Dystocia – poor progress of labor – is one of the leading indications for operative delivery, and it has previously been shown that mechanical problems in labor are responsible for a great number of all cesarean sections.[98] Cephalopelvic disproportion should be suspected in cases with an unengaged fetal head during labor, or in women with previous cesarean section due to dystocia. Efforts have been made to establish ultrasound diagnostic criteria to estimate cephalopelvic disproportion during early labor, based on results from ultrasound determination of the true conjugate and the transverse diameter of the pelvic inlet before labor.[99,100] This requires, however, special equipment and considerable expertise. Dystocia in late labor can be caused by persistent occiput position. Clinical evaluation of the position of the fetal head by digital palpation is sometimes uncertain and inaccurate due to scalp edema, which causes difficulties in recognition of the sutures and the fontanelles. Akmal *et al.*[101] studied the accuracy of intrapartum routine digital examination in defining the position of the fetal head and found that digital examination during labor failed to identify the correct fetal position in the majority of 496 cases. Likewise, he found among 64 women that digital examination during instrumental delivery failed to identify the correct fetal head position in 26.6% of cases.[102] Ultrasound diagnosis of persistent occiput posterior position is simple, by visualization of the facial bones and orbits anteriorly and the spine posteriorly. In contrast, persistent occiput anterior position is confirmed when the facial bones and orbits are placed posteriorly and the spine anteriorly. The risk of cesarean section can be estimated during the early stage of active labor by the sonographically determined occiput position.[103] Rayburn *et al.*[104] studied 86 patients with arrested labor and showed that intrapartum ultrasound significantly improved the diagnosis of persistent occiput position, and could be of help in the management of delivery. Chou[105] confirmed this recently. If midpelvic forceps or vacuum extraction is to be performed, precise knowledge of the position of the fetal head is mandatory; a more proper forceps application and proper axis of traction may then be applied. Persistent occiput anterior position associated with labor dystocia is indicative of fetal macrosomia, and shoulder dystocia can be expected.[104] A new method to assess the descent of the fetal head in labor with transperineal ultrasound has been presented.[106] Head deflection may cause either a brow or a face presentation and then an abnormally broad diameter makes the passage through the maternal pelvis difficult. Such head deflection can be detected by ultrasound. Clinically, face presentation can be mistaken for breech presentation, especially if there is facial edema. Ultrasound examination can accurately exclude such an unpleasant surprise in the delivery unit. Knowledge of the position of the mentum anterior and occiput posterior is mandatory for allowing vaginal delivery in cases with face presentation, and this can be confirmed by ultrasound. With a brow presentation, engagement of the fetal head and delivery usually cannot take place if it persists. The brow presentation can, however, be converted to either a vertex or face presentation to allow vaginal delivery.[107] With a transverse lie during early labor, the position of the head and back as well as the location of the placenta should be identified before an external version or a cesarean section is undertaken. When the back is anterior, the risk of cord prolapse is greater. Information obtained from ultrasound can facilitate the performance of the cesarean section.

Breech presentation

A recently published review of RCTs concerning the preferred method of delivery for breech at term, showed that cesarean delivery occurred in 550/1227 (45%) of those women allocated to a vaginal delivery protocol.[108] Perinatal mortality and morbidity was greatly reduced in the planned cesarean section group (RR = 0.31, 95% CI 0.19–0.52). Reviewers concluded that planned cesarean section for breech at term should be the preferred method of delivery. Result of this review has considerably influenced obstetrical praxis regarding the delivery mode for breech at term.

Nowadays, there is enough evidence that external cephalic version reduces not only breech presentation at delivery, but also cesarean section rate.[109] Ultrasound may be of help during an external version of a breech fetus at term. Ferguson *et al.*[110] performed successful external version in 11 of 15 women at term who presented in active labor. In contrast, a review of three RCTs of 889 women shows that external cephalic version (ECV) is not useful in preterm breech presentations.[111] However, if ECV fails and vaginal breech delivery is the patient's preference or if a breech presentation is diagnosed during early labor, a thorough and targeted ultrasound evaluation should be performed. Valuable information that can be obtained by ultrasound includes:

(1) type of breech (frank, complete or footling)
(2) estimated birth weight
(3) amniotic fluid volume assessment
(4) placental location (rule out placenta previa)
(5) rule out malformations (anencephaly, infantile polycystic kidneys).

Additional information that substantially influences the decision making can also be obtained by ultrasound, i.e.:

(1) fetal head position (hyperextension)
(2) nuchal or extended arm
(3) nuchal cord
(4) cord presentation
(5) cephalopelvic disproportion.

The gold standard for evaluation of the maternal pelvis has long been x-ray pelvimetry. This technique can expose both fetus and mother to possible long-term radiation hazards.[107] Rojansky *et al.*[99] proposed a simple ultrasound method for diagnosis of hyperextension of the fetal head by measurement of the cranio-spinal angle, and a method to measure the obstetrical conjugate by TA ultrasound. He studied 72 laboring women with breech presentations and performed both traditional x-ray and ultrasound evaluation of the head position, type of breech and pelvic adequacy. A highly significant correlation between the two methods was demonstrated. He suggests that the ultrasound approach is reliable and may replace the x-ray method in management of breech presentation in labor. Although similar suggestions have been proposed previously,[100,112,113] sonographic pelvimetry has not yet become a routine praxis.

Ultrasound indications for cesarean sections, according to Rojansky, are: a cranio-spinal angle of 150°, an obstetrical conjugate of <10 cm and certain non-frank breech presentations. Ballas *et al.*[114] suggest that hyperextension of the fetal head (angle $>90^{\circ}$) that was present on radiographic assessment should be a contraindication to labor. Among 20 babies reported to have an angle $>90^{\circ}$, 8 of 11 delivered vaginally sustained cervical cord lesions. The nine babies delivered by cesarean section had no cervical damage. Sherer[115] suggests an additional indication for abdominal delivery, namely 'nuchal arm' (extension of an arm behind the fetal head). This condition can be diagnosed by ultrasound. He pointed out that nuchal arm is a cause of severe birth trauma, and can result in persistent Erb's palsy, torticollis and convulsions. Ultrasound can identify a nuchal cord with single or multiple coils, although its clinical value is still controversial.[116] Lange *et al.*[117] defined cord presentation as the finding on ultrasound of loops of the umbilical cord below the fetal body and occupying the lower segment. Estimation of birth weight should be performed in patients with breech presentations, who prefer vaginal delivery; weights between 2000 and 4000 g are reasonable limits within which a trial of labor can be permitted.[118,119] When fetal weight is estimated in breech presentations, dolichocephaly should be identified by the cephalic index, and corrections made for this. For the purpose of avoiding errors due to dolichocephaly, formulas based on FL, AD or AC should be used.[31,32]

Intrapartum management of multiple gestations

Ultrasound is an indispensable diagnostic tool for intrapartum management of multiple gestations. Presentations and estimated weights are most important when deciding on the mode and route of delivery. Estimation of fetal weight in twin gestations during labor seems to be reliable regardless of presentation, gestational age or the presence of discordant twins.[120,121] The general goal is vaginal delivery unless the presenting twin is lying non-longitudinally. A retrospective study comparing neonatal morbidity in term twins delivered by cesarean section with vaginal delivery found that neonatal respiratory disorders were significantly more common in the first group.[122] In vertex/vertex twins, vaginal deliveries are most often planned. It has to be remembered, however, that in about 20% of the cases, the second twin will change position once the first is delivered.[123] Therefore, ultrasound assessment should always be performed after delivery of the presenting twin, so that a transverse lie can be turned into a longitudinal lie.[123–126] Moreover, ultrasound should be used to assess the FHR of the second twin, and may be of help if a suddenly compromised second twin needs a swift delivery by internal version and extraction. The same maneuver should be done if external version of the second twin to longitudinal lie fails. If there is a vertex/non-vertex presentation, the ultrasonic estimated birth weight will be of vital importance when deciding on the route of delivery. Estimated birth weights between 2000 and 4000 g can be allowed for breech deliveries,[124] provided there is a pelvic adequacy, no substantial growth discordance, no cord presentations, nuchal cord, extended arm or head deflection. A retrospective study of 408 twin deliveries showed that external cephalic version of the second twin and subsequent vaginal delivery in vertex/non-vertex was successful in 75% of the cases. Internal podalic version and assisted breech delivery was performed in 20 cases and the remaining two were delivered by cesarean section. Apgar scores were not significantly different among the various groups and no complications arouse from external cephalic version performed on the second non-vertex twin.[127]

Induction of labor

Pre-eclampsia, intrauterine growth retardation, postdate pregnancies and diabetic pregnancies are common causes of labor induction. In postdate pregnancies, the

presence of severe oligohydramnios, fetal macrosomia and unfavorable cervix can be revealed by ultrasound. Bishop[128] originally described evaluation of the cervix before induction of labor by digital vaginal examination. The results of numerous studies concerning the evaluation of the cervix by ultrasound are contradicting.[129–136] An unfavorable cervix results in failed induction in 3–5% of the cases. A careful evaluation of the cervix before induction of labor may help to avoid complications, such as failed inductions, leading to cesarean section. Since the introduction of TV ultrasound cervicometry, it has been possible to assess the cervical status more objectively, and our ability to predict the course of labor seemed to be improved.[129] A sagittal section of the cervix can be seen between the anterior anechogenic bladder and echogenic rectum. Although the cervical length and dilatation can be objectively measured by ultrasound, the consistency of the cervix can be assessed only by digital vaginal examination. Therefore, a combination of digital examination and vaginal ultrasound assessment was recommended. The Bishop score would seem to be the best and most cost-effective method to assess the cervix and predict the likelihood of success of labor induction and the duration of such an induction. It seems that TV ultrasound does not predict successful labor induction in post-term pregnancy as well as digital cervical examination.[130] Reis *et al.*[131] obtained similar results concerning induction at term. They found ultrasound measurement of the cervix and fibronectin test failed to predict accurately the outcome of induced labor. Digital examination and obstetric history were the only variables independently associated with labor duration and predicted accurately vaginal delivery within 24 h. Roman *et al.*[137] showed that neither the Bishop score nor the cervical length by ultrasound was a good predictor for the outcome of labor induction in an unfavorable cervix. In contrast, recently published studies as regards the value of ultrasound in the prediction of successful induction of labor found sonographic parameters (cervical length, occipital position posterior, cervical angle) superior to the Bishop score.[132,133] The same authors studied induction of labor for prolonged pregnancy and found cervical length and parity to be significant independent prediction of the likelihood of cesarean section, prediction of induction to delivery interval and the likelihood of vaginal delivery within 24 h of induction.[134,135] In postdate pregnancies or diabetic pregnancies, fetal macrosomia should be ruled out since large-for-date infants have an increased risk of traumatic birth injury.[136–138] Formulas based on FL and AC has the best correlation with actual birth weight in macrosomia.[139] Great efforts have been made to diminish the number of cases of shoulder dystocia, which is a nightmare for the obstetrician.[140–143] A cut-off value of 1.4 cm for the difference between the chest diameter and BPD[143] or 2.6 cm for the difference between AD and BPD[144] can be helpful in estimating the risk of shoulder dystocia, and can thus be helpful in deciding the appropriate route of delivery. The fetal subcutaneous tissue/FL ratio is an additional gestational age-independent parameter for the intrapartum identification of a macrosomic fetus.[145] Vaginal birth after cesarean section has been advocated as a safe method to reduce the increasing cesarean section rate.[146] Prior to a trial of labor, the myometrial thickness in the area of the prior cesarean scar can be examined by ultrasound. It has been shown that defects in the lower uterine segment or abnormal uterine thickness can be visualized by ultrasound.[148]

Third stage of labor

Herman *et al.*[149] investigated the third stage of labor by dynamic ultrasound. They showed that, immediately after delivery of the fetus, the placenta-free uterine wall became thick and the uterine wall at the site of the placenta remained thin. As soon as the contraction phase began, the wall behind the placenta contracted gradually and only when it attained its final thickness did the placenta detach. No hematoma was observed between the placenta and the uterine wall. Ultrasound during the third stage of labor can help clarify whether the placenta has already detached or still is adherent to the uterine wall. Directly after the delivery of the placenta, the uterine cavity is visualized as a thin bright central line. Krapp *et al.*[91] have shown that the disappearance of blood flow between the basal part of the placenta and the myometrium is the hallmark of normal placental separation: persistent blood flow due to abnormal vascular connections is suggestive of placenta accreta. Although this method can be helpful in making an early diagnosis and thus preventing heavy postpartum hemorrhage by early manual removal of the placenta, the clinical application is of limiting value due to the lack of appropriate ultrasound equipment at delivery suites.

Intrapartum uterine rupture

The actual site of uterine rupture is usually difficult to visualize by ultrasound.[150] Indirect ultrasound signs of uterine rupture are retroperitoneal hematoma and free peritoneal blood, most often localized in the cul-de-sac, the paracolic gutters or the subdiaphragmatic areas.[151,152] Sometimes, an extruded fetus or placenta can be seen. Although the clinical signs and symptoms of uterine rupture are most important, the use of ultrasound may be of additional aid in diagnosing this dangerous complication.

Puerperium

Normal ultrasound appearance of the postpartum uterus

The puerperium is defined as the period of 6–8 weeks after birth during which the reproductive tract anatomically and physiologically returns to the

non-pregnant state. When faced with puerperal abnormalities, it is useful to know the normal ultrasound appearance, and the dynamic changes of the uterus during the puerperium, to better distinguish pathological from normal conditions. The involution changes concerning the size, shape and position of the uterus, as well as the appearance of the uterine cavity, can be evaluated by ultrasound.[153–160] In the early puerperium, TA ultrasound examinations are to be recommended. The woman should have a moderately filled urinary bladder. Gentle compression with the probe should be used and measurements should be made between uterine contractions to avoid uterine distortion. During the middle or late puerperal period, the TV approach is preferable. Color Doppler[161–163] and TV duplex Doppler[164] with high resolution have made it possible to study the vascular changes of the uterine involution non-invasively, and these methods have improved our ability to recognize puerperal abnormalities. The puerperal uterus should be assessed in sagittal, coronal and transverse sections (Figures 36.2 and 36.3). The coronal section is preferable for investigation of uterine malformations. Some ultrasound pictures are typical for the puerperium (Figures 36.4 and 36.6).[165] The involution of the uterus is a dynamic process that has no parallel in normal adult life. The uterine dimensions and the uterine cavity diminish progressively and substantially during the puerperium. There are two physiological lifesaving processes occurring soon after placenta delivery: thrombotamponade (enhanced blood clotting activity) and myotamponade (compression of the vessels by myometrial contraction). The appearance of ultrasound finding during early puerperium reflects these physiological changes. The normal shape of the uterus in the sagittal plane during the first postpartum days has been described as a 'hockey stick',[166] or a 'crescent'[156] (Figures 36.4a and 36.6a). This form of the uterus is typical only in the early puerperium and it is artificial. An extremely high degree of uterine deformability is caused by a heavy uterine corpus, a hypotonic lower uterine segment and supine position of the examined woman. In the second postpartum week, the shape changes and becomes more globular. The position of the uterus also changes. In the early period the uterus arches over the sacral promontory in a retroverted position. Wachsberg *et al.*[166] pointed out the importance of this uterine angulation and its effect on the measurements of uterine length. The uterus rotates (Figure 36.5) along its internal cervical os and in the majority of women it achieves an anteverted position in the beginning of the second postpartum week. This position is then retained. In only a few women does the uterus return to a retroverted position at the end of puerperium.[165] Concomitantly with the changes in dimension, shape and position of the uterus, the uterine cavity goes through a marked process of involution. During the first three postpartum days,

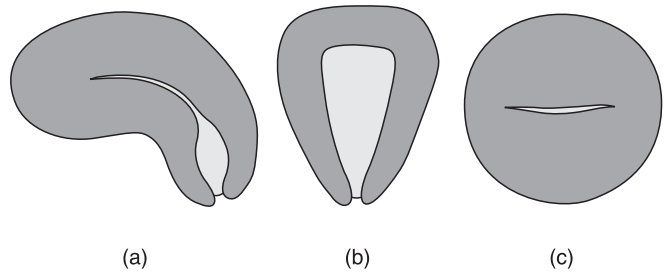

Figure 36.2 Three standard sections of the puerperal uterus: a longitudinal (a), a coronal (b) and a transverse (c).

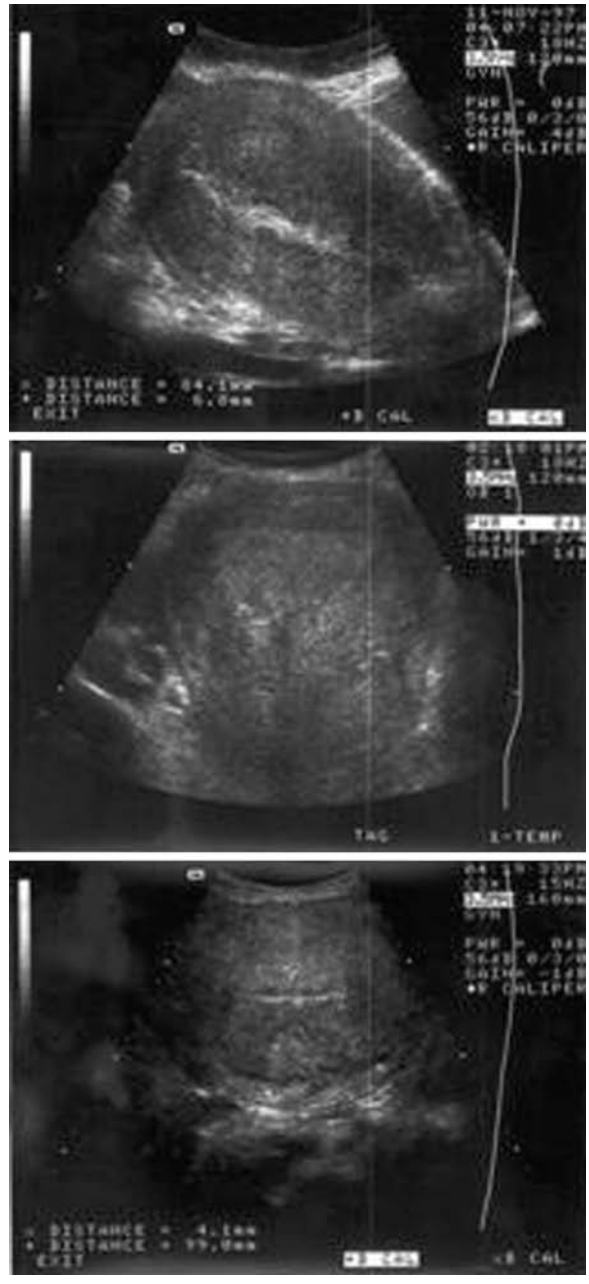

Figure 36.3 TA ultrasound scans of a normal puerperal uterus on day 1: a longitudinal scan (a), a coronal scan (b) and a transverse scan (c).

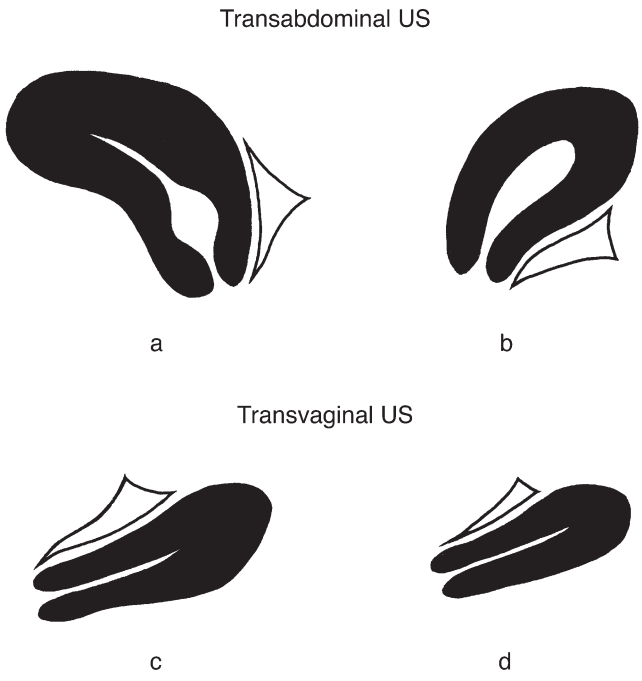

Figure 36.4 The normal ultrasound appearance of the uterus and uterine cavity during the puerperium. TA approach: (a) during the first 3 days postpartum, a 'hockey stick'-shaped retroverted uterus with an empty cavity in the upper part and fluid collection with mixed echo pattern in the lower uterine segment; (b) on days 7–14 postpartum, the uterus is oval-shaped and anteverted with fluid/mixed echo in the whole uterine cavity. TV approach: (c) 4 weeks postpartum, the size of the uterus is considerably diminished; the cavity is empty and is seen as a thin central line; (d) 8 weeks postpartum, the involution process is complete and the uterus has achieved non-pregnant dimensions and appearance.

lifesaving uterine contraction approaches the anterior and posterior uterine walls and just virtual cavity appears. It is empty and decidua appears as a thin white line from the fundus to the level of the internal cervical os (Figure 36.6a). Sometimes this line can be irregular and thicker, which probably depends on the amount of retained decidua. The separation of the placenta and membranes generally occurs in the spongy layer; however, the level varies. Already in 1931, Williams wrote concerning the line of separation of the placenta and membranes: 'While separation generally occurs in the spongy layer, the line is very irregular so that in places a thick layer of decidua is retained, in others only a few layers of cells remain, while in still others the muscularis is practically bare'.[167] The variation in the sonographic appearance of the cavity could be seen as a demonstration of these physiological variations in the retained decidua. The thin white line seen on ultrasound might possibly represent cases in which only the basal decidual layer is retained or if the muscularis is practically bare (Figure 36.6a), whereas the thicker and more irregular lines might represent cases with retention of the more spongy decidual layer and perhaps fragments of membranes. It is unusual to find a collection of fluid or any echogenic masses in the upper part of the cavity at that time. In the lower uterine segment, however, a collection of fluid with mixed echo patterns is almost always present. It comprises blood clots and probably small fragments of retained membranes.[165,166,168,169] This finding has no clinical significance and the mass is usually expelled spontaneously. Small echogenic or

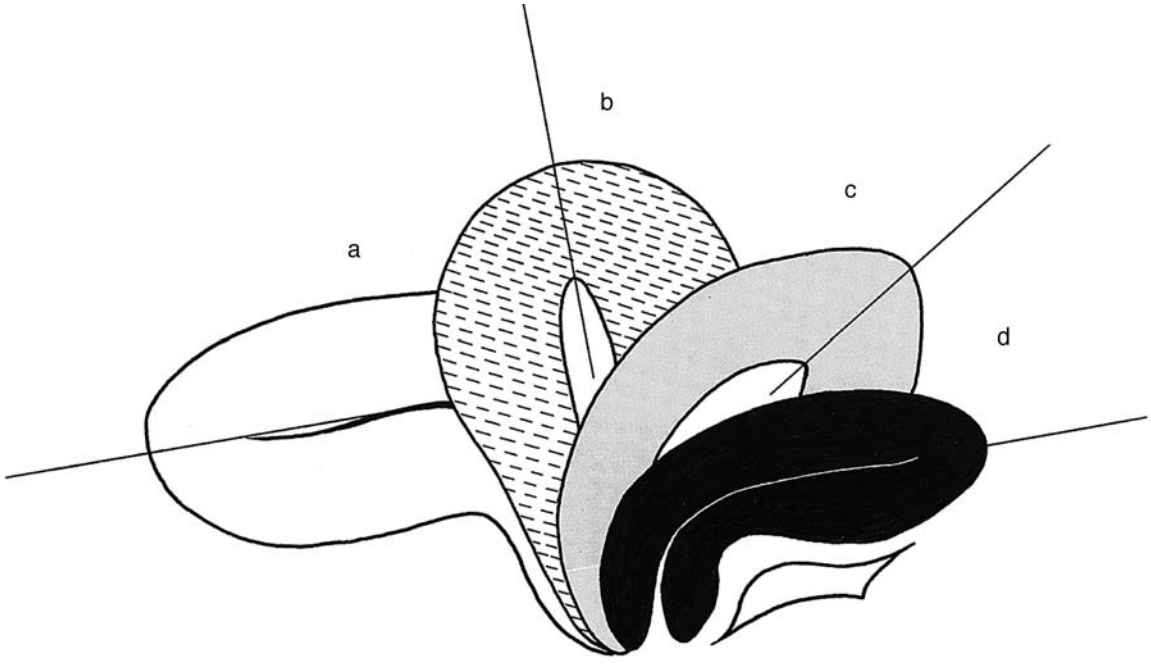

Figure 36.5 The normal rotation process of the uterus during the puerperium. The uterus usually rotates about 100–180° and changes its position from retroverted to an anteverted position during the involution period.

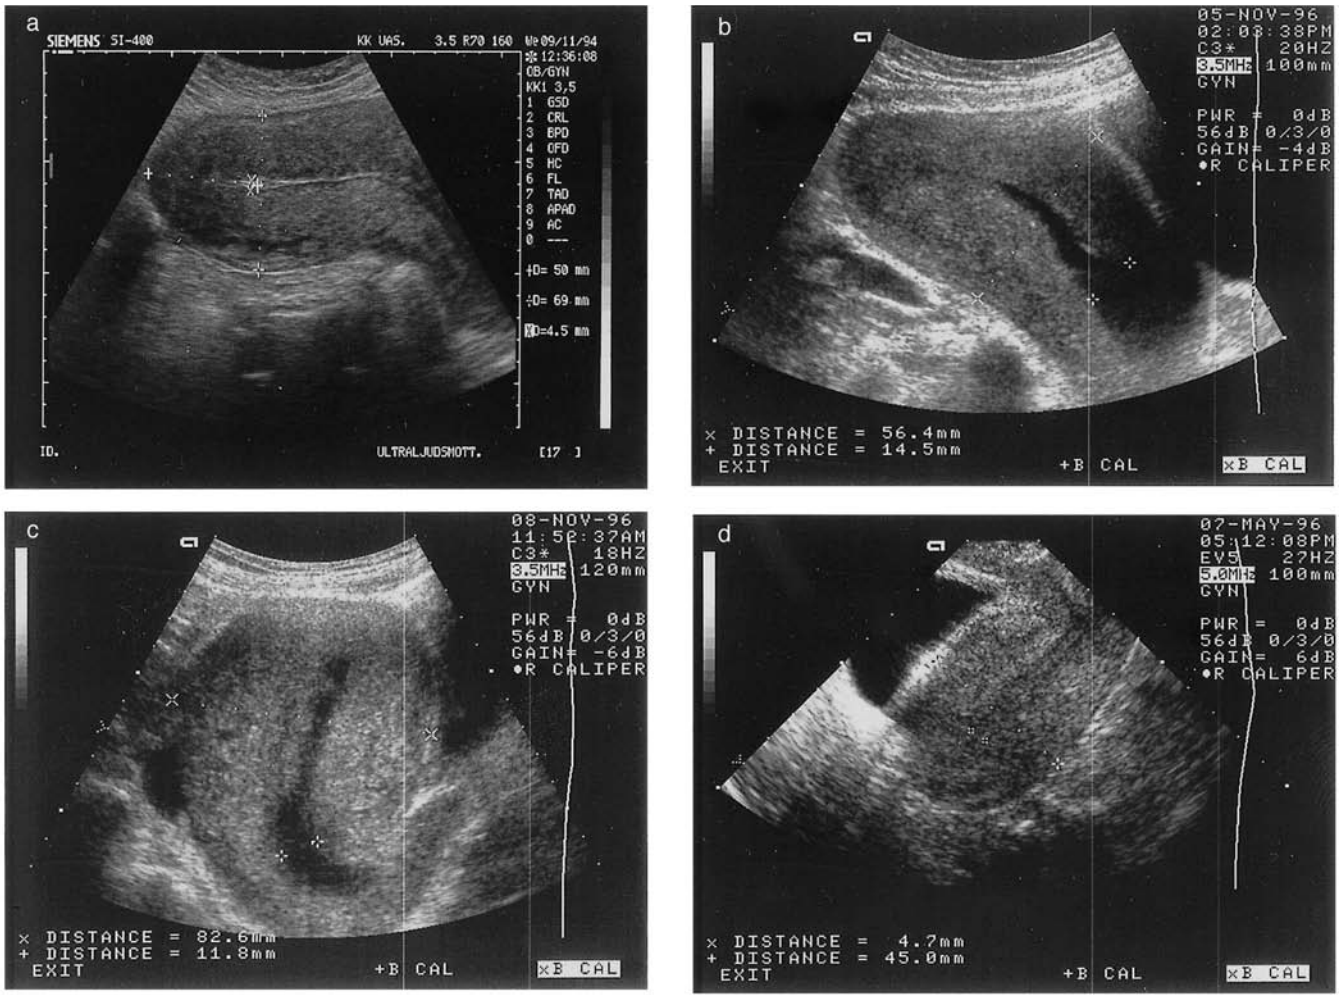

Figure 36.6 The normal ultrasound appearance of the postpartum uterus, TA approach (a, b, c) and TV approach (d). (a) On the first postpartum day the uterus has a hockey stick shape, a retroverted position and a thin endometrium. Prominent vascular channels are seen in the posterior myometrial wall. (b) One week postpartum, pure fluid is seen in the uterine cavity. (c) Two weeks' postpartum, the uterus has an oval shape, an anteverted position and a heterogenous pattern is seen in the whole uterine cavity. (d) Four weeks postpartum, the uterus is considerably diminished in size. It is empty and the uterine cavity is seen as a thin line.

echolucent dots in the cavity are harmless physiological findings.[168] In contrast, Sokol *et al.*[170] found in 16 of 40 women echogenic material in the uterine cavity within 48 h after normal vaginal delivery. On the posterior wall of the uterus, the prominent uterine vascular channels are regularly seen.[160] From days 7–14, endometrial fluid can be seen in the whole cavity, not only in the lower segment (Figure 36.6b and c). Moreover, echogenic and non-echogenic areas are seen in the whole uterine cavity, probably comprising a mixture of blood, blood clots and offcasts of necrotic decidua (Figure 36.6c). The diameter of the cavity in the upper part of the uterus may then be quite wide, which reflects a normal healing process of the placental site inside the uterine cavity, necrotic changes of retained decidua and an abundant shedding of lochia. In contrast, Edwards *et al.*[171] found an echogenic mass in a great proportion of normal puerperal women. At 4 weeks postpartum, the uterus is again empty and the uterine cavity is seen as a thin central line (Figure 36.6d). Sometimes, a small amount of fluid can be seen. By 8 weeks' postpartum, the involution process is complete, and the uterus has non-pregnant dimensions. It lies in an anteverted position in 88% of the cases.[165] In 12% of cases, the uterus has a retroverted position corresponding well to the normal prevalence of retroversion of the uterus in the general population. Decidua and necrotic vessel ends are exfoliated, the placental site is recovered and a new endometrium is regenerated from the basal layer of the decidua adjacent to the myometrium. In 1953, Sharman performed endometrium biopsies and identified fully restored endometrium from the 16th postpartum day.[172] Ultrasonically, the cavity appears as a thin white line. This corresponds to an inactive endometrium and reflects the hypoestrogenic state of the puerperium (the physiologic menopause). It is not common to find fluid or echogenic masses in the uterine cavity at that time. There are conflicting data about the presence of gas in the uterine cavity during the normal puerperium. Previous studies have suggested a correlation between gas and endometritis caused by *Escherichia coli* or

Clostridium perfringens.[159,173] These conditions are, however, nowadays very rare. Wachsberg and Kurtz[174] detected gas in the uterine cavity in 21% of the normal population, and suggested that gas in the uterine cavity did not necessarily indicate endometritis, but could be considered as a normal finding. Other investigators have not been able to confirm this.[165,168,169] Whether or not a small amount of gas is seen in the uterine cavity has, however, no clinical significance. Lavery and Shaw[160] described the prominent uterine vascular channels in the normal early postpartum period. With color Doppler, a venous blood flow could be demonstrated, which usually disappears during the second and third postpartum weeks. Besides conventional ultrasound, Doppler technology is used to study hemodynamic events occurring during the puerperium.[161–164,175,176] Normal pregnancy requires the growth of many new vessels. Consequently, during puerperium dramatically regressive changes occur. The physiological destruction of the uterus involves not only muscle cells and decidua but also arteries. Tekay[161] and Kirkiinen[162] assessed the peripheral vascular resistance of the uterine arteries in the postpartum period and found that the PI value started to increase in the early puerperium, remained unchanged during the next 6 weeks and finally increased to reach the non-pregnant values about 3 months after delivery. The prediastolic notch is also detected in the early puerperium and these hemodynamic changes can be partly explained by the immediate contraction of the uterus.[161,162] Fluid collections in the fossa of Douglas are not a common finding during the puerperium.[165,169]

Retained placental tissue

Retained placental tissue in the uterine cavity postpartum is associated with a high risk of excessive bleeding, either immediate or delayed. Immediate postpartum bleeding requires urgent management; manual evacuation of the uterine cavity is warranted. Ultrasound can be a valuable aid to confirm an empty uterine cavity after the evacuation by demonstrating the easily visible bright echogenic linear echo in the middle part of the uterus. Delayed postpartum hemorrhage occurs in about 1–2% of cases. It is most often the result of abnormal involution of the placenta site in the uterine cavity and endometritis, but it may be caused by retention of placental tissue. In developed countries, one-half of the postpartum women who are admitted to hospital with this condition undergo uterine surgical evacuation. In developing countries, it is the major contributor to maternal death.[177] Two etiological factors were identified as risk factors, namely primary postpartum hemorrhage and a history of manual removal of a retained placenta. Uterus curettage was performed in 63% of cases. Histological confirmation of the residual placental tissue was obtained in 37% following ultrasound diagnosis and in 33% without previous ultrasound examination. The decision whether to perform uterine evacuation for retained placental tissue depends on both the clinical finding and the ability to visualize retained placenta by ultrasound. Although prompt curettage seems to be necessary in many cases, it usually does not remove identifiable placental tissue.[178] Moreover, it is more likely to traumatize the implantation site and induce more bleeding. Consequently, the rate of complications is high. Hoveyda *et al.*[179] reported in his review regarding secondary postpartum hemorrhage that the frequency of perforation of the uterus was 3% and hysterectomy about 1%. Alexander *et al.*[177] identified 45 papers on the management of women with secondary postpartum hemorrhage and they concluded that no information was available from randomized trials to inform the management of women with this condition. Since curettage in the postpartum period can be dangerous, it is of great value to have a tool that can diagnose retained placental tissue. Many conflicting data exist about the ultrasound appearance of retained placenta tissue. The first studies were performed with old static ultrasound equipment.[154,173,180] They described various ultrasound images of retained placental tissue, and the rate of false-positive diagnosis was high. Despite the markedly improved imaging possibilities in the 1990s, confirmation or exclusion of retained placental tissue is still difficult.[163,164,168,169,173,179,180–182] We cannot expect the same ultrasound picture during the early (Figure 36.8a) and late periods (Figure 36.7b) of the puerperium. The ultrasound appearance of retained placental tissue may vary depending on the presence of different kinds of intrauterine contents. Necrotic decidua, blood, blood clots and inflammatory necrotic changes may essentially influence the ultrasound image. Nevertheless, the most common finding associated with retained placental tissue is an echogenic mass[164,168,169,180–181] (Figures 36.7a and 36.8a). In contrast, Edwards *et al.*[171] found in his study an echogenic mass on day 7 in 51% of normal cases, in 21% on day 14 and in 6% on day 21. He questioned the ultrasound finding of an echogenic mass in the uterine cavity as a sign of retained placental tissue. The definition of an echogenic mass was not specified. Even Sokol *et al.*[170] found 'echogenic material' in 40% of cases during 48 h after normal delivery. However, echogenic material was localized in the lower uterine segment in 14 of 16 women. On the other hand, ultrasound appears as a valuable tool to confirm an empty cavity. Lee and Mandrazzo[173] found an empty cavity in 20 of 27 patients with late puerperal bleeding. In only one case was retained placental tissue confirmed. The same authors reported that histological confirmation was obtained in eight of nine patients with ultrasound-suspected retained placental tissue. If the ultrasound finding shows an empty uterus with a thin white decidua/endometrium, pure endometrial fluid or only small

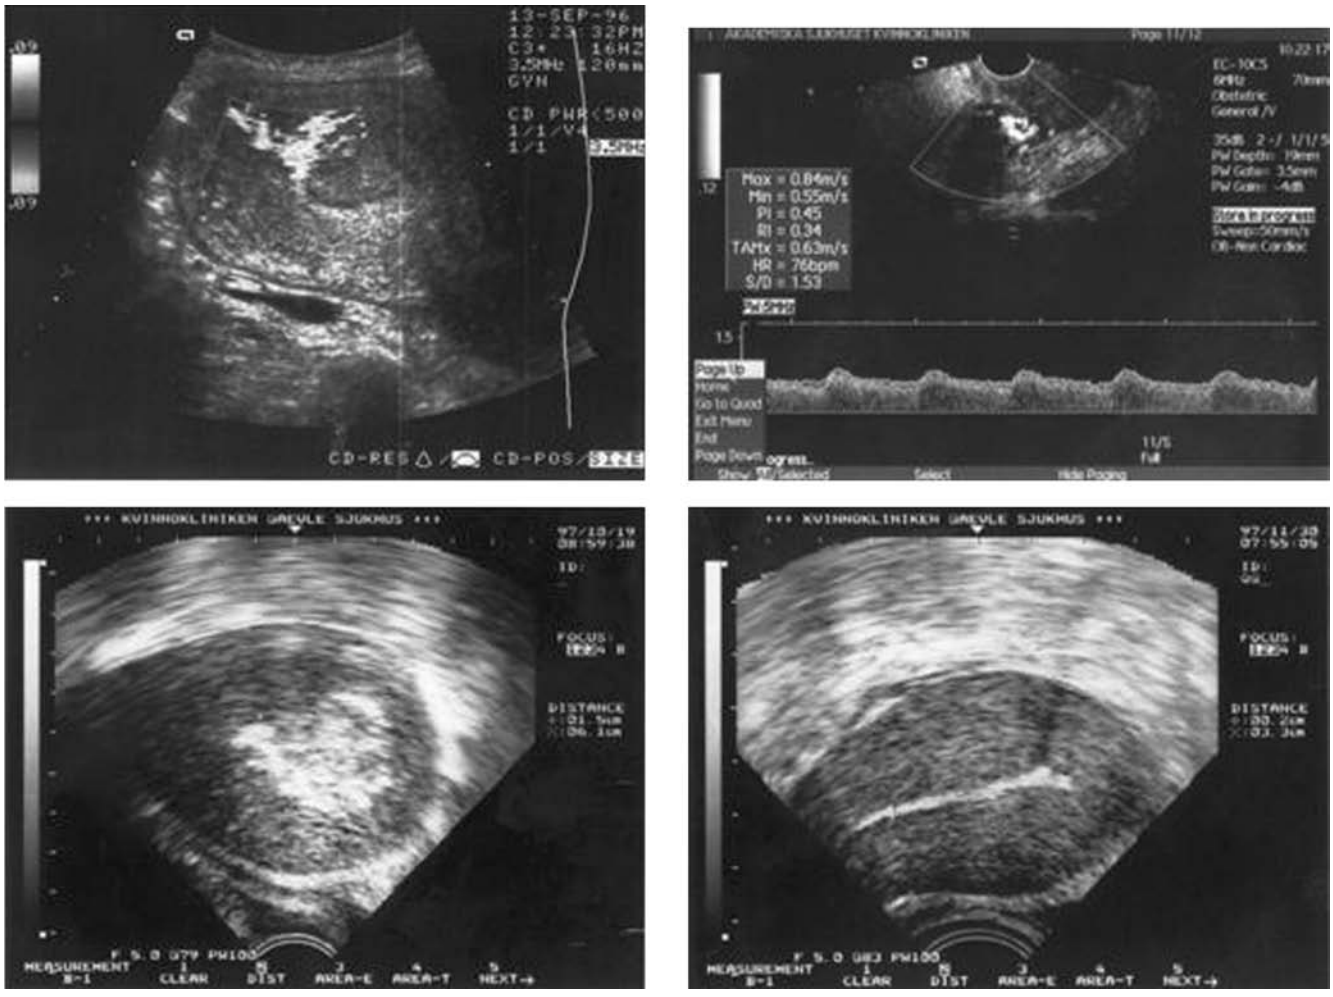

Figure 36.7 Puerperal abnormalities as seen by the TV (a,b) or TA (c,d) approach. (a) Retained placental tissue is seen as an echogenic mass surrounded by a distinct halo and easy detectable flow on the side of the mass. (b) Retained placental tissue that has persisted for a long time postpartum and is seen as 'a stippled pattern'. (c) After cesarean section, gas is observed in the uterine cavity with clean and dirty shadowing well visualized. (d) A necrotic myoma that caused dysfunctional puerperal bleeding is seen in the uterine cavity.

