases when HSV-2 infection is reactivated in HIV-infected persons.[96]

Epidemiology

Humans appear to be the only natural reservoir of HSV.[88] Direct contact, most often sexual, with infected genital secretions or mucosa is the principal mode of transmission of HSV. Direct contact other than sexual intercourse can result in viral spread if an area of viral shedding comes into contact with the skin or mucous membranes of a susceptible person. Because of virus fragility, transmission by fomites is rare. HSV can be acquired both from persons with symptomatic infection and from asymptomatic excretors, although transmissibility is greater from the former. However, asymptomatic viral shedding accounts for much of the transmission of HSV. Herpes simplex virus DNA can be detected by PCR in genital specimens from HSV-2-seropositive women on 28% of days, and the virus may be transmitted to a sexual partner during such periods of subclinical shedding. Although the risk of transmission of HSV-2 from an infected person to a susceptible sexual partner is higher when genital lesions are present, because individuals with symptomatic genital herpes usually abstain from sexual activity during this period of time and asymptomatic shedding occurs much more frequently than symptomatic disease, most experts believe that transmission results from asymptomatic shedding in most cases.[97] The risk of heterosexual acquisition of HSV is greater in women than in men.[88,98] In a study of HSV-2 transmission between monogamous couples in which only one member of each couple had a history of genital herpes, the annual rate of acquisition was 9.7%, being higher in women and in those who lacked HSV-1 antibodies.[98] Infection with HSV-2 occurs mainly following puberty and corresponds to the period of intense sexual activity between 14 and 44 years. Rates of infection with HSV-2 are higher in unmarried individuals, in females, in those with increased numbers of sexual partners, in individuals with history of STI and in those of lower socioeconomic status,[90,99,100] although the association with the last factor has been inconsistent[90,99]; in the United States the infection is more common among Blacks and Hispanics. Recurrences are less common in women than in men; overall, approximately 60–90% of those with an initial episode will have recurrences.[88]

The prevalence of genital HSV-1 infection, which is usually acquired through oral–genital contact, has also increased dramatically and has replaced HSV-2 as the principal causative pathogen of genital herpes in several developed countries.[101] In Israel, for example, a retrospective analysis of positive herpes isolates found that HSV-1 accounted for 66% of isolates.[102]

In neonates, most infections result from the retrograde spread of HSV-2 secondary to maternal genital infection or via passage of the infant through an infected birth canal. The risk of transmission of HSV to the neonate is 10 times greater if delivery occurs during an episode of primary genital infection (33–50%) than if it occurs during a recurrence (~3%).[88,90,95] Up to one-half of neonates acquiring HSV infection have been exposed to mothers with primary disease occurring in late pregnancy.[2] In most of the remaining cases, the newborn is infected from an asymptomatic mother shedding the virus.[103] The risk of neonatal infection correlates directly with the amount of virus present in the birth canal at delivery, and with the duration of ruptured membranes. Cesarean section significantly reduces this risk if performed within 4 h of rupture of membranes; whereas if membranes are ruptured for more than 4 h, infants acquire the infection irrespective of the route of delivery.[92] Use of fetal scalp electrodes also predisposes for neonatal infection.[104] Transplacental transmission can also occur, although rarely: a recent study has

documented congenital infection in 9 out of 192 (4.7%) cases of neonatal HSV.[93] Also rarely, neonatal herpes can be acquired postnatally from an infected family member. The occurrence of neonatal HSV-1 associated genital herpes (including fatal cases) after Jewish ritual circumcision has been reported.[105]

Herpes simplex virus has a global distribution. The worldwide prevalence of genital herpes infection continues to increase despite the increased public awareness of STIs, and seroprevalence of HSV-2 has reached unprecedented rates.[98] Much of this may be related to the chronicity of the infection and the high rate of unrecognized cases. In Western countries HSV is by far the most prevalent genital ulcer disease, well ahead of syphilis and chancroid.[98] The estimated annual incidence of clinically apparent infection in the United States is 50 cases per 100,000 adults, and this rate has been increasing constantly. The highest annual incidence among women occurs at 20–24 years of age and is estimated to be 210 per 100,000.[83] Using HSV-2 specific antibody assays, it was estimated that 16–33% of the general population in the United States have antibodies to this HSV type.[90] Up to 46% of women attending a STD clinic and 9% of college students were reported to have serologic evidence of genital herpes. In adults $\geq$30 years of age, HSV-2 antibody was found in approximately 25% of White women and over 60% of Black women; seropositivity rate was associated with increasing age.[100] Similar rates of seroprevalence (10–40%) were found in other Western countries.[98]