echolucent or hyperechogenic dots, a clinically significant amount of retained placental tissue is unlikely.[164,165,168,169] Patients with persistent dysfunctional postpartum bleeding are highly suspected of having retained placental tissue, and they often show a typical ultrasound image with a 'stippled pattern' of scattered hyperechogenic foci[168] (Figure 36.7b). Later on, the retained placental tissue becomes increasingly echogenic and the scattered appearance disappears[168] (Figure 36.8c). A heterogenous pattern may cause confusion since retained placental tissue and necrotic decidua with organized blood clots can give similar images during the first or second postpartum week. Neil *et al.*[182] compared ultrasound with clinical assessment for the diagnosis of retained placental tissue related to secondary postpartum hemorrhage. They concluded that both clinical assessment and ultrasound scan have limited diagnostic accuracy. TA two-dimensional imaging alone is not specific enough. TV ultrasound has been advocated[164] with the use of a high-frequency (6.5 MHz) TV probe to better differentiate between retained placental tissue and blood clots mixed with necrotic decidua. TV pulsed and color Doppler are promising noninvasive methods to improve the diagnostic accuracy of ultrasound concerning retained placental tissue.[161–163] Achiron *et al.*[164] looked at the myometrial arterial blood flow around intracavitary contents and found that patients with an RI below 0.35 had residual tissue (Figure 36.8b). These patients are suitable for invasive treatment. An RI above 0.45 should exclude diagnosis. Values between 0.35 and 0.45 were designated as a 'gray zone'. These patients could be treated conservatively with repeated ultrasound examinations, and curettage should be performed only if conservative treatment failed. Alcazar *et al.*[175] found an RI value < 0.45 to be suggestive of retained placental tissue. We observed easily detectable flow, always on the side of the circumscript echogenic mass, which was histologically proven to be retained placental tissue (Figures 36.7a and 36.8a). It may be speculated that this highly vascularized area is

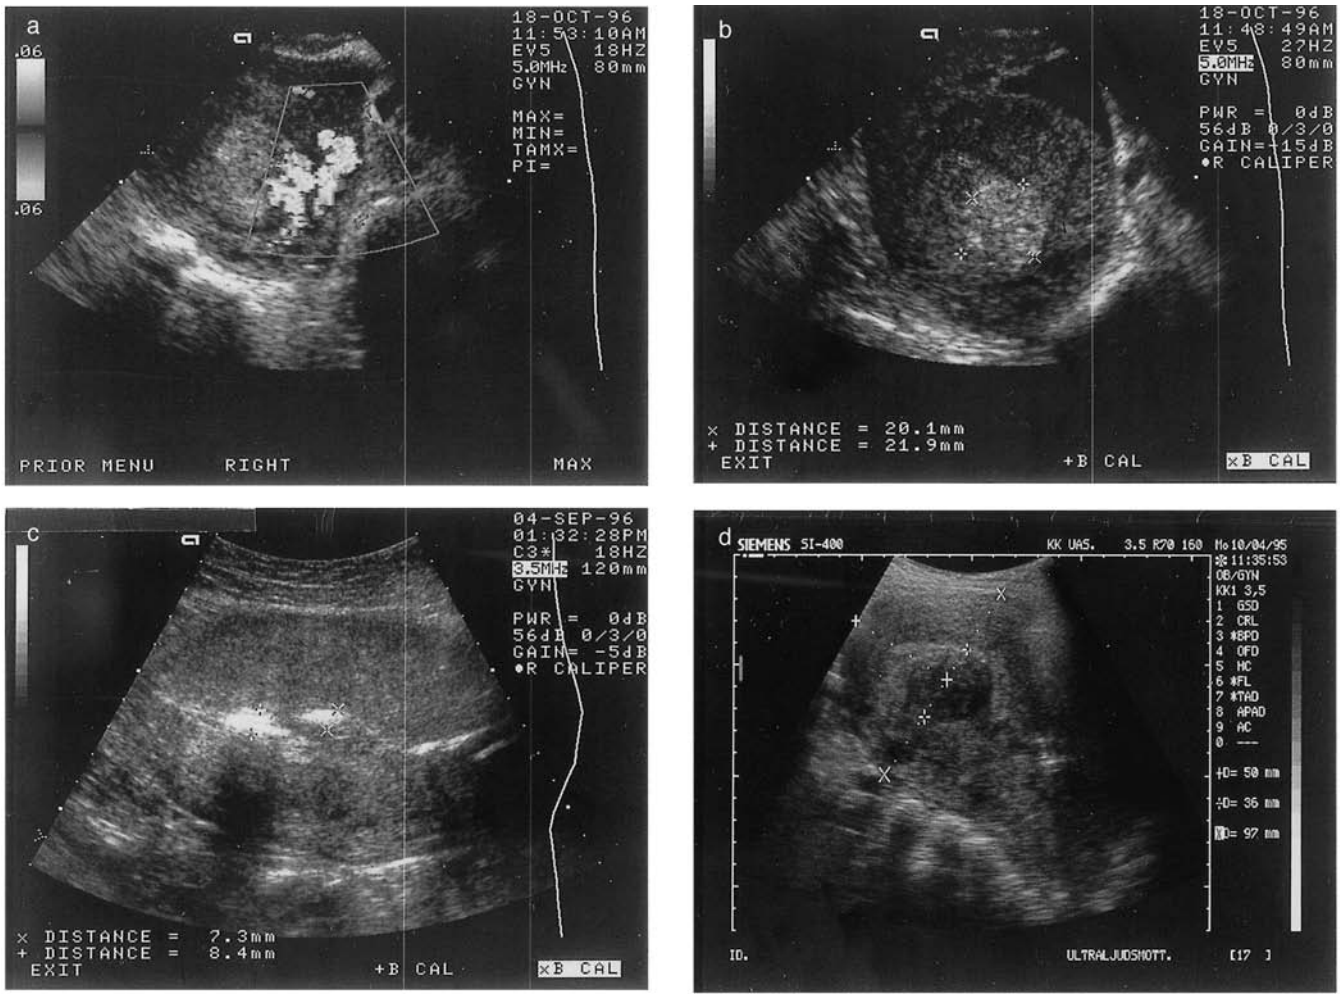

Figure 36.8 Puerperal abnormalities revealed by ultrasound: (a) retained placental tissue 2 days postpartum; (b) low-resistance blood flow on the side of the mass; (c) retained placental tissue 6 weeks postpartum; (d) a thin, echogenic endometrium soon after curettage.

responsible for the blood supply to retained placental tissue. Kelly *et al.*[183] described a rare case of severe secondary postpartum hemorrhage – arteriovenous malformation of the uterus. By color Doppler ultrasound, a localized area of increased vascularity within the myometrium may be detected. Pulsed Doppler usually reveals a low-resistance turbulent flow. Thus, uterine artery embolization may be performed and unnecessary curettage should be avoided. In contrast, Van Schobroeck[176] found enhanced myometrial vascularity (EMV) to be a common transient ultrasound finding if asymptomatic and it does not require treatment. On the other side, if in symptomatic patients residual placental tissue is suspected on ultrasound, EMV is an additional ultrasonic finding, which can help in guiding the appropriate management. The accuracy of TV sonohysterography has recently been evaluated and compared with TV ultrasound.[163,184] This new method seems to be more effective for evaluation of residual trophoblastic tissue. Power Doppler and three-dimensional ultrasound seem to be new unexplored modalities that could improve our abilities to diagnose clinically significant retained placental tissue. All of these new modalities need further evaluation before their usefulness can be recommended.

Postpartum endometritis

Whenever the obstetrician is faced with postpartum bleeding accompanied by signs of endometritis, the most important question is whether there is retained placental tissue in the cavity or not. Previously, it has been considered that ultrasound finding of retained placental tissue and endometritis overlap. Recent studies have, however, contradicted this view.[169] Only if endometritis is the result of retained placental tissue can a similar ultrasound appearance be observed. An isolated endometritis without retained placental tissue has no pathognomonic ultrasound finding. Confusion can sometimes arise in the presence of large retained and organized blood clots in the uterine cavity, which may mimic retained placental tissue. Clinical improvement following conservative treatment with antibiotics and uterotonic medications

speaks against the presence of retained placental tissue. Uterine involution could be delayed in cases of endometritis, particularly if endomyometritis is present.[185] The detection of gas in the uterine cavity has been considered as a sign of endometritis. Madrazo[159] found endometrial gas in 15% of the patients with proven puerperal endometritis. Wachsberg and Kurtz,[166] however, observed gas in 21% of women postpartum; none of these women developed endometritis. Whenever gas is present in the uterine cavity a follow-up ultrasound should be performed to confirm its disappearance. It usually resolves during the first two postpartum weeks. If ultrasound is performed after intrauterine manipulations or cesarean sections, it should be kept in mind that highly echogenic foci caused by air are normal findings that must not be misinterpreted as retained placental tissue or endometritis. Kirkiinen found that blood flow to the infected uterus could be different from normal.[162] Deutchman and Hartman[185] have described an uncommon result of endometritis – postpartum pyometra. A lucent area within the uterus with no echogenic components is suggestive of pus. Ultrasound can assist in the proper diagnosis and be of help in guiding a drainage procedure.

Septic pelvic thrombophlebitis, well known as an 'enigmatic puerperal fever', is another uncommon complication of the puerperium. It most commonly presents in the early postpartum period and antibiotic treatment is usually unsuccessful. Rudoff *et al.*[186] suggest ultrasound examination in case of clinical suspicion of pelvic thrombophlebitis. Although ultrasound diagnosis of ovarian vein thrombophlebitis is well described,[187–189] the diagnosis is still difficult and ultrasound expertise is needed. Asymmetric dilatation of the ovarian or other pelvic vein may sometimes be observed.[187] Furthermore, a complex or hypoechoic mass near the lower pole of the kidney, particularly in a clinical setting of an enigmatic puerperal fever should suggest thrombophlebitis. An echogenic intracaval mass is considered diagnostic and anticoagulation treatment should be added.[189]

Cesarean section

Nowadays, when cesarean section rates are continuously rising, a higher incidence of all puerperal complications should be expected. The ultrasound appearance of the uterus after cesarean section usually shows three distinctive patterns: (1) gas in the cavity, (2) a small rounded area at the incision site that reflects tissue reaction due to localized edema[190–192] and (3) some echogenic dots at the incision site, which are related to the type of closure and the suture material used.[192] All these characteristics are normal findings and no correlation with pathological conditions is found. The ultrasound appearance of endometrial gas is an intensively hyperechogenic focus equivalent in echogenic to bowel gas with clean or dirty shadowing or reverberation artifacts[174,193] (Figure 36.7c). Fat and calcium have a similar ultrasound appearance. The gas usually disappears during the first two weeks after surgery. The involution rate of the uterus following cesarean section is not different from the involution rate after vaginal delivery. Nakai *et al.*[194] studied uterine blood flow resistance after cesarean section and concluded that the RI for the uterine artery did not show any change during the early postpartum period. The significant infectious morbidity is associated with cesarean section. Ultrasound may be useful in postpartum women with clinical suspicion of a postoperative complication like phlegmona,[191] abscess, pyometra, hematometra, wound infection and subfascial hematoma. If surgical drainage is chosen as therapy, ultrasound guidance can be helpful. Ultrasound can also confirm the suspicion of an intra-abdominal postoperative hemorrhage by visualization of free fluid in the abdomen. Baker *et al.*[190] described bladder flap hematoma after a low uterine transverse cesarean section. A solid or complex mass between the posterior bladder wall and the anterior uterine wall may be observed by ultrasound. An abscess appears as a cystic structure with internal debris surrounded by thicker irregular walls. An infected hematoma initially has a similar ultrasound appearance. During the resolution process, it may change and appears more solid. However, the physician must be aware that ultrasound diagnosis is just a complement and the clinical condition of the patient should guide the therapeutic approach.

Uterine myoma

Myoma may obstruct the birth canal, and thus be a cause for cesarean section. Intracavitary myoma may cause problems, such as placental detachment, with subsequent postpartum bleeding. Ultrasound is the best tool to make a correct diagnosis (Figure 36.7d). A myoma is characterized by hypoechogenicity. Due to degenerative processes, a myoma may appear as a bizarre heterogenous pattern of solid and fluid areas, and thus be misinterpreted as retained placental tissue. Pinpoint tenderness on palpation may direct the ultrasound examination and reveal the presence of a necrotic myoma.

Developmental abnormalities of the uterus

The prevalence of the congenital uterine malformations in the general population is unknown. Failed fusion of the two Mullerian ducts to form the genital organs may cause reproductive, fetal and maternal hazards. In addition to an increased risk of premature labor and abnormal fetal presentations, retained placental tissue with postpartum hemorrhage may be a consequence of this uterine abnormality. It is well known that uterine anomalies may remain undiscovered except when they are associated with reproductive or obstetric problems.

Already in 1976, Bennett suggested puerperal ultrasonic hysterography as a screening procedure prior to radiological examination in women whose reproductive performance suggests a diagnosis of congenital malformation of the uterus.[195] Since then a few studies concerning the issue have been published.[196,197] Szoke and Kiss[196] examined in 1977 patients in whom manual examination revealed a uterus differing in shape from the normal, the patient had a breech presentation in her previous or present pregnancy and the involution of the uterus was slow. The ultrasound echo technique was applied and uterine anomalies were found in five cases postpartum. In 1984, Land *et al*.[197] performed ultrasonic hysterography in 104 patients between the second and fifth postpartum days. An unexpectedly high number of women (16%) showed an abnormal uterine configuration. The coronal section seems to be the most appropriate section to reveal uterine cavity anatomy. It is difficult to obtain the coronal section by abdominal examination in non-pregnant patients. However, the puerperium when the uterus is extremely large is an exception. The ultrasound examination should be performed in the early puerperium because a large uterus lies in near proximity to the ultrasound probe and the highly echogenic decidua outlines well the shape of the cavity. Puerperal ultrasound can detect such an abnormality, providing an explanation for complications in labor and the puerperium.

Postpartum urinary retention

Postpartum urinary retention is a relatively common condition and the incidence ranges between 1% and 18%.[198] According to the International Continence Society, 100 ml is considered as the upper limit of residual urine. Ultrasound is the method of choice when assessing urinary bladder and residual urine postpartum. Invasive catheterization with the discomfort and the risk of infection can be avoided. Conventional bladder scanner is not to be recommended during the puerperium. A large uterus may contain fluid and thus a misinterpretation may be done. Many different techniques for bladder volume measurement are used and the accuracy of the method varies widely.

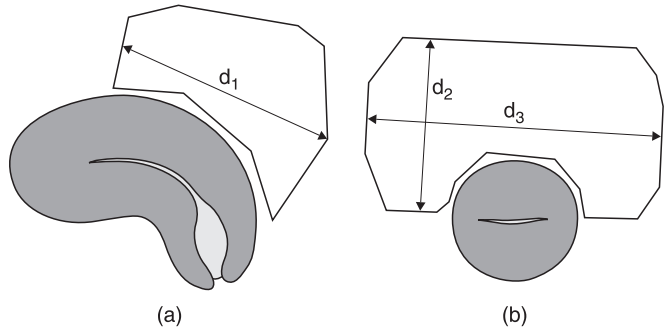

Figure 36.9 Residual urine volume measurement.

We prefer a method where the longest distance of the maternal bladder (d_1) is measured in a longitudinal section, and then two perpendicular diameters (d_2 and d_3) are measured in the transverse section (Figure 36.9). The estimated amount of residual urine can be calculated using the formula for approximation of the ellipsoid:

Volume (ml) $= (d_1 \times d_2 \times d_3)/2$ (Figure 36.9).

37 Safety of diagnostic ultrasound in obstetrics

B. Breyer, A. Kurjak and K. Maeda

Introduction

Diagnostic ultrasound has become an integral component of perinatal care. Even after widespread use for almost four decades there has not been a single known instance of identifiable adverse effects caused by the diagnostic intensity of ultrasound. Nevertheless, the need for continuing vigilance for biosafety is well recognized. It has long been recognized that, given certain circumstances, ultrasound exposure can influence biological systems. Diagnostic medical insonation, however, is generally assumed to be safe.

This chapter addresses some complex issues about safety, and presents a review of available data from the literature as well as from the personal experience of the authors.

Physical background

Ultrasound waves

Ultrasound waves convey mechanical energy through matter by passing energy from particle to particle. Longitudinal waves induce pressure variations along their way. In soft tissues, these waves are the most common type. Other modes, like transverse or shear waves, can spread an appreciable distance, only in solids. When transmitted into bodily liquids, such waves are absorbed within a very small distance. Waves that spread only very short distances are not really of interest from a diagnostic point of view, but when considering safety, such absorption within a short distance is exactly the type of phenomenon that may be of concern. All waves attenuate very strongly in bone.

Describing ultrasound waves

Ultrasound waves and pulses can be described using the following parameters:

(1) *Propagation speed*. The average speed for longitudinal waves in human soft tissue is 1540 m/s. In calcified bones, the speed is about twice that in soft tissues. In gases, it is about 330 m/s. Shear waves travel more slowly.
(2) *Wavelength* (λ) is inversely proportional to frequency. It greatly influences the resolution of diagnostic machines. The higher the frequency, the shorter the wavelength. For example, the wavelength in the body at 3 MHz is approximately 0.5 mm.
(3) The *pulse length* for Doppler measurements is often longer than for B-mode imaging. These pulses are transmitted at a repetition frequency typically of the order of a few kilohertz.
(4) The *attenuation* of ultrasound is proportional to frequency. Absorption causes heating of tissues.
(5) *Ultrasound pressure amplitude* is the maximum pressure induced by the compressional wave at a point in the tissue. If we operate with continuous wave (CW) [as in fetal cardiotocographic (CTG) monitoring] the wave is continuous. If, however, we use pulses (such as in imaging), ultrasound is transmitted in the form of short pulses and the maximum positive (compressional), maximum negative (rarefaction) and average pressure during the pulse or during the total time must be taken into account.

Energy is measured in watt seconds or joules; *power* is measured in watts; *intensity* is measured in watts per square meter or centimeter. The *attenuation* property is measured in decibels per centimeter per megahertz.

In diagnostic applications, ultrasound waves are mainly used in the form of beams and are usually transmitted in the form of pulses. In pulse applications, the energy flow exists in time only during the pulse. Considering an example when the pulse duration is one-thousandth of the repetition period, the intensity during the pulse is about 1000 times higher than the overall time average intensity.

Ultrasound beams can be focused in various ways, but the important feature from the safety standpoint is that focusing concentrates ultrasound energy and

thus, potentially, increases the hazard. For safety consideration, only transmission focusing is relevant. In scanning applications the beam moves, while in Doppler spectrometry and M-mode imaging one tends to keep the beam in one position for a prolonged time.

The ultrasound pulse consists of a few pressure oscillations around the static atmospheric pressure. When considering safety, the positive peak pressure p_c and the negative peak pressure p_r play a role. At high intensities, the positive peak pressure may become a few times higher than the negative peak pressure. These effects are much more expressed in liquids in which there is little attenuation compared to human tissues in which attenuation is much greater.

Acoustic parameters used to describe ultrasound exposure

In order to concisely and exactly describe ultrasound waves with regard to their potential hazard a multitude of parameters are used. Intensity is the first such parameter. Later, it was recognized that this was not enough and therefore additional parameters were introduced:

(1) *Acoustic power* output is the total acoustic power that exits from a transmitting transducer. In commercial B-mode instruments, the power ranges between 0.3 and 280 mW; in color Doppler mapping, between 15 and 400 mW; in pulsed Doppler spectrometry, between 10 and 450 mW.[1–3]

(2) *Spatial peak temporal average intensity* (I_{SPTA}) is the intensity averaged over time, but measured in the position of the spatial peak (focus). When considering the potential hazard of heating, we take this I_{SPTA} into account. In commercial B-mode instruments, this ranges between 0.3 and 990 mW/cm^2; in color Doppler mapping, between 20 and 2000 mW/cm^2; and in pulsed Doppler spectrometers, between 170 and 9000 mW/cm^2.

(3) The intensity at the point of maximum pressure in a pulse is the *pulse peak intensity*. This is the temporal peak intensity.

(4) When considering the potential hazard of cavitation, *spatial peak pulse average* (I_{SPPA}) is among the significant parameters. In commercial pulsed Doppler instruments, this ranges between 1 and 770 W/cm^2.

(5) *Peak negative pressure* is also among the parameters for evaluation of the cavitation probability. It is easier to measure than the peak positive pressure, which may be greatly distorted in shape. The peak pressure varies in all types of modern equipment between 0.4 and 5 MPa.[1–3]

The above parameters play a role in the body, but are far easier to measure in water. In addition, it is much easier to standardize them in water. Two approaches are used: the measurement of all parameters in water or the immediate calculation of the *in situ* values taking into account conventional standard attenuation values, e.g. 0.3 dB/cm MHz. Bone is considered to be very attenuating so that nearly all the energy is absorbed within a short path. Various organ or situation models have been conceived to represent specific situations, e.g. full bladder and uterus with an embryo.

Instrument properties and acoustic output

In purely practical terms, it is necessary to know what properties of the scanners are important for their safe use, both when acquiring a new machine and when using existing ones. Some properties are inherent to the instrument while others depend on the application and the way in which the instrument is used.

Heating of tissues is proportional to I_{SPTA} *in situ*. The general trend is an increase in the output of diagnostic ultrasound instruments.[1] Since the 1980s, there have been instruments in the market with I_{SPTA} above 1 W/cm^2 in pulsed Doppler operation regimens.[2] The actual intensity greatly depends on the mode of operation and settings (ALARA principle[4,5] should be followed). The lowest intensity is used in fetal heart monitors (CW Doppler systems with the intensity below 100 W/cm^2), and then, in order of increasing intensities: B-mode imaging scanners, two-dimensional (2D) Doppler machines and pulsed Doppler instruments. In many instruments, it is possible to operate in various regimens. High-end scanners normally have the possibility of quasi-parallel operation in various regimens, e.g. gray scale, 2D flow mapping and Doppler spectrometry, at the same time. In fact, the scanner switches quickly between the various modes.

The actual acoustic power and pressure in the pulses greatly depend on the mode of operation; depth and length of examination also influence the exposure. The frequency influences the penetration ability and thus may influence the acoustic power used. For example, the use of higher-frequency intracavitary probes implies two opposite effects; that is, the scanning distance (range) is reduced but the frequency is increased and, therefore, the attenuation per centimeter is reduced. Thus, the acoustic energy traversing the region of interest is about the same.

In the current commercially available instrumentation, I_{SPTA} varies with the mode: in B-mode imaging the median is 35 mW/cm^2; in M-mode the median is about 100 mW/cm^2; in 2D velocity mapping (color Doppler) the median is about 290 mW/cm^2 and in pulsed Doppler the median is 1200 mW/cm^2. The factor of increase of intensity between the various modes is about three from mode to mode.[1–3]

Another source of heat may be heating of the transducer because of internal dissipation. When intracavitary probes are used, this may be a factor for serious consideration. The extent of heating depends on the probe design and materials used.

Cavitation is less likely with short pulses. In B-mode imaging, the pulse length is usually less than 0.5 μs, but in pulsed Doppler applications it can be up to 20 μs. It is possible to control this length by varying the 'sample volume'. Shorter 'sample volumes' generally yield smaller I_{SPTA}.

Ultrasound therapy

In order to have an idea of what these intensities may mean it is worth mentioning that the ultrasound machines used in physical therapy operate at intensities between 0.5 and 3 mW/cm^2. Therapy using these machines is based on tissue heating, particularly heating of boundaries between soft and connective tissue and bones. There exists an extensive body of data[1–3] on ultrasound machine outputs.

There is the ever-developing ultrasound-treatment field that includes lithotripsy, physiotherapy and 'ultrasound knives' of various types, particularly of brain and liver surgery. Therefore, it is sensible to consider how these applications, where the biological effect is the essence of the application, compare to diagnostic applications where, in ideal cases, information is gathered without causing any biological effect.

Physiotherapy devices use continuous waves or very long pulses of intensity between 0.5 and 3 W/cm^2. The mechanism used is heating. The therapist must continuously move the probe in order not to overheat some structure in the patient.

Lithotripsy is done with short pulses that 'bang' on the stones. Their average intensity is fairly low compared to the effects on the stones. However, their acoustic pressures are very high, reaching nearly 10 MPa. The range of pressures overlaps with the diagnostic equipment.

The important difference between these therapy applications and the diagnostic applications is the frequency, normally 10–50 times lower in therapy.

The application of ultrasound for treatment of disease in the mother may inadvertently lead to damage to the fetus if serious precautions are not taken.

Safety of diagnostic ultrasound in obstetrics

Obstetrics is a particularly sensitive field. A general rule is that fast growing and developing tissues are more sensitive to outside influences. This applies to embryonic and fetal tissues in particular. The potential hazard varies in extent and nature during the intrauterine development.

Before implantation, physical stress can cause abortion. After implantation, various tissues and organs become susceptible to damage at different times. Between 5 and 10 weeks of gestation, the neural tube is prone to damage; the forebrain development is particularly important until the 20th week of gestation. The development of the right and left side of the brain is not symmetrical in time, nor is the end result. Thus, it is important to be aware of possible neurological effects and that such effects may show as some sort of sidedness.

Heating and its effects

The human body is a thermodynamic system. Chemical reactions depend on the temperature. The sensitivity of the reactions dictates the very narrow temperature span in which the human body operates well.

A very long temperature increase of 1.5°C above 37°C does not present a health hazard for humans.[6–10] It has been shown that exposure of mouse embryos for 5 min to a temperature increase of 4°C is hazardous for their development. The temperature range between the two extremes both in temperature and duration is the present 'gray zone' of knowledge. The consensus is that exposure of adult proliferative tissue to heat at 42°C for up to 2 h[11] can cause only reparable damage. The effects are proportional to I_{SPTA} and the absorption coefficient. The absorption coefficient is proportional to frequency. Absorption also depends on the tissue type. In the case of longitudinal waves, absorption is at least an order of magnitude greater in bone than in soft tissues. Bodily fluids absorb very little so that they are unlikely to heat up due to the traversing of ultrasound. Tissues with high connective tissue content absorb more. However, they allow little attenuated ultrasound to reach structures positioned beyond them. On the other hand, the absorption of shear waves is very high in soft tissues and, thus, if any shear wave is induced in a bone it will be absorbed within a millimeter in the adjacent soft tissue. This may then significantly increase the temperature on such a boundary. Blood vessels and perfusion in the target area act as a cooling system and take the heat away. If the perfusion is poor, the heat may accumulate. Fatty tissue and bones are structures with relatively poor perfusion and little consequent cooling. The heating may have multiple maxima, i.e. near the transducer at the focus and at specific media interfaces. The main problem may be the heating of nervous tissue caused by absorption within itself, by heating at the adjacent bone/soft tissue boundaries (skull vertebrae). The same applies to bone marrow.[12] While it is known that hyperthermia can be teratogenic in animals, there is no study in large mammals confirming that diagnostic ultrasound-induced hyperthermia causes such effects. It should be borne in mind that a higher body temperature, e.g. due to fever, may increase the damaging ultrasound energy.

Non-thermal effects

Effects other than thermal are conceivable. In 1972, Hill considered the possibility of mechanical effects.[13]

Either cavitation or other forces induced by altering compression and rarefaction forces may damage the molecules of which the body is composed. Transient cavitation is known to have damaging potential, as collapsing bubbles generate shock waves that disrupt nearby structures. The temperature at the point of implosion is extremely high (a few thousand degrees). In addition, relatively stable, oscillating bubbles induce microstreaming of liquids around them, possibly causing changes in metabolism or mechanical damage to cell membranes. If cavitation is a possible cause of hazard then the mechanical index (MI)[14,15] accepted by the Food and Drug Administration (FDA)[16] might yield some means of comparing various scanners and modes of operation.

In order to measure the pressure *in situ,* it is necessary to take into account the attenuation in the intervening tissue. Using this convention, the attenuation is taken to be 0.3 dB/cm MHz. It is a good idea to have this index displayed on the screen in order to choose the operation regimen that yields the required data while maintaining the MI as low as possible.

Streaming[17,18] of absorbing and attenuating liquids due to ultrasound passage is due to the variation of energy concentration along the path (actually it is the change of the impulse). It depends on the attenuation coefficient of the liquid and its viscosity. Particles in the liquid can contribute to streaming. A particular type of streaming is microstreaming around an oscillating gas bubble.

The basic biological effect that would cause concern in the case of collapsing bubbles is the generation of free radicals. This could lead to alteration of chromosomes. If the free radicals are formed outside the membrane, the time needed for transport of such radicals to the nucleus is longer than their half-life. However, there is no confirmed evidence of chromosomal effects, particularly in living mammals.

Another possible non-thermal mechanism may be due to direct mechanical vibration of cell membranes. This might cause changes in ion (calcium in particular) permeability.[4]

The soft tissue to gas boundary may present a particularly favorable situation for mechanical effects because the gas side presents very low resistance. Rarefaction pressures may present a potential hazard when using high-energy Doppler with the beam hitting the lung.[19] However, the fetal lung is not at such risk as it is not filled with air. The reports of change in neurological development such as speech and handedness[20–22] have not been confirmed by independent studies.

Clinical aspects

The whole body of knowledge concerning the biological effects of ultrasound is relevant only if it helps in the estimation of whether diagnostic ultrasound as used today is hazardous for the patients and, if so, to what extent. It should be noted that even a significant change in rare conditions (for example, those that appear once in 10,000) may not be detectable, because the statistics require too great a number of controlled cases. In such investigations, we must concentrate on the type of damage that is most likely to occur, based on the understanding of the underlying mechanisms. Because of the bone/soft tissue interface the central nervous system is the most likely candidate for thermal damage. Damage of a small area in the brain may not yield easily detectable consequences unless it affects a sensory mechanism (vision, hearing, etc.). Other organs, once they consist of a large number of cells, can repair partial mechanical damage. If the damage happens early, destruction of a small number of cells may have very serious late consequences in the form of defective development.

While there is no independently confirmed experimental proof of such damage, the indications are that any effects are obtained only when the temperature rises by more than 2°C for a few minutes. With scanned beams and modern equipment, it is very improbable that such a long time would be spent at one spot.

The application of echo/contrasts ought to be restricted to adult scanning for the time being, because the existence of microbubbles may increase the probability of non-thermal effects.

In vitro experiments yield a variety of demonstrated effects.[13,23,24] Such experiments can help indicate the direction of investigation in whole organisms, but they lack the important property of living tissues, namely, that the individual cells are interconnected in a tissue unlike cells suspended in a culture. Under such conditions, the probability of non-thermal mechanisms occurring is much higher than in whole tissues.

All the experimental indications of damage caused by diagnostic ultrasound, although independently confirmed, indicate that the probability is low. This means that in practice caution is advised, but no absolute recommendation against the use of diagnostic ultrasound measurements is advised.

Standards and labeling recommendations

There are no easy methods for measuring the temperature increase in a patient *in vivo*. Thus, it is necessary to resort to estimates based on experimental work. Present solutions to this problem are certainly approximate and partial, but the pressure of the reality warrants such approaches. The National Council on Radiation Protection and Measurements (NCRP) and The American Institute of Ultrasound in Medicine/National Electrical Manufacturers Association (AIUM/NEMA)[14] have developed models. The latter body has devised an index for estimating the heating likelihood, which is not expected to exceed under normal circumstances. This so-called thermal index (TI) may be displayed on the screen to give the operator real-time relative guidance on the potential heating of the

tissues scanned. The value applies to the situation *in situ*. There exists no internationally accepted standard for any of the proposed indicators of thermal hazard. The AIUM/NEMA TI provides an estimate of temperature increase. By convention, TI is the ratio of total acoustic power to the acoustic power required to raise tissue temperature by 1°C. Although its basis is an approximate calculation of the actual temperature increase for a 'standard' tissue at a distance, it may not be interpreted literally. It is a relative indication of the possible temperature increase. The subvariants of the TI are meant for specific situations, i.e. TIS for homogenous soft tissue, TIC for temperature increase of bone near the surface (e.g. skull) and TIB for temperature increase at the bone boundary in the beam focus area. Using this labeling standard, if the scanner is not capable of producing a TI >1, it does not have to be displayed. Other national and international bodies have conceived other means of estimation. The capability of an ultrasound system to cause heating may be described by the ratio of acoustic power to the maximum temperature rise. The idea is to perform an actual worst-case calculation and to define the conditions (and instrument settings) that yield the maximum temperature increase so that all else is less hazardous. This is still under development, as a consensus about the tissue and beam properties has not been achieved.[11] Various sources give differing data[9,25–28] on ultrasound absorption in tissues and its action upon them. Nevertheless, the ultimate aim should be a consensus in recommendations given by various bodies and organizations. This should be based on realistic estimates of the possibility of ultrasound-induced heating. This is, among other things, an important guideline for the industry to discontinue the increase in ultrasound energy outputs in new apparatus models.

This leads to guideline conclusions by expert groups, e.g. European Federation of Societies of Ultrasound in Medicine and Biology (EFSUMB) Watchdogs or the AIUM bioeffects committee, which came to the consensus that when using the I_{SPTA} of 720 mW/cm^2, the maximum temperature rise *in situ* would not exceed 2°C, and thus will be safe to use. The present FDA regulation gives I_{SPTA} values of 720, 430, 94, 17 mW/cm^2 for peripheral vessel, cardiac, fetal and ophthalmic (i.e. eye lens) applications, respectively. The regulation is not limited to I_{SPTA} but includes an MI. Measurements in humans would be difficult or unduly aggressive and thus are impossible. Experiments on excised tissue or experimental animals cannot be directly extrapolated to humans but give important guidelines as to where to look for danger. The time-limited soft tissue experiments with ultrasound pulses equivalent to pulsed Doppler mode have shown heating below 2.5°C in various experiments. However, higher temperature increases have been measured in animals at skull bone/brain boundaries.[11]

The safety of Doppler ultrasound

In general, it is emphasized that ultrasonic examination should be performed only for medical indications, and diagnostic ultrasound users should recognize the sensitivity of young biological tissues of developing embryos and fetuses exposed to intense ultrasound.[10] The users also should know the ultrasonic intensity of their devices, the mechanisms of ultrasound bioeffect, and the prudent use of the devices, because they are responsible for the ultrasound safety. An important ultrasound bioeffect is thermal effect due to temperature rise induced by ultrasound absorption, because malformations were reported in the exposure of animal embryos and fetuses to high temperature in biological experiments. No hazardous thermal effect is expected when the temperature rise of exposed tissue is less than 1.5°C, and local temperature is lower than 38.5°C.[29] Five minutes' exposure to 41°C temperature can be hazardous to the tissue. Inertial cavitation and other mechanical effects are concerned in the non-thermal bioeffects of ultrasound.

The intensity of Doppler ultrasound

No hazardous thermal effect is expected in common B-mode imaging device because of minimum heat production due to low ultrasound intensity, i.e. the World Federation of Ultrasound in Medicine and Biology (WFUMB)[29] concluded that the use of simple imaging equipment is not contraindicated on thermal grounds. The real-time B-mode, simple 3D and 4D imaging devices, ultrasonic fetal heartbeat detector and fetal monitor are included in the category. Diagnostic ultrasound safety was established in Japan, after the Japanese Industrial Standard regulated the output power of diagnostic ultrasound devices below 10 mW/cm^2 in 1980, which was 1/100 of hazardous CW ultrasound[30–32] intensity at 1 W/cm^2. However, ultrasound safety has been discussed again after the introduction of Doppler flow velocity measurement, because pulsed Doppler method required definitely higher power than B-mode ultrasound.

Maximum intensity of commercial Doppler ultrasound is 1–3 W/cm^2. It is definitely higher than that of B-mode imaging, and it is the level of ultrasound physiotherapy for the tissue heating. Ultrasound safety is important even in physiotherapy, e.g. the therapeutic transducer should be always moved on the bone, so young bone and pregnant women are contraindicated for physiotherapy. The difference between therapeutic ultrasound and pulsed Doppler is exposure duration, i.e. it is short in Doppler flow measurement and long in therapeutic ultrasound. Therefore, thermal effect is a big concern in Doppler ultrasound bioeffect. Temperature rises not only at the sample volume, but also in all tissues passed by the ultrasound beam. The International

Table 37.1 Relation of non-hazardous exposure time (*t* min) to the temperature rise above 37°C and absolute temperature is calculated by Eq. (2), which is obtained from the results of experimental heating of animal fetuses[34]

Temperature rise (°C)	Absolute temperature (°C)	Non-hazardous exposure time; *t* (min)	log *t*
1	38	1000.0	3.00
2	39	251.8	2.40
3	40	63.10	1.80
4	41	15.85	1.20
5	42	3.98	0.60
6	43	1.0	0

Society of Ultrasound in Obstetrics and Gynecology (ISUOG) has also discussed the safe use of Doppler ultrasound.[33] Ultrasound intensity is less in color/power Doppler flow mapping due to the scanning procedure than in pulsed Doppler because of stable irradiation. Temporal averaging intensity of common color Doppler ultrasound is also less than 720 mW/cm^2, which is lower than in pulsed Doppler devices, and lower than the FDA regulation.[16] Thermal effect is discussed in the first place, due to possible teratogenicity of heating. Exposure duration is important for the safety of Doppler velocimetry.

The effect of heating on mammal fetuses

A teratogenic effect was reported by the biologists after the exposure of animal embryos and fetuses to high temperature, that is, malformations were found in various species by experimental heating. The temperature was 39–50°C. Teratogenic effect on mammals are summarized in the report of the National Council for Radiation Protection and Measurement (NCRP).[34] A discrimination line is found between the hazardous and non-hazardous areas in the NCRP report. There is no malformation if the fetus is heated in the area under the discrimination line, which is determined by connecting the points of high temperature/short exposure and low temperature/long exposure. Non-hazardous exposure is as short as 1 min in 43°C, and infinite in physiological body temperature. In case of ultrasound irradiation, TI indicates the temperature rise, therefore absolute temperature is obtained by summing 37°C and the temperature rise derived from TI.

Non-hazardous exposure time of the fetus to the heating

The guideline on the safety of mammals against heat can be found in the revised safety statement of AIUM[35] published in 1998, which is based on the NCRP report in 1992, where an inverse relation was found between hazardous temperature level and exposure time. AIUM[35] stated that the fetus tolerates 50 h at 2°C rise (absolute temperature is 39°C), and 1 min at 6°C rise (43°C). They also showed the relation of the temperature rise (T) above 37°C and non-hazardous exposure time (t min) by Eq. (1), and non-hazardous time (t min) is shown by Eq. (2), which is revised from Eq. (1):

$$T\,(^{\circ}\mathrm{C}) = 6 - [(\log_{10} t)/0.6] \quad (1)$$

$$t = 10^{(3.6 - 0.6T)} \quad (2)$$

The relation of non-hazardous exposure time and the temperature rise as well as absolute temperature is shown by Eq. (2) (Table 37.1, Figure 37.1). The safety regarding the thermal effect of ultrasound can be discussed by the relation of exposure time and temperature, when the heat production of Doppler ultrasound is estimated from TI, which indicates the temperature rise above 37°C in the worst case of temperature rise in ultrasound exposure to standardized tissue model, i.e. maximum temperature rise is known by TI.

Maintaining the safety of Doppler sonography

General safety of diagnostic ultrasound device

Electrical and mechanical safety is assured in ultrasound devices by the manufacturer under international and domestic guidelines. In a Doppler scanner, TI, MI, transducer temperature and other related indices are displayed on the monitor screen,[36] enabling the users to maintain the safety of ultrasound diagnosis by themselves. Obstetric setting should be confirmed before Doppler flow velocity measurements during pregnancy. Ultrasonic examinations should be done under medical indications. Although the ISUOG safety statement[33] reported that there is no reason to withhold the use of scanners that have received current FDA clearance in the absence of gas bodies, AIUM[35] stated that for the current FDA[16] regulatory limit of 720 mW/cm^2, the best available estimate of the maximum temperature increase can exceed 2°C. Pulsed ultrasound intensity threshold to

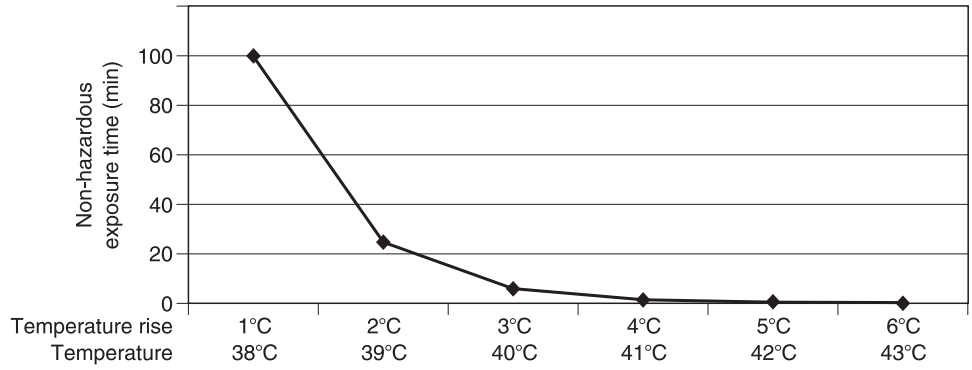

Figure 37.1 Relation of non-hazardous exposure time to the temperature rise between 1°C and 6°C above 37°C (38–43°C of absolute temperature) in experimental heating of animal fetuses[34] [graphed by Eq. (2)].

suppress cultured cell-growth curve was 240 mW/cm^2 in our studies.[32] The FDA regulation may be still controversial from the opinions and reports.

Thermal effect of Doppler scanner

The TI is a useful index of temperature rise induced by ultrasound exposure. Standard tissue models are exposed to ultrasound and TI is determined in the worst case, i.e. the highest temperature rise is the base of TI.[36] One TI stands for 1°C temperature elevation, and in the same manner, temperature rises for 3°C above 37°C, and absolute temperature is 40°C, if TI is 3. Local temperature rise is estimated only by TI at present, therefore TI is the index to estimate tissue temperature in ultrasound examination, to study the ultrasonic thermal effect, and to avoid the possible thermal hazard of intense ultrasound. TI and temperature rise are low in the soft tissue exposure, and high in the bone exposure. Soft tissue TI (TIS) is, therefore, used in the case of embryo that has no bone before 10 weeks of pregnancy, and bone TI (TIB) is applied for the fetus with bone after 10 weeks. Cranial TI (TIC) is the index for the intracranial flow examination.

No hazardous thermal effect is expected when the temperature rise of exposed tissue is less than 1.5°C, and local temperature is lower than 38.5°C, while a 5-min duration of 41°C can be hazardous to the tissue. Its temperature rise is 4°C above 37°C, and TI can be 4. Ultrasound examination is totally safe in the exposure with TI <1. In daily practice, therefore, TI should be <1, particularly in the long fetal examination, the screening of pregnancy or the research study of no limit. The output power is reduced if TI >1 on the monitor, then TI decreases to the level <1.[36] Clear flow velocity waveform is recorded and even output power is reduced to 60% in the experiment on the small hand artery.

The revised safety statement of AIUM[35] stated that an equal or less than 2°C temperature rise above 37°C showed no adverse effects with exposure duration up to 50 h, and that the upper limit of safe exposure duration was 16 min at 4°C rise and 1 min at 6°C rise above normal, respectively. The AIUM opinion on the effect of high temperature is similar to the report of NCRP,[34] and the safety statement is acceptable if the temperature rise is accurately determined by the TI, because TI indicates the worst tissue temperature elevation due to ultrasound exposure in clinical study.

Although the revised safety statement is useful in a retrospective safety confirmation after ultrasound exposure of known exposure time and TI, fetal exposure to the temperature rise for 4–6°C may be controversial, where absolute temperature is 41–43°C. Non-hazardous exposure time at temperatures higher than 40°C is critically short in the NCRP report[34] and AIUM statement,[35] where the safety margin remains very narrow,[2] excess heating may not be completely avoided and it may be imperfect to precisely keep strict exposure time at the highest temperature. The aim of this report is, therefore, to propose a practically applicable safe exposure time in the prospective situation before a Doppler ultrasound diagnosis.

Two modes in the time of exposure to diagnostic ultrasound

Two modes can be classified in the use of Doppler ultrasound. The TI <1 (AIUM) or the temperature rise below 1.5°C (WFUMB) after temperature equilibrium can be adopted for the infinite exposure. Therefore, this mode is suitable for research work, where exposure duration is rarely determined before the study. TI may also be <1 in the screening of the fetus during pregnancy and in fetal heart rate monitoring.

A pulsed Doppler study is another situation where the user requires improved Doppler flow wave by using TI >1. In some ultrasound lectures, the speakers stated that in the Doppler studies safety was proved by shortened exposure when TI >1. The technique is the same as in the NCRP report,[34] which proved non-hazardous by the short exposure to high temperature. Therefore, the Doppler examination with TI >1 can be also non-hazardous by the short exposure.

The relation of non-hazardous exposure to high temperature, high temperature rise and large TI is

Table 37.2 Thermal index (TI), tissue temperature, non-hazardous exposure time in the NCRP report,[34] the safety factors and exposure time to ultrasound are listed. Although the user can voluntarily set the safety factor and exposure time, we recommend choosing the safety factor at 50 and exposure time at 5 min when TI is 2

TI	Absolute temperature (°C)	Non-hazardous exposure time of NCRP report (min)	Exposure time (min) obtained by dividing non-hazardous exposure time of NCRP report by various safety factors			
			Safety factor			
			3	**10**	**50**	**100**
6	43	1	0.3	0.1	0.02	0.01 (no use)
4	41	16	5	0.2	0.03	0.02 (no use)
3	40	64	21	6	*1*	0.6
2	39	256	85	25	*5*	2.5

achieved by using Eq. (2) (Table 37.1 and Figure 37.1). Exposure time is as long as 250 min, about 4 h, when TI is 2 and temperature is 39°C, 1 h if TI is 3 and temperature 40°C, and 15 min even if TI is 4, where the temperature is 41°C according to the reports of NCRP[34] and AIUM.[35] These criteria are extremely useful in the retrospective confirmation of Doppler ultrasound safety of past examination. However, the prospective exposure time setting before examination should be further discussed.

Prospective exposure time setting before Doppler examination

Exposure time is preset before the Doppler examination, where the TI is voluntarily increased to >1 with the intention of improving Doppler flow. The NCRP report is the base of decision, where non-hazardous exposure time is determined by the temperature rise estimated by TI (Tables 37.1 and 37.2, Figure 37.1). It is unique in the present proposal that the non-hazardous exposure time obtained is divided by the 'safety factor' of 3–100, and actual exposure time is obtained. The procedure was the same as the past regulation of simple ultrasound devices in Japan, where hazardous threshold intensity of CW ultrasound in our experimental study was divided by the safety factor of 100 and output intensity was regulated to be lower than 10 mW/cm^2. There was no problem in the safety of dagnostic ultrasound before the introduction of Doppler flow studies. Though the factor is voluntarily changed by the user, appropriate values will be discussed in this paper. As ultrasound intensity may increase by about three times in the case of standing wave, 3 is the lowest safety factor. The intensity increases due to the distortion of ultrasound wave, and the possible estimation error of TI[11] or others are further added to the safety factor.

For example, non-hazardous exposure time is 252 min at 39°C (Table 37.1), where the temperature rises for 2°C and corresponding TI is 2. If the safety factor is 50, 252 min is divided by 50, and the exposure time is 5 min. By the same procedure, 1 min of exposure time is preset when TI is 3 (Table 37.2). The safety factor of 100 may be too conservative, though the factor can be selected by the user. Mildly longer exposure than the preset value may be included in the safety factor in most cases. Possibly 50 is the appropriate safety factor in the actual Doppler examination. The exposure time setting is coincidentally close to the safety statement of the British Medical Ultrasound Society (BMUS),[37] where the exposure time is 4 min when TI is 2 and 1 min if TI is 2.5.

The users can voluntarily change the safety factor and prolong the exposure time, because they are responsible for the ultrasound safety. However, they may also be responsible at the same time for the increased risk factor caused by the reduction of the safety factor.

Other thermal issues

Ultrasound thermal effect has been discussed mainly in relation to teratogenicity in the first trimester, whereas animal fetal skull or the brain surface was heated and the temperature elevation was more than 4°C by the exposure to intense ultrasound.[38] Thermal damage of the brain cannot be denied in this case. Therefore, the use of maximum intensity level of Doppler ultrasound is inadvisable in the flow study even in late pregnancy.

Caution should be used regarding the temperature of the tissue exposed to Doppler ultrasound in febrile patients, where the basic temperature is higher than 37°C. For example, if TI is 2 in a 38°C febrile patient,

the temperature rise above the physiologic condition is 3°C, the situation is the same as TI 3 in non-febrile normal temperature cases, and therefore, 1 min of exposure time is allowed if the safety factor is 50.

Exposure duration should be recorded by the user in every study of voluntarily increased exposure time, while TI which appeared on the monitor screen is recorded on the photograph or computer memory. The safety indices including TI and MI are recommended to be described in the 'Methods' section of the reports of Doppler ultrasound study on human subjects.

Transducer temperature in transvaginal scan

The transvaginal scan user should be careful about the direct heating of the attached tissue due to high surface temperature of the transducer, which directly attaches to the vaginal wall, and because the subjects are closer to the transducer than to the abdominal ultrasound. The transducer temperature, which is displayed on the monitor screen, should be lower than 41°C. Every intracavitary scan user should also be careful of the transducer temperature.

Mechanical effects of diagnostic ultrasound

MI is used for the estimation of mechanical bioeffect. It is rarefactional sound pressure expressed in megapascals, divided by the square root of ultrasound frequency (MHz). The MI indicates the non-thermal bioeffect of ultrasound, particularly in the collapse of gas bubbles in various liquids. Although gynecologic examination by contrast medium is still infrequent, its common use in adult circulation should be carefully studied in the mechanical bioeffect. Although common B-mode imaging devices are low in the thermal effect, its mechanical effect is similar to the Doppler devices because instantaneous intensity of its ultrasound pulse is not much different from Doppler machines, and therefore, even simple imaging devices should be carefully handled in relation to mechanical effect. It is rare to use contrast medium in obstetrical tissue; free radicals formed in the liquid due to inertial cavitation hardly reach the floating cells because of their short life, and no cavitation may occur within the cell due to the high viscosity of cell plasma. However, the biological effects of acoustic streaming, capillary blood cell stasis by the standing wave, or direct ultrasonic pressure require further basic studies. As hemorrhage is found in the lung of neonatal animals after the exposure to intense ultrasound, MI <1 is recommended particularly in neonatal lung examination. The International Electrotechnical Commission (IEC) is working on the classification of diagnostic ultrasound devices by the MI.

Conclusion

Diagnostic ultrasound safety has been mainly discussed on the thermal effect. Simple real-time B-mode, 3D and 4D imaging devices, fetal heart detector and fetal monitor are not contraindicated due to thermal effect, because of their very low ultrasound intensity. Doppler flow machines are mainly discussed with thermal effect, because of their definitely high ultrasound intensity. Safe fetal exposure time to ultrasound determined by the NCRP criteria on the exposure to high temperature estimated by TI is useful in the retrospective evaluation of past ultrasound examination. In prospective estimation of ultrasound safety in daily practice, the principle of safe diagnostic ultrasound is the reduction of ultrasonic intensity and exposure time when displayed TI is >1. The research work and pregnancy screening follow the principle. Moderately higher TI is allowed in clinical study when the users require more improved Doppler flow wave by increased intensity, where a limited short exposure time is prescribed and the users adhere to the preset time by their own responsibility. We recommend using the non-hazardous exposure time of the NCRP report after dividing it by the safety factor of 50, where exposure time is 5 min if TI is 2, and 1 min if TI is 3. Higher TI or longer exposure may be applied by reducing the safety factor under the users' responsibility. Attention should be paid to the decreased safety in the febrile patient. Transvaginal transducer should be used under 41°C. The mechanical effect may be similar in simple B-mode Doppler devices. MI is recommended to be <1 in ultrasound examination, particularly in the studies on air in neonatal lung.

38 Behavioral perinatology assessed by four-dimensional sonography

A. Kurjak, J. M. Carrera, W. Andonotopo, G. Azumendi, M. Medic and A. Salihagic-Kadic

Three-dimensional (3D) ultrasound has been available for more than 10 years. However, the 3D image freezes the object and therefore does not provide information on movements or any information about the dynamic changes in the object of interest. A technique was needed that would enable 3D imaging to be performed in a real-time mode. This technique has been recently introduced and has been called 4D sonography, because time becomes a parameter within the 3D imaging sequence. This new diagnostic tool enables the continuous monitoring of the fetal face and other surface features of the fetus such as fetal extremities. This permits exciting new possibilities for the study of fetal behavior.

Four-dimensional ultrasound provides a new tool for observation of the fetal face. Simultaneous imaging of complex facial movements was not possible using real-time 2D ultrasound. Four-dimensional ultrasound integrates the advantage of the spatial imaging of the fetal face with the addition of time. This new technology therefore allows the appearance and duration of each facial movement and expression to be determined and measured.

In a relatively short period of time 4D sonography has stimulated many multicentric studies on fetal behavior and even fetal awareness with more convincing imaging and data than those obtained by conventional ultrasonic and non-ultrasonic methods. The purpose of this article is to review and illustrate presently available data on 4D ultrasound fetal behavior imaging in all three trimesters of pregnancy.

Neurophysiology of fetal behavior

For centuries, maternal registration of fetal movements and obstetrician auscultation of fetal heartbeats were the only methods of follow-up of fetal well-being *in utero*. However, during the past few decades, the development of ultrasonic techniques has enabled the direct visualization of the fetus *in utero*, as well as the real-time assessment of fetal activity. Ultrasonic studies have revealed the fascinating diversity of fetal intrauterine activities. It has been shown that fetal activity occurs as early as the late embryonic period, which is far earlier than a mother can sense. Furthermore, qualitative and quantitative aspects of behavioral patterns expand rapidly as the pregnancy progresses, and the random movements of the fetal body, which are the earliest sign of fetal activity, change into the well-organized behavioral patterns observed late in gestation. Analysis of the dynamics of fetal behavior has led to the conclusion that fetal behavioral patterns directly reflect the developmental and maturational processes of the fetal central nervous system (CNS). Nevertheless, the ultrasound findings and their relevance in the assessment of the development of the CNS can be interpreted only in comparison with the structural developmental events in the particular period of gestation. Therefore, understanding the relation between fetal behavior and developmental processes in different periods of gestation may make possible the distinction between normal and abnormal brain development, as well as the early diagnosis of various structural or functional abnormalities.

Structural development of human CNS

All the neurons and glial cells originate from the embryonic ectoderm, precisely a structure called the neural plate. During the fourth postconceptional week, the neural plate bends into a neural tube, whose further growth reshaping and histological characteristics directly reflect complicated histogenetic processes. The results of those processes are specific transitional embryonic zones, which cannot be observed in an

Table 38.1 Dynamics of the most important progressive processes in the development of the human brain

	Beginning	The most intensive period	Ending
Proliferation	3–4 weeks of gestation	8–12 weeks of gestation	Approximately 20 weeks of gestation
Migration	Simultaneously with proliferation	18–24 weeks of gestation	38 weeks of gestation
Synaptogenesis	8 weeks of gestation	13–16 weeks of gestation, after 24 weeks of gestation, eighth month to second year of postnatal life	Puberty

adult brain. Three embryonic zones, ventricular, intermediary and marginal (seen from ventricular to pial surface), are present in all parts of the neural tube, whereas the telencephalon contains two additional zones, subventricular and subplate.[1]

Histogenetic processes are proliferation, migration and differentiation of neurons and glial cells, as well as the synaptogenesis and development of chemical specificity of neurons. The dynamics of the main hystogenetic processes is shown in Table 38.1.

It is important to point out that proliferation of neurons and glial cells occurs only in the ventricular zone and in the subventricular zone of the telencephalon. All the future neurons and glia originate from these zones, form other transitional zones during their migration toward the pial surface and finally reach their permanent position and form the permanent synapses. The early appearance of interneuronal connections, shown in Table 38.1, implicates a possibility of an early functional development. However, these first synapses exist only temporarily and disappear due to the normal developmental processes. That is, simultaneously with these progressive processes, so-called reorganization processes occur. Some embryonic zones, types of neurons and glia and synapses that play a crucial role in certain periods of fetal brain development eventually disappear, significantly changing the structure and function of the brain. Reorganization processes include apoptosis, disappearance of redundant synapses, axonal retreat and transposition, and transformation of the neurotransmitters' phenotype. The temporal overlapping of the major histogenetic processes during the fetal brain development can be seen only in primates.

Obviously, the development of the human brain is not completed at the time of delivery. In an infant born at term, characteristic cellular layers can be observed in motor, somatosensor, visual and auditory cortical areas. Although proliferation and migration are completed in a term infant, synaptogenesis and neuronal differentiation continue very intensively.[2] The brain stem demonstrates a high level of maturity, whereas all histogenetic processes actively persist in the cerebellum.[3] Therefore, only subcortical formations and the primary cortical areas are developed completely in a newborn. Associative cortex, barely visible in a newborn, is scantily developed in a 6-month-old infant. Postnatal formation of synapses in associative cortical areas, which intensifies between the eighth month and the second year of life, precedes the onset of the first cognitive functions, such as speech. Following the second year of age, many redundant synapses are eliminated. The elimination of synapses begins very rapidly, and continues slowly until puberty, when the same number of synapses as seen in adults is reached.[3]

Functional development of the fetal nervous system

The functional development of the human fetus cannot be studied directly, but ultrasonic studies have made possible the visualization of the fetal motor activity *in utero*. The ultrasonic studies of fetal spontaneous motor activity and the motor responses to stimulation, in comparison with the morphological studies and experiments on animal models, have given us an insight into the complex dynamic of fetal development. An overview of the functional development of the fetal nervous system, which will be discussed further in the text, is given in Table 38.2.

Fetal motor development

The first synapses in the human nervous system appear approximately simultaneously with the formation of the cortical plate, i.e. around the eighth postconceptional week.[4,5] It is the period when the earliest electrical activity and transmission of information[6] occurs. The first spontaneous fetal movements were observed at 7.5 postconceptional weeks. These movements, consisting of slow flexion and extension of the fetal trunk accompanied by the passive displacement of the arms and legs[7] and appearing in irregular sequences, were described as 'vermicular'.[8] In a little while, they are replaced by various general movements, which include the head, trunk and limb, such

Table 38.2 Chronology of the functional development of fetal nervous system. Detailed description is given in the text

Weeks of gestation	Motor system	Sensor system	Circadian rhythm
6	Earliest spontaneous movements, gross body movements	Development of taste buds; development of nociceptors	
7		Generalized movements after cutaneous stimulation	
8	Movements of extremities, head and trunk; isolated limb movements	Localized movements after cutaneous stimulation	
9			
10	Sporadic breathing movements; spontaneous movements observed over 15% of 24-h time	Peripheral afferents from nociceptors to spinal cord begin to form – reflexive reactions to pain; cutaneous reflexes seen in hands	
11			
12			
13			Spontaneous movements and breathing movements associated with heart rate acceleration
14	Facial movements – swallowing, yawning, grimacing; very intensive motor activity, 15 different types of body movements can be observed; sporadic eye movements	Legs sensitive to cuntaneous stimulation – reflexes	
15		Secretion of leptin and VIP-possible regulators of appetite	
16			
17			
18		Alterations in cerebral blood flow in response to painful stimuli	
19			
20		Nociceptors present all over the body	
21			
22			
23		Elevation of cortisol and beta endorphin levels in response to painful stimuli	
24	Breathing movements eye observed over 14% of 24-h period		Consolidation of movements – alternation of EM and NEM periods
25		Cochlear function established (22–25 weeks); response to vibroacoustic stimulation without lag time	
26

as 'rippling' seen at 8 weeks, 'twitching' and 'strong twitching' at 9 and 9.5 weeks, respectively, and 'floating', 'swimming' and 'jumping' at 10 weeks.[9] Isolated limb movements appear almost simultaneously with the generalized movements.

Simultaneously with the onset of spontaneous movements, the earliest cutaneous reflex activity can be observed, allowing the assumption of the existence of the first afferent–efferent circuits (Table 38.2). The first reflex movements are massive and indicate a very limited number of synapses in a cutaneous reflex pathway.[10] At that time, head tilting after perioral stimulation is noted. During the eighth week of gestation these massive reflex movements are replaced with local movements, probably due to an increase in the number of axodendritic synapses. Hands become sensitive at 10.5 weeks and lower limbs begin to participate in these reflexes approximately at 14 weeks.[10–14] From the 10th week onward, the number and frequency of movements increase. By 14–19 weeks, the fetus is very active, with the longest period of inactivity lasting only 5–6 min. In the 15th week, 15 different movements can be observed. Besides the general body movements and isolated limb movements, retroflection, anteflection and rotation of the head can easily be seen. Moreover, face movements such as mouthing, yawning, hiccups, suckling and swallowing can be added to a wide repertoire of fetal motor activity in this period (see Table 38.2).[15] However, in such an early gestational period, the dynamic pattern of neuronal production and migration, as well as the immature cerebral circuits, are considered too immature for the cerebral involvement in the motor behavior (for a review see Kostovic *et al.*[16]). Only at the end of this period do a quantifiable number of synapses appear in the structures preceding the cerebral cortex, probably forming a substrate for the first cortical electric activity, noted at the 19th week.[16] Studies of anencephalic fetuses have also provided apparent evidences that around 17–20 gestational weeks, motor behavior becomes influenced by the supraspinal structures. That is, in these fetuses the incidence of movements was normal or even increased, but the complexity of movement patterns changed dramatically and movements were stereotyped and simplified.[17,18]

The number of spontaneous movements tends to increase until the 32nd week of pregnancy, when their frequency begins to decrease.[19–21] By term, the average number of generalized movements per hour was found to be approximately 31, with the longest period between movements ranging from 50 to 75 per min.[22] This decrease is considered a result of cerebral maturation processes, rather than a consequence of the decrease

in the amniotic fluid volume. Simultaneously with the decrease in the number of generalized movements, an increase in the facial movements, including opening/closing of the jaw, swallowing and chewing, can be observed. These movements can be seen mostly in the periods of absence of generalized movements and that pattern is considered to be the reflection of the normal neurological development of the fetus.[19] However, the changes in not only the number of movements but also their complexity are shown to be the result of maturational processes. Our recent 4D ultrasound study, which will be described later in the text, has shown an even wider repertoire of fetal face and hand movements in the third trimester of gestation than has been previously described.[23] Obviously, the story of fetal intrauterine activity is far from being completed and the development of new recording techniques could enrich our perspective of the intrauterine life. It has been demonstrated that the fetal movement patterns in the second half of pregnancy are almost identical to those observed after birth,[24,25] although the repertoire of movements in newborns includes some patterns that cannot be observed in the fetus, such as the Moro reflex.[26] The detailed description of fetal movement patterns at different gestational ages, studied by conventional as well as 4D ultrasound, will be given later in the text.

Many factors, such as cigarette smoking[27] or injection of corticosteroids for fetal lung maturation,[28] were proved to decrease the number of spontaneous fetal movements. Furthermore, fetal activity is increased in mothers suffering some kind of emotional stress.[29] The quality of fetal movement patterns is altered in fetuses suffering intrauterine growth restriction. The movements become slower, monotonous, resembling cramps, and their variability in strength and amplitude is reduced. These changes could indicate the existence of brain lesions in growth-restricted and possibly hypoxic fetuses. That is, despite the earlier assumptions, the alterations in the amplitude and complexity of movements in these fetuses do not appear due to oligohydramnios. In cases of premature rupture of fetal membranes and a subsequently reduced volume of amniotic fluid, movements occur less frequently, but their complexity resembles that of movements performed in the normal volume of amniotic fluid (for a review see Prechtl and Einspieler[30]). Obviously, the qualitative as well as quantitative analysis of fetal movements reveals the integrity of the fetal nervous system, and can be used for the detection of various cerebral dysfunctions, and probably neuromuscular diseases.[29,30]

Development of specialized movements

Studies on animals, especially various species of mammals, as well as their comparisons with the ultrasonic recordings of human fetuses, have revealed that some specialized movement patterns, crucial for the survival of newborns, such as swallowing or rhythmic respiratory movements, develop and mature during gestation. Although these patterns differ somewhat from adult patterns, in the near-term fetuses they are developed sufficiently to enable the survival of the fetus.

In the human fetus, breathing movements occur around the 10th week of gestation.[31] Early in gestation, they are present almost continually and are associated with the activity in the postural muscles of the neck and limbs. However, the frequency and complexity of the breathing pattern change as pregnancy progresses. The total breathing time in a 24-h interval extends, as well as the duration of individual breathing and non-breathing intervals.[32,33] Changes in breathing patterns are considered to be a result of the maturation of the fetal lungs and respiratory and sleep centers in the fetal CNS. In the 38th and 39th weeks of gestation, frequency of movement decreases to 41 respirations per minute and the movements become as regular as in the postnatal period.[34] Approximately at the 30th week of gestation, the regulation of fetal breathing movements by the plasmatic level of carbon dioxide is established and the number of respirations increases following an excess of carbon dioxide in maternal blood.[35,36] This sensitivity to the alterations in the plasmatic carbon dioxide level is connected to the maturation of fetal respiratory neural centers, which is thought to occur during the last 10 weeks of pregnancy (see Table 38.2).[37] The process of maturation of fetal breathing movements is accelerated in some conditions such as premature rupture of membranes. For instance, decrease in fetal breathing has been observed following premature rupture of membranes[38,39] and during the three days prior to the initiation of labor.[37,40] Kisilevsky *et al.* compared the body movements and breathing patterns in normal fetuses at 24–33 weeks of gestation and fetuses threatening to deliver prematurely. High-risk fetuses had a reduced level of body movements and an earlier onset of extended periods of breathing, which occurred at 30 weeks in contrast to 33 weeks in the control group.[41] However, in this study, accelerated maturation of breathing was not observed in the presence of ruptured membranes. Fetuses delivered prematurely had less breathing than those delivered at term. Maternal consumption of alcohol or methadone and, according to some authors, even cigarette smoking, is known to decrease the incidence of breathing movements.[42–44] On the other hand, aminophiline, used for the treatment of bronchial asthma, as well as conjugated estrogens and betamethasone increase the frequency of breathing.[45,46] An increased number of fetal movements following the elevation of the glucose concentration in maternal blood has been noted at the 34th week of gestation.[47,48]

Another indispensable prerequisite for the survival of the newborn is the ability to feed, i.e. to ingest food. In the human fetus, swallowing has been noted as early as 11 weeks of gestation,[49] with daily swallowing rates

near term of 200–500 ml.[50,51] Swallowing of amniotic fluid proteins and growth factors contributes to the growth and maturation of the fetal gastrointestinal tract, and possibly to the fetal somatic growth.[52] That is, the amniotic fluid provides 10–14% of the nitrogen requirements of the normal fetus, and esophageal atresia is often associated with lower birth weight.[53] Many authors agree that swallowing patterns develop *in utero* in all species in which there is significant fetal fluid excretion (urine and lung liquid) into the amniotic cavity. Thus, fetal swallowing contributes to the regulation of amniotic fluid volume.[52] In some, although not all cases with fetal esophageal atresia, the volume of amniotic fluid is increased. The normal volume of amniotic fluid in some of these cases could be explained by the coexistence of tracheoesophageal fistula, which could allow the intake of liquid during respiratory movements (for a review see Ross and Nijland[54]). Furthermore, polyhydramnios sometimes, though not always, develops in anencephalic fetuses. However, some of these fetuses have an intact swallowing reflex, whereas cases with normal amniotic fluid volume and decreased fetal swallowing have been described (for a review see Ross and Nijland[54]). Spontaneous fetal swallowing is, like most motor patterns, correlated with neurobehavior. The development of dypsogenic mechanisms and their influence on fetal swallowing will be described later in the text. Here, we have to emphasize that fetal swallowing patterns differ significantly from those seen in the adult and that the fetus daily swallows 5–10 times more fluid per body mass unit.[55]

Development of the fetal sensor system

The combination of ultrasonic studies, pathoanatomical examinations and studies of premature infants has provided a wide spectrum of evidence that the ability to register vibrations, acoustic stimuli and even light is acquired during intrauterine life. It is well known that the fetus can sense pain and respond to painful stimulus with a variety of responses, such as movements, circulatory and hormonal responses, although the question of the emotional response to pain or memorization of the unpleasant events *in utero* still remains unresolved. The fetus can also sense the taste of amniotic fluid and even functions such as appetite, satiety and thirst seem to be developed during intrauterine life (see Table 38.2).

Fetal vestibular and auditory system

It is generally accepted that reflexes of the brain stem, which include vestibulary, olfactory and auditory reflexes, develop early in gestation.[56] Vestibular ganglionic cells mature earlier than the neurons of lateral and inferior vestibule nuclei, which are functional from 9 gestational weeks onward.[57] Vestibule stimulation is thought to contribute to the development of fetal movements. That is, the gravity-free environment in the uterus appears to promote the development of vestibulary reflexes.[58] According to electrophysiological examinations of the evoked potentials in prematurely delivered healthy infants, cochlear function develops between 22 and 25 weeks of gestation, whereas its maturation continues during the first 6 months after delivery.[59–61] Maternal heartbeats and motility of the gastrointestinal tract during digestion appear to generate 90 dB of noise[62] *in utero*. However, fluid in the fetal ear as well as the immaturity of the cochlea complicate the transmission of sound, so that only strong acoustic stimuli can produce fetal reflex movements, such as startle motion of the trunk and/or flexion of the extremities, accompanied by changes in the heart rate. These are seen during or soon after vibroacoustic stimulation.[61] Applying acoustic stimulation with a wide spectrum of frequencies directly on the maternal abdomen, Shahidullah and Hepper have registered reflex movements with a short lag time in 20-week-old fetuses, and movements without the lag time in 25-week-old fetuses.[63] However, these movements were explained as a reflex response to vibroacoustic stimulation or proprioceptor stimulation. Kisilevsky *et al.* reported an increased number of fetal movements and heart rate during acoustic stimulation performed with the sound transmitter placed 10 cm above the maternal abdomen, in 30-week-old fetuses.[64]

Fetal vision

The intrauterine environment is not completely deprived of light. Moreover, some experimental results indicate that the development of visual and auditory organs could not be possible without any light or acoustic stimulation.[62] Although the structural development of sensor pathways is a prerequisite for functional development, the final organization of the brain circuitries relies predominantly on guidance from external output.[16] In the cortical area,[17] synaptogenesis persists between 24 weeks and 8 months after delivery,[65] whereas myelination of the optical tract begins at 32 weeks of gestation[66] and cones of the central foveola reach adult proportions late in childhood.[67]

Fetal pain

During the past decade, fetal perception of pain has been not only an object of interest for scientists, but also an important issue in public debates, in relation to late abortion and an increasing number of intrauterine operations. The pain consists of two components: perception of the stimulus and an emotional reaction or unpleasant feeling with regard to the noxious stimulus. These occur in two anatomically and physiologically distinct systems in the brain. The response to painful stimulation can be regarded at three different levels:

somatosensory response, pain-induced autonomic and endocrinological reflexes and pain-related behavior (for a review see Vanhatalo and van Nieuvenhuizen[68]). In the human fetus, the first nociceptors appear at the seventh week of gestation and by the 20th week, these are present all over the body. Peripheral afferents begin to make synapses to the spinal cord, approximately during weeks 10–30.[69] The myelination of these pathways[70] and the development of functional spinal reflex circuitry occur almost simultaneously.[70,71] Higher parts of the pain pathways include the spinothalamic tract, established at 20 weeks and myelinated by 29 weeks of gestation,[72] and thalamo-cortical connections, which begin to grow into the cortex at 24–26 weeks.[66] Finally, at 29 weeks, evoked potentials can be registered from the cortex, indicating that the functional connection between periphery and cortex operates from that time onward.[12,71]

The earliest reactions to painful stimuli are motor reflexes, resembling withdrawal reflexes. These reactions are completely reflexive and are guided by the spinal cord. Higher perception or processing of painful sensation does not exist at this stage.[10] However, some investigators indicate that facial reflexes in response to somatic stimulation, which could indicate the emotional reaction to pain, develop rather early in gestation.[13] These reflexes are thought to be coordinated by subcortical systems and probably reflect development of these lower brain circuitries.[73] As for the autonomic responses to pain, an elevation of cortisol and beta-endorphin levels in plasma in response to needle pricking of the innervated hepatic vein was registered in a 23-week-old fetus, whereas the stimulation of the uninnervated umbilical cord had no effect.[74,75] Alterations in cerebral blood flow, i.e. blood flow redistribution during invasive procedures, were noted in an 18-week-old fetus.[76] These results indicate that painful stimuli trigger a wide spectra of reactions in the CNS, such as activation of the hypothalamic pituitary axis or autonomic reflexes, even without reaching the cortex. Furthermore, we have to emphasize that these hormonal, autonomic and metabolic responses can be neutralized by analgesics such as fentanyl.[76,77] The reduction of fetal responses to pain is extremely important because many studies have shown the influence of the early pain experiences on the later behavioral variables or on the later developmental outcomes.[78] One of the most important effects of painful experience is a prolonged stress response.[79] It includes fluctuations in blood pressure and cerebral blood flow, and hypoxemia, which may predispose to intracranial hemorrhage.[76] Experiments on animals have revealed that elevated cortisol levels, equivalent to those secreted during the stress response in humans, were associated with degenerative changes in the fetal hypothalamus.[80] Finally, long-term follow-up studies of fetuses treated in the intensive care units (ICU) and exposed to pain and/or stress have demonstrated the correlations between the stay in ICU and altered pain thresholds and abnormal pain-related behavior later in life.[79,81] All these findings underline the importance of a stress-free environment for normal physiological and psychological development.

Fetal taste, appetite and satiety

It is generally believed that appetite and satiety functions develop during the intrauterine period in all precocial species. In the human fetus, taste buds are developed from the seventh week of gestation onward.[82] Sucrose increases swallowing in the human fetus, whereas the incidence of swallowing movements decreases following the injection of Lipiodol, a bitter extract of poppy seeds, into the amniotic fluid.[82] The main endocrine regulators of appetite, leptin and neuropeptide Y (NPY) are secreted as early as 15 and 18 weeks, respectively, in the human fetus, but the ontogeny and functions of their regulatory pathways have not been delineated in the human fetal brain.[83–85] However, experiments on animals have shown the increase of swallowing upon ingestion of NPY.[86] Swallowing was increased following the injection of leptin, which is in contradiction with leptin function in adults.[87] Therefore, some authors postulated that the presence of NPY pathways and the immaturity of leptin pathways may potentiate feeding and facilitate weight gain in newborns, despite high body fat levels.[52]

Development of dipsogenic mechanisms

Experiments on animal models, especially fetal lambs, have shown that dipsogenic mechanisms begin to modulate fetal swallowing during intrauterine life. For instance, in fetal lambs, swallowing and arginine vasopressin secretion increase following the central administration of hypertonic saline and angiotensin II.[88,89] Ross *et al.* have identifed the hypertonicity-activated neurons in dipsogenic hypothalami nuclei, such as the parvocellular and magnocellular division of periventricular nucleus and supraoptic nucleus in near-term ovine fetus.[90–92] These authors also suggested that exaggerated fetal swallowing under physiologic conditions (5–10 times more liquid in proportion to the adult) might be the result of tonic activation of angiotensin II receptors and production of nitric oxide.[93,94] Nevertheless, the fetus appears to have a reduced sensitivity to osmotic stimuli[95–97] when compared to the adult, despite the intact dipsogenic nuclei. Reduced swallowing during systemic hypotension despite the elevated renin plasma levels, together with the increased amount of liquid swallowed under normal conditions, indicates that fetal dipsogenic response might differ from that of the adult.[98]

Cyclic behavior and development of circadian rhythms

Fetal life *in utero* is organized in cyclical patterns. Periods of activity alternate with periods of rest.

The observation of human infants resulted in the hypothesis that the alternations of activity and inactivity periods reflect the elementary ultradian rhythm of the fetal CNS, uninfluenced by external input.

For instance, eye movements, which become observable at 16–18 weeks of gestation, begin to consolidate at 24–26 weeks of gestation, and the periods of eye movements (EM) begin to alternate with non-eye movement (NEM) periods. During the last 10 weeks of gestation, both switching and maintaining mechanisms responsible for this ultradian rhythms mature, and constant mean values of duration of EM and NEM periods are achieved by 37–38 weeks. At that time, EM and NEM last 27–29 min and 23–24 min, respectively, which is similar to the values in the neonate.[99] In the adult human, rapid eye movements (REM) are present during active sleep, alternate with the slow eye movements (SEM) or deep sleep and are accompanied by changes in electrocortical activity.[100] In the fetus, REM and SEM can be registered at 33 weeks of gestation. At 36–38 weeks of gestation, they become integrated with other parameters of fetal activity, such as heart rate and fetal movements, into organized and coherent behavioral states.[101]

In fetal animals, simultaneous measurements of fetal electrocortical activity, eye and body movements have shown that deep sleep, characterized by high-voltage waves and decreased fetal activity, occurred during 54% of the total time each day. The total length of REM sleep period, characterized by low-voltage waves and rapid eye movements, lasted 40% of the total time each day. Wakeful state (6% of the day) is characterized by low-voltage waves.[102] In human premature newborns, born 4 weeks prior to term, 60–65% of the total sleeping period is REM sleeping, whereas in a term newborn, the REM sleeping period is 50% of the total 16 h of sleep.[103] The intensive activity of neuronal circuits during REM sleep is thought to contribute to the development of the CNS.[103]

The circadian system is a kind of biological clock that receives information from the environment and sends efferent outputs that orchestrate circadian rhythms.[104] In mammals, the major role in orchestration of these rhythms is played by the suprachiasmatic nucleus (SCN) of the hypothalamus, which oscillates with a period of close to 24 h. Biological oscillations of SCN are entrained by the light/darkness cycle, which is registered by retinal receptors and transmitted by the retino-hypothalamical tract. Efferent pathways from SCN include projections into the various nuclei of the hypothalamus, and possibly, endocrine SCN secretion. In the human fetus, as well as other mammal species, SCN is developed by midgestation, but its maturation continues after birth, as shown by an increase in the number of neurons containing adrenalin vasoperssine and vasoactive intestinal polipeptide (VIP) during the first year of postnatal life (for a review see Kelly[104]). Circadian rhythms in behavior, cardiovascular function and hormones are present in human fetuses, as well as in fetal sheep and monkey, and are entrained to the light/darkness cycle. However, the question whether that rhythm is generated by the fetus itself or influenced by maternal rhythms remains to be resolved, although some animal experiments indicate the importance of the maternal SCN. In this case, the transmission of the signal to the fetus would necessarily require an endocrine mediator, but no such molecule has been identified yet. The latest results suggest the role of the maternal pineal hormone melatonin. This hormone is present in humans, as well as in other mammals, and its plasma concentrations exhibit daily variations, with the peak during the night. Therefore, its role in sleep induction has been suggested (for a review see Kelly[104]). Seasonal alterations in melatonin concentrations have also been reported. Daily oscillations of melatonin concentrations in plasma are present throughout gestation,[104] and various human tissues including the CNS express some types of melatonin receptors.[105,106] However, its role in the orchestration of fetal circadian rhythms remains to be confirmed.

Basic technology of 4D sonography

The rapid development of digital ultrasound systems allows 3D image reconstructions and, lately, 4D real-time inspection of anatomical regions and pathological changes. However, 3D images are static and do not provide information on movements and dynamic changes of the object of interest.[23] Moreover, fetal movements are the source of significant artifacts and volume scanning should be performed during the fetal inactive phase, i.e. whenever the fetus is active, qualitative 3D image is unobtainable. This fact limits the usage of classic 3D ultrasound. Four-dimensional ultrasound overcomes this disadvantage, making it possible to obtain qualitative 3D images regardless of fetal movements. The only limiting factor for 4D sonography is the quantity of adjacent amniotic fluid.

The acquisition of volume data sets is performed by 2D scans with special transducers (linear, convex, transvaginal) designed for 2D scans, 3D and real-time 4D volumes.[107] The real-time 4D mode is obtained from simultaneous volume acquisition and computing of 3D images, which is in fact multidimensional ultrasound.[108] The movement of the ultrasound beam over the region of interest (ROI) is automatic. Such a design enables simplified 3D and 4D acquisition. Ultrasound probes include a scanning mechanism moved by a built-in electromotor. The processing speed allows continuous acquisition and processing of 4D volumes.

The volume acquisition begins with a 2D image and superimposed volume box. The initial 2D image is the central 2D image of the volume. According to the dimensions of the volume box, the volume scan sweeps between the margins of the volume box. The

Figure 38.1 3D surface rendering of the normal hand movement. Note the alteration of the palm position.

volume box is set to frame the ROI. The following steps are important for producing reliable 4D images:

(1) Orientation in real-time 2D mode.
(2) Selection of ROI.
(3) Starting the volume scan. Volume data are shown in a multiplane display on the monitor (transverse, sagittal and coronal).

During the 3D and 4D acquisition, sweep time depends on the volume box size, scan quality and adjusted scan parameters such as depth, number of focuses and other parameters that affect the B-mode image frame rate.