In developing countries, the serologic prevalence of HSV-2 is generally higher, ranging from 40% to 80%. In Kinshasa, the seroprevalence was found to be higher among HIV positive prostitutes (95%) than among HIV negative prostitutes (75%).[98]

The prevalence of genital herpes in pregnant women depends on the population studies. In an inner city cohort, serologic evidence of HSV-2 infection was detected in 36% of women attending an obstetric clinic in the 1970s.[91] More recently, 32% of pregnant women followed by private obstetricians in Stanford, California, were seropositive.[99] In three studies of asymptomatic pregnant women, cervical isolation rates of 0.2–0.65% were reported.[91,100,104] Pregnancy had no influence on the frequency of asymptomatic virus shedding.[100]

The increasing incidence of genital HSV infection in women has been accompanied by an increase in neonatal HSV in some areas of the United States. In King County, Washington, the incidence increased from 1.6 to 11.9 cases per 1,000,000 live births.[100] More recently, the incidence of neonatal HSV has been estimated to be between 1 in 2000 to 1 in 10,000 live births and was higher in premature than in full-term infants.[92,93,104]

Clinical manifestations

The manifestations of genital herpes vary widely, not only among individuals, but also between episodes of the same patient. It has been estimated that at least two-thirds (and up to 90%) of HSV-2 seropositive women did not have histories compatible with genital herpes – they were infected asymptomatically.[92,100] Corey has suggested that asymptomatic genital herpes often is unrecognized symptomatic infection.[98]

The clinical episodes are classified as follows: genital herpes in the absence of antibodies to HSV-1 and HSV-2 is called primary infection; a first episode infection in the presence of antibodies to either HSV-1 or HSV-2 is termed first episode non-primary infection; and a recurrent infection is one caused by the same virus (usually HSV-2) that previously infected the patient and has reactivated after a latent period.

Primary herpes genitalis

The average incubation period after the genital acquisition of HSV-1 or HSV-2 is approximately 4 days (range 2–12), although the incubation period can reach 20 days. Local and systemic symptoms associated with primary HSV-1 infection are generally of the same intensity as those associated with primary HSV-2 infection. Local prodromal symptoms, including itching, erythema, paresthesia, burning sensation and pain, usually precede genital lesions by 1–2 days. Vulvar involvement is common, and the cervix is affected in almost 90% of the patients, while vaginal lesions are present in less than 5% of infected women. The initial lesions are small painful vesicles or pustules; the mean duration of local pain and virus shedding is 12 days. Vaginal discharge is present in approximately 75%. The cervix is friable, a mucopurulent discharge is often noted. In general, new lesions continue to appear over 4–10 days. After a few days, the individual lesions coalesce into large wet ulcers that persist for 1–2 weeks, and eventually heal without scars, usually within 3 weeks of onset of lesions. Tender inguinal adenopathy appears in most patients and is the last sign to resolve. Dysuria is present in most cases.

Systemic symptoms occur in more than two-thirds of women with primary infection and usually last for 3–7 days. They include fever, malaise, myalgia, headache, abdominal pain and backache. Self-limited neurologic signs, such as stiff neck, photophobia, and inflammatory cerebrospinal fluid, can be seen. Approximately one-third of women and 10% of men with primary infection have meningeal signs, whereas such signs are rare among patients with non-primary infection. Autonomic nervous system dysfunction can also occur, manifesting as urinary retention, constipation, lower extremity weakness, due to sacral radiculopathy or transverse myelitis. Benign recurrent lymphocytic meningitis (Mollaret's meningitis) can also complicate genital herpes. Herpetic encephalitis with poor prognosis can rarely complicate primary infection. Viral dissemination to the lungs, liver and kidneys is rare in the normal host.

Pharyngitis can accompany primary genital herpes in approximately 10% of cases. Primary infection of the perianal and anal area may be responsible for

severe rectal pain, discharge and tenesmus. Systemic symptoms are prominent in patients with herpatic proctitis.

First episode non-primary infection

About one-half of all patients with first attack genital herpes have preexisting antibodies to HSV-1 or HSV-2. Compared with primary infection, women with non-primary first episode have less often (~16%) and fewer systemic symptoms, fewer lesions and shorter duration of pain (~9 days) and shedding of virus (~7 days). The lesions heal within a mean of 16 days. Extragenital manifestations and complications are uncommon.[98]

Recurrent infection

The clinical course is usually mild. At least one-half of the patients have prodromal symptoms ranging from mild tingling sensations occurring 0.5–48 h before the eruption, to shooting pains in the buttocks, legs or hips occurring as long as 5 days before the eruption. Uncommonly, systemic symptoms can occur. Genital lesions involve mainly the labia and perineum; the cervix is affected in only 12% of the episodes. There are fewer lesions present than in primary infection; they shed the virus during approximately 5 days and heal completely within 7–10 days. Other manifestations, such as dysuria, vaginal discharge and tender lymphadenopathy, occur less often and extragenital lesions and systemic complications are very rare. Most patients (90%) with a documented first episode of genital HSV-2 infection have at least one recurrence within 12 months after diagnosis, 38% have six or more recurrences, and 20% have 10 or more recurrences. Genital HSV-1 infections recur less frequently than do genital HSV-2 infections, explaining why most cases of symptomatic HSV-1 genital disease are primary cases. Irrespective of viral type and whether or not suppressive therapy is used, recurrence rates decrease over time.

Pregnancy does not appear to modify the clinical course of primary or recurrent infection, although cases of severe gestational primary infection with dissemination and high death rate have been reported.[91,106] Among young women with recently acquired genital herpes infection, approximately 80% will have an average of two to four symptomatic recurrences during pregnancy.[107,109] Concomitant cervical shedding is identified in 15–30% of women with symptomatic vulvar recurrences.[107] The prevalence of positive cultures at any time during pregnancy or delivery is 1–2%.

Congenital infection may be recognized at birth along with jaundice, hepatosplenomegaly, a bleeding diathesis, microcephaly, microphthalmia, seizures, chorioretinitis and skin vesicles. In the newborn clinical presentation can range from a mild localized infection to a fatal disseminated one. Onset of disease usually occurs in the first week after birth, but it has been described up to one month after delivery. The herpetic lesions can involve the central nervous system (cranial nerve palsy, seizures, coma), the skin, and less often, the eye. If the central nervous system is affected the mortality is high, and survivors usually suffer from profound neurologic dysfunction. Disseminated infection, with or without central nervous system involvement, can affect the liver, the lungs or the hematopoietic system, leading to respiratory failure and disseminated intravascular coagulation.[110]

In order to avoid unnecessary tension in couples, it should be explained that many first clinical episodes of symptomatic genital herpes may represent infection that was acquired years before, and that a new diagnosis of genital herpes in a member of a monogamous couple does not necessarily imply recent acquisition of infection from another partner.

Diagnosis

The clinical spectrum of genital herpes being diverse, the clinical diagnosis has reasonable specificity but poor sensitivity[113]; it is prudent to seek laboratory confirmation of the diagnosis. The Tzanck smear and the Papanicolaou smear may detect cellular changes suggestive of HSV infection, but both tests have low sensitivity.

Culture

Viral culture represents the most sensitive method for diagnosing HSV infection.[90] Vesicles should be unroofed with sterile needle, and the base of the lesion should be rubbed vigorously with a cotton or a Dacron-tipped swab (calcium alginate swabs may inactivate herpes virus). The swab should be placed immediately into a suitable transport medium and maintained at 4°C, where it can stay no longer than 3 days before being processed. Samples can be stored for longer periods of time at −70°C, but should not be kept at −20°C because the virus will be destroyed immediately. The older the lesion the lower the chance to detect the virus: it can be isolated from 90% of vesicles, from 70% of ulcerative lesions, and from only 30% of crusted lesions. The yield of virus recovery is also low (~50%) in lesions of recurrent episodes because recurrent disease is associated with a lower viral load than primary infection.[100] Cultures of amniotic fluid for HSV have given both false-positive and false-negative results for congenital infection, making such tests of questionable usefulness.[112] Cytopathic effects appear rapidly, usually within 24–48 h if the virus inoculum is high.

Rapid diagnostic tests

The most sensitive tests for antigen detection use labeled monoclonal antibodies that bind to HSV proteins. The sensitivity of these tests for specimens obtained from visible lesions ranges between 65% and 90% compared with virus isolation, and the results are available within 1–2 h. These methods should not be used to detect viral shedding in asymptomatic women because of the low virus titers.