Four-dimensional rendering

The pixel is the smallest element of 2D images, while the voxel is the smallest information unit in 3D and 4D imaging. Volume rendering provides visualization of animated voxel-based images on a 2D screen. Because of the development of instant computer technology and fast data transmission, volume acquisition and data processing are accelerated to enable 3D rendering in real time (4D). Fast volume data processing enables calculation of 5–30 volumes per second depending on the system hardware and size of the render box. As 4D imaging is almost a real time, there is always some delay as a result of the time needed to reconstruct 3D images from 2D scans. It is always desirable to achieve as many volumes per second (volume rate) as possible. The number of volumes per second is some kind of trade-off between image quality and frame rate. The quality of 3D and 4D images mostly depends on 2D image quality. Prior to volume acquisition it is important to achieve the best 2D image quality, adjusting depth, focus position and number of focuses, frequency and gain. All 2D image artifacts will be also present on 3D and 4D image reconstruction. Good 4D image acquisition depends on ROI size and volume box size, ROI position or direction of view and accessibility to the object. The render box determines the contents that will be rendered. Structures that are not selected by volume box will be cut from 3D reconstruction.

ROI can be sized, moved and rotated in all directions arbitrarily by the operator. Volume data can be acquired from different 2D modes: gray-scale imaging, CFI and power Doppler imaging. There are different rendering modes available: surface, transparent (maximum, minimum, x-ray) and light, some of them can be active simultaneously in real time.

Volume rendering is a process of visualization of 3D structures on an animated 2D screen and rendering modes determine how the 3D image will be presented on screen.

Surface rendering or gray-scale rendering

In the surface rendering mode, only signals from the surface of ROI are extracted and displayed in the plastic appearance. Surface rendering examination of the fetus focuses the sonographer's attention exclusively on the fetal external anatomy (Figure 38.1).

This mode is capable of clear visualization of fetal normal surface anatomy or surface anomalies such as myelomeningocoele, omphalocele, cleft lip/palate, macroglossia and limb defects (Figures 38.2–38.6). Furthermore, visualization of the spatial relationship between surface structures enables accurate diagnosis of subtle malformations and anomalies such as micrognathia, overlapping fingers, hexadactilia and auricular malposition or malformation.

Surface rendering gives the best result when ROI structures are surrounded by fluid or hypoechoic tissue. By selecting the threshold level, voxels with gray values below the threshold value selected are not shown on the reconstructed image. Selecting the threshold parameter influences the quality of the surface rendered image.

The surface image can be displayed in 'textural' mode. The gray values can be colored by different color maps, but the most successful map for 4D image is the 'body heat' map. The texture mode can also be 'smoothed', showing smooth surfaces on 4D

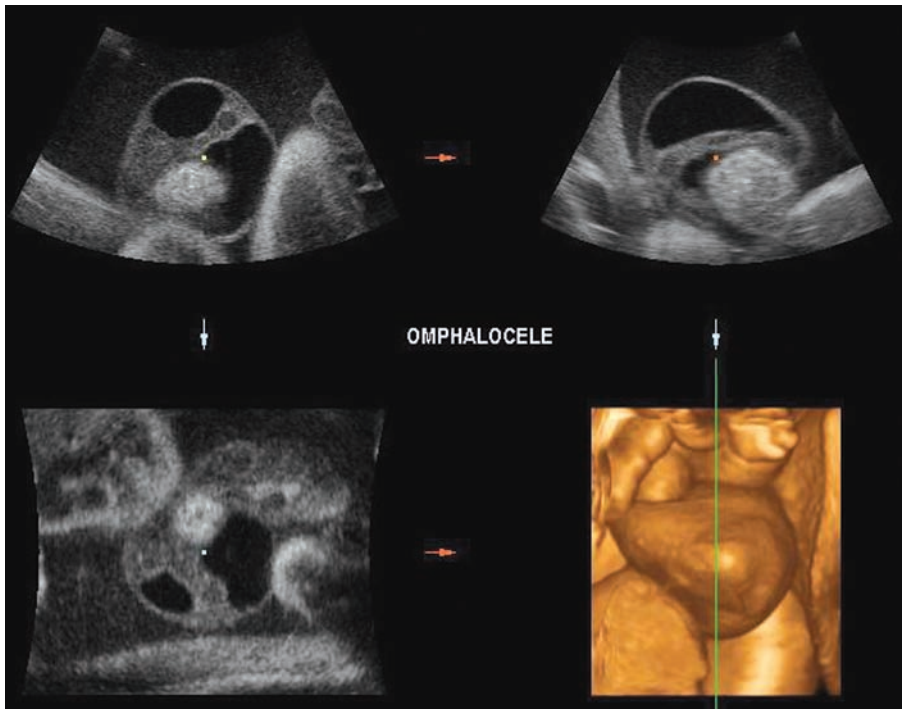

Figure 38.2 3D surface rendering of omphalocele.

Figure 38.3 3D surface rendering of macroglossia.

Figure 38.4 3D surface rendering of myelomeningocoele.

reconstructions. Texture and smooth surface displays are suitable for use in applications such as fetal face, abdominal wall, genitals, umbilical cord (Figure 38.7) and the surfaces of the urinary bladder.[109–111]

The surface can be displayed in 'light' mode. Closer structures are brighter, while distant structures are displayed darker. A variation of the light mode is 'gradient light mode', showing virtual illumination from a spot light source.[112]

Transparent mode

In the transparent mode, contrary to the surface mode, only the signals from the inner layers of the ROI are extracted, providing spatial reconstruction of the internal structure of the ROI. According to the echogenicity of extracted signals there are two submodalities: maximum and minimum modes. In the maximum mode there are only the signals of the highest echogenicity, whereas in the minimum mode only the signals of the

Figure 38.6 3D surface rendering of arthrogryposis of the fingers showing rigid and fixed posture.

lowest echogenicity are extracted from the entire volume. In the transparent mode only maximum gray values are displayed. This mode is suitable for visualization of fetal bones, endometrium and breast.

Minimum mode

Minimum gray values are displayed for visualization of vessels, cystic structures and parenchyma of different organs.[113]

Maximum mode

Maximum gray values are displayed. It is suitable for visualization of fetal bone structures and is the method of choice for imaging of the spatial relationships between bones.[114] Moreover, this modality offers an option of complete visualization of curved bones such as ribs or clavicle on a single image.

Evaluation of the complete skeleton, particularly the thoracic skeleton in the developing fetuses, often is difficult with 2D ultrasound because of curvature of the bones. Ribs can be completely observed using the 3D ultrasound transparency mode. This modality reduces the echogenicity of soft tissues, leaving behind echogenic structures, namely, the bones. The curvature and relationship of the rib ends to the vertebral bodies and the anterior chest wall can be demonstrated as well as the entire length.

The vertebral column is originally curved anteroposteriorly. If it is pathologically curved laterally, it is impossible to display the whole vertebral column in a single sectional image by 2D ultrasound. The advantage of 3D ultrasound (Figure 38.8) is the ability to visualize both curvatures at the same time. Anomalies such as scoliosis, kyphosis, lordosis and spina bifida may be overlooked by 2D ultrasound, but are easy to recognize by using the 3D maximum mode. Congenital malformations of the fetal spine can be identified more easily using 3D surface and transparent mode reconstruction together. Specific vertebral body levels may be accurately identified by simultaneous evaluation of axial planes of the spine within the volume rendered image. It is difficult to acquire the entire spine in a single volume and thus multiple volumes are often necessary to evaluate the spine completely.

Volume contrast imaging (VCI)

Using 4D it is possible to make high-contrast 2D images. The rendered algorithm is a combination of surface texture mode and minimum transparency 4D

Figure 38.8 3D maximum mode showing the vertebral column.

mode. It is possible to display a couple of millimeters thin volume slice showing very good contrast between different tissues. The user can define the thickness of the slice that is scanned using 4D image rendering. The reconstructed image shows improved tissue contrast. VCI is used for better visualization of nodular or diffuse lesions in parenchyma of organs such as liver and spleen.

Spatio-temporal image correlation (STIC) in fetal echocardiography

STIC is a new method for clinical investigation of the fetal heart. The reconstructed volume scan offers a user-friendly technique to acquire data from the fetal heart and its visualization in a 4D sequence. The volume acquisition occurs in two ways. First, data are obtained by a single, automatic volume sweep. In the second step, the system examines the data in proportion to their spatial and temporal domain and processes a 4D sequence. This sequence presents the heart beating in real time in a multiplanar display. After the volume acquisition, the heart can be assessed off-line, without depending on the patient.[115,116]

Removing overlaying structures

This option is called Magic-Cut or the electronic scalpel. During 3D and 4D scanning in most cases there are structures that interfere or are superimposed on the reconstructed image. The Magic-Cut tool enables successful removal of overlaying structures using 3D imaging. Unwanted structures can be cut off from the image in all three directions along the *x*, *y* and *z* axes. There is also a possibility of using this tool to remove some structures from real-time 4D volumes. The cutting tool enables the operator to have improved visualization of the object from all directions.[117]

Data review and networking

Volume data sequences can be stored on the hard disk of the ultrasound unit or in different media (CD-R, MO-Disc) in various formats: 2D image, 2D cine (selected sequence of 2D images), 3D volume (sequence of 3D rotating images) and 4D volume. Since the complete volume data set is saved, it is possible to review saved examinations without any loss of image quality. Stored data can be interactively processed with the possibility of additional 3D reconstruction.

Three-dimensional and 4D imaging provides additional dimensions to conventional 2D sonography. The main advantage of ultrasound in general is dynamic imaging of the human body. Four-dimensional imaging is following this tradition, permitting visualization of dynamic changes inside the body and its organs. Using 4D ultrasound in obstetrics, it is possible for the first time to monitor the quality and quantity of fetal movements on 3D real-time reconstructed images.

Assessment of fetal behavior

Prenatal motility is considered to reflect the developing nervous system but it also involves the functional and maturational properties of fetal hemodynamics and the muscular system. Despite medical reports from 100 years ago and 25 years of systematic research initiated by Prechtl and associates, the study of prenatal behavior is in its infancy.

Fetal behavior can be defined as fetal activities observed or recorded with ultrasonographic equipment. As it is not yet possible to assess the functional development of the CNS directly, investigators have started to analyze fetal behavior as a measure of neurological maturation.[118]

A turning point in the assessment of fetal behavior was the introduction of real-time ultrasound. This technique allowed the investigation of spontaneous fetal motor activity *in utero*.[117,119] For the first time, studies of spontaneous prenatal movements and behavior *in utero* were carried out and published. Since fetal body movements give important information about the condition of the fetus, their quantitative as well as qualitative aspects were analyzed. de Vries *et al.* described the developmental pathway of fetal movements in a longitudinal study of 12 healthy nulliparous women.[15] They reported not only how to describe a particular movement, but also how these movements were performed in terms of speed and amplitude.[15]

Assessment of fetal movements

Using ultrasound imaging, de Vries *et al.* focused on the first half of pregnancy, while Roodenburg *et al.*

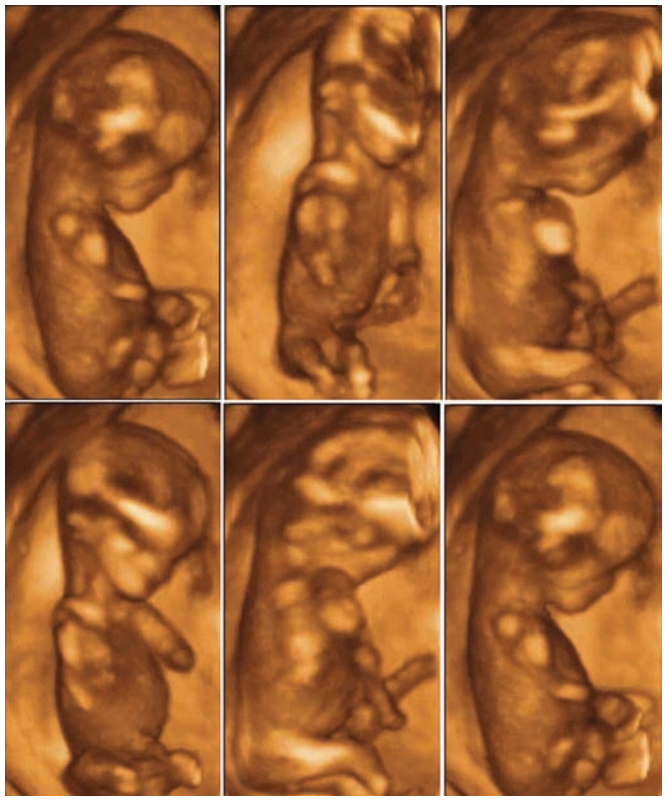

Figure 38.9 4D ultrasound sequence of the fetus at 12 weeks of gestation showing general movements. The complex movements of the limb, trunk and head are clearly visible and cause a shift in fetal position. In the first sequence, the right limb is bent in the elbow joint. In the next sequence, the fetus has dropped the hand and has begun to deflect the elbow joint. In the last sequence, further elevation of the hand is seen.

investigated the second half of pregnancy.[24,120] In a classic paper, de Vries and her team classified at least 13 different movement patterns.[24]

Classification of movement patterns[121]

(1) Just discernible movements (between 7 and 8.5 weeks)
(2) Startle
(3) General movements (Figure 38.9)
(4) Hiccup
(5) Breathing
(6) Isolated arm or leg movement
(7) Isolated retroflexion of the head
(8) Isolated rotation of the head
(9) Isolated anteflexion of the head
(10) Jaw movements
(11) Hand–face contact – in this pattern of movement, the hand slowly touches the face, the fingers frequently extend and flex (Figures 38.12–38.15)
(12) Stretch
(13) Rotation of the fetus.

Relying on the observations of apparently typical spontaneous human fetal movements, de Vries *et al.* recorded variations in general movements that they believed suggested abnormalities of the CNS.[122] Following their lead, other researchers have selected, as a dependent variable, general movements or 'gross movements' involving the whole body.[123] Fetal motor behavior has been described.[124–127] The descriptor of general movements has been applied to the movements of preterm newborns.[128,129] Unfortunately, the lack of definition specificity, long-term follow-ups and the reliability of descriptions have limited the usefulness of some of these studies. Nevertheless, careful observation and analysis of fetal movements could be useful in the assessment of the integrity of the fetal CNS, as will be described later in the text.

The Zagreb group has evaluated the advantages of 4D over 2D real-time sonography in the assessment of early fetal behavior.[117] With 4D transvaginal sonography these authors found body movements at 7 weeks of pregnancy (Table 38.3).[117] The observed body movements consisted of the changing position of the head toward the body. Therefore, this technology enables the visualization of the moving phenomenon 1 week earlier than 2D ultrasound. At 7 weeks of gestation, the dominant embryonic feature is the head, which is strongly flexed anteriorly. Upper and lower limb buds are visible on the lateral aspects of the embryo. However, embryonic movements are not frequent and consist mainly of moving of the head toward the rest of the body. At 8–9 weeks, the head is less flexed and the changes in the position of the head toward the body are clearly visible.

General movements are the first complex fetal movement patterns observable by 2D ultrasound.[15] They can be recognized from 8–9 weeks of pregnancy and continue to be present until 16–20 weeks after birth.[130] According to Prechtl these are gross movements, involving the whole body.[121] Movements of the limbs, trunk and head are of variable speed but smooth in appearance. They wax and wane in intensity, force and speed, and they have a gradual beginning and end.[121] The qualitative characteristics of general movements can be altered by some pathological conditions, such as in fetuses of women with type 1 diabetes mellitus or fetuses with anencephaly.[17,131] The range of movements varies from forceful and jerky in character and of large amplitude in anencephalic fetuses (Figure 38.10) to monotonous and rigid or chaotic in diabetic pregnancies. Qualitative alterations of general movements (Figure 38.11) seem to be useful in the assessment of the severity of associated neurological disability. The complex sequences of extension and flexion of the legs and arms (Figure 38.9) may be assessed better with 4D ultrasound. Furthermore, 4D sonography seems to be the method of choice for detecting subtle changes such as superimposed rotations and changes in the direction of the movements. The application of this new technique could improve the analysis of fetal movements and could allow the definition of precise criteria for the assessment of the integrity of the fetal nervous system.

Table 38.3 The incidence of spontaneous embryonic/fetal movement according to gestational age (adapted from Kurjak *et al.*[117])

Gestational age (weeks)	CRL (mm)	No movements	Gross body movements	Limb movements	Complex limb movements
7–8	0–15	31	12	0	0
9–10	16–30	26	11	7	0
11–12	31–50	19	16	12	8

CRL, crown–rump length

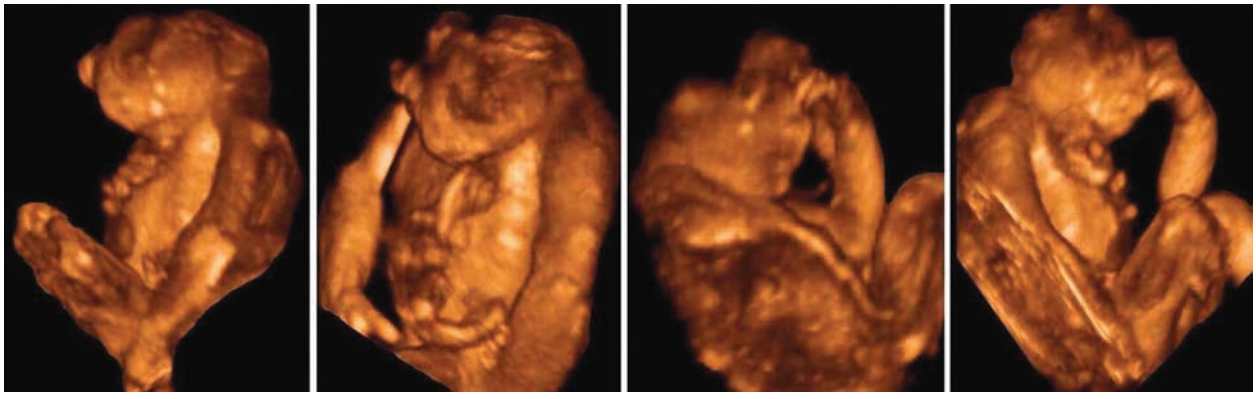

Figure 38.10 4D sequence of anencephalic fetus at 19 weeks of pregnancy. Only hand to head movements in one direction of the left arm could be seen; their onset was abrupt and jerky. Body movements in anencephalic fetus showed a lack of positional changes, with a waxing and waning in intensity. Using this technique, the function of lower-level CNS responsible for these forceful, monotonous changes is evaluated.

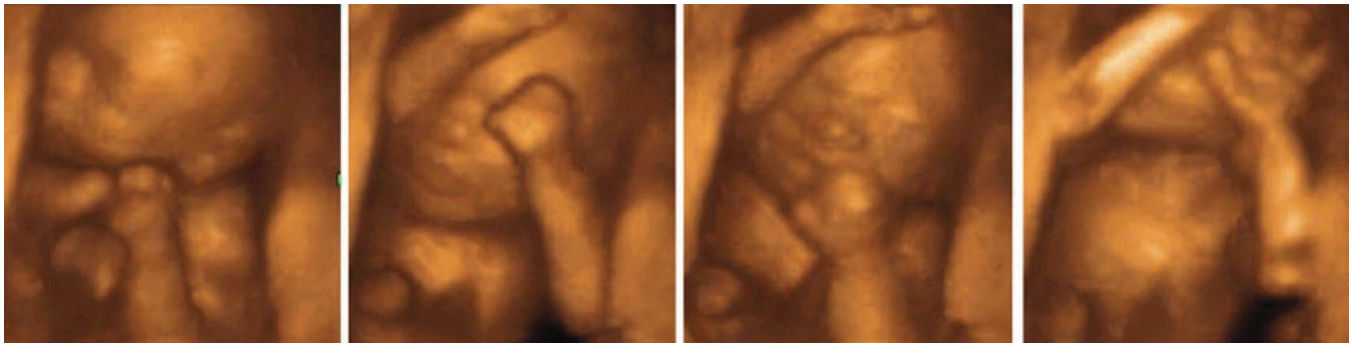

Figure 38.11 4D sequence of normal fetus at the same age as in Figure 38.10. Hand movement could be observed in any direction. We could see head movement (retroflexion and rotation) followed by palm opening position simultaneously. Qualitative alteration of movements can be used as a marker of the severity of associated neurological disability.

According to the literature, there is a period between 8 and 12 weeks concerning the first appearance of limb movements.[15,131] de Vries *et al.* found isolated arm and leg movements at 8 weeks of pregnancy.[15] With 4D ultrasound, the limb movements were detected at 8–9 weeks of gestation (Table 38.3).[117] In this period, limbs are elongated and their segments are discernible. Isolated arm and leg movements were clearly visible and consisted of changes in position of the extremities toward the body without observable flexion or extension in the joints.

Limb movements become more complex with advancing gestational age. Specific movements can be recognized at 14 weeks by 2D ultrasound. The organization of the movement pattern occurs as their frequency increases.[126] It seems that the fetal arms explore the surrounding environment and cross the midline, while the palmar surface is oriented toward

Table 38.4 Developmental motor characteristics of low-risk fetuses (adapted from Geerdink and Hopkins[128])

Gestational age (weeks)	Description
8	Trunk flexion and extension
12	Isolated random-appearing movement of extremities
14	All movement patterns present; an increased frequency of movement that is more 'organized' in appearance compared with movement at 12 weeks; arms appear to 'explore' while legs extend against uterine wall; arm crosses midline, extending palmar surface to opposite uterine wall
16	Decreased frequency of movements from 14 weeks, with pincer grasp, thumb in mouth
20	More bilateral movement (e.g. legs extend together against uterine wall, arms flex and hands are often held together near the face)
26–32	Independent movement of extremities to all parts of the uterus and specific body parts; no cephalocaudal development, but apparent distal–proximal development in extremities
37–38	Decreased frequency of movements; hand often molded to occiput or dorsum of hand rests against uterine wall

the uterine wall. The fetal legs are extended to the uterine wall. This phenomenon can be seen 2 weeks earlier using 4D ultrasound.[117] However, these movement patterns are less organized in comparison with those observed at 14 weeks by 2D ultrasound. Complex limb movement consists of changes in the position of the limb segments toward each other, seen by 4D ultrasound. More limb joints are active and move simultaneously, for example, as extension or flexion in arm and elbow or hip and knee. The elevation of the hand, extension of the elbow joint, with a slight change in direction and rotation, can be seen simultaneously.

Sparling and Wilhelm also described spontaneous movements in fetuses from 12 to 35 weeks of gestation (Table 38.4) and recorded the characteristics of hand movement.[126] Many movements appeared to be directed to a body part or the uterine wall. The hands of the fetuses moved with a variety of frequencies and apparent force. Joint ranges of motion changed throughout the movements rather than remaining the same, as in floating. These movements suggested primary and secondary circular reactions in which a movement is repeated, presumably because it has functional importance to the organism.[127,129] During later gestational periods, the fetuses' hands are directed to and manipulate body parts and features of the environment, such as the umbilical cord.

Our recent study, using 4D sonography, shows that the number of isolated arm movements decreases gradually from 13 through 16 weeks (Table 38.5a). All recordings were made during 15-min periods. The incidence varied between 50 and 120 with a median value of 60 at 13 weeks, between 17 and 27 with a median value of 23 at 14 weeks, between 0 and 6 with a median value of 2 at 15 weeks and between 18 and 28 with a median value of 25 at 16 weeks. The highest range was registered at 13 weeks of gestation. Data

Figure 38.12 This picture shows the hand to face contact.

from Table 38.5(b) demonstrate the incidence of hand to head movements (Figure 38.15). There is a notable decrease in their incidence, followed by a plateau at 14 weeks of gestation. The incidence varied from 4 to 29 at 13 weeks and from 0 to 7 at 16 weeks of gestation. Table 38.5(c) shows the incidence of hand at mouth movements (Figure 38.13). The incidence varied between 0 and 4 with a median value of 2 at 13 weeks and between 0 and 2 with a median value of 2 at 16 weeks. The highest range was found at 15 weeks of gestation. At 13 weeks, a plateau was observed and was present until 16 weeks. Although this plateau was evident, mild fluctuations occurred. In contrast to most other movement patterns, hand near mouth movements (Table 38.5d) decreased gradually from 13 weeks onward, with a single fluctuation in the 14th week (it varied between 0 and 3 with a median value of 1). The incidence of hand to face movement (Figures 38.12 and 38.15) is characterized by a decrease

Table 38.5 The incidence of several characteristics of hand movements from 13 to 16 gestational weeks shown by 4D sonography: (a) isolated hand movement, (b) hand to head movements, (c) hand to mouth movements, (d) hand near mouth movements, (e) hand to face movements, (f) hand near face movements, (g) hand to ear movements and (h) hand to eye movements (adapted from Kurjak *et al.*[23])

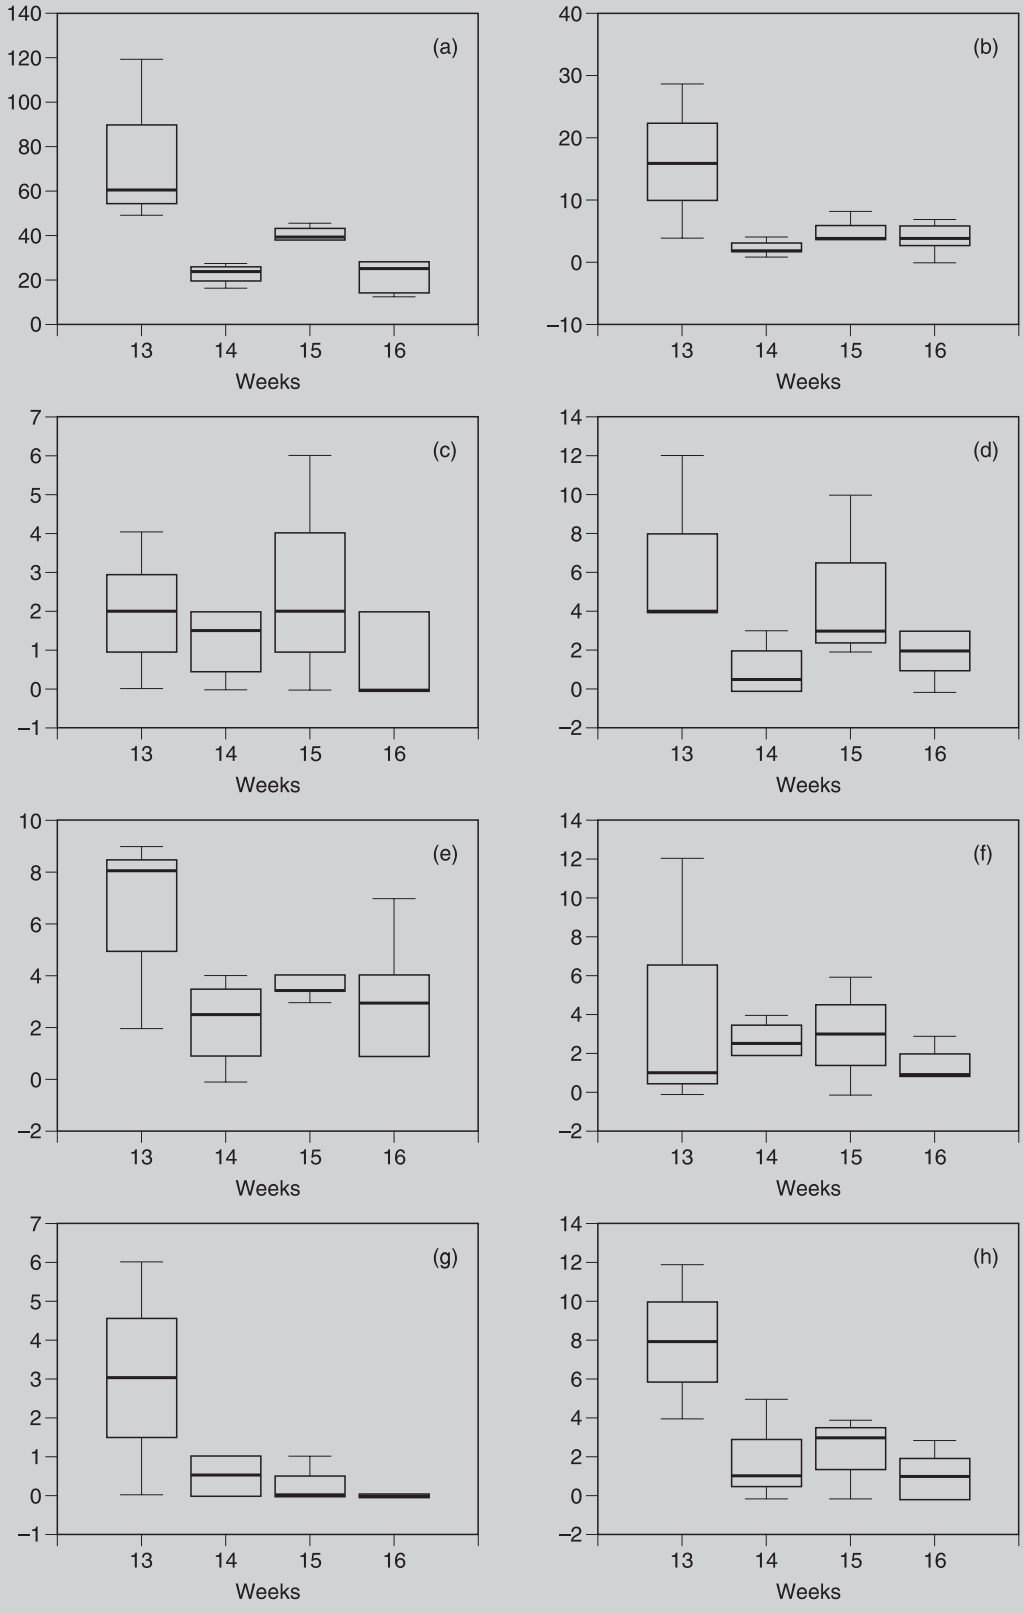

Figure 38.13 The hand movement in direct contact with the mouth.

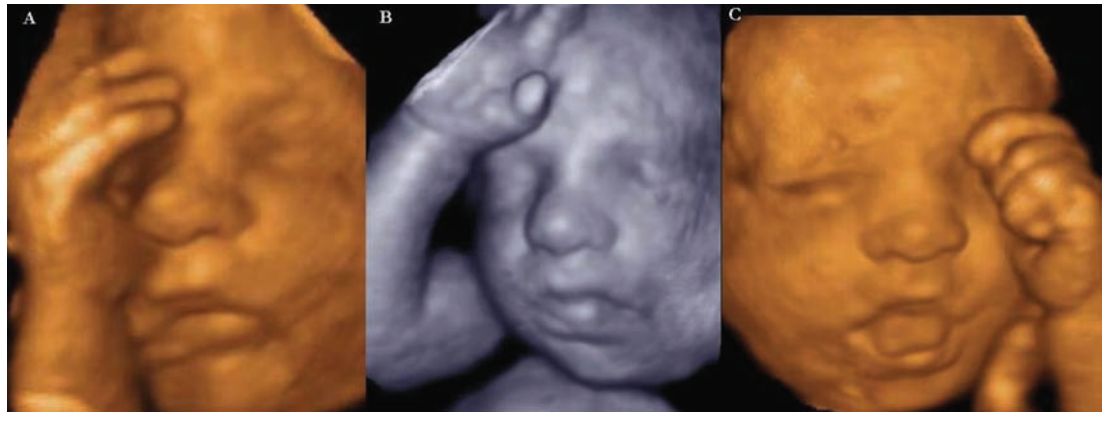

Figure 38.15 Several 3D images of hand direction to the face (a), to the head (b) and to the eye (c).

at 14 weeks followed by a plateau (Table 38.5e). From 13 weeks onward, the hand near face movement pattern was visible in all 15 fetuses, with an incidence of 2–9 and a median value of 8. At 16 weeks, the range was from 1 to 7 with a median value of 3. Although the plateau was observed, mild fluctuation was evident, especially at 15 weeks. From Table 38.5f, we can see that the incidence of hand near face movement is stable between 13 and 16 weeks of gestation with a slight increase at 14 and 15 weeks. At 13 weeks, the range was the widest (from 0 to 12), with the median value of 3. The incidence of hand to ear movements decreased between 13 and 16 weeks (Table 38.5g). It varied between 4 and 12 with a median value of 8 at 13 weeks and between 0 and 3 with a median value of 0 at 16 weeks. The incidence of the hand to eye movement (Figure 38.15) pattern showed the same developmental trend as the incidence of the hand to head and hand to face movement patterns (Table 38.5h). At 13 weeks, the incidence was between 4 and 12 occurrences per 15 minutes' observation time with a median value of 8. At 16 weeks, the range was from 0 to 3 with a median value of 1.[23]

Other developmental tendencies in hand movement have been noted.[132] Movements such as thumb in mouth and bilateral leg extension against the uterine wall were considered as functionally important. The frequently observed leg extension against the uterine wall was believed by the authors to be a possible precursor to later participation in the birthing process. Early movements of the arms appeared to assist the fetus in identifying components of its environment. Attributing function to any of these early movements, however, does not imply that the assigned function is preliminary to or necessary for the appearance of a spontaneous behavior.[25,132]

Assessment of fetal facial expressions by 4D ultrasound

Recent studies have demonstrated that during the second and third trimesters it is possible to study the

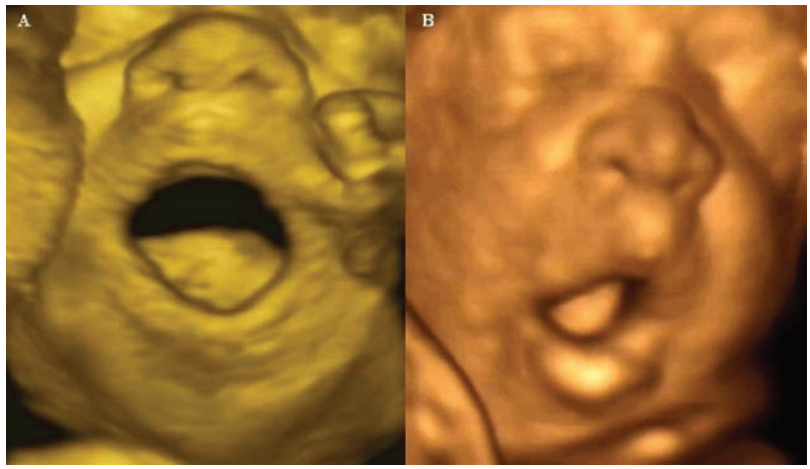

Figure 38.16 Yawning expression of the fetus. An involuntary wide opening of the mouth, with maximal widening of the jaw, followed by quick closure, often with retroflexion of the head and sometimes elevation of the arms.

full range of fetal facial activities. In addition to yawning, sucking and swallowing described by 2D real-time imaging, it is now possible to study the full range of facial expressions including smiling, crying and eyelid movements.[23,133]

The fetal behavioral patterns have been evaluated in 10 gravidas in the third trimester, between 30 and 33 weeks of gestation.[23] The incidence of eyelid movements ranged between 4 and 20 with a median value of 17, mouthing movements ranged between 2 and 19 with a median value of 12 and mouth and eyelid movements ranged between 0 and 13 with a median value of 5. The incidence of pure mouth movements such as opening of the mouth ranged between 4 and 13 with a median of 5, tongue expulsion ranged between 0 and 2 with a median of 2, yawning ranged between 0 and 2 with a median of 1 and pouting ranged between 0 and 9 with a median of 3. The incidence of facial expressions such as smiling ranged between 2 and 7 with a median of 2 and scowling between 2 and 4 with a median of 2. It is evident that eyelid and mouthing movements are predominant at this gestational age. The continuity between fetal and neonatal behavior has also been suggested.[132] These findings may stimulate multicentric studies of fetal behavior and responsiveness as a sign of neurological maturation. In the long term, fetal behavioral studies may become a means of assessing fetal well-being.[23]

Classification of facial movement patterns

The Zagreb group has attempted to evaluate 4D sonography in the assessment of fetal facial expression. They have classified eight different facial expressions:

(1) *Yawning*: This movement is similar to the yawn observed after birth: an involuntary wide opening of the mouth, with maximal widening of the jaws followed by quick closure, often with retroflexion of the head and sometimes elevation of the arms. This movement pattern is non-repetitive (Figure 38.16).
(2) *Swallowing*: This indicates that the fetus is drinking amniotic fluid. Swallowing consists of displacements of the tongue and/or larynx. Swallowing activity develops earlier than sucking in the course of fetal development.
(3) *Sucking*: This consists of rhythmical bursts of regular jaw opening and closing at a rate of about one per second, placing the finger or thumb on the roof of the mouth behind the teeth and sucking with lips closed. Thumb sucking is a very frequent fetal behavioral pattern (Figure 38.17).
(4) *Smiling*: A facial expression characterized by turning up the corners of the mouth (Figure 38.21).
(5) *Tongue expulsion*: A facial expression characterized by expulsion of the tongue (Figure 38.18).
(6) *Grimacing*: The wrinkling of the brows or face in frowning to express displeasure (Figure 38.22).
(7) *Mouthing*: A facial expression characterized by mouth manipulation to investigate an object. Mouthing is most common in the fetus and it may develop into a persistent, stereotyped behavior pattern (Figure 38.19).
(8) *Isolated eye blinking*: A reflex that closes and opens the eyes rapidly. Brief closing of the eyelids by involuntary normal periodic closing, as a protective measure, or by voluntary action (Figures 38.20 and 38.21).

They have also tried to identify emotional expressions as a combination of several of the facial expressions mentioned above (Figures 38.20–38.22).

The early results, presented above, indicate that fetal facial grimaces, resembling the emotional expressions in humans, are present during the third trimester of gestation. However, the precise criteria for distinction of these expressions in the fetus remain to

Figure 38.17 This picture shows sucking expression. The fetus is placing the thumb into the mouth, probably on the roof of the mouth and sucking with lips closed.

Figure 38.18 Facial expression characterized by tongue expulsion.

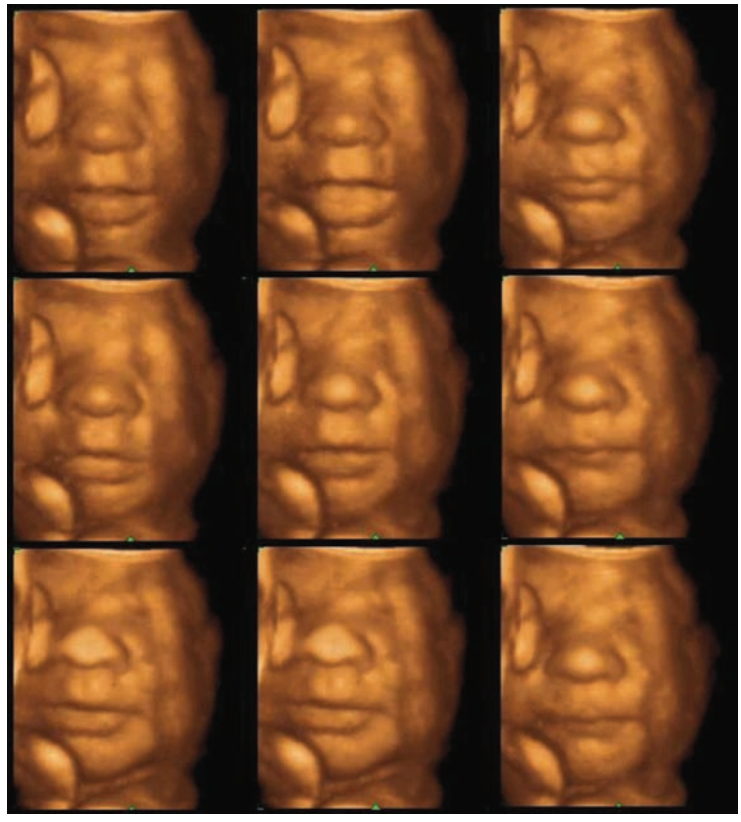

Figure 38.19 In this image sequence, mouthing can be observed as a facial expression pattern. We can see a series of rhythmic movements involving the mandible and tongue, characterized by constant frequency and duration until disappearance.

be established. A possibility of study of fetal facial expressions allows new research questions to be dealt with and indicates a great potential for 4D sonographic studies in the psychological and fetal behavioral sciences. Facial expressions are an important channel of non-verbal communication. The characteristics of facial expressions can provide the expert a different means of understanding the hidden side of the fetus *in utero*, a side that may not be accessible in the form of any verbalizations. However, clear evidences that fetal emotional processing exists in the third trimester of gestation or that it is related to facial expressions are still lacking and extensive multicentric studies should be conducted in order to clarify this idea. We believe that the fetal facial expressions and fetal behaviors related to emotions could reveal a part of the emotional aspect of intrauterine life. If this assumption becomes confirmed, it is possible to

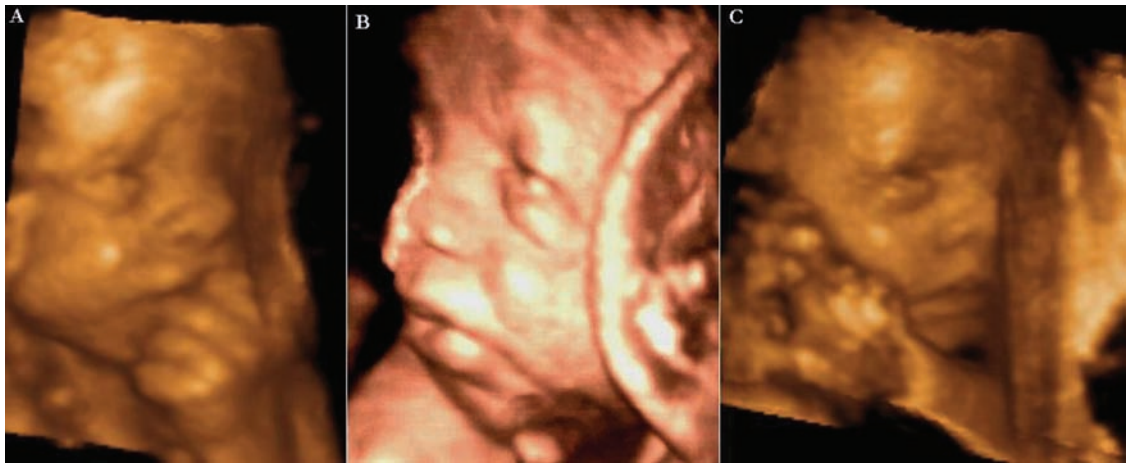

Figure 38.20 The picture shows fear expressions of the fetus. We can see the hand to the mouth movement together with opening of the eyelid. We assumed that this complex expression could be related to the imminent possibility of fetal danger, a nearby threat, a displeasure position or bodily harm. http://face-and-emotion.com/dataface/emotion/x_fear.html

Figure 38.21 Several facial expressions characterized by turning up of the corners of the mouth shows the smiling fetus.