Serology

Serology may be helpful in diagnosing primary HSV infection by demonstration of seroconvertions or a fourfold rise in antibody titers. Detection of IgM is less accurate by the presently available methods; however, it can be used in infants for the diagnosis of neonatal infection.[88] Such antibodies usually appear within the first 4 weeks of life and may persist for many months. Recently, type-specific serologic testing for HSV, using enzyme-linked immunosorbent assays or immunoblot tests based on HSV-specific glycoproteins G1 and G2, have been commercially available for clinical use. Type-specific serologic tests may be useful for diagnosis in patients with symptomatic genital disease who have healing lesions (in whom culture is likely to be negative). Testing should be performed at the time of an initial episode and, if negative, repeated 3 months later. Because almost all HSV-2 infections are sexually acquired, type-specific HSV-2 antibody indicates anogenital infection, but the presence of HSV-1 antibody does not distinguish anogenital from orolabial infection.[23] Type-specific serologic analysis can aid in the classification of infection as primary, non-primary, or recurrent, and thus may guide counseling. It may help to manage sex partners of persons with genital herpes, and may also be used in screening.

The differential diagnosis of labial ulcerations seen in genital herpes includes primary syphilis (one or more painless, indurated ulcers occurring at the site of inoculation), and chancroid (painful, tender, non-indurated ulcerationss characterized by a serpiginous border surrounding a friable base covered with gray or yellow, necrotic, purulent exudates). Noninfectious conditions that can mimic genital herpes include Crohn's disease, Behçet's syndrome, trauma, contact dermatitis, erythema multiforme, Reiter's syndrome, psoriasis, and lichen planus.

Treatment

Although herpes infections enjoy the most efficacious antiviral therapy, the available agents neither eradicate latent virus nor affect subsequent risk, frequency or severity of recurrences after administration of the drug is discontinued. The mainstay of herpes antiviral therapy is acyclovir. It has demonstrated the ability to alleviate symptoms of both primary and recurrent herpes infection. Acyclovir is available in both oral and intravenous forms for systemic treatment and in ointment for topical use. Recently, two new derivatives, famcyclovir and valacyclovir (an acyclovir prodrug) have been approved for the treatment of herpes infections. Their main advantage resides in their favorable pharmacokinetic profile, allowing administration of fewer doses per day compared to acyclovir. HSV infections that are resistant to acyclovir, valacyclovir, or famciclovir are rare, and when they occur, they are usually in immunocompromised persons.

The CDC recommendations for the use of acyclovir, valacyclovir and famciclovir in sexually acquired herpes infections are listed in Table 158.5. Systemic acyclovir provides partial control of the symptoms and signs when given to patients with first clinical episode or when used as suppressive therapy. Topical acyclovir provides no benefit in the episodic treatment of genital herpes and is not recommended.[23] In recurrent episodes the effect of acyclovir therapy can be achieved only if the treatment is instituted during the prodrom or at the first sign of a recurrence; even then the benefit of the treatment is quite limited, and the impact on pain and itching is minimal.[88] Consequently, its use in immunocompetent patients with recurrent disease is not generally recommended.[23]

Daily suppressive therapy with oral acyclovir in patients with frequent recurrences of HSV (i.e., six or more episodes per year), reduces the frequency of episodes by at least 75%. Suppressive treatment will also significantly reduce although not totally eliminate viral shedding and the potential for its transmission.[91,113] Safety and efficacy have been documented for as long as 5 years of daily administration. Patients should be advised yearly to discontinue the suppressive therapy; since frequency of genital recurrences decreases over time for both patients who receive suppressive therapy and those who do not, withholding the drug periodically allows for reassessment of whether suppression is still needed.

Symptomatic sex partners should be managed in the same manner as any patient with genital lesions.