Figure 38.22 In this picture the fetus shows wrinkling of the brows or frowning face, may be to express displeasure or anger. The frontalis muscle can also be responsible for the appearance of grimacing. However, the main agent responsible for the appearance of scowling is the corrugator muscle.

imagine that we could construct a system that relates discrete emotions, like happiness, anger, sadness, etc., and various intensities of fetal facial expressions *in utero* to external events. A system might be able to be constructed where componential and general internal states like pleasure control each parameter unit and establish a pleasure score of the fetus that can be used to drive facial expressions.

Conclusions

Behavioral perinatology assessed by 4D sonography should be an interdisciplinary area of research involving concepts and conducting studies of the dynamic interplay between behavioral processes in fetal, neonatal and infant life.[134–136] Understanding the technical aspects of 4D ultrasound is important for utilizing its full potential. Furthermore, image postprocessing should be considered as a part of examination. Sometimes, additional information about the range of interest can be provided with post-processing.

The study of fetal behavior has provided us with an important contribution to understanding the hidden function of the developmental pathways of the fetal CNS and the potential to investigate neurologic deficits *in utero*.

39 Fetal central nervous system

R. K. Pooh and K. Pooh

Introduction

Recent advances in prenatal imaging technologies such as transvaginal ultrasound, three-dimensional (3D) ultrasound, and magnetic resonance imaging have been remarkable and have contributed to prenatal evaluation of fetal abnormalities *in utero*. Owing to these technologies, fetal malformations have been reliably diagnosed with increasing accuracy and at earlier gestation. As regards to fetal central nervous system (CNS) assessment, a new field of *neurosonography*[1] has been established. Many of the congenital CNS anomalies, which were disclosed in the late pregnancy or after birth, have been recently demonstrated by use of high frequency transvaginal sonography before viability. More advances of technological development will clarify unknown neuropathological facts during fetal period.

Diagnostics of the fetal CNS is one of the most difficult fields in perinatology. There are several reasons why the prenatal CNS evaluation is difficult: (1) lack of essential knowledge of CNS anatomy and pathology; (2) rapid changes of normal CNS development during pregnancy; and (3) inexperience in the use of CNS neuroimaging techniques.

When beginners start prenatal CNS imaging, the above three may be the most frequent reasons for difficulties encountered in prenatal assessment. However, after overcoming those problems, there still exist difficulties in assessment of fetal CNS diseases, because of difficulty in prediction of neurological prognosis and existence of gray zone between normality and abnormality.

CNS development

The brain is a 3D structure and should be comprehended in the three orthogonal views of sagittal, coronal, and axial sections. During fetal period, the embryonal premature CNS structure develops to mature structure (Figure 39.1). Within this rapid change of development, various developmental disorders and/or insults result in various phenotypes of fetal CNS abnormalities. For understanding fetal CNS diseases, basic knowledge of the development of the nervous system is essential. The developmental stages and their major disorders are described in Table 39.1.

It is believed that the brain anatomy must be complicated and there must be lots of terms to remember. In this chapter, essential anatomical structures are selected for neuroimaging and comprehension of fetal CNS diseases. Figures 39.2 and 39.3 show the basic anatomy in the axial, sagittal, and anterior coronal sections of the brain. For understanding hydrocephalus, ventriculomegaly, and/or other intracranial lesions, the ventricular system (Figure 39.4) and cerebrospinal fluid (CSF) circulation (Figure 39.5) should be understood.

Technology

Transabdominal sonographic technique, by which it is possible to observe the fetal internal organs through the maternal abdominal wall and uterine wall, is the most widely used method for fetal imaging diagnosis. Using the transabdominal approach, fetal brain structure mostly in the axial section and fetal back structure including the vertebrae and spinal cord in the sagittal section can be well demonstrated. However, in the transabdominal approach to the fetal CNS, there are several obstacles such as maternal abdominal wall, placenta, and fetal cranial bones.

Introduction of high-frequency transvaginal transducer has contributed to establishing 'sonoembryology'[2] and recent general use of transvaginal sonography in early pregnancy has enabled early diagnoses of major fetal anomalies.[3] During middle and late pregnancy, fetal CNS is generally evaluated through the maternal abdominal wall. The brain, however, is a 3D structure, and should be assessed in the basic three planes of sagittal, coronal, and axial sections. Sonographic assessment of the fetal brain in the sagittal and coronal sections requires an approach from fetal parietal direction (Figure 39.6). Transvaginal sonography of the fetal brain has opened up a new field in medicine, 'neurosonography'.[1] The transvaginal approach to the normal fetal brain during the second and third trimester was introduced in the beginning of the 1990s. It was the

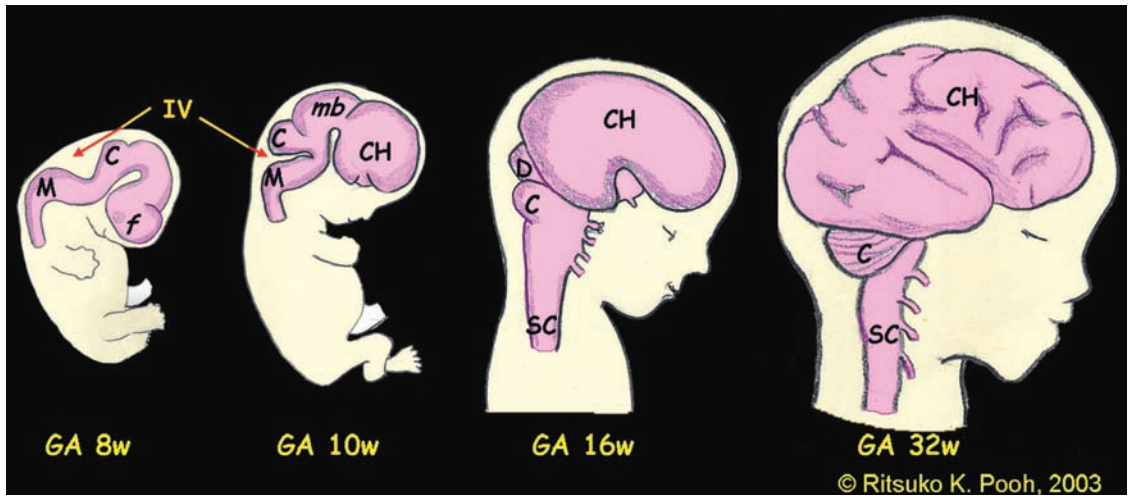

Figure 39.1 Developing brain and spinal cord during pregnancy. Fetal central nervous system changes in size and appearance from early premature structure into late mature structure with gyral formation. CH, cerebral hemisphere; C, cerebellum; D, diencephalons; M, medulla; SC, spinal cord; f, forebrain; mb, midbrain; IV, fourth ventricle.

Table 39.1 Developmental stages and major disorders

Development stage	Disorders
Primary neurulation (3–4 weeks' gestation)	Spina bifida aperta, cranium bifidum
Caudal neural tube formation (secondary neurulation, from 4 weeks' gestation)	Occult dysraphic states
Procencephalic development (2–3 months' gestation)	Holoprosencephaly
	Agenesis of the corpus callosum, agenesis of the septum pellucidum, septo-optic dysplasia
Neuronal proliferation (3–4 months' gestation)	Micrencephaly, macrencephaly
Neuronal migration (3–5 months' gestation)	Schizencephaly
	Lissencephaly, pachygyria polymicrogyria
Organization (5 months' gestation–years postnatal)	Idiopathic mental retardation
Myelination (birth–years postnatal)	Cerebral white matter hypoplasia

first practical application of 3D CNS assessment by 2D ultrasound.[4] Transvaginal observation of the fetal brain offers sagittal and coronal views of the brain from fetal parietal direction[5–8] through the fontanelles and/or the sagittal suture as ultrasound windows. Serial oblique sections[3] via the same ultrasound window reveal the intracranial morphology in detail. This method has contributed to the prenatal assessment of congenital CNS anomalies and acquired brain damage *in utero*.

Three-dimensional ultrasound is one of the most attractive modalities in the field of fetal ultrasound imaging. There are two scanning methods, namely free-hand scan and automatic scan. Automatic scan by dedicated 3D transducer produces motor-driven automatic sweeping and is called fan scan. With this method, a shift and/or angle-change of the transducer is not required during scanning and scan duration needs only several seconds. After acquisition of the target organ, multiplanar imaging analysis is possible. Combination of both transvaginal sonography and 3D ultrasound[9–12] may be a great diagnostic tool for evaluation of the 3D structure of fetal CNS. There are several useful functions in 3D ultrasound as follows:

- Surface imaging of the fetal head
- Bony structural imaging of the calvaria and vertabrae
- Multiplanar imaging of the intracranial structure
- Three-dimensional sono-angiography of the brain circulation

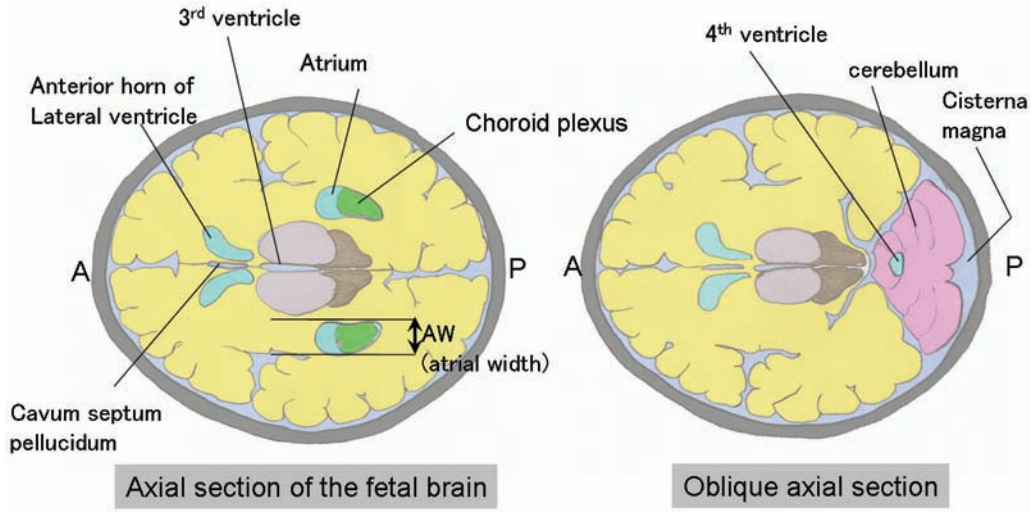

Figure 39.2 Basic anatomical knowledge for neuroimaging in the axial and oblique axial sections.

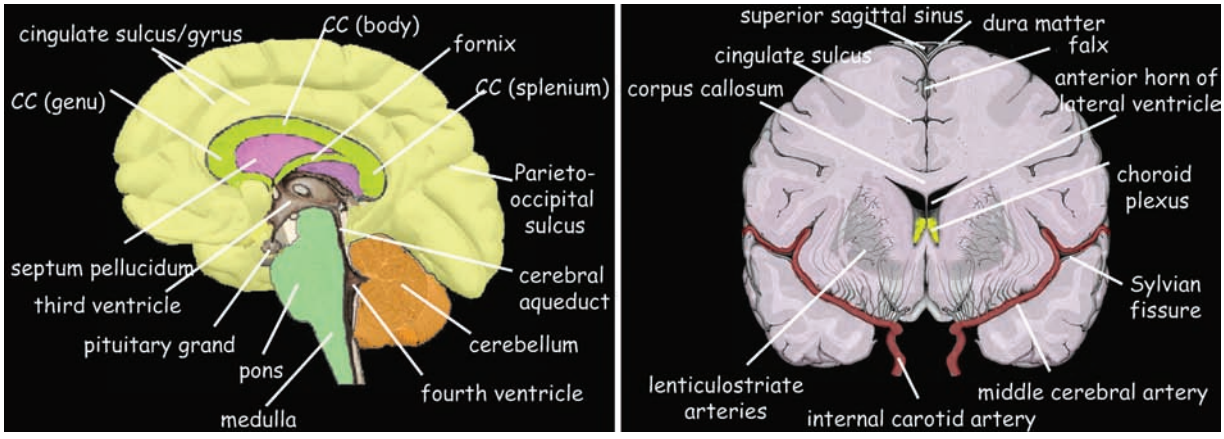

Figure 39.3 Basic anatomical knowledge of sagittal (left) and anterior coronal cutting sections of the brain. CC, corpus callosum.

- Volume calculation of target organs such as intracranial cavity, ventricle, choroid plexus, and intracranial lesions
- Simultaneous volume contrast imaging by 4D ultrasound.

In multiplanar imaging of the brain structure, it is possible to demonstrate not only the sagittal and coronal sections but also the axial section of the brain, which cannot be demonstrated from parietal direction by a conventional 2D transvaginal sonography. Parallel slicing provides a tomographic visualization of internal morphology similar to magnetic resonance imaging (MRI). Volume extracted image and volume calculation of the fetal brain in early pregnancy was reported in the 1990s.[13,14] We used VOLUSON 730 Expert (GE Medical Systems, Milwaukee, USA) with transvaginal 3D transducer and 3D View version 3.2 software (Kretztechnik AG, Zipf, Austria) for volume extraction and volume estimation of the brain structure. Furthermore, with application of 4D ultrasound,

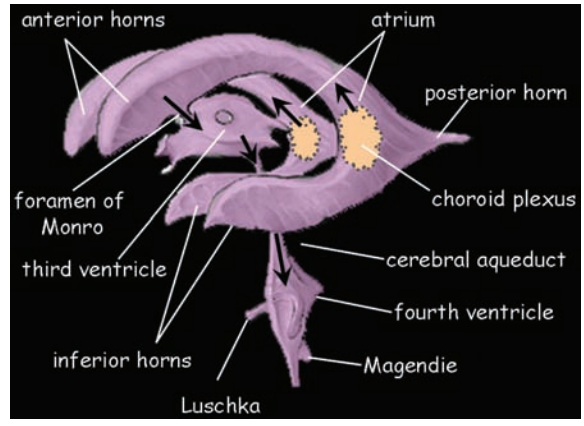

Figure 39.4 Basic anatomical knowledge of ventricular system and cerebrospinal fluid (CSF) flow.

real-time images with increased contrast resolution can be obtained in not only the same plane as 2D cutting section but also vertical plane to 2D image.[15] Fetal neuroimaging with advanced 3D/4D technology

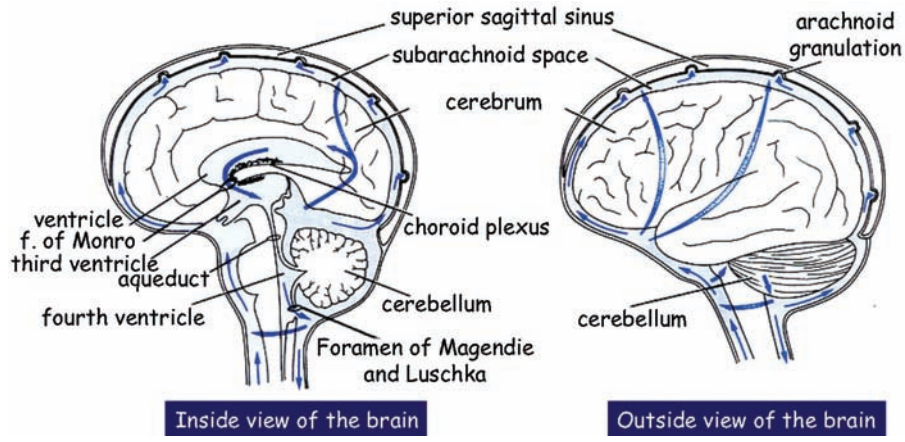

Figure 39.5 Cerebrospinal fluid (CSF) circulation. Inside and outside views of the brain. CSF is produced from choroid plexus of ventricles. CSF runs through the third ventricle, aqueduct and fourth ventricle, goes to the surface of the brain and spinal cord, and is then absorbed by arachnoid granulation. From *Handbook on hydrocephalus for patients*, Research Committee of 'Intractable Hydrocephalus', Japanese Ministry of Health and Welfare, © 1993, with permission. (Schema by courtesy of chairman of the Committee, Prof. K. Mori.)

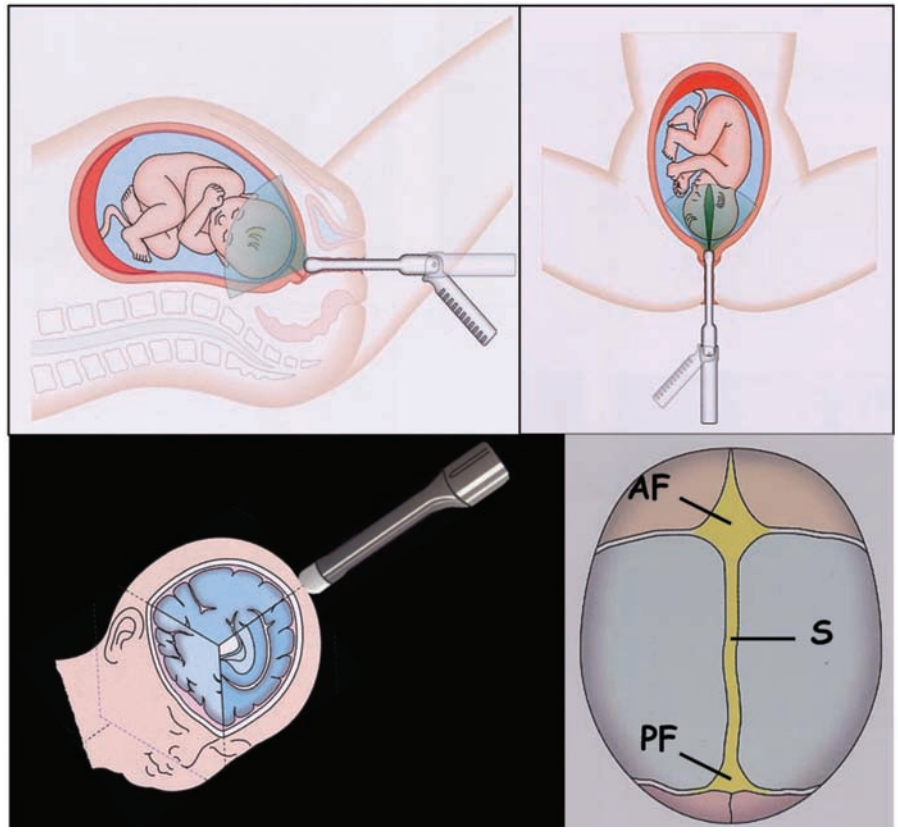

Figure 39.6 Schema of transvaginal sonography. (Upper left) Lateral view of vertex presenting fetus and transvaginal transducer. (Upper right) Frontal view of transvaginal approach. Clear imaging is possible by rotating and angle-changing of the transducer. (Lower left) Scheme of transfontanelle/trans-sutural approach of the fetal brain. (Lower right) Cranial bony structure from parietal direction. AF, anterior fontanelle; S, sagittal suture; PF, posterior fontanelle. These spaces are used as ultrasound windows.

is easy, noninvasive, and reproducible. It produces not only comprehensible images but also objective imaging data which can be graphed in volume calculation. Easy storage/extraction of raw volume data set enables off-line analysis and consultation with neurologists and neurosurgeons.[16,17]

Recent fast MRI is being used increasingly as a correlative imaging modality because it uses no ionizing radiation, provides excellent soft tissue contrast, has multiple planes for reconstruction, and a large field of view.[18] Recent advances in fast MRI technology, such as half-Fourier and the 0.5-signal-acquired single-shot

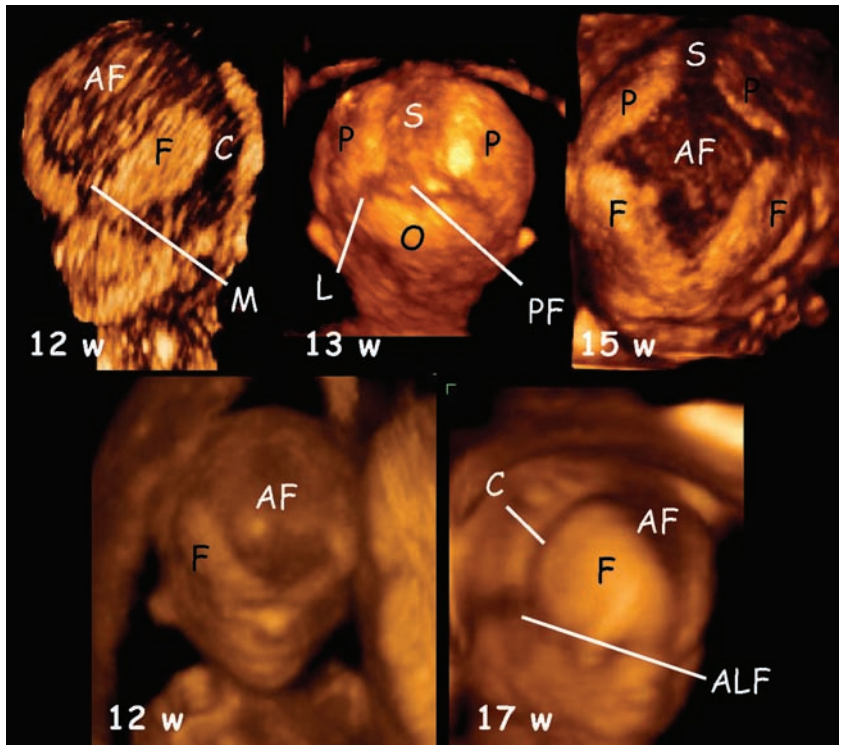

Figure 39.7 Fetal cranial structure in early gestation (3D ultrasound images). (Upper left) 12 weeks, from the oblique front. (Upper middle) 13 weeks, from the back. (Upper right) 15 weeks, from the top of head. (Lower left) 12 weeks, from the front. (Lower right) 17 weeks. Oblique position. Premature shape of cranial bones, sutures, and fontanelles at 12–13 weeks changes its appearance to the neonatal shape. AF, anterior fontanelle; PF, posterior fontanelle; ALF, anterolateral fontanelle; F, frontal bone; P, parietal bone; O, occipital bone; C, coronal suture; M, metopic suture; S, sagittal suture; L, lambdoid suture.

fast spin-echo (SE), half-Fourier rapid acquisition with relaxation enhancement (RARE) sequences, has remarkably improved the T2-weighted image resolution despite a short acquisition time, and minimized fetal and/or maternal respiratory motion artifacts without the need for fetal sedation.[19] MRI has a great potential especially in the evaluation of CNS and several reports have been published on normal and abnormal CNS anatomy by using fast MRI techniques.[20–23]

Normal fetal CNS imaging

The calvaria and its major sutures develop between 12 and 18 weeks of fetal life, with dura as guiding tissue in the morphogenesis of the skull.[24] The cranial bones are detectable by sonography from 10 weeks of gestation on. At 12 weeks, premature cranial bones and sutures in between are detectable (Figure 39.7). The sagittal suture, lambdoid sutures, and posterior fontanelle are recognizable from 13 weeks. As the fetal parietal portion has the anterior/posterior fontanelles and sagittal suture, which is the widest suture among the fetal cranial sutures,[25] transvaginal approach to the fetal brain using these spaces as ultrasound windows demonstrates the detailed brain structure without obstacles of the cranial bone, and is the most reasonable way for brain assessment. Recent advanced 3D ultrasound has been able to depict vertebral body, intervertebral disk space, and vertebral lamina (Figures 39.8 and 39.9).

From 8 weeks of gestation, the premature sonolucent ventricular system is detectable (Figure 39.10). Before 16 weeks of gestation, lateral ventricles are occupied by the choroid plexus (Figure 39.11). Basic knowledge of images in several cutting sections obtained by transvaginal scanning is shown in Figure 39.12. Three orthogonal views by 3D ultrasound are useful for obtaining easy orientation. Multiplanar image analysis is possible (Figure 39.13). Using new technology of 3D tomographic ultrosound imaging (TUI), the brain structure can be observed in parallel cutting slices of any section (Figure 39.14). TUI demonstrates the brain just like magnetic resonance imaging (MRI). Furthermore, off-line analysis allows us to change slice width and to rotate all images in any angle. Three-dimensional transvaginal power Doppler demonstrates clear anatomical vascular formation (Figure 39.15). Vertebrae and spine should be observed carefully for detection of back abnormalities such as spina bifida or scoliosis. Fetal sagittal sectional screening is preferable (Figure 39.16).

Volume analysis by 3D ultrasound provides exceedingly informative imaging data.[15] Volume analysis of the structure of interest provides an intelligible evaluation of the brain structure in total, and longitudinal and objective assessment of enlarged ventricles and intracranial occupying lesions. Any intracranial organ can be chosen as a target for volumetry no matter how distorted its shape and appearance may be (Figure 39.17).

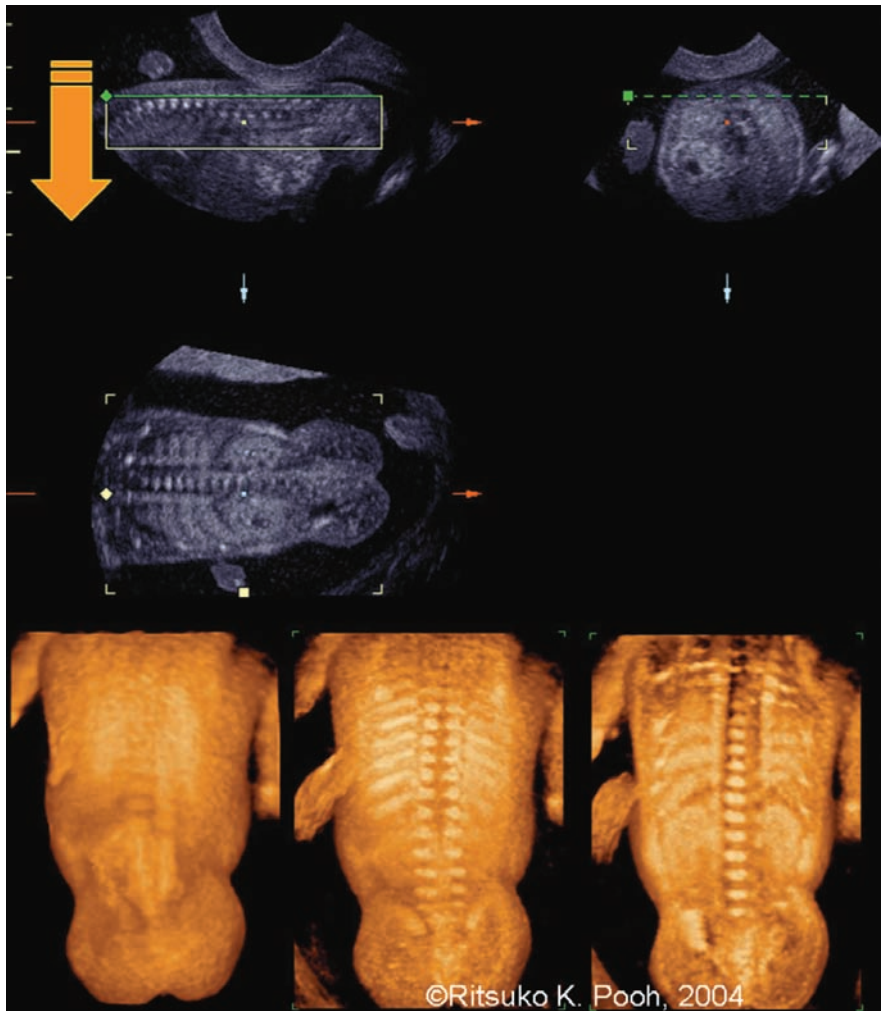

Figure 39.8 Three orthogonal views and 3D reconstructed image of normal fetus at 16 weeks of gestation. Movement of region of interest (arrow) provides 3D reconstruction image of the surface level (lower left), neural arch level (lower middle), and vertebral body level (lower right).

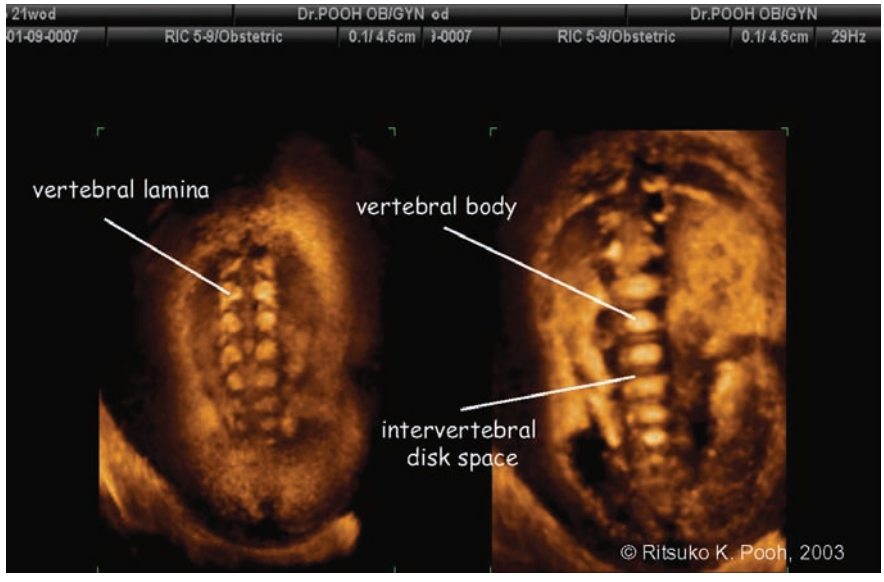

Figure 39.9 Fetal vertebral structure by 3D ultrasound at 21 weeks of gestation.

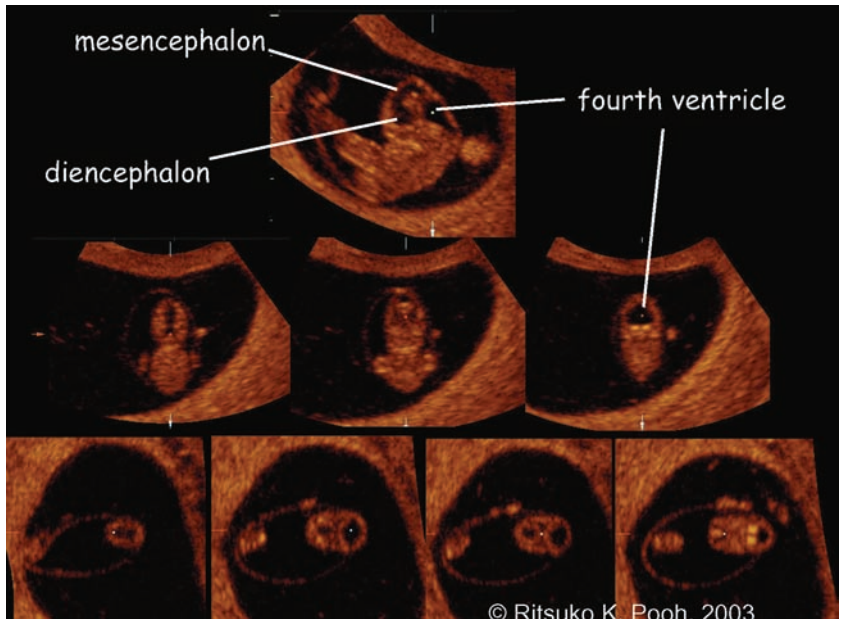

Figure 39.10 Normal intracranial structure at 8 weeks of gestation in parallel cutting slices of three orthogonal views. Sagittal, coronal, and axial sections from above. Premature sonolucent ventricular system is visible.

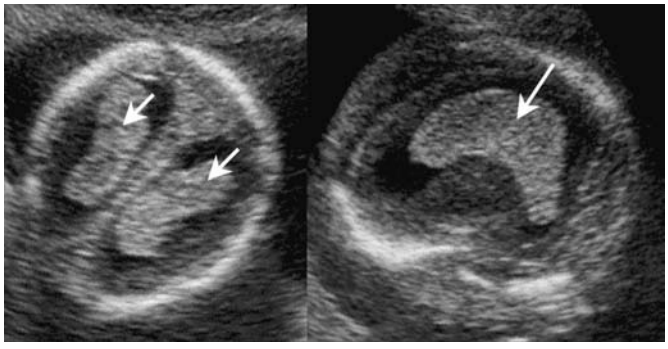

Figure 39.11 Normal intracranial structure at 14 weeks of gestation. Axial view (left) and parasagittal view (right). Choroid plexus (arrows) occupies most of the lateral ventricle.

Hydrocephalus and ventriculomegaly *in utero*

Both 'hydrocephalus' and 'ventriculomegaly' are terms used to describe dilatation of the lateral ventricles. However, these two should be distinguished from each other. Hydrocephalus signifies dilated lateral ventricles resulted from increased amount of cerebrospinal fluid and intracranial pressure, while ventriculomegaly is a dilatation of lateral ventricles without increased intracranial pressure due to hypoplastic cerebrum or other intracerebral abnormalities such as agenesis of corpus callosum. Of course, ventriculomegaly can sometimes change into the hydrocephalic state. In sonographic imaging, those two

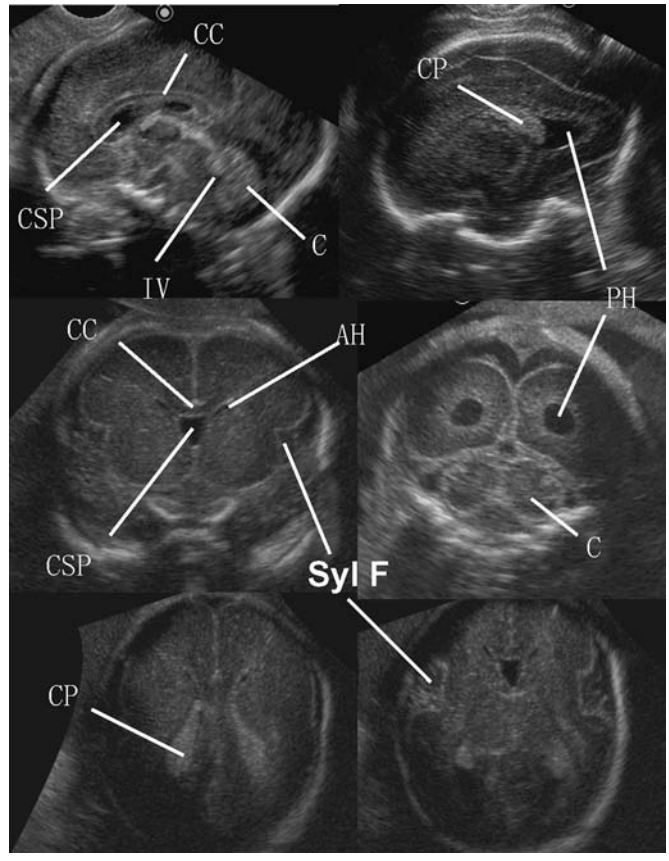

Figure 39.12 Normal views of fetal brain at 26 weeks of gestation. Sagittal (upper), coronal (middle) and axial (lower) sections. CC, corpus callosum; CSP, cavum septum pellucidum; C, cerebellum; IV; fourth ventricle; AH, anterior horn of the lateral ventricle; PH, posterior horn of the lateral ventricle; CP, choroid plexus; Syl F, sylvian fissure.

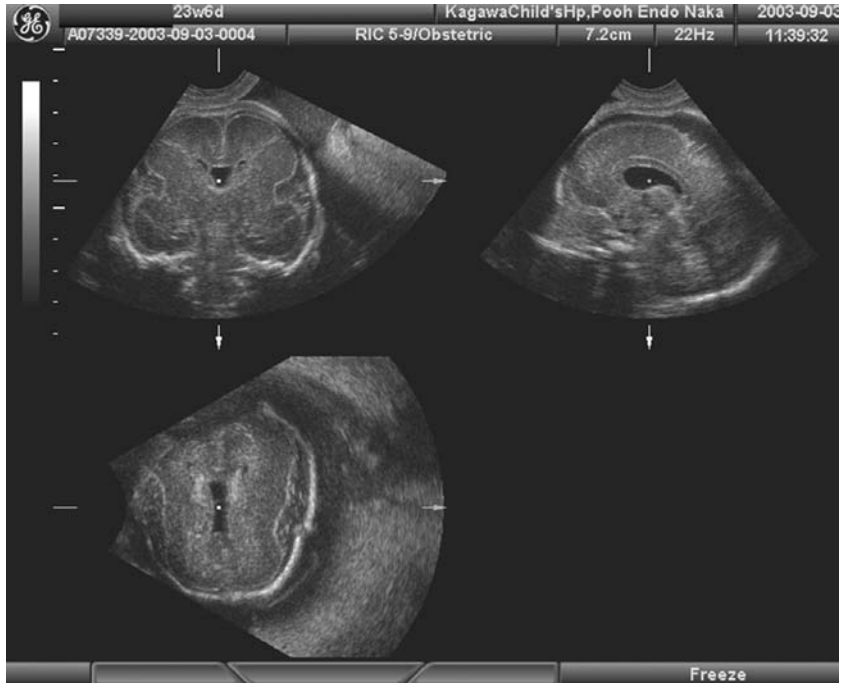

Figure 39.13 Three-dimensional multiplanar image analysis (normal brain at 23 weeks of gestation). Three orthogonal views are useful for obtaining orientation of the brain structure. Coronal (left upper), sagittal (right upper), and axial (left lower) images can be visualized on a single screen. Any rotation of the brain image around any (*x*,*y*,*z*) axis is possible.