The safety of systemic acyclovir therapy among pregnant women has not been established, although current registry data do not indicate an increase in the number of birth defects.[114] There is no information on the effectiveness of preterm acyclovir treatment of mothers with recurrence of genital herpes at time of delivery. Acyclovir administration to pregnant women is indicated only for life-threatening maternal HSV infection. All infants with evidence of neonatal herpes should be treated with systemic acyclovir.[115]

Case detection and prevention

During symptomatic episodes of genital herpes, patients should abstain from sexual contact until the lesions are healed completely. Because most instances of transmission result from exposure to an asymptomatic carrier, the use of a condom is recommended for any person who has evidence of prior HSV-2 infection. When condoms are used during more than 70% of sexual encounters between an HSV-2-positive man and an HSV-2–negative woman, the risk of transmission is reduced by more than 60%. Another approach is the use of antiviral suppressive therapy in the seropositive partner. Neither approach, however, completely eliminates the risk of transmission.[97]

During the initial antenatal visit, the pregnant women should be questioned carefully about a history of genital herpes in herself or her partner. The development of signs and symptoms of genital herpes at any time during pregnancy requires that samples from

Table 158.5 Centers for Disease Control and Prevention recommended regimens for treatment of sexually acquired herpes infection[23]

Condition	Regimen
First clinical episode	
Genital herpes	Acyclovir 200 mg orally 5 times a day for 7–10 days or Acyclovir 400 mg orally 3 times a day for 7–10 days or Valacyclovir 1 g orally twice a day for 7–10 days or Famciclovir 250 mg orally 3 times a day for 7–10 days
Herpes proctitis	Acyclovir 400 mg orally 5 times a day for 10 days
Recurrent episodes	Acyclovir 200 mg orally 5 times a day for 5 days or Acyclovir 800 mg orally 2 times a day for 5 days* or Valacyclovir 500 mg orally 2 times a day for 3–5 days or Valacyclovir 1.0 g orally once a day for 5 days or Famciclovir 125 mg orally 2 times a day for 5 days
Suppressive therapy	Acyclovir 400 mg orally 2 times a day or Valacyclovir 500 mg orally once a day or Valacyclovir 1.0 g orally once a day or Famciclovir 250 mg orally 2 times a day
Severe disease	Acyclovir 5–10 mg/kg body weight IV every 8 h for 5–7 days or until clinical resolution is attained
Perinatal infection	Acyclovir 30 mg/kg body weight IV per day for 10–14 days

*An even shorter regimen of acyclovir for the treatment of recurrent episodes (800 mg orally 3 times a day for 2 days) was found to be significantly superior to placebo (Wald A, *et al. Clin Infect Dis* 2002;34:944)

the patient be cultured to confirm the diagnosis. Weekly cultures should be obtained if a positive culture is documented and should be repeated until a negative result is obtained.[23] Although primary genital HSV in early pregnancy may cause spontaneous abortion, congenital infection is uncommon. Hence, therapeutic abortion is not recommended for pregnancies complicated by primary infection.[2] Because primary genital herpes contracted late in pregnancy usually is associated with prolonged shedding and frequent reactivation, it has been suggested that weekly viral cultures should be obtained from these women.[90] If viral shedding ceases before labor ensues and there is no clinical evidence of disease activity, vaginal delivery should be permitted. However, if viral shedding continues until delivery, a cesarean section is recommended.[90] Since infants born vaginally to mothers with primary infection are at particular risk of invasive disease, consideration should be given to the early empiric use of acyclovir in this circumstance.[2]

Although many infants with perinatal HSV infection are born to mothers with asymptomatic genital infection, the risk of transmission of the virus to the newborn remains very low (1/5000 live births to mothers with history of recurrent genital herpes). Weekly surveillance for asymptomatic HSV shedding in mothers near term is extremely expensive.[2] Moreover, asymptomatic intrapartum shedding of HSV is not predictable from antepartum cultures for HSV.[2] Based on these considerations, the following approach is now recommended by most authorities.[112] Any woman with a history or recurrent genital herpes should have a careful genital examination conducted during admission for delivery. If lesions consistent with herpes are present, abdominal delivery should be undertaken. Cesarean section should be done ideally before membranes rupture or as soon thereafter as possible; however, abdominal delivery does not prevent all cases of neonatal herpes, even when done before the membranes rupture. In a recent surveillance study, 10 of 184 infants with neonatal herpes were delivered by cesarean section before the membranes ruptured.[116] If no maternal lesions are present at delivery, vaginal delivery is recommended.

Several small randomized studies have suggested that suppressive acyclovir therapy during the last four weeks or so of pregnancy in women with a history of genital herpes decreases the occurrence of clinically apparent genital HSV disease at the time of delivery, with an associated decrease in the rate of cesarean sections performed because of genital HSV. However, because viral shedding still occurs (albeit with reduced frequency), neonatal infection is still possible. There are currently insufficient data to justify the routine use of suppressive therapy in pregnant women who have had genital herpes.[97]

The infected mother and any other infected family members must be instructed in proper hygienic techniques to prevent postnatal transmission of infection to the newborn. Breast feeding is allowed unless lesions of the breast are present.

An HSV-2 glycoprotein-D-subunit vaccine was recently demonstrated to be safe and, in women who were seronegative for HSV-1 and HSV-2 before

vaccination, reasonably effective in preventing clinically apparent HSV-1 or HSV-2 genital herpes disease (efficacy, 75%).[57] The vaccine was neither effective in men, nor in women with preexisting anti–HSV-1 antibodies.[117] Further study of this vaccine in women who are seronegative for HSV-1 and HSV-2 is under way.

Trichomoniasis

Trichomoniasis is one of the most common sexually transmitted diseases, affecting millions of people worldwide.[118] It represents a vexing health problem especially for women in whom it can cause a persistent discomfort if untreated. More recently, trachomonal infection has been incriminated as a significant risk factor for premature rupture of membranes, preterm birth and posthysterectomy vaginal cuff cellulitis.[119] The association of trichomoniasis with HIV acquisition seems to be clear.[120]

The pathogen and pathogenesis

Trichomonas vaginalis is a motile, ovoid, flagellated anaerobic protozoan. *T. vaginalis* lives only in the genitourinary tract, and human beings are its only natural hosts. This extracellular parasite has four anterior flagella and a fifth posterior flagellum which extends along its body and is embedded in an undulating membrane. The presence of hormonal receptors has been demonstrated on the protozoan's cell surface. The parasite is actively mobile and is easily identified by its characteristic twitching motility. *T. vaginalis* can survive only on squamous epithelial cells lining the anterior fornix of the vagina, Skene glands and urethra in women and in the urethra, the prostate and the foreskin of uncircumcised men.[121]

Trichomonas vaginalis attaches to mucosal cells via specific adhesions. It can damage epithelial cells by releasing a cell-detaching factor[122] and cause microulcerations; there is no invasion of the mucosa.[118] *T. vaginalis* produces phospholipases and proteases,[122] and activates the alternative complement pathway. The parasite attracts polymorphonuclear neutrophils which can kill the organism. On the other hand, it can sense and move away from toxic materials such as products of polymorphonuclear oxidative metabolites and metronidazole.[119,121] Protective immunity does not occur with trichomoniasis. The antigenic diversity, which is displayed on the parasite's external membrane and subject to regulation, may also contribute to the pathogenicity.[122] Trichomoniasis is often associated with a change of the normal vaginal environment consisting of an overgrowth of facultative and anaerobic bacteria and reduction of lactobacilli.

Evidence regarding the association between *T. vaginalis* infection and adverse pregnancy outcome has been conflicting.[118,121–125] Trichomoniasis during pregnancy has been associated with premature rupture of membranes, preterm birth, low birth weight, postpartum fever and postabortal infection. It has been suggested that the role of trichomonal infection is rather indirect, acting via the associated overgrowth of anaerobic bacteria.[121] In a large multicenter study, after adjusting for demographic, behavioral, and microbiological variables, trichomonas was significantly associated with low birth weight, premature rupture of membranes, and preterm delivery.[123] However, pregnant women with asymptomatic trichomoniasis who were treated with metronidazole had higher rates of preterm delivery than those who received placebo.[126]

Epidemiology

Trichomoniasis is transmitted almost exclusively by sexual contact. The parasite is more readily transmitted to women (85% infectivity after exposure) than to men (70% infectivity).[122] Perinatal acquisition has also been documented with transmission rates of 2–17% of female offspring of infected women.[127] Because the organism can survive for hours on moist objects and clothing used by infected women, nonsexual transmission by fomites is theoretically possible although it should be extremely rare, and no well-documented cases were reported.[121] Yet, high prevalence of trichomoniasis was found in some institutionalized populations.[118] The incidence of trichomoniasis is highest among Black women, women with multiple sexual partners and in those with history of STI.[119] Unlike other STIs, trichomonal infection is more evenly distributed among sexually active women of all age groups, with a mean age of 35 years; Reproductive hormone levels may be partly responsible for higher prevalence of trichomoniasis in older women. Trichomoniasis is frequently seen with other STIs, particularly chlamydial infection (15–28% coinfection rate) and gonorrhea (10%), and may be a sensitive marker of high-risk sexual behavior. It is also often seen in association with bacterial vaginosis.[120] Hence, women with trichomonal infection should be evaluated for the presence of other STIs. The infection is less common among women using oral contraceptives than in women using no form of birth control.[119] Estrogens may act by changing the vaginal environment or directly on the pathogen itself.[128]