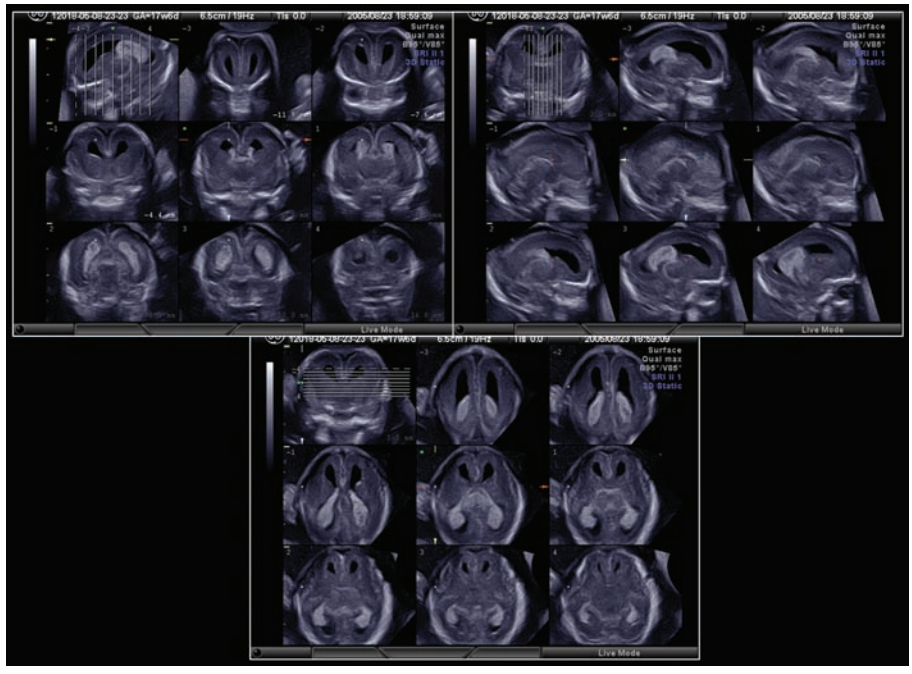

Figure 39.14 Normal intracranial structure at 19 weeks of gestation in parallel cutting slices of three orthogonal views. Sagittal, coronal, and axial sections from above.

intracranial conditions can be differentiated by visualization of subarachnoid space and appearance of choroids plexus. In normal condition, subarachnoid space, visualized around both cerebral hemispheres is preserved during pregnancy (Figure 39.18). Choroid plexus, which secretes CSF within the ventricles, is a soft tissue and easily affected by pressure. Obliterated subarachnoid space and dangling choroid plexus in the case of hydrocephalus (Figures 39.19 and 39.20). In contrast, the subarachnoid space and choroid plexus are well preserved in cases of ventriculomegaly (Figure 39.21). It is difficult to evaluate obliterated subarachnoid space in the trans-abdominal axial section and this method may not differentiate

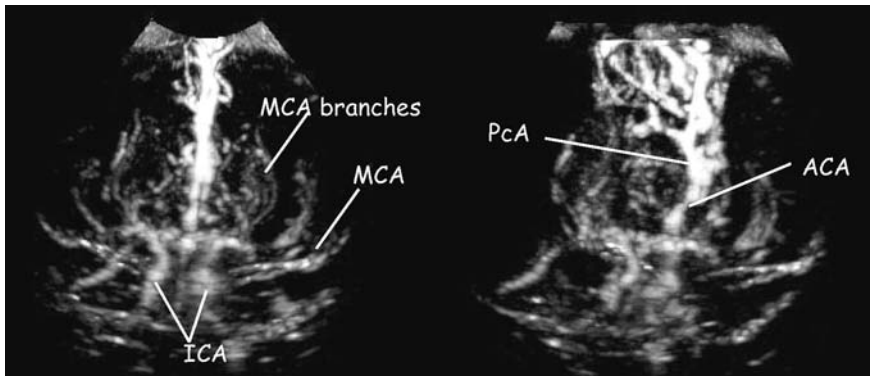

Figure 39.15 Three-dimensional power Doppler image of fetal brain circulation. (Left) View from the front. Bilateral internal carotid arteries (ICA) and middle cerebral arteries (MCA) and branches of MCA are demonstrated. (Right) Oblique view. Anterior cerebral artery (ACA) and pericallosal artery (PcA) are demonstrated.

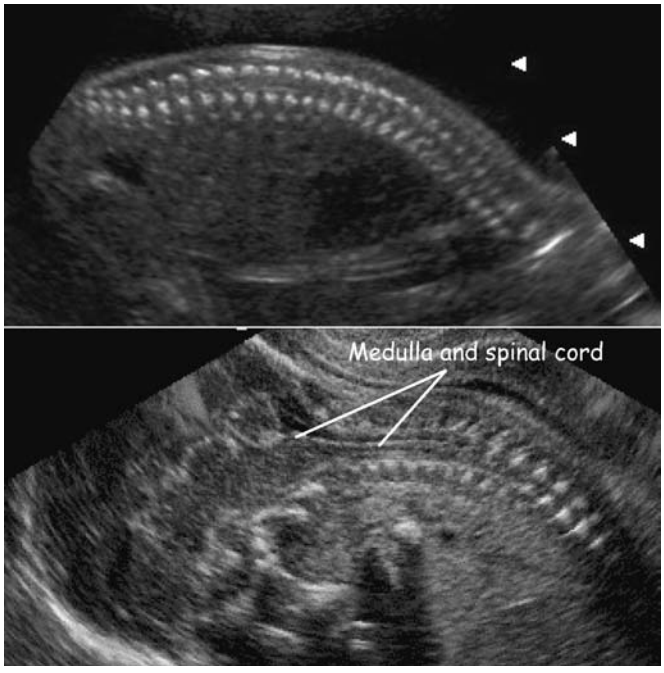

Figure 39.16 Normal vertebral structure in the sagittal section at 19 weeks of gestation. Lower figure shows the medulla and spinal cord in the craniospinal region.

accurately hydrocephalus with increased intracranial pressure from ventriculomegaly without pressure. Therefore, it is suggested that the evaluation of fetuses with enlarged ventricles should be performed in the parasagittal and coronal views by transvaginal way or 3D multidimensional analysis. In some cases with hydrocephalus, the septum pellucidum is destroyed and both ventricles are fused to each other (Figure 39.19). This condition should be differentiated from lober type of holoprosencephaly. Furthermore, intracranial venous blood flow may be related to increased intracranial pressure. In normal fetuses, blood flow waveforms of dural sinuses, such as superior sagittal sinus, vein of Galen, and straight sinus have pulsatile pattern (Figure 39.22).[26] However, in cases with progressive hydrocephalus, normal pulsation disappears and blood flow waveforms display a flat pattern (Figure 39.23).[26] In cases with progressive hydrocephalus, there may be seven stages of progression (Figure 39.24): (1) increased fluid collection of lateral ventricles; (2) increased intracranial pressure; (3) dangling choroids plexus; (4) disappearance of subarachnoid space; (5) excessive extension of the dura and superior sagittal sinus; (6) disappearance of venous pulsation; and finally (7) enlarged skull. In general, both hydrocephalus and ventriculomegaly are still evaluated by the measurement of biparietal diameter (BPD) and atrial width (AW) in transabdominal axial section. As a screening examination, the measurement of AW is useful with a cut-off value of 10 mm.[27,28] As described above, however, hydrocephalus and ventriculomegaly should be differentiated from each other and hydrocephalic state should be assessed by changing appearance of the intracranial structure. To evaluate enlarged ventricles, examiners should carefully observe the structures mentioned below and specify causes of hydrocephalus:

- choroids plexus, dangling or not
- subarachnoid space, obliterated or not
- ventricles, symmetry or asymmetry
- visibility of third ventricle
- pulsation of dural sinuses
- ventricular size (3D volume calculation if possible)
- other abnormalities.

Genetic hydrocephalus is rare but important in counseling couples on subsequent pregnancy. X-linked hydrocephalus (HSAS, hydrocephalus due to stenosis of the aqueduct of Sylvius), MASA (mental retardation-aphasia-shuffling gait-adducted thumbs) syndrome, X-linked complicated spastic paraparesis (SP1), and X-linked corpus callosum agenesis (ACC) are all due to mutations in the L1 gene.[29] The gene encoding L1 is located near the telomere of the long arm of the X chromosome in Xq28. Therefore, it was suggested to refer to this clinical syndrome with the

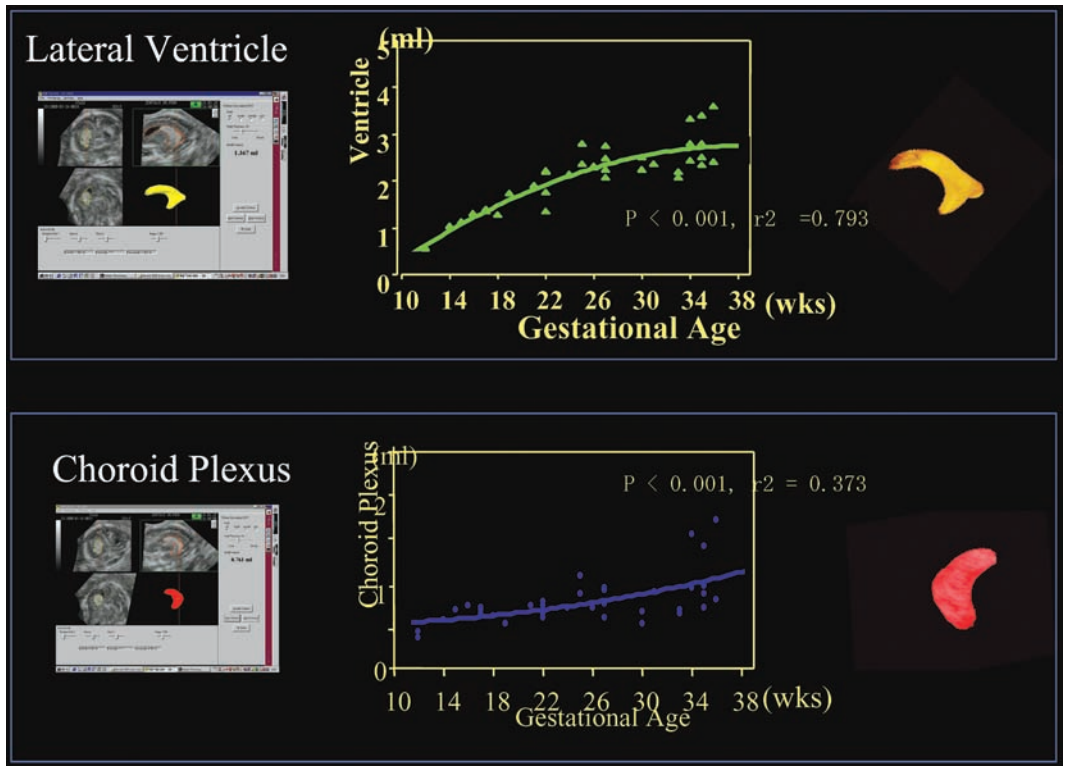

Figure 39.17 Three-dimensional volume extraction and volumetric analysis of lateral ventricle and choroid plexus. On three orthogonal sections, the target organ can be traced automatically or manually with rotation of volume imaging data. After tracing, volume extracted image (right) is demonstrated and volume calculation data is shown. Middle graphs show normograms of ventricular size (upper) and choroid plexus size (lower) during pregnancy.

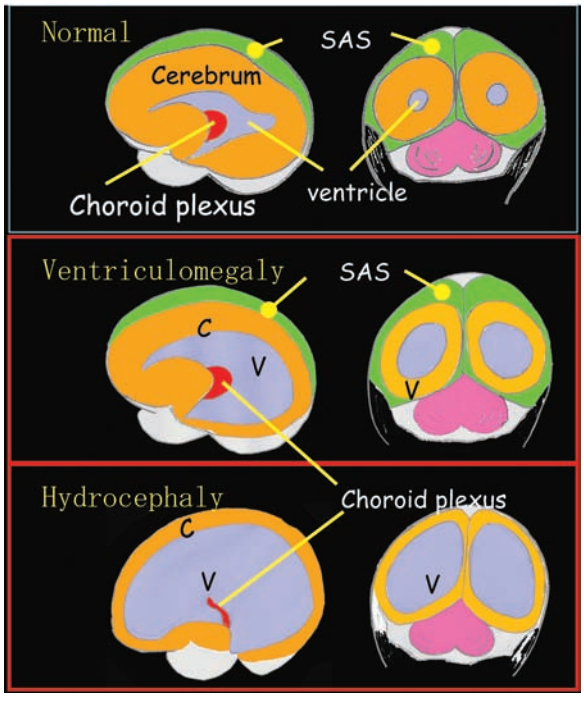

Figure 39.18 Schema of ventriculomegaly and hydrocephaly. In cases of ventriculomegaly without increased intracranial pressure, subarachnoid space (SAS) and choroid plexus appearances are well preserved, while in cases of hydrocephaly with increased intracranial pressure, dangling choroid plexus and gradual disappearance of SAS are seen.

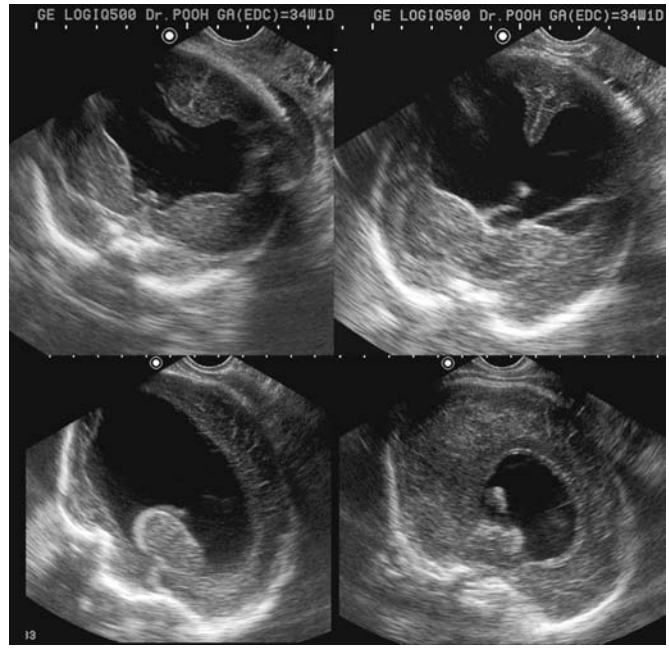

Figure 39.19 Ultrasound images of hydrocephalus at 34 weeks of gestation. (Upper) Coronal images. Septum pellucidum was destroyed maybe due to enlargement of bilateral ventricles and both ventricles were fused. Dangling choroid plexus is seen. (Lower) Parasagittal and sagittal images. Dangling choroid plexus and obliterated subarachnoid space are seen.

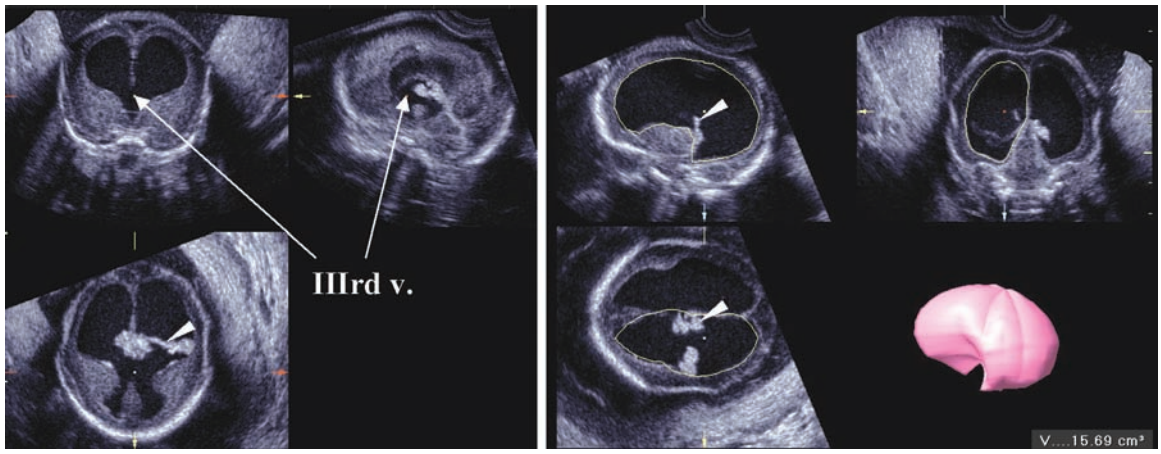

Figure 39.20 Hydrocephalus due to aqueductal obstruction at 19 weeks of gestation. (Left) Three orthogonal views with anterior coronal (upper left) and median sagittal (upper right) and axial (lower left) slices. Bilateral ventriculomegaly and third ventriculomegaly (IIIrd v.) are seen. No enlargement of fourth ventricle indicates obstruction of the aqueduct. (Right) Three orthogonal views with parasagittal (upper left), posterior coronal (upper right), and axial (lower left) slices. Subarachnoid space is already obliterated and dangling choroid plexus (arrowheads) is seen. Lower right pink figure shows extracted 3D ventricular image by VOCAL mode. Ventricle in this case was 10-fold size of normal 19-week-ventricle.

acronym CRASH, for corpus callosum hypoplasia, retardation, adducted thumbs, spastic paraplegia, and hydrocephalus.[29] It has been reported that mutations which produce truncations in the extracellular domain of the L1 protein are more likely to produce severe hydrocephalus, grave mental retardation or early death than point mutations in the extracellular domain or mutations affecting only the cytoplasmic domain of the protein.[30] For the families, prenatal CNS diagnosis of male infants is important. Morphology-based approach becomes feasible between postmenstrual weeks 15 and 20. Prior to this gestational age, the diagnosis should rely on molecular biology tests.[31]

Borderline ventriculomegaly is defined as a width of the atrium of the lateral cerebral ventricles of 10–15 mm. The majority with prenatally detected isolated mild ventriculomegaly are developmentally normal.[32] Pilu and his colleagues[33] reviewed 234 cases of borderline ventriculomegaly including an abnormal outcome in 22.8% and concluded that borderline ventriculomegaly carries an increased risk of cerebral maldevelopment, delayed neurological development, and possibly, chromosomal aberrations.

The treatment of hydrocephalus includes a miniature reserver,[34,35] shunt procedure, and neuroendoscopy. Ventriculoperitoneal shunt is the most popular procedure. Effectiveness of shunt procedure for congenital hydrocephalus has been proven from earlier. However, it has been known that there are various complications of shunting, such as shunt infection obstruction of the shunt tube, over drainage, under drainage, and slit ventricle syndrome. To reduce these complications, various types of shunt devices, such as antisiphon device or pressure programmable valve shunt device have been developed. Third ventriculostomy by neuroendoscopy has recently been performed in children with obstructive hydrocephalus,

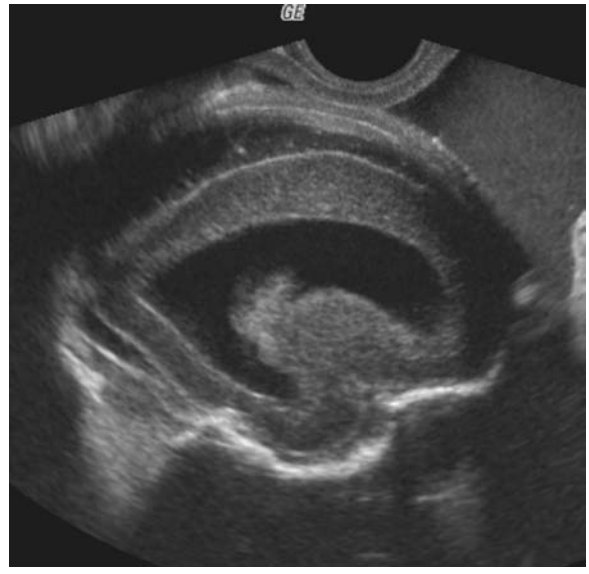

Figure 39.21 Ultrasound image of ventriculomegaly at 29 weeks of gestation. Enlarged ventricle exists but subarachnoid space is well preserved and no dangling choroid plexus is seen. From these findings, nonincreased intercranial pressure (ICP) is estimated. This condition should be differentiated from hydrocephalus with increased ICP.

and the number of shunt-independent cases has been increased. It has been controversial, however, whether infants less than the age of 1 year have a higher risk of treatment failure after neuroendoscopic procedures than older children. Some conclude that neuroendoscopy presents an effective alternative for the treatment of hydrocephalus in cases under the age of 1 year.[36] However, third ventriculostomy still does not seem to be effective in neonates because of their prematurity of absorption ability in neonates and small infants.

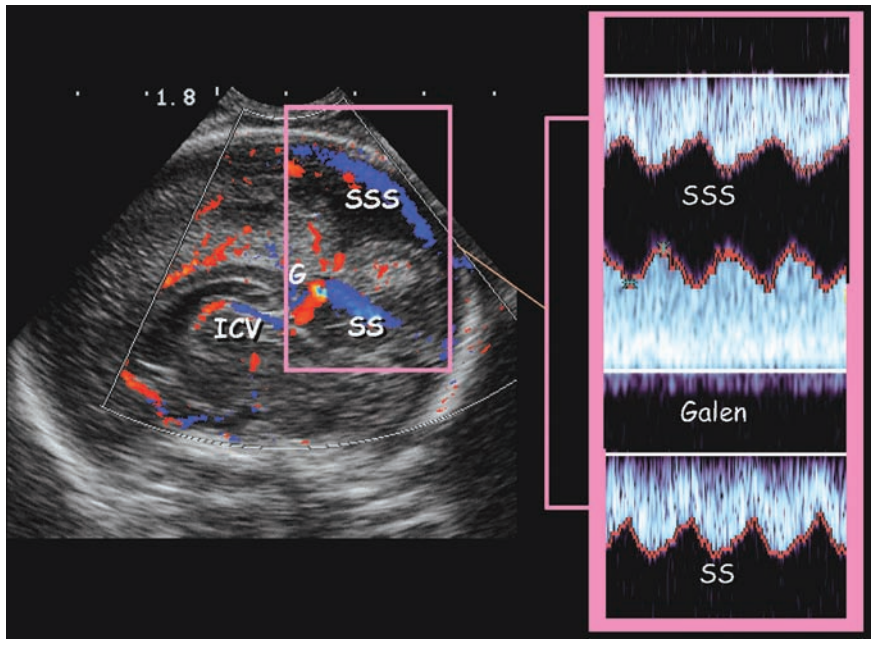

Figure 39.22 Normal cerebral venous circulation. (Left) Sagittal image of color Doppler. SSS, superior sagittal sinus; ICV, internal cerebral vein; G, vein of Galen; SS, straight sinus. (Right) Normal blood flow waveforms of dural sinuses. In normal fetuses, venous flow always has pulsations.

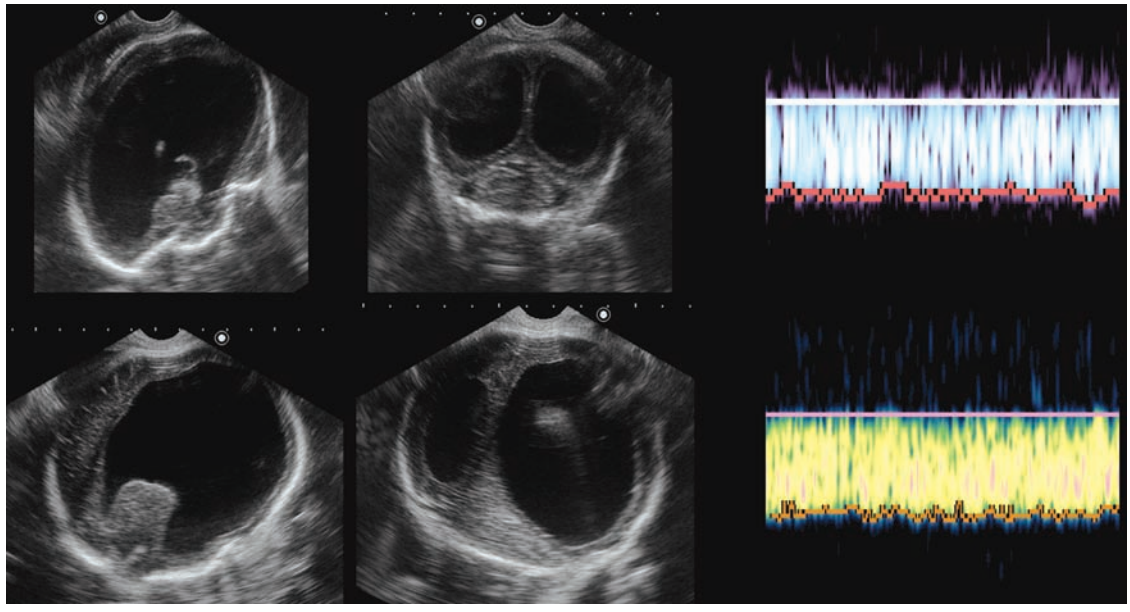

Figure 39.23 Disappearance of venous pulsation in cases with hydrocephalus. Normal dural sinuses have pulsatile patterns of flow waveform (Figure 39.22). In cases with progressive hydrocephalus, venous pulsation disappeared (right figures) maybe because of excessive extension of the dura and dural sinuses.

Congenital CNS anomalies

Cranium bifidum

Prevalence: Anencephaly; 0.29/1000 births,[37] overall neural tube defect (NTD); 0.58–1.17/1000 births.[38–40] Many reported remarkable reduction of prevalence of NTDs after using folic acid supplementation and fortification,[37–40] although some reported no decline of anencephaly rate.[41]

Definition: As in spina bifida, cranium bifidum is classified into four types of encephaloschisis (including anencephaly and exencephaly), meningocele, encephalomeningocele, encephalocystocele, and cranium bifidum occulutum. Encephalocele occurs in the occipital region in 70–80%. Acrania, exencephaly, and anencephaly are not independent anomalies. It is considered that dysraphia (absent cranial vault, acrania) occurs in very early stage and disintegration of the exposed brain (exencephaly) during the fetal period results in anencephaly.[42]

Etiology: Multifactorial inheritance, single mutant genes, specific teratogens (valproic acid), maternal

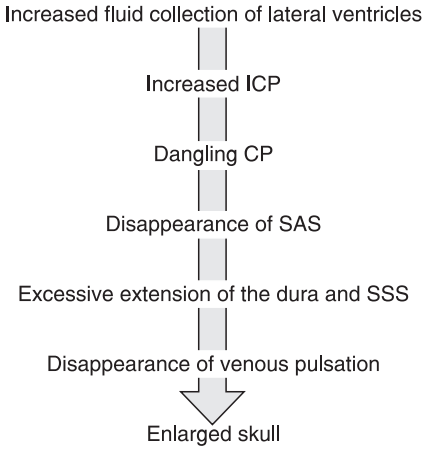

Figure 39.24 Progressive stages of hydrocephalus. ICP, intracranial pressure; CP, choroid plexus; SAS, subarachnoid space.

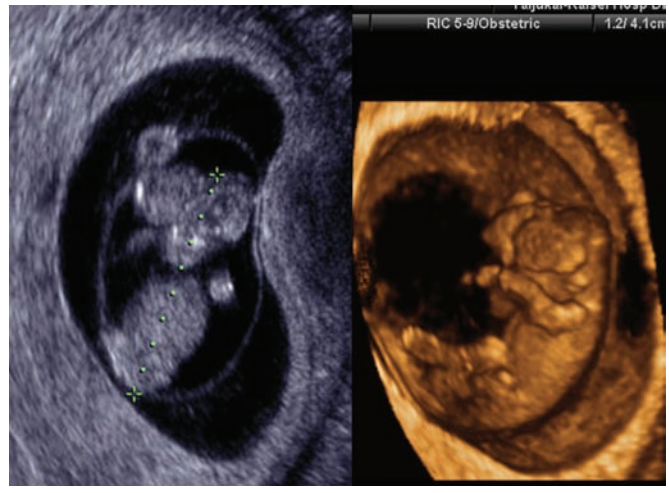

Figure 39.25 Acrania at 10 weeks of gestation. (Left) Ultrasound coronal image at 10 weeks. Note the normal appearance of amniotic membrane, which indicates that this condition is not amniotic band syndrome. (Right) Three-dimensional ultrasound image of the same fetus as in the left image.

diabetes, environmental factors, predominant in females.

Pathogenesis: Failure of anterior neural tube closure or a restricted disorder of neurulation.

Associated anomalies: Open spina bifida (inencephaly), Chiari type III malformation, bilateral renal cystic dysplasia, and postaxial polydactyly with occipital cephalocele (Meckel–Gruber syndrome), hydrocephalus, polyhydramnios.

Prenatal diagnosis: Acrania in Figure 39.25, anencephaly in Figure 39.26, and early detection of inencephaly in Figure 39.27.

Differential diagnosis: Amniotic band syndrome (ABS). In cases of ABS, cranial destruction occurs secondarily to an amniotic band, similar appearance is observed. However, ABS has completely different pathogenesis from acrania/excencephaly.

Prognosis: Anencephaly is a uniformly lethal anomaly. Other types of cranium bifidum, various neurological deficits may occur, depending on types and degrees.

Recurrence risk: Used to be high recurrence risk of 5–13%; however, the risk has recently declined by use of folic acid supplementation and fortification.

Obstetrical management: Termination of pregnancy can be offered in cases with anencephaly.

Neurosurgical management: For other cranium bifidum, surgical operation aims at transposition of cerebral tissue into the intracranial cavity. Ventriculoperitoneal shunt for hydrocephalus.

Spina bifida

Prevalence: 0.22/1000 births,[37] overall NTD; 0.58–1.17/1000 births.[38–40] Many reported remarkable reduction of prevalence of NTDs after using folic acid supplementation and fortification.[37–41]

Definition: Spina bifida aperta, manifest form of spina bifida is classified into four types: meningocele, myelomeningocele, myelocystocele, and myeloschisis. Spina bifida occuluta is a generic term of spinal diseases covered with normal skin tissue, and does not indicate spinal diseases which cannot be diagnosed by external appearance. Cutaneous abnormalities near the spinal lesion are found; skin bulge (subcutaneous lipoma), dimple, hair tuft, pigmentation, skin appendage and hemangioma. In cases with thickened film terminale, dermal sinus, or diastematomyelia (split cord malformation), abnormal tethering and fixation of the spinal cord occur.

Etiology: Multifactorial inheritance, single mutant genes, autosomal recessive, chromosomal abnormalities (trisomy 18, 13), specific teratogens (valproic acid), maternal diabetes, environmental factors, predominant in females.

Pathogenesis: Spina bifida aperta: an impairment of neural tube closure. Spina bifida occuluta: caudal neural tube malformation by the processes of canalization and retrogressive differentiation.

Associated anomalies: Chiari type II malformation, hydrocephalus, scoliosis (above L2), polyhydramnios, additional non-CNS anomalies.

Prenatal diagnosis: Figures 39.28–39.31.

Differential diagnosis: Sacrococcygeal teratoma.

Prognosis: Disturbance of motor, sensory, and sphincter function. Depends on lesion levels. Below S1, unable to walk unaided; above L2, wheelchair dependent; variable at intermediate level.

Recurrence risk: Decreased, almost no recurrence rate[43] by use of folic acid supplementation and fortification.

Obstetrical management: In cases with spina bifida aperta, especially with defect of skin, cesarean section is preferable to protect the spinal cord and nerves and prevent infection.

Neurosurgical management: Spina bifida aperta: in cases with defect of normal skin tissue, immediate closure of spina bifida after birth reduces spinal infection. Spinal cord reconstruction is the most important

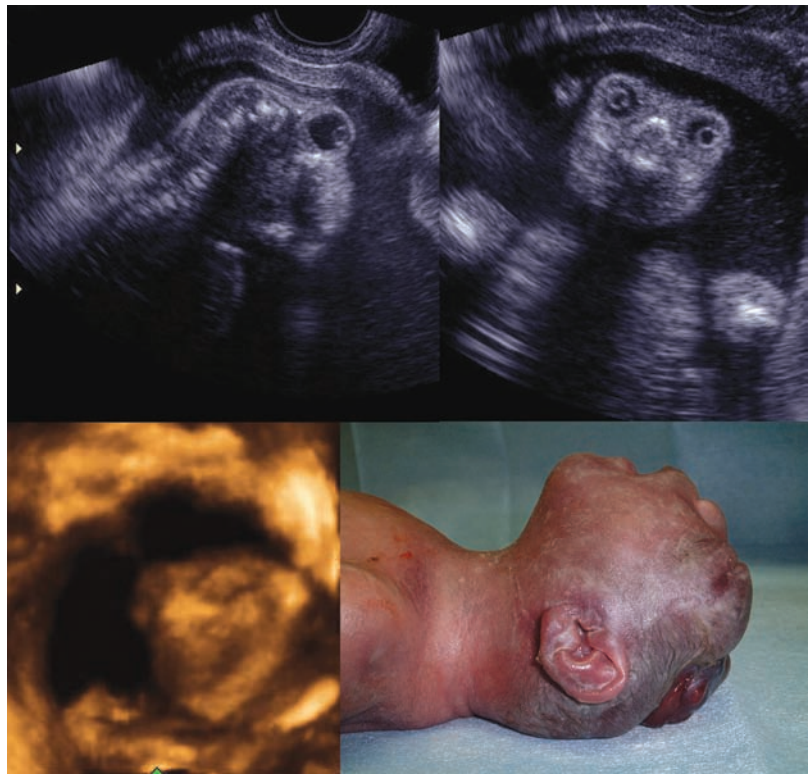

Figure 39.26 Anencephaly in middle gestation. (same case as in Figure 39.25). (Upper left) Ultrasound sagittal image at 23 weeks of gestation. (Upper right) Ultrasound coronal image. (Lower left) Three-dimensional ultrasound image. (Lower right) External appearances of stillborn fetus at 25 weeks of gestation. It is clear that excencephalic brain tissue scattered in the amniotic space compared with this case at 10 weeks.

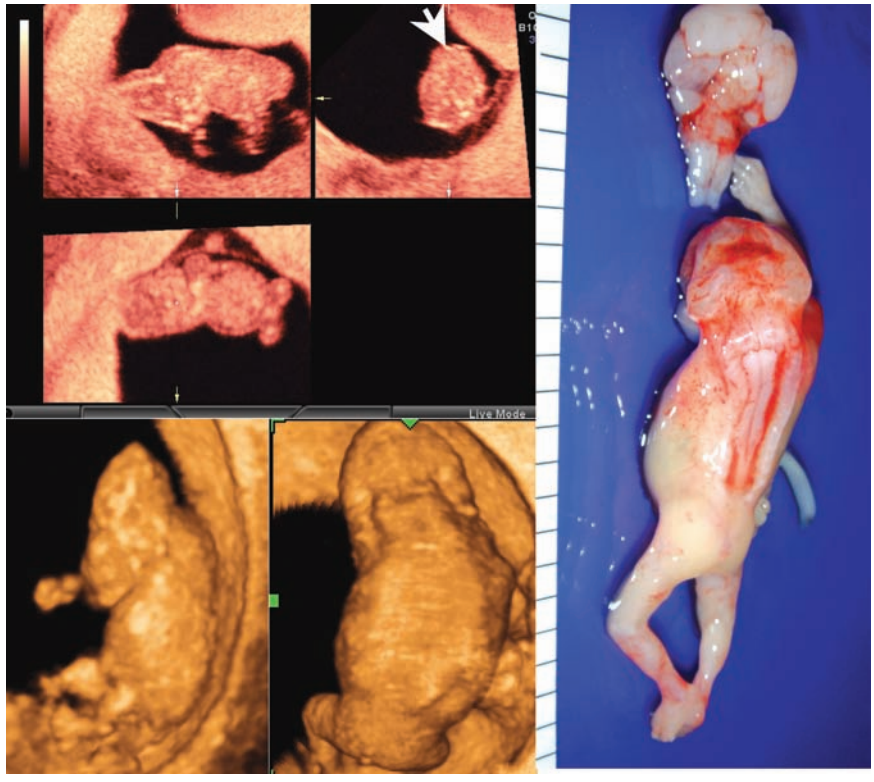

Figure 39.27 3D detection of a fetus with iniencephaly and acrania at 10 weeks of gestation. (Upper left) Three orthogonal views of the fetus. Spina bifida (arrow) was demonstrated in the coronal section. (Lower left) Three-dimensional images show the fetal lateral and dorsal views. (Right) External appearance of aborted fetus at the end of 11 weeks of gestation. The brain and a part of spinal cord were detached at delivery.

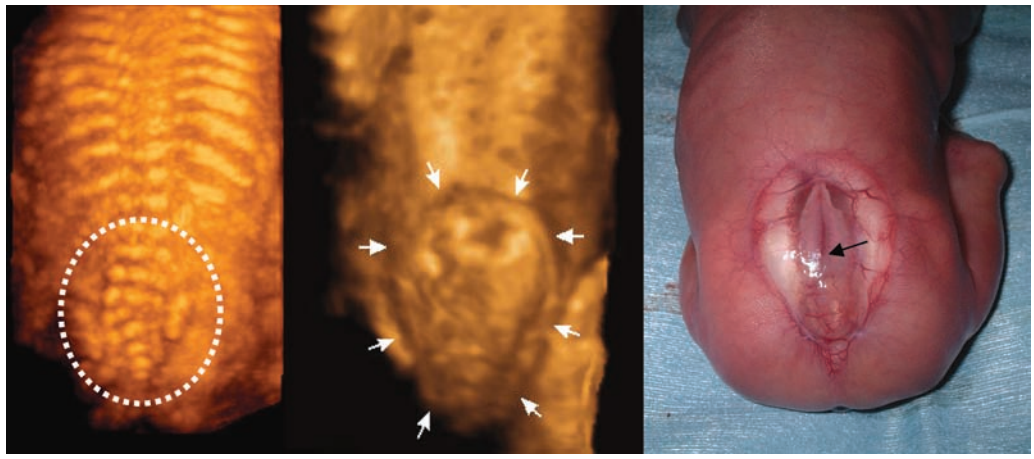

Figure 39.28 Prenatal ultrasound image of myelomeningocele, spina bifida at 20 weeks of gestation. (Left) Three-dimensional bony demonstration of lumber spina bifida. Three-dimensional ultrasound shows the exact level of spina bifida. (Middle) Three-dimensional surface reconstruction of large myelomeningocele (white arrows). (Right) External appearance of aborted fetus at 21 weeks of gestation. Note the central canal of the spinal cord (black arrow) in large myelomeningocele.

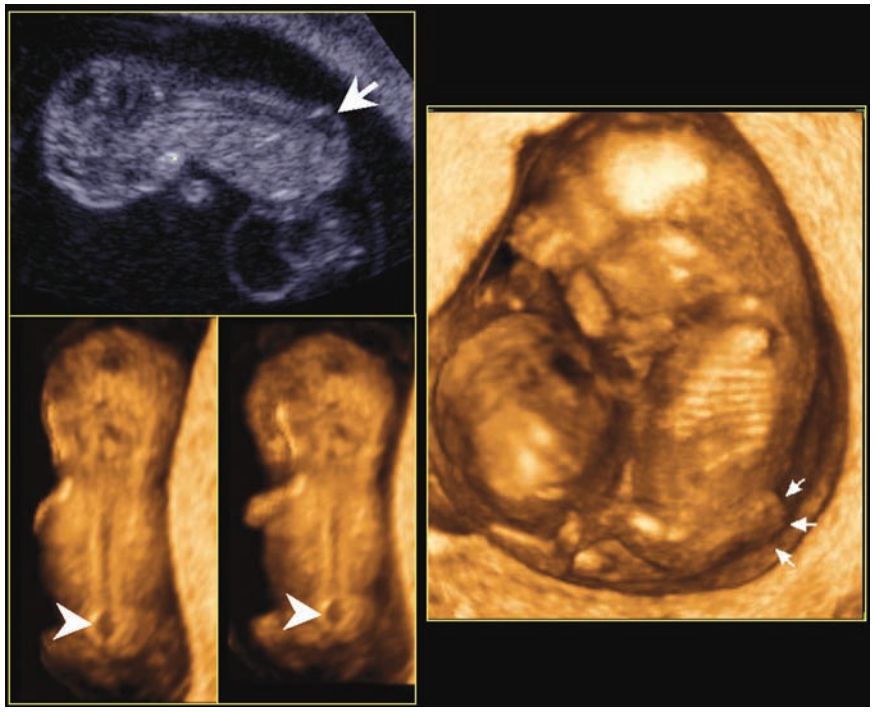

Figure 39.29 Myelomeningocele in early pregnancy. Two-dimensional sagittal view at 9 weeks of gestation (upper left) shows the cystic lesion (arrow). Three-dimensional dorsal views at 9 weeks (lower left) clearly demonstrate a neural tube defect at the lower lumber and sacral level (arrowheads). Right figure shows the same fetus at 12 weeks of gestation. Arrows indicate the lumbosacral myelomeningocele.

role of operation. Miniature Ommaya reservoir placement and subsequent ventriculoperitoneal shunt are required for hydrocephalus (see Chapter 5). For symptomatic Chiari malformation, posterior fossa decompressive craniectomy and/or tonsillectomy is performed. Spina bifida occuluta: the aim of surgical treatment is decompression of the spinal cord and cutting off tethering to the spinal cord (Figures 39.32 and 39.33).

Chiari malformation

Prevalence: Depends on prevalence of spina bifida (Chiari type II malformation). According to recent remarkable reduction of prevalence of NTDs after using folic acid supplementation and fortification, prevalence has declined. Other types are rare.

Definition: Chiari classified anomalies with cerebellar herniation in the spinal canal into three types by contents of herniated tissue: contents of type I is a

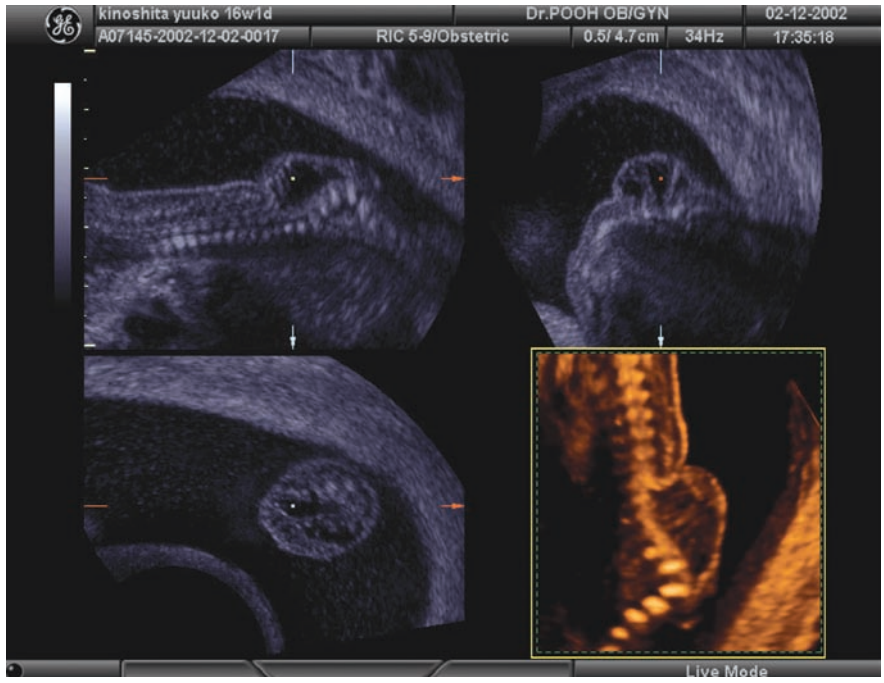

Figure 39.30 Three-dimensional ultrasound image of myelomeningocele with kyphosis at 16 weeks of gestation. Three orthogonal views and surface reconstruction image. (Upper left) Sagittal ultrasound image. Spinal cord completely protrudes into the sac surface from spinal canal and severe kyphosis is seen (upper right). Axial ultrasound view. (Lower left) Coronal ultrasound view of myelomeningocele. Lower right figure demonstrates the sagittal vertebral bony structure by 3D thick slice.

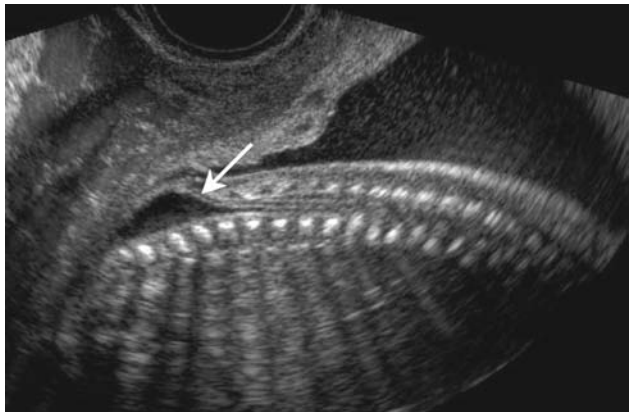

Figure 39.31 Two-dimensional sagittal section of myelomeningocele at 19 weeks of gestation. The spinal cord (arrow) protrudes from spinal canal toward the sac surface of myelomeningocele.

lip of cerebellum, type II part of cerebellum, fourth ventricle and medulla oblongata, pons, and type III large herniation of the posterior fossa. Thereafter, type IV with just cerebellar hypogenesis was added. However, this classification occasionally leads to confusion in neuroimaging diagnosis. Therefore, at present, the classification as given below is advocated:

Type I: Herniation of only cerebellar tonsil, not associated with myelomeningocele.

Type II: Herniation of cerebellar tonsil and brain stem. Medullary kink, tentorial dysplasia, associated with myelomeningocele.

Type III: Associated with cephalocele or craniocervical meningocele, in which cerebellum and brainstem are herniated.

Type IV: Associated with marked cerebellar hypogenesis and posterior fossa shrinking.

Synonyms: Arnold–Chiari malformation.

Etiology: Depends on the types.

Pathogenesis: Schematic picture and macroscopic findings, MRI images are in Figures 39.32 and 39.33. Chiari malformation occurs according to: (1) inferior displacement of the medulla and the fourth ventricle into the upper cervical canal; (2) elongation and thinning of the upper medulla and lower pons and persistence of the embryonic flexure of these structures; (3) inferior displacement of the lower cerebellum through the foramen magnum into the upper cervical region; and (4) a variety of bony defects of the foramen magnum, occiput, and upper cervical vertebrae.[44]

Associated anomalies: Hydrocephalus caused by obstruction of fourth ventricular outflow or associated aqueductal stenosis. Myelomeningocele or myeloschisis (type II), cephalocele or craniocervical meningocele (type III), cerebellar hypogenesis (type IV), and syringomyelia (type I).

Prenatal diagnosis: Prenatal ultrasound diagnosis by features; lemon sign which indicates deformity of the frontal bone, banana sign which indicates abnormal shape of cerebellum without cisterna magna space (Figure 39.34), medullary, kink small clivus-supraocciput angle.[45] Figure 39.35 shows the sagittal ultrasound imaging of Chiari type II malformation compared to normal structure.

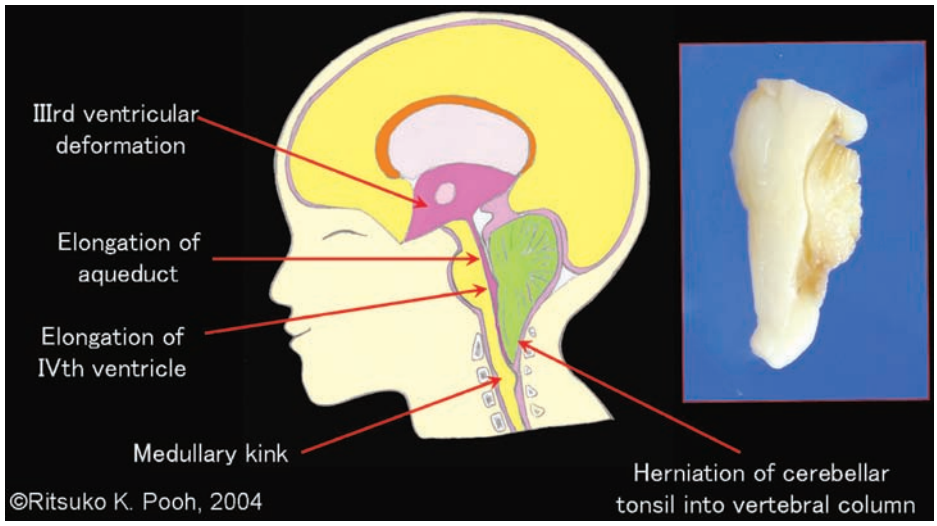

Figure 39.32 Schema and macroscopic finding of Chiari type II malformation. Chiari type II malformation is characterized by inferior displacement of the lower cerebellum through the foramen magnum with obliteration of the cisterna magna, inferior displacement of the medulla into the spinal canal, and elongation of the fourth ventricle and aqueduct. Right picture shows the macroscopic view of the elongated aqueduct, fourth ventricle, and cerebellum from the specimen of an aborted fetus at 21 weeks of gestation.

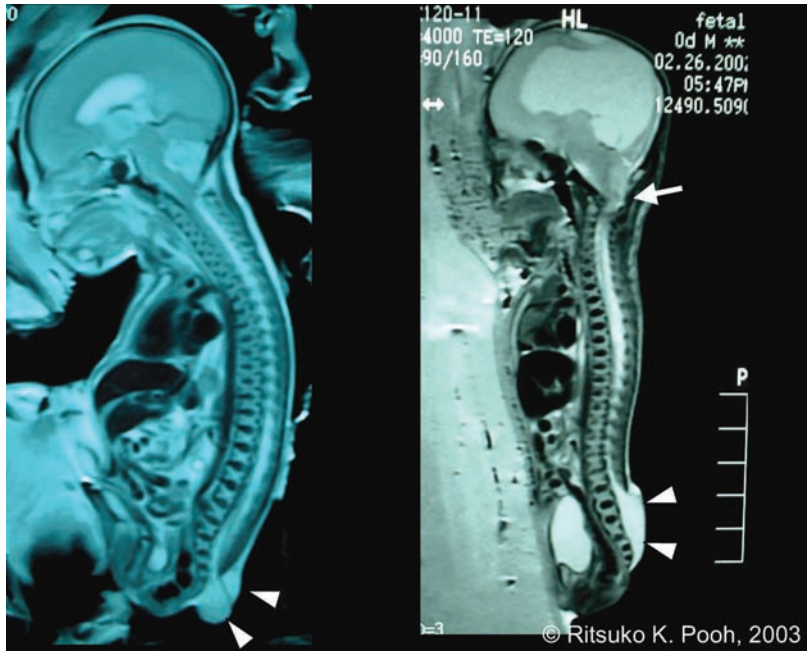

Figure 39.33 Magnetic resonance (MR) images of aborted fetuses at 20–21 weeks of gestation. (Left) At 20 weeks of gestation. Sacral myelomeningocele (arrowhead) and Chiari type II malformation are demonstrated. (Right) At 21 weeks of gestation. Lumbosacral myelomeningocele with Chiari type II malformation is seen. In this case, myelomeningocele is complicated with holoprosencephaly. Normal karyotype. Severe medullary kink (arrow) is seen.

Differential diagnosis: Craniosynostosis.

Prognosis: Nearly every case of myelomeningocele is accompanied by morphological Chiari II malformation. Many cases with Chiari II are asymptomatic. However, clinical features due to Chiari malformation, such as feeding disturbances, laryngeal stridor, or apneic episode, are found in approximately 9–30% of cases. In cases with these clinical features, vital prognosis is often poor.

Recurrence risk: Depends on types of Chiari malformation. Decreased according to decline of NTD recurrence rate by use of folic acid supplementation and fortification.

Neurosurgical management: Neurosurgical decompression of foramen magnum (FMD) for any type of Chiari malformation. Syringo-subarachnoid shunt for Chiari type I.

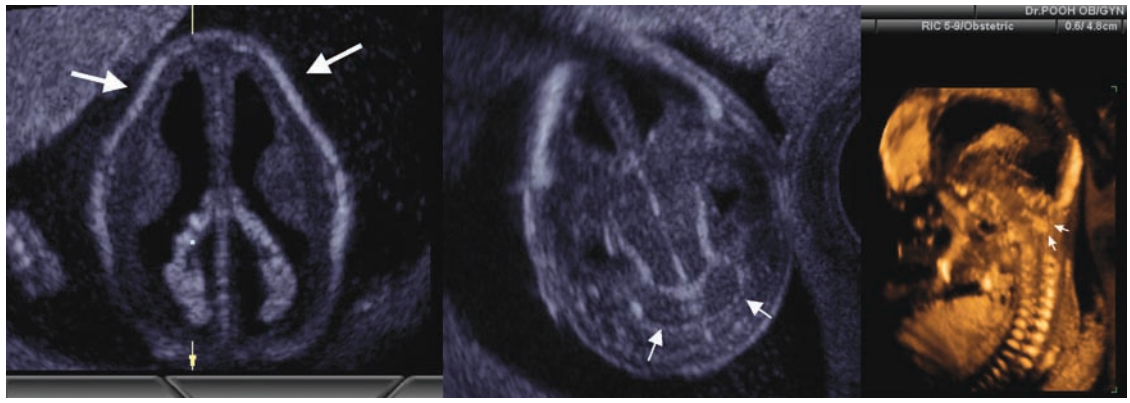

Figure 39.34 Chiari type II malformation at 16 weeks of gestation. Chiari type II malformation is observed in most cases with myelomeningocele and myeloschisis. (Left) Typical lemon sign (arrows). (Middle) Typical banana sign (arrows). (Right) Three-dimensional reconstruction internal image of Chiari type II malformation (arrows).

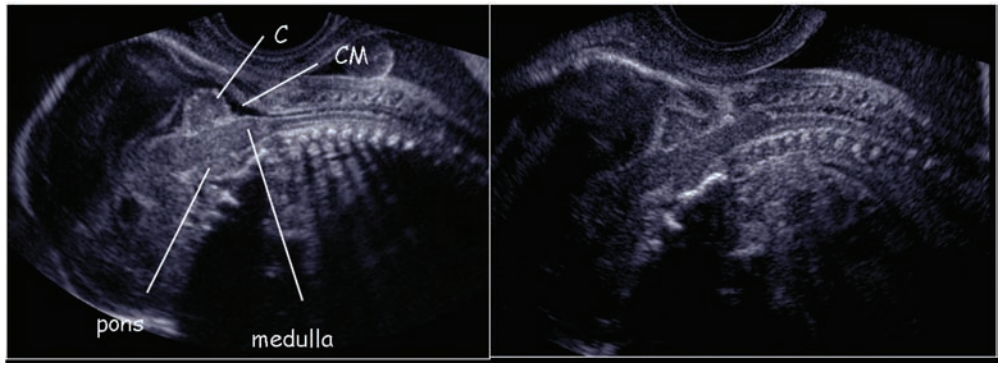

Figure 39.35 Medullary kink in a case of Chiari II malformation at 19 weeks of gestation. (Left) Medullary kink (arrowhead) associated obliterated cisterna magna is demonstrated. (Right) Comparative normal image in the same cutting section at the same gestation. The cisterna magna, cerebellum, and medullospinal portions are clearly demonstrated.

Holoprosencephaly

Incidence: 1 in 15,000–20,000 live births, however, initial incidence may be more than 60-fold in aborted human embryos.[45,46]

Classification:[44] Holoprosencephalies are classified into three varieties:

- Alobar type: a single-sphered cerebral structure with a single common ventricle, posterior large cyst of third ventricle (dorsal sac), absence of olfactory bulbs and tracts and a single optic nerve.
- Semilobar type: with formation of a posterior portion of the interhemispheric fissure.
- Lobar type: with formation of the interhemispheric fissure anteriorly and posterorly, but not in the midhemispheric region. The fusion of the fornices is seen.[47]

Etiology: 75% of holoprosencephaly has normal karyotype, but chromosomes 2, 3, 7, 13, 18, and 21 have been implicated in holoprosencephaly.[44] Particularly, trisomy 13 has most commonly been observed. Autosomal dominant transmission is rare.

Pathogenesis: Failure of cleavage of the prosencephalon and diencephalon during early first trimester (5–6 weeks) results in holoprosencephaly.

Associated anomalies: Facial abnormalities such as cyclopia, ethmocephaly, cebocephaly, flat nose, cleft lip and palate are invariably associated with horoprosencephaly. Extracerebral abnormalities are also invariably associated, such as renal cysts/dysplasia, omphalocele, cardiac disease and/or myelomeningocele.

Prenatal diagnosis: Alobar type in Figure 39.36 and semilobar type in Figure 39.37. Figure 39.38 shows facial appearance in cases of holoprosencephaly.

Differential diagnosis: Hydrocephalus, hydranencephaly.

Prognosis: Extremely poor in alobar holoprosencephaly. Uncertain in lobar type. Various but poor in semilobar type.

Recurrence risk: 6%,[48] but much lower in sporadic or trisomy cases, much higher in genetic cases.

Management: Chromosomal evaluation is offered.

Figure 39.36 Alobar holoprosencephaly at 15 weeks of gestation. Three orthogonal images of intracranial structure show a complete single ventricle within a single-sphered cerebral structure.

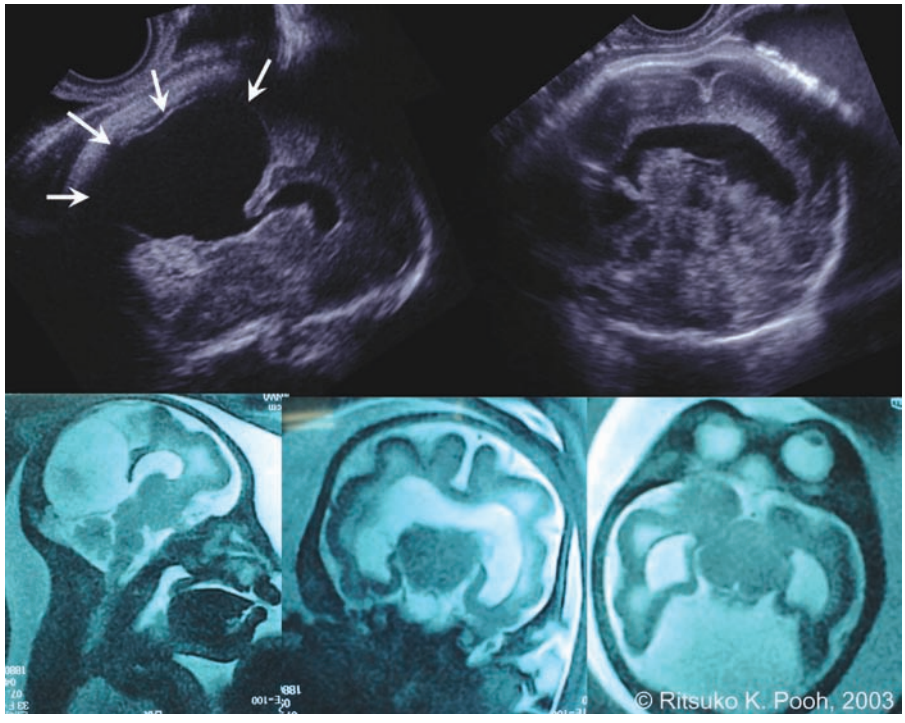

Figure 39.37 Semilobar holoprosencephaly at 33 weeks of gestation. Upper left shows dorsal sac (arrows) in the median section. Upper right demonstrates the fused ventricle. Lower figures are fetal MR images. Sagittal (left), coronal(middle), and axial (right) sections. A blind end of nasal cavity and hypotelorism are seen in the sagittal and axial MR images, respectively.

Agenesis of the corpus callosum

Prevalence: Uncertain, but 3–7/1000 in the general population is estimated.

Definition: Absence of the corpus callosum, which may be divided into (complete) agenesis, partial agenesis, or hypogenesis of the corpus callosum (Figure 39.39).

Complete agenesis: complete absence of the corpus callosum.

Partial agenesis (hypogenesis): absence of splenium or posterior portion in various degrees.

Etiology: Chromosomal aberration in 20% of affected cases, such as trisomy 18, 8, and 13. Autosomal dominant, autosomal recessive, X-linked recessive, part of

Figure 39.38 Facial abnormality in cases of holoprosencephaly. Upper figures are prenatal 3D facial images and lower figures show postpartum face appearance of each baby. (Left) Alobar holoprosencephaly at 20 weeks. (Middle and right) Semilobar type in late pregnancy. Hypotelorism and exophthalmos are common. Left and middle cases had cleft lip and palate and obstruction of the nasal cavity. Right case had a single and obstructed nasal cavity.

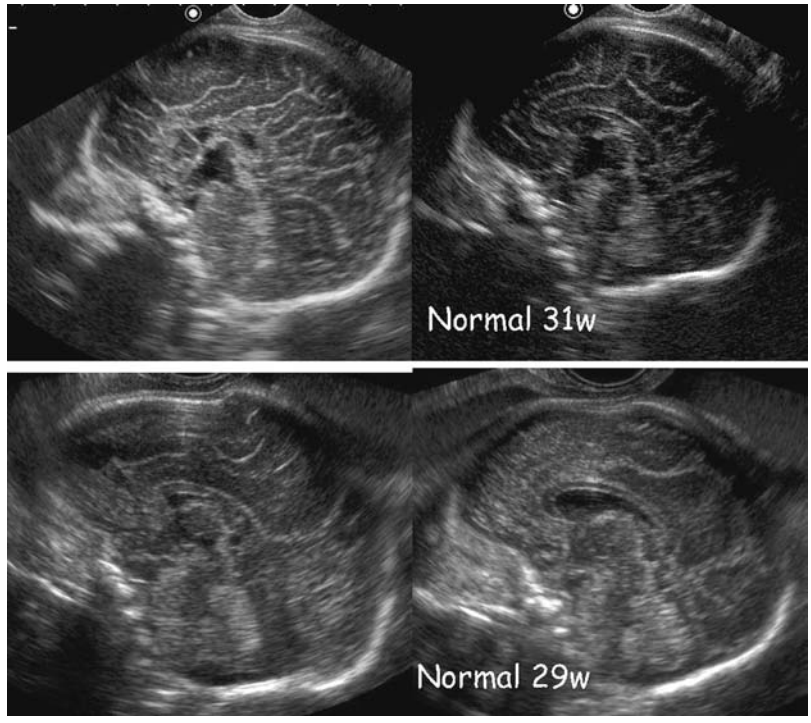

Figure 39.39 Complete agenesis (upper) and hypogenesis (lower) of the corpus callosum. All images are transvaginal median (mid-sagittal) images. Right images are normal images of the corpus callosum at the same gestational age as each left image.

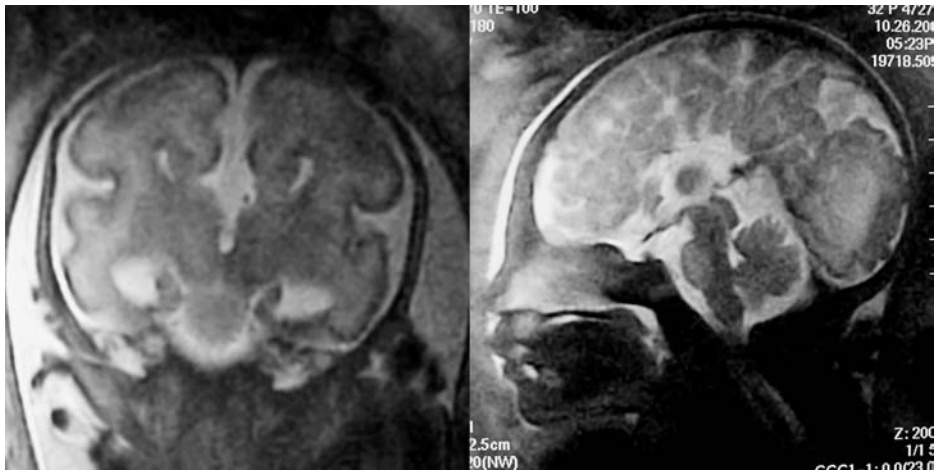

Figure 39.40 Fetal MR images of complete agenesis of the corpus callosum at 33 weeks of gestation. Anterior coronal section (left) and median section (right). No communicated bridge is seen. Note the bull's horn like appearance of the anterior horns of lateral ventricle in the coronal image.

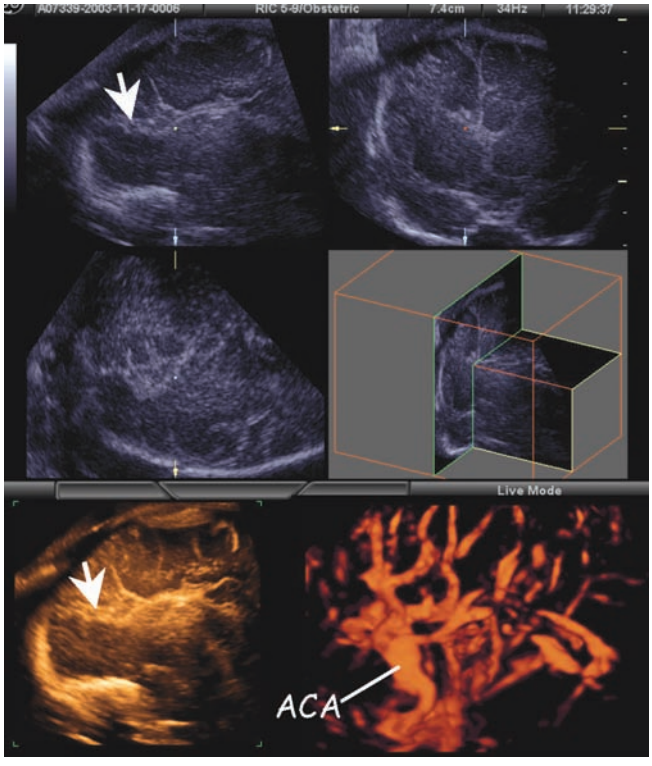

Figure 39.41 Agenesis of the corpus callosum with abnormal gyration at 36 weeks of gestation. Upper figure shows the three orthogonal view of the brain with agenesis of the corpus callosum with an abnormal gyrus (arrow). Lower left figure is a thick slice of the sagittal section. Abnormal gyration (arrow) is more clearly demonstrated. Lower right shows the intracranial angiostructure by 3D power Doppler. Normal pericallosal artery does not exist and radial formation of the branches of anterior cerebral arteries (ACA) is seen.

mendelian syndrome such as Walker–Warburg syndrome, and X-linked dominant such as Aicardi syndrome.

Pathogenesis: Uncertain, but callosal formation may be associated with migration disorder.

Associated anomalies: Colpocephaly (ventriculomegaly with disproportionate enlargement of trigones, occital horns, and temporal horns, not hydrocephaly), superior elongation of the third ventricle, interhemnispheric cyst, lipoma of the corpus callosum.

Prenatal diagnosis: Fetal MRI in Figure 39.40 and median sonographic images in Figure 39.41. Colpocephaly is shown in Figure 39.42.

Diagnosis: As the corpus callosum is depicted after 17 or 18 weeks of gestation by ultrasound, it is impossible to diagnose agenesis of the corpus callosum prior to this age.[49]

Prognosis: Various, depends on associated anomalies. Most cases with isolated agenesis of the corpus callosum without other abnormalities are asymptomatic and prognosis is good. Complete agenesis has a worse prognosis than partial agenesis.[50] Epilepsy, intellectual impairment, or psychiatric disorder[51] may occur later on.

Recurrence risk: Depends on etiology. Chromosomal, 1%; autosomal recessive, 25%; X-linked recessive male, 50%.

Management: Standard obstetrical care. Chromosomal evaluation is offered. In cases with interhemispheric cyst, postnatal fenestration or shunt procedure may be performed.

Absent septum pellucidum: septo-optic dysplasia

Incidence: Unknown, rare.

Definition: Absent septum pellucidum: absence of the septum pellucidum with or without associated anomalies. The septum pellucidum can be destroyed by concomitant hydrocephalus or by contiguous ischemic lesions such as porencephaly. An isolated absent septum pellucidum[52] exists but is rare. Septo-optic dysplasia: absence of the septum pellucidum and unilateral or bilateral hypoplasia of the optic nerve.

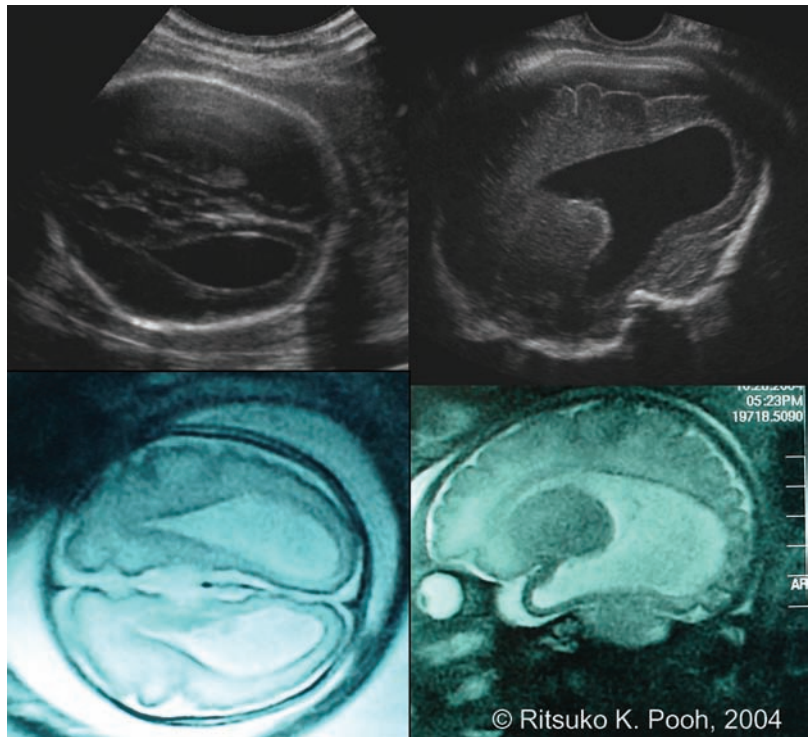

Figure 39.42 Fetal ultrasound and MR images of characteristic ventricular shape in a case with agenesis of the corpus callosum. (Upper left) Ultrasound axial image. (Upper right) Ultrasound parasagittal image. (Lower left) MR axial image. (Lower right) MR parasagittal image. Note the tear-drop appearance of the lateral ventricles in the axial section. Ventricular appearance in the parasagittal section is called 'colpocephaly'.

Synonyms: de Morsier syndrome (septo-optic dysplasia).

Etiology: maternal drug (multidrug, valproic acid,[53] cocaine[54]), autosomal recessive, HESX1 homeodomain gene mutation.[55]

Pathogenesis: May occur as a vascular disruption sequence, with other prosencephalic or neuronal migration disorders.

Associated anomalies: Schizencephaly, gyral abnormalities, heterotopias, hypotelorism, ventriculomegaly, communicating lateral ventricles, bilateral cleft lip and palate, hypopituitarism.

Differential diagnosis: Dysgenesis of the corpus callosum, lobar holoprosencephaly.

Prognosis: Depends on associated anomalies. Variable degree of mental deficit, multiple endocrine dysfunction. In cases with isolated absent of septum pellucidum, prognosis may be good.

Recurrence risk: Unknown.

Management: Confirmation of diagnosis after birth is important for genetic counseling. Endocrine dysfunction should be searched and corrected. Shunt procedure in cases with progressive ventriculomegaly.

Lissencephaly

Incidence: Unknown, rare.

Definition: Characterized by a lack of gyral development and divided into two types:

Lissencephaly type I: a smooth surface of the brain. Cerebral wall is similar to that of an approximately 12-week-old fetus.[56] Isolated lissencephaly. Miller–Dieker syndrome with additional craniofacial abnormalities, cardiac anomalies, genital anomalies, sacral dimple, creases, and/or clinodactyly.

Lissencephaly type II: cobblestone appearance. Walker–Warburg syndrome with macrocephaly, congenital muscular dystrophy, cerebellar malformation, retinal malformation. Fukuyama congenital muscular dystrophy with microcephaly and congenital muscular dystrophy.

Synonyms: Agyria, pachygyria, Walker–Warburg syndrome was known as HARD±E syndrome (*h*ydrocephalus, *a*gyria, *r*etinal *d*ysplasia, with or without *e*ncephalocele).

Etiology: Isolated lissencephaly is link to chromosome 17p13.3 and chromosome Xq24-q24. Miller–Dieker syndrome is also linked to chromosome 17p13.3. Walker–Warburg syndrome is autosomal recessive inheritance. Fukuyama congenital muscular dystrophy is linked to chromosome 9q31, fukutin.[57]

Pathogenesis: Defective neuronal migration with four, rather than six, layers in the cortex.

Associated anomalies: Polyhydramnios, less fetal movement, colpocephaly, agenesis of the corpus callosum, Dandy–Walker malformation are observed in Miller–Dieker syndrome. Micrognathia, flat nose,

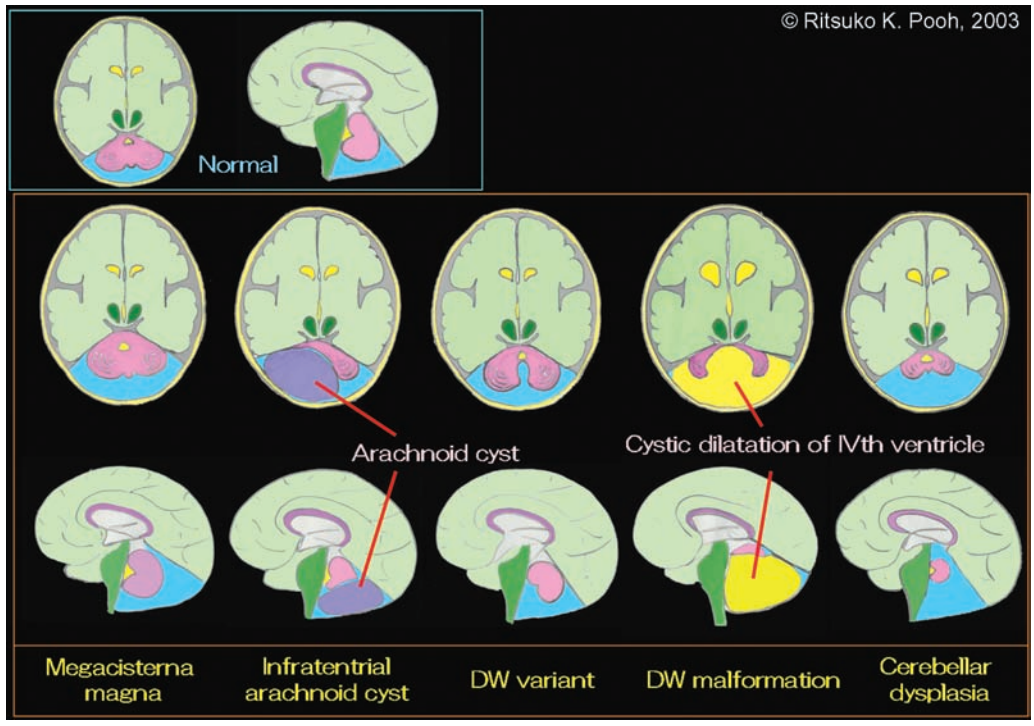

Figure 39.43 Differential diagnosis of 'hypoechoic lesion' of the posterior fossa.

high forehead, low-set ears, cardiac anomalies, genital anomalies in male are often observed in Walker–Warburg syndrome.

Prenatal diagnosis: Prenatal diagnosis[58–60] of lissencephaly without previous history of an affected child probably cannot be reliably made until 26–28 weeks' gestation.[42]

Prognosis: Type I: hypotonia, paucity of movements, feeding disturbance, seizures. The prognosis is poor, and death occurs. Type II: severe seizures, mental disorders, severe muscle disease with hypotonia. Death in the first year is common.

Recurrence risk: Depends on etiology.

Management: Karyotyping is recommended to detect the chromosomal defect. Standard obstetrical care.

Schizencephaly

Incidence: Rare.

Definition: A disorder characterized by congenital clefts in the cerebral mantle, lined by pia-ependyma, with communication between the subarachnoid space laterally and the ventricular system medially (Figure 6-52); 63% is unilateral and 37% bilateral. Frontal region in 44% and frontoparietal 30%.[56]

Etiology: Uncertain. In certain familial cases, a point mutation in the homeobox gene, EMX2 was found.[61,62] Cytomegalovirus infection was also related in some cases.[63]

Pathogenesis: Neuronal migration disorder.

Associated anomalies: Ventriculomegaly, microcephaly, polymicrogyria, gray matter heterotopias, dysgenesis of the corpus callosum, absence of the septum pellucidum, and optic nerve hypoplasia.

Differential diagnosis: Porencephaly, arachnoid cyst, or other intracranial cystic masses. MRI is useful in diagnosis of schizencephaly.[64]

Prognosis: Variable. Generally suffer from mental retardation, seizures, developmental delay and motor disturbances.

Recurrence risk: Unknown.

Management: Ventriculoperitoneal shunt for progressive hydrocephalus.

Dandy–Walker malformation, Dandy–Walker variant, megacisterna magna

Incidence: Dandy–Walker malformation has an estimated prevalence of about 1/30,000 births, and is found in 4–12% of all cases of infantile hydrocephalus.[65] Incidence of Dandy–Walker variant and megacisterna magna is unknown.

Definition: At present, the term Dandy–Walker complex[66] is used to indicate a spectrum of anomalies of the posterior fossa that are classified by axial computed tomography (CT) scans as it follows. Dandy–Walker malformation, Dandy–Walker variant, and megacisterna magna seem to represent a continuum of developmental anomalies of the posterior fossa.[66] Figure 39.43 shows the differential diagnosis of hypoechoic lesion of the posterior fossa.

- (Classic) Dandy–Walker malformation: cystic dilatation of fourth ventricle, enlarged posterior fossa, elevated tentorium, and complete or partial agenesis of the cerebellar vermis.

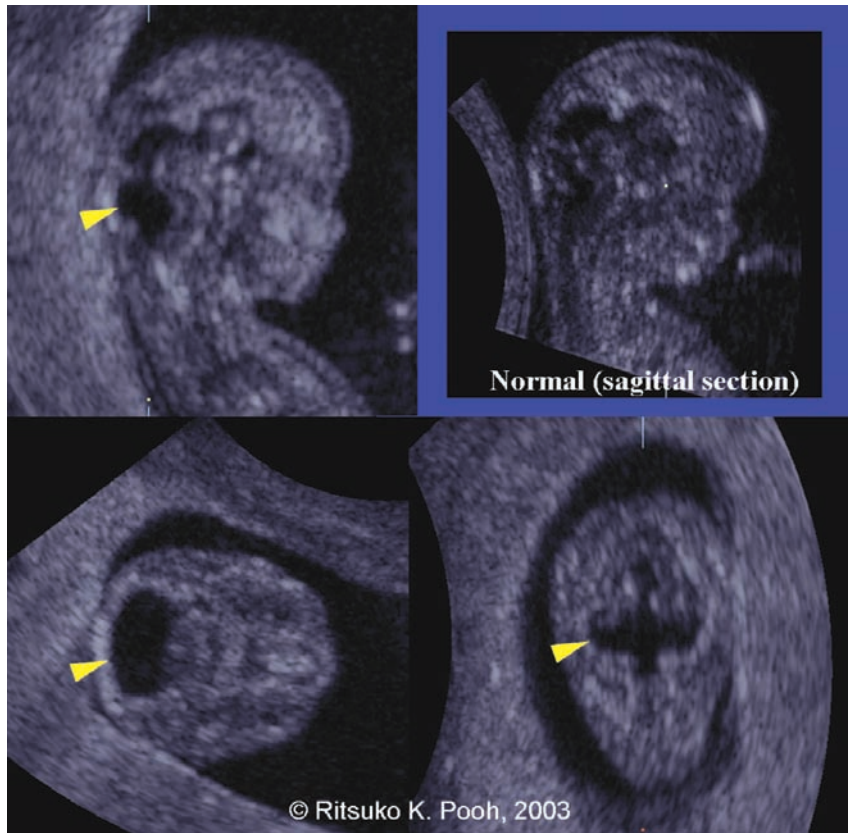

Figure 39.44 Early stage of Dandy–Walker malformation at 11 weeks of gestation. Abnormal dilatation of the posterior fossa (arrowheads). Upper right figure is a sagittal image at the same gestational age in a normal case. Amniocentesis revealed trisomy 9 mosaicism and the fetus died *in utero* at 19 weeks.

- Dandy–Walker variant: variable hypoplasia of the cerebellar vermis with or without enlargement of the posterior fossa.
- Megacisterna magna: enlarged cisterna magna with integrity of both cerebellar vermis and fourth ventricle.

Etiology: Mendelian disorders such as Warburg, chromosomal aberration such as 45,X, partial monosomy/trisomy, viral infections, and diabetes.

Pathogenesis: During development of the fourth ventricular roof, a delay or total failure of the foramen of Magendie to open occurs, allowing a buildup of CSF and development of the cystic dilation of the fourth ventricle. Despite the subsequent opening of the foramina of Luschka (usually patent in Dandy–Walker malformation), cystic dilatation of the fourth ventricle persists and CSF flow is impaired.

Associated anomalies of Dandy–Walker malformation: Hydrocephalus. Other midline anomalies, such as agenesis of the corpus callosum and holoprosencephaly and occipital encephalocele. Extracranial abnormalities such as congenital heart disease, NTDs, and cleft lip/palate. A frequency of additional anomalies ranging between 50% and 70%.

Prenatal diagnosis: Dandy–Walker malformation is shown in Figures 39.44 and 39.46; Dandy–Walker variant is shown in Figure 39.45. To observe the agenesis of the cerebellar vermis, axial cutting section is preferable. To observe the elevated tentorium, sagittal section is preferable.

Differential diagnosis: infratentorial arachnoid cyst, other intracranial cystic tumor, hydrocephalus, and cerebellar dysplasia (Figure 39.47).

Prognosis: Progressive hydrocephalus, not observed in neonates but often progressive during the first month. In cases diagnosed *in utero* or during the neonatal period, outcome is generally unfavorable. Nearly 40% die, and 75% of survivors exhibit cognitive deficits. Prognosis of Dandy–Walker variant is good. Clinical significance of megacisterna magna is uncertain.

Recurrence risk: Depends on etiology. Generally 1–5% (Dandy–Walker malformation).

Management: Cyst–peritoneal shunt, cyst–ventriculoperitoneal shunt.

Arachnoid cyst

Prevalence: 1% of intracranial masses in newborns.