Acquisition of HIV has been associated with trichomoniasis in several studies conducted in Africa, possibly as the result of local inflammation often caused by the protozoan.[120]

Trichomoniasis is the most prevalent non-viral STI. It has been diagnosed in about 5% of US women in family planning clinics compared with 13–25% of women attending gynecology clinics, up to 40% of women attending STD clinics and 50–75% of prostitutes.[118,122] The incidence of trichomonal infections appears to be declining during the last decade in the US and Western Europe. A Swedish STD clinic reported a prevalence of 5.4% in 1980, while in 1987, it was only 0.7%.[129] A decline by 30% in the incidence of trichomoniasis was observed in genitourinary medicine clinics in England and Wales between 1976

and 1986.[130] In Israel in the early 1990s, trichomonal infection was diagnosed in 7% of women attending a gynecology clinic for vaginal symptoms and in 2% of asymptomatic women seen in the same clinic (author's unpublished data). In a study conducted recently in Burkina Faso, trichomononiasis was diagnosed in 27.8% of women with genitourinary complaints.[131]

In pregnant women, the prevalence of trichomoniasis is generally similar to that in the general feminine population. In a multicenter survey between 1984 and 1989 among pregnant American women from urban clinics, the prevalence of trichomoniasis at mid-pregnancy was 12.6% (range 8.5–21.8%). The infection rate was 6.2% among White women, 6.6% among Hispanic and 22.8% in Black women.[132] Women colonized with *T. vaginalis* were significantly more likely to be Black, cigarette smokers, unmarried, less educated, had greater number of sexual partners and a history of gonorrhea.[123] A study from Britain reported a 4% infection rate among third-trimester women.[127] In Africa the prevalence rate of trichomoniasis in pregnant women has ranged from 10% to 30%, and it often did not differ significantly from that among prostitutes.

Clinical manifestations

Between 10% and 50% of women attending an STD clinic who carry *T. vaginalis* are asymptomatic, while most (90%) infected men appear to be asymptomatic.[119] The incubation period in women ranges from 5 to 28 days.[133] Symptoms are nonspecific and cannot be used to differentiate trichomoniasis from other genital infections. They begin or exacerbate during or immediately following the menstrual period. Vaginal discharge is noted by 50–75% of infected women. About 10% of the women describe the discharge as malodorous. One-fourth to one-half of the symptomatic women complain of pruritus which is often severe. Up to one-half of patients report a dyspareunia; the same proportion of women may note dysuria. Urinary tract infection may be common; thus consideration should be given to the presence of trichomoniasis for women with dysuria as a sole complaint. Lower abdominal pain, possibly resulting from pelvic lymphadenitis, has been described by 5–12% of the patients; salpingitis caused by other sexually transmitted organisms should be ruled out. Physical examination reveals a diffusely erythematous vulva in up to one-third of the patients; edema may be noted with more severe infection. Excessive, rather loose discharge, which pools in the posterior vaginal fornix, is noted in most infected women. The typical yellow-green and frothy discharge is seen in less than a half of the patients. Although yellow secretions are suggestive of trichomoniasis, they can also be seen in mucopurulent cervicitis and desquamative inflammatory vaginitis; a frothy discharge is also found in bacterial vaginosis. The vaginal walls are erythematous in up to 75% of patients with trichomoniasis. The exocervix is often inflamed; punctate hemorrhages (colpitis macularis) with strawberry appearance are observed with a naked eye in about 1–2% of cases, but in 45% when colposcopy is used. The presence of this finding strongly suggests trichomoniasis.[118]

The vaginal discharge has a high pH (> 4.5) in up to 90% of cases. A positive whiff test (malodor produced by application of 10% KOH on a sample of the vaginal discharge) and the presence of excessive numbers of polymorphonuclear leukocytes on a wet mount preparation are noted in about 75% of patients.[118]