Definition: Congenital or acquired cyst, lined by arachnoid membranes, and filled with fluid collection which is of the same character as the CSF. The number of cysts is mostly single, but two or more cysts can be occasionally observed. Location of arachnoid cyst is

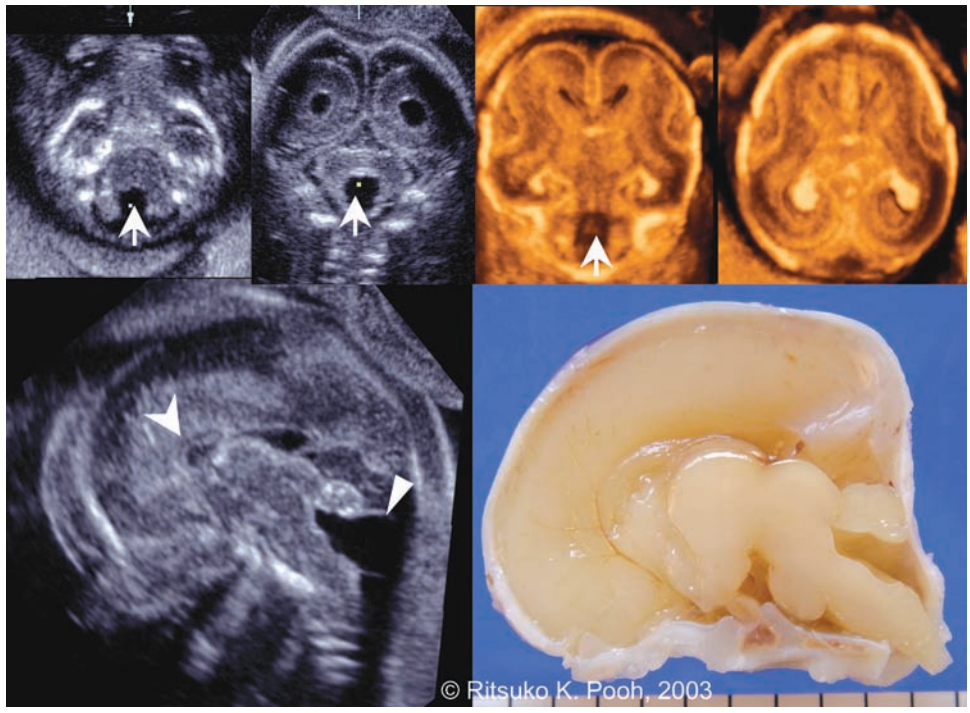

Figure 39.45 Dandy–Walker variant at 20 weeks of gestation. Upper figures show the 2D axial, 2D posterior coronal, and 3D thick slices of oblique coronal and axial sections from the left. Hypoplasia of the vermis (arrows) is demonstrated and no marked ventriculomegaly was seen. Lower left figure shows the median section. Partial agenesis of the corpus callosum (arrowhead), floated celebellum (triangle arrowhead), and cystic formation of the posterior fossa are seen. Lower right figure shows the median cutting section of the specimen of an aborted fetus at 21 weeks of gestation. This case had other complicated anomalies and the karyotype was partial trisomy of chromosome 10.

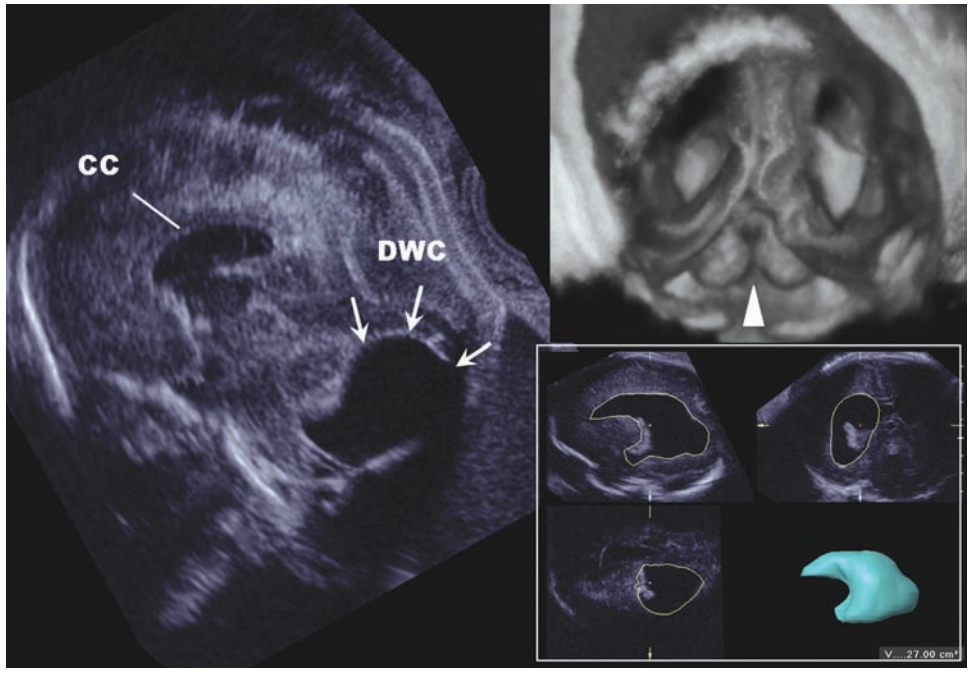

Figure 39.46 Dandy–Walker malformation at 28 weeks of gestation. Left figure shows the median section of the brain. Corpus callosum (CC) is normally demonstrated and Dandy–Walker cyst (DWC, arrows) is seen in the posterior fossa. Right upper figure is a 3D view of the posterior coronal section. Hypoplastic vermis of the cerebellum (arrowhead) is seen. Right lower figures, three orghogonal views and an extracted ventricular appearance, demonstrate moderate ventriculomegaly in this case.

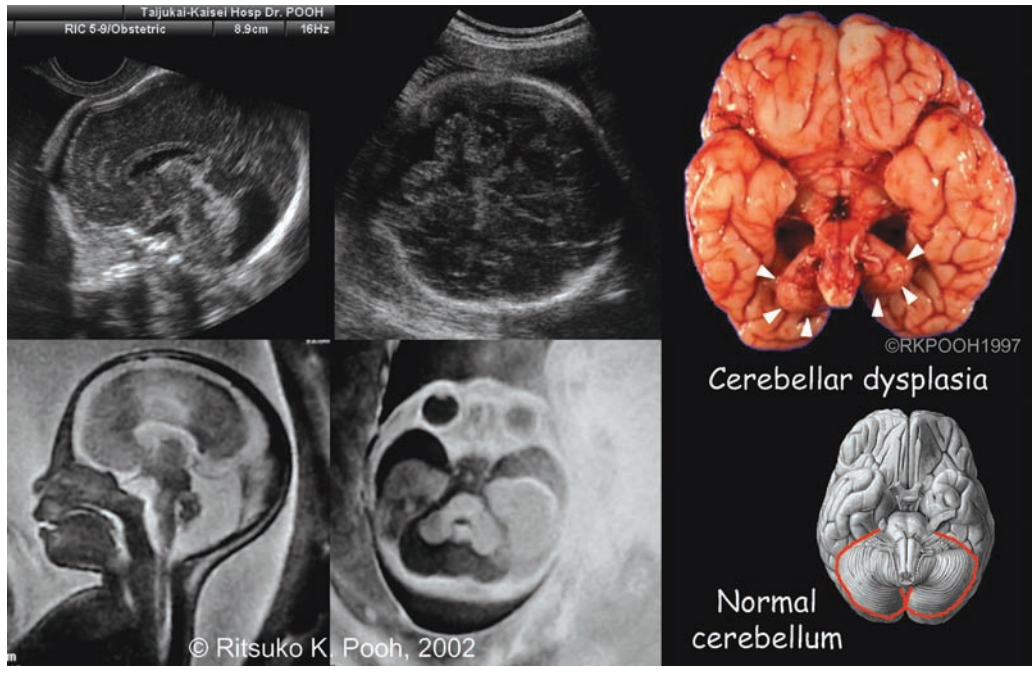

Figure 39.47 Cerebellar dysplasia in a case of trisomy 18. (Upper left) Transvaginal median image. Small cerebellum within a normal size of posterior fossa. (Upper middle) Transabdominal axial image. (Lower left) Fetal MR sagittal image. (Lower middle) MR axial image. (Upper right) Macroscopic photograph of cerebellar dysplasia in another case of trisomy 18. Compared with normal cerebellum shown in the right lower figure, hypoplastic cerebellum is easily identified.

various; approximately 50% of cysts occur from the Sylvian fissure (middle fossa), 20% from the posterior fossa, and 10–20% each from the convexity, suprasellar, interhemisphere, and quadrigeminal cistern. Interhemisperic cysts are often associated with agenesis or hypogenesis of the corpus callosum.

Etiology: Unknown.

Pathogenesis: Congenital arachnoid cyst is formed by maldevelopment of the arachnoid membrane. CSF accumulation in the subarachnoid space or intra-arachnoid layers from a choroid plexus-like tissue within the cyst wall, leads to a progressive distension of the lesion.

Associated anomalies: Unilateral or bilateral hydrocephalus, macrocrania.

Prenatal diagnosis: Figures 39.48–39.50. Detection in the first trimester was reported.[67]

Differential diagnosis: Porencephaly, schizencephaly, third ventriculomegaly, intracranial cystic type tumor, vein of Galen aneurysm, Dandy–Walker malformation, large cisterna magna, external hydrocephalus.

Prognosis: Generally good. Postnatally, many are asymptomatic and remain quiescent for years, although others expand and cause neurological symptoms by compressing adjacent brain, ventriculomegaly, and/or expanding the overlying skull.

Recurrence risk: Unknown.

Obstetrical management: Arachnoid cysts may increase or decrease its size. Therefore, expectant management of antenatally diagnosed cases is suggested.[68] In cases with accompanying hydrocephalus, mode and timing of delivery may be modified.

Postnatal management: In cases with these symptoms or with prospects of neurological symptoms, treatment should be considered. Operation methods include:

- Cyst fenestration by craniotomy
- Cyst fenestration by neuroendoscopy
- Cyst-peritoneal shunt.

Craniotomy, shunting, or neuroendoscopic method is still controversial.[69,70]

Craniosynostosis

Incidence: Unknown.

Definition: Premature closure of cranial suture, which may affect one or more cranial sutures. Simple sagittal synostosis is most common. Various cranial shapes depend on affected suture(s).

Sagittal suture	Scaphocephaly or dolichocephaly
Bilateral coronal suture	Brachycephaly
Unilateral coronal suture	Anterior plagiocephaly
Metopic suture	Trigonocephaly
Lambdoid suture	Acrocephaly
Unilateral lambdoid suture	Posterior plagiocephaly
Coronal/lambdoid/metopic or squamous/sagittal suture	Cloverleaf skull
Total cranial sutures	Oxycephaly

Syndromes

Crouzon syndrome: acrocephaly, synostosis of coronal, sagittal and lambdoid sutures. With ocular proptosis, maxillary hypoplasia.

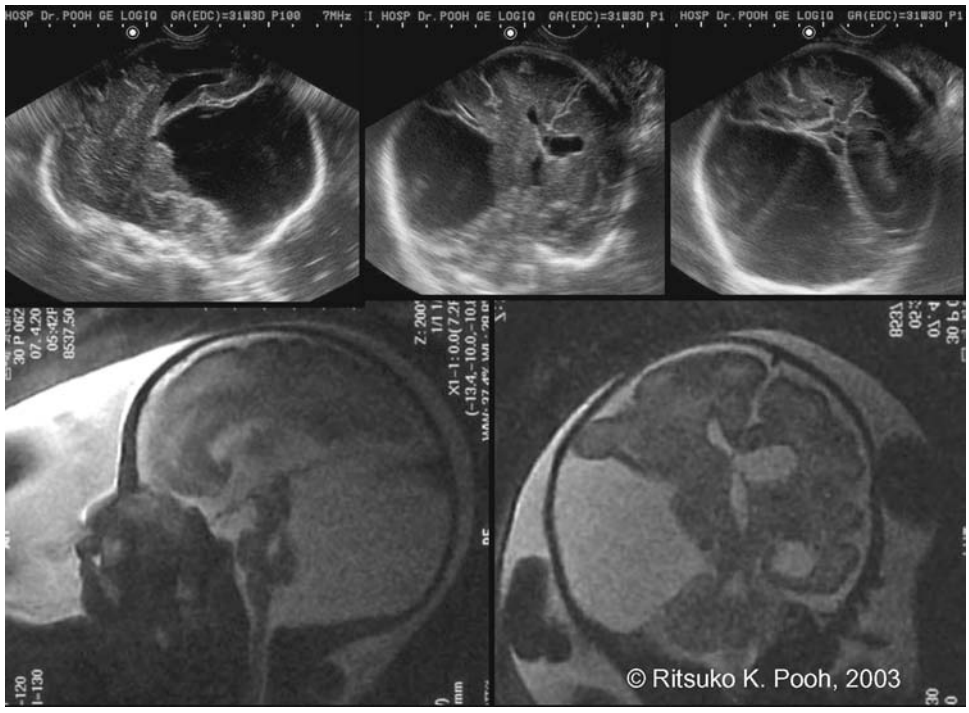

Figure 39.48 Fetal arachnoid cyst at 31 weeks of gestation. (Upper) Transvaginal ultrasound image. Sagittal (left) and coronal (middle, right) sections. (Lower left) Fetal MR sagittal image. The cyst occupies supra- to infratentorial space. Not only cerebrum but also the cerebellum is compressed by the cyst. (Lower right) Fetal MR coronal image. Midline is conspicuously arcuated. Unilateral scalp and skull bone are extended due to the existence of the huge cyst. Note the difference between right and left head size.

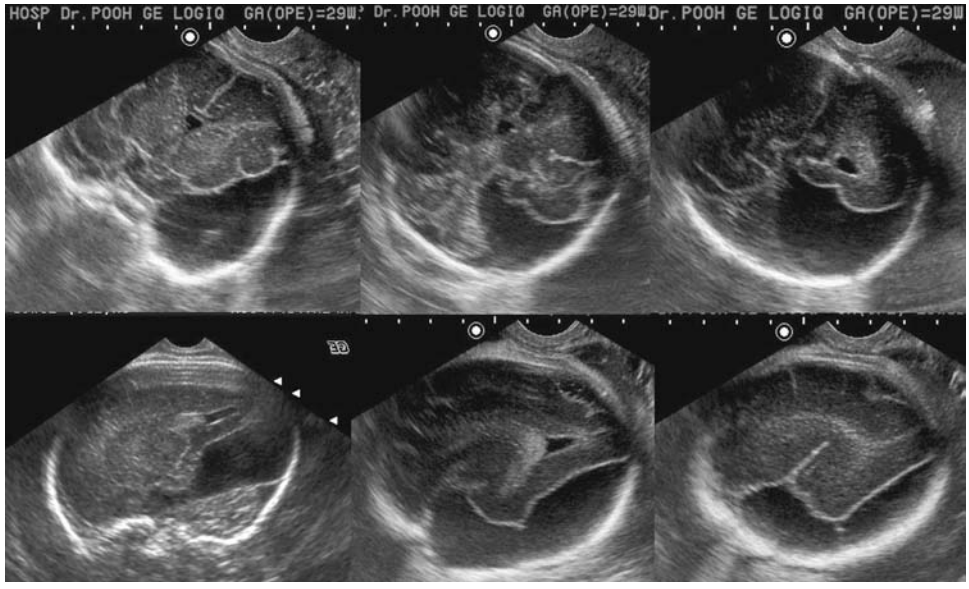

Figure 39.49 Transvaginal ultrasound images of middle fossa arachnoid cyst at 29 weeks of gestation. (Upper) Serial coronal sections. (Lower) Serial sagittal sections. Compressed adjacent cerebrum is demonstrated.

Apert syndrome: brachycephaly, irregular synostosis, especially coronal suture. With midfacial hypoplasia, syndactyly, broad distal phalanx of thumb and big toe.

Pfeiffer syndrome: brachycephaly, synostosis of coronal and/or sagittal sutures. With hypertelorism, broad thumbs and toes, partial syndactyly.

Antley–Bixler syndrome: brachycephaly, multiple synostosis, especially of coronal suture. With maxillary hypoplasia, radiohymeral synostosis, choanal atresia, arthrogryposis.

Etiology: Crouzon (AD, variable), Apert (AD, usually new mutation), Pfeiffer (AD), Antley–Bixler (AR). In five autosomal dominant craniosynostosis syndromes

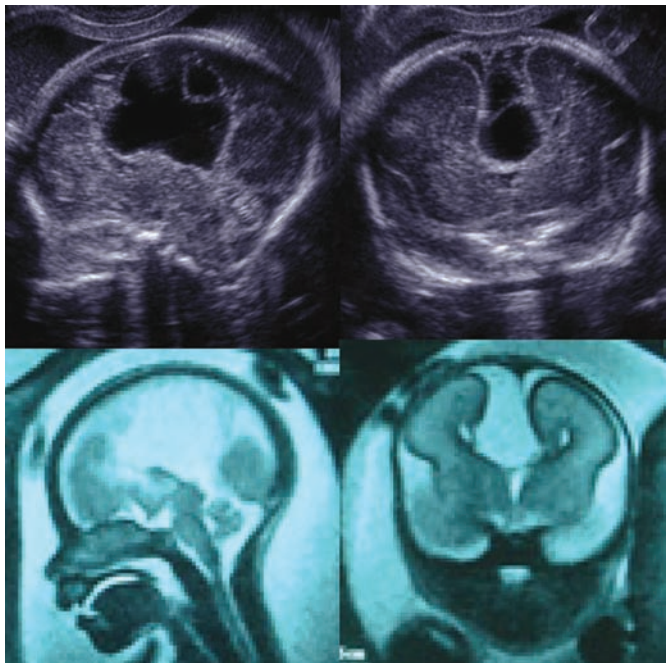

Figure 39.50 Ultrasound and MR images of interhemispheric cyst at 24 weeks of gestation. (Upper left) Ultrasound median section. (Upper right) Ultrasound anterior coronal section. (Lower left) MR median section. (Lower right) MR anterior coronal secrion. Cystic lesion exists between hemispheres. Intracystic cyst is visible in the ultrasound images.

(Apert, Crouzon, Pfeiffer, Jackson–Weiss, and Crouzon syndromes with acanthosis nigricans) result from mutations in FGFR genes.[71]

Pathogenesis:[72] (1) Cranial vault bones with decreased growth potential; (2) asymmetrical bone deposition at perimeter sutures; (3) sutures adjacent to the prematurely fused suture compensate in growth more than those sutures not contiguous with the closed suture; (4) enhanced symmetrical bone deposition occurs along both sides of a nonperimeter suture continuing prematurely closed suture.

Associated anomalies: Hypertelorism, syndactyly, polydactyly, exophthalmos.

Prenatal diagnosis: Figure 39.51 shows prenatal appearance in Apert syndrome and Figure 39.52 shows the postnatal findings. Abnormal craniofacial appearance can be detected by 2D/3D ultrasound.[73,74]

Prognosis: Various. In some of trigonocephaly and syndromic types, prognosis is poor.

Recurrence risk: Depends on etiology.

Management: Operative aim of cranioplasty is improvement of intracranial pressure and cosmetic change.

Vein of Galen aneurysm

Incidence: Rare.

Definition: Direct arteriovenous fistulas between choroidal and/or quadrigeminal arteries and an overlying single median venous sac.

Synonyms: Vein of Galen malformation.

Etiology: Unknown.

Pathogenesis: Venous sac most probably represents persistence of the embryonic median prosencephalic vein of Markowski, not the vein of Galen, per se.[75]

Associated anomalies: cardiomegaly, high cardiac output, secondary hydrocephalus, macrocrania, cerebral ischemia (intracranial steal phenomenon), subarachnoid/cerebral/intraventricular hemorrhages.

Prenatal diagnosis: 2D and 3D color/power Doppler detection is possible.

Differential diagnosis: Arachnoid cyst, porencephalic cyst, intracranial teratoma. Color/power Doppler is helpful for differential diagnosis.

Prognosis: According to earlier review, outcome did not differ between treated and nontreated group and over 80% of cases resulted in death.[76] However, recent advances in treatment have improved outcome, such that 60–100% survive and over 60% have a good neurological outcome.[77,78]

Recurrence risk: Unknown.

Management: Evaluation of the fetal high-output cardiac state for the proper obstetrical management. Percutaneous embolization by microcoils is recent main postnatal treatment and remarkably improved outcome.

Choroid plexus cysts

Incidence: 0.95–2.8% of all fetuses scanned.[79–81]

Definition: Cysts with fluid collection within the choroids plexus, which may exist unilaterally or bilaterally. They are depicted in the second trimester and usually resolve by the 24th week.

Etiology: Normal variant, chromosomal aberration such as trisomy 18 and others.

Pathogenesis: Choroid plexus is located within the ventricular system and produces CSF. Within the choroidal villi, choroid plexus cysts exist, surrounded by the loose stroma of the choroid plexus.[82]

Associated anomalies: In cases of trisomy 18, associated anomalies include growth retardation, congenital heart diseases such as ventricular septum defect and double outlet right ventricle, overlapping finger, facial anomaly, cerebellar dysplasia, and others.

Prenatal diagnosis: Figure 39.53. Macroscopic photo is shown in Figure 39.54. It is impossible to distinguish normal from abnormal karyotypes only by location and appearance of choroid plexus cyst. Detection of additional anomalies is important for differential diagnosis.

Differential diagnosis: Intraventricular hemorrhage.

Prognosis: Choroid plexus cysts, per se, are usually asymptomatic and benign, but rarely, symptomatic and disturbs CSF flow.[83,84] Isolated choroids plexus cysts may be normal variation.

Recurrence risk: Unknown.

Management: Fetal karyotyping examination should be offered if additional abnormalities are found.

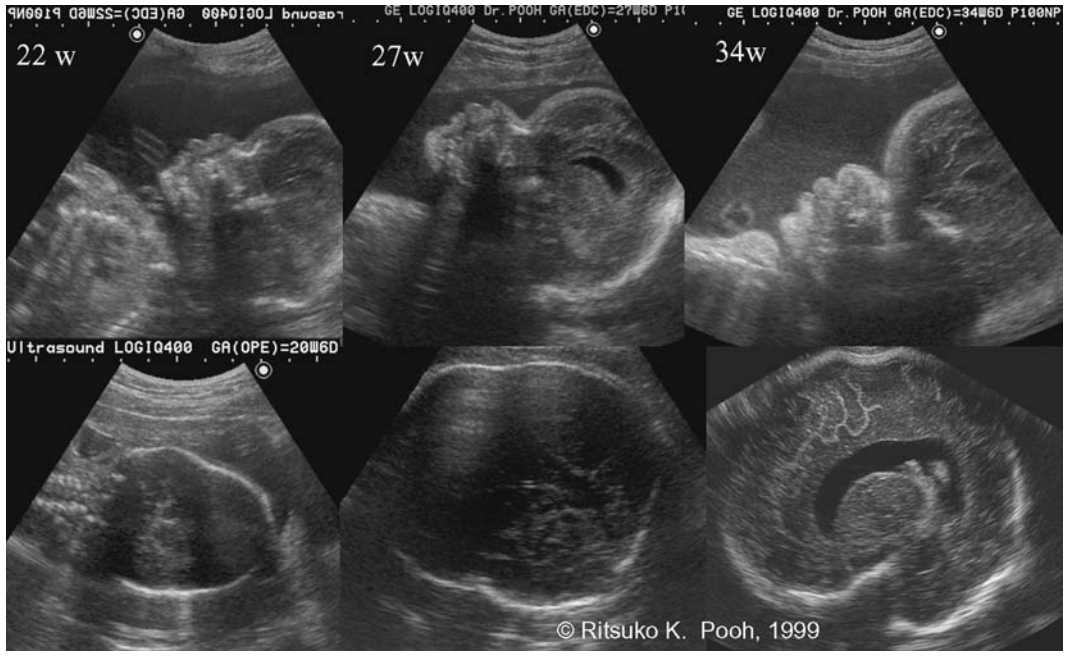

Figure 39.51 Prenatal craniofacial appearance of Apert syndrome. (Upper) Longitudinal changing appearance of frontal bossing and low nasal bridge at 22, 27, and 34 weeks of gestation in a case of Apert syndrome. (Lower left) Irregular cranial shape at 20 weeks. (Lower middle) Cranial shape at 34 weeks. Note the bilateral indentation. (Lower right) Intracranial sagittal ultrasound image at 34 weeks. Mild ventriculomegaly is seen.

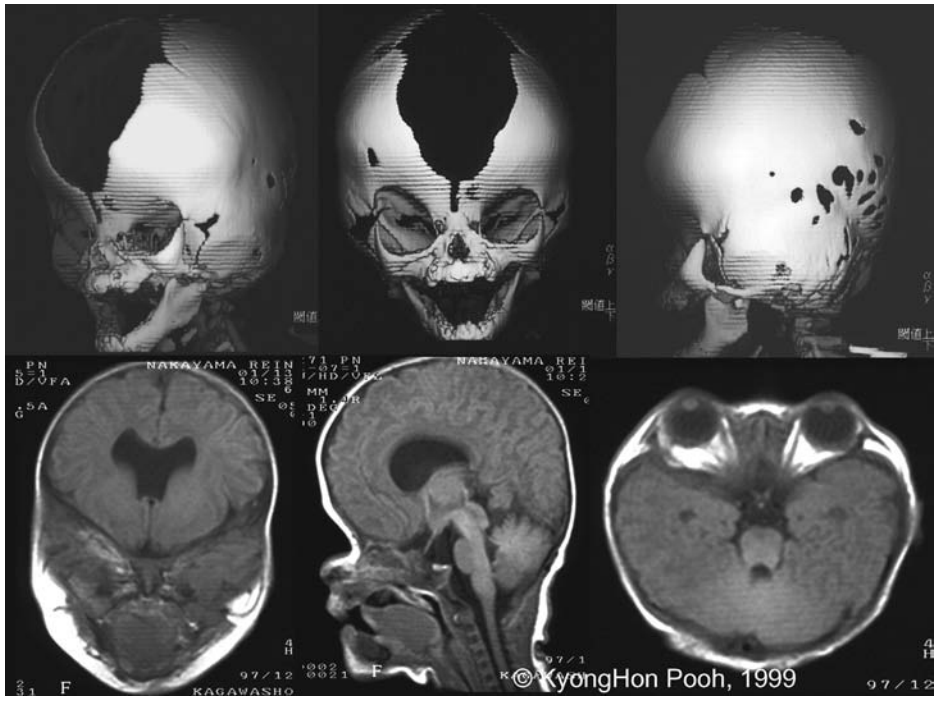

Figure 39.52 Three-dimensional reconstruction CT and MR images of Apert syndrome (the same case as in Figure 39.51). (Upper) Three-dimensional reconstruction CT. Fusion of bilateral coronal suture and squamous suture, defect of frontoparietal cranial structure, and craniofacial bony dysplasia are recognizable. (Lower) Postnatal MR images. Marked shortening of anterior cranial fossa is seen. Mild ventriculomegaly and absent septum pellucidum are seen.

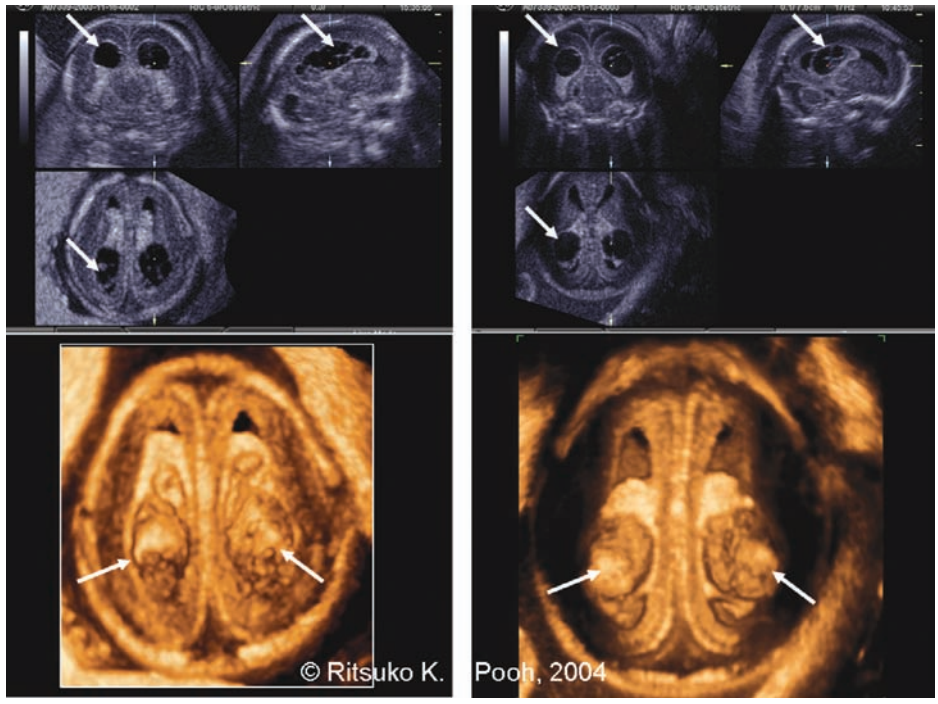

Figure 39.53 Choroid plexus cysts (CPC) in cases of trisomy 18 (left) and normal karyotype (right). (Left figures) Three orthogonal views and inside 3D view of CPC in a case of trisomy 18 at 17 weeks of gestation. Various additional anomalies were detected. (Right figures) Three orthogonal views and inside 3D view of CPC in a case with normal karyotype at 16 weeks. No additional abnormalities. Normal postnatal course. It is impossible to distinguish normal from abnormal karyotypes only by location and appearance of choroid plexus cyst. Detection of additional anomalies is important for differential diagnosis.

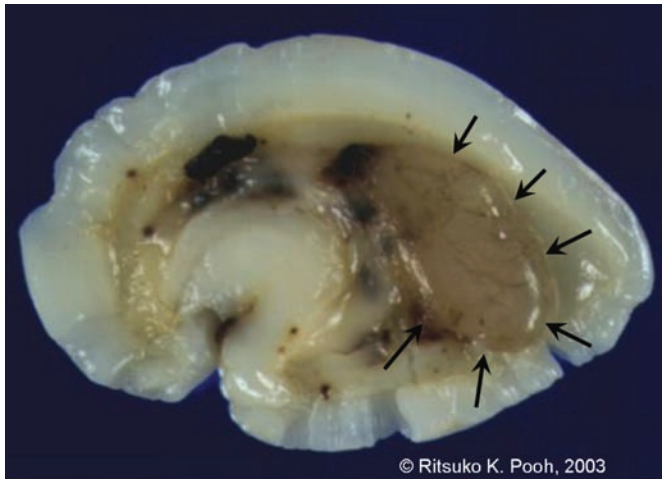

Figure 39.54 Macroscopic appearance of choroid plexus cyst. Arrows indicate the choroid plexus cyst. The specimen was from an aborted fetus of trisomy 18 at 20 weeks of gestation.

Acquired brain abnormalities *in utero*

In terms of encephalopathy or cerebral palsy, *timing of brain insult, antepartum, intrapartum, or postpartum?* is one of the serious controversial issues including medico-socio-legal-ethical problems.[85] Although brain insults may relate to antepartum events in a substantial number of term infants with hypoxic–ischemic encephalopathy, the timing of insult cannot always be clarified. It is a hard task to give antepartum evidences of brain injury predictive of cerebral palsy. Fetal heart rate monitoring cannot reveal the presence of encephalopathy, and neuroimaging by ultrasound and MRI is the most reliable modality for disclosure of silent encephalopathy. Many cases with cerebral palsy with acquired brain insults, especially, term-delivered infants with reactive fetal heart rate tracing and good Apgar score at delivery, are not suspected of having encephalopathy and are often overlooked for months or years. Recent imaging technology has revealed brain insult *in utero*.

Brain tumors

Incidence: Extremely rare.

Definition: Tumors located in the intracranial cavity.

Histological types: Brain tumors are divided into *teratoma*, most commonly reported and nonteratomatous tumor. Nonteratomatous tumors include *neuroepithelial tumor*, such as medulloblastoma, astrocytoma, choroids plexus papilloma, choroids plexus carcinoma, ependymoma, ependymoblastoma, and *mesenchymal tumor* such as craniopharyngioma, sarcoma, fibroma, hemangioblastoma, hemangioma and miningoma, and others of lipoma of the corpus callosum, subependymal giant-cell astrocytoma associated with tuberous sclerosis (often accompanied by cardiac rhabdomyoma).[86,87]

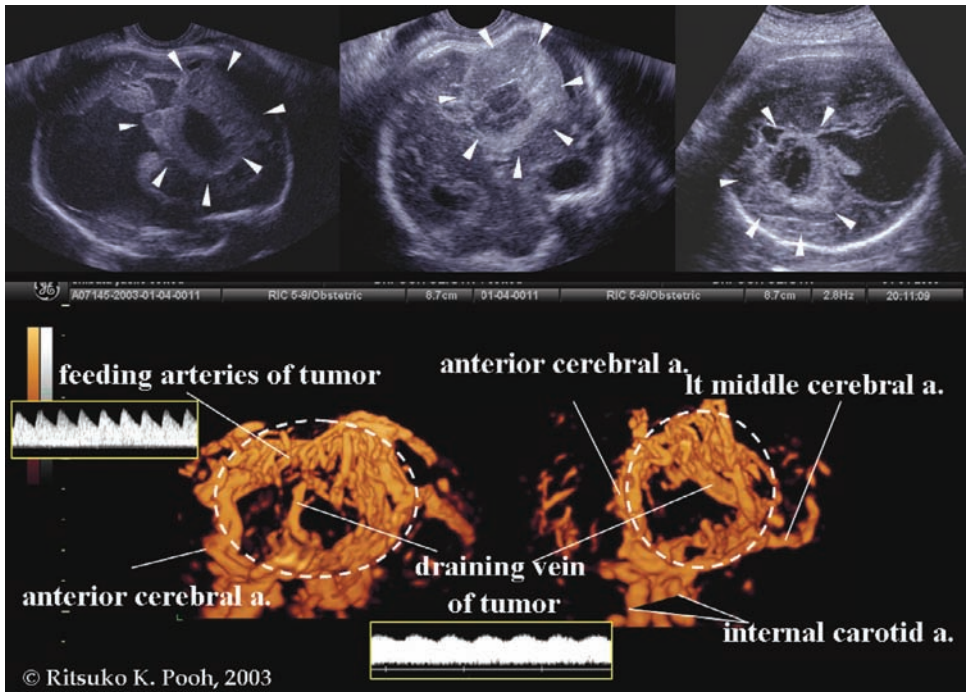

Figure 39.55 Ultrasound images and tumoral vascular visualization by 3D power Doppler in a fetus of intracranial tumor with interventricular hemorrhage (35 weeks and 5 days of gestation). (Upper) Sagittal, coronal, and axial ultrasound images. Huge tumor (arrowheads) with hemorrhage within the tumor in the fronto-parietal lobe, complicated with unilateral hydrocephalus with intraventricular hemorrhage (arrow). (Left lower) Oblique sagittal view from fetal left side. (Right lower) Oblique coronal view from fetal frontal side. Tumor is fed by numerous feeding arteries from anterior cerebral artery. Feeder arteries have low resistant flow waveform. One large vein which drains blood from tumor is visible. The draining vein has pulsatile flow.

Location of tumor: Supratentorial predominance in neonatal tumor. Infratentorial predominance in medulloblastoma. Choroid plexus papilloma is located within the lateral ventricles.

Associated abnormalities: Macrocrania or local skull swelling, epignathus, secondary hydrocephalus, intracranial hemorrhage, intraventricular hemorrhage, polyhydroamnios, heart failure by high-cardiac output,[88] hydrops.

Diagnosis: Intracranial masses with solid, cystic or mixture pattern with or without visualization of hypervascularity by ultrasound and fetal MRI. Brain tumor should be considered in cases with unexplained intracranial hemorrhage.

Prenatal diagnosis: Prenatal diagnosis of intracranial tumor and its vascularization by 3D power Doppler is shown in Figure 39.55.

Differential diagnosis: Arachnoid cyst, vein of Galen aneurysm, porencephaly, schizencephaly, periventricular leukomalacia, subdural hemorrhage.

Prognosis: Fetal demise, stillborn may occur. Prognosis in neonates is generally poor, but depends on timing of diagnosis and the histological type of tumor. Choroid plexus papilloma has minimal mortality rate and high likelihood of neonatal outcome. Mortality rate of teratomas is over 90%, medulloblastoma over 80%. Other tumors have various prognoses.

Recurrence risk: Unknown.

Management: Cesarean section may be considered. Neurosurgical tumor resection including subtotal hemispherectomy by craniotomy and chemotherapy are possible treatments for neonatal tumors. Radiation therapy is usually not indicated in neonates.

Subependymal pseudocysts

Prevalence: 2.6–5% of all neonates, 1% of premature newborns, unknown in fetuses.

Definition: Cystic formation, which is located in the caudothalamic groove or in the caudate nucleus, lateral to the wall of the anterior horns of lateral ventricles.

Synonyms: Periventricular pseudocysts.[89,90]

Etiology: Infection (cytomegalovirus, rubella), subependymal hemorrhage, metabolic diseases, chromosomal deletions (del q6, delp4) cocaine exposure and others.

Pathogenesis: Cystic cavity is lined by a pseudocapsule, consisting of aggregates of germinal cells and glial tissue, but no epithelium can be found. Origin of pseudocysts is uncertain. Maybe cystic matrix regression or germinolysis.

Associated anomalies: Congenital infection such as cytomegalovirus, congenital heart diseases, associated CNS abnormalities.

Prenatal diagnosis: Figure 39.56.

Differential diagnosis: Periventricular leukomalacia.

Prognosis: Good in cases with isolated subependymal pseudocysts. In cases with accompanied abnormalities, such as cardiac disease, cytomegalovirus

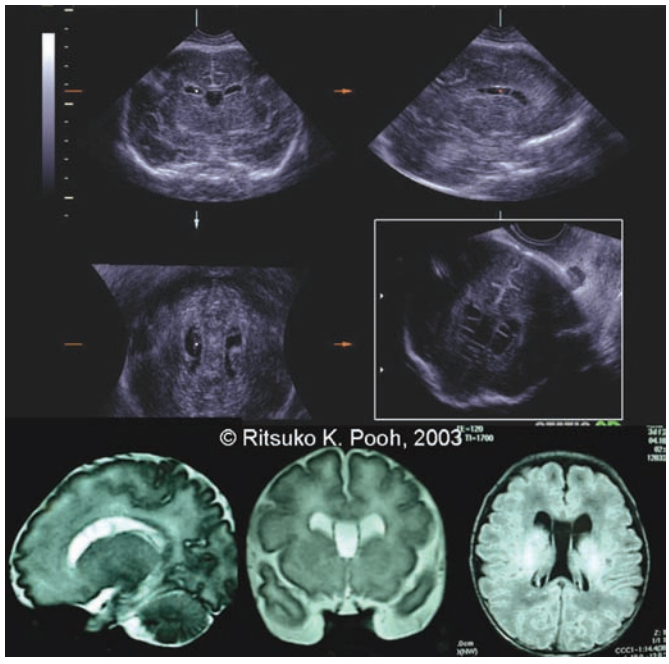

Figure 39.56 Subependymal cysts (fetal ultrasound images and neonatal MR images). (Upper) Coronal and sagittal images. (Middle left) Axial image. (Middle right) Anterior coronal section. Note bilateral bead-like cystic formation. (Lower) MR sagittal, coronal, and axial images at 3 days after birth. No neurological symptoms at the age of 1 year.

infection, other intracranial abnormalities, or cases with atypical pseudocysts, prognosis may be poor.[89–91]

Recurrence risk: Unknown.

Management: In many cases, cysts regress in several months after birth. Normal obstetrical/neonatal care.

Porencephaly

Incidence: Unknown.

Definition: Fluid-filled spaces replacing normal brain parenchyma; may or may not communicate with the lateral ventricles or subarachnoid space.

Synonyms: Porencephalic cyst.

Etiology: Ischemic episode, trauma[92] demise of one twin, intercerebral hemorrhage, infection.

Pathogenesis: Easy to occur when immature cerebrum has some factors with propensity of dissolution and cavitation, (high content of water, myelinated fiber bundles, deficient astroglial response). Timing of ischemic injury (maybe as early as second trimester) is strongly related to porencephaly, hydranencephaly.[93]

Associated anomalies: Intercerebral hemorrhage, interventricular hemorrhage, hydrocephalus.

Prenatal diagnosis: Figure 39.57. Some cases *in utero* have been reported.[94,95]

Differential diagnosis: Schizencephaly, arachnoid cyst, intracranial cystic tumor, other cysts. Porencephalic cyst never causes a mass effect, which is observed in cases with arachnoid cyst or other cystic mass lesions. This condition is acquired brain insult and differentiated from schizencephaly of migration disorder.

Prognosis: Various, depends on timing and size of lesion. Seizures, neurological deficits, and cerebral palsy often occur.[96]

Recurrence risk: Unknown.

Management: Ventriculoperitoneal shunt if hydrocephalus progresses.

Hydranencephaly

Incidence: 1–2.5/10,000 births.

Definition: Absence of the cerebral hemispheres and a sac-like structure containing CSF surrounding the brainstem and basal ganglia.

Etiology: Ischemic episode, trauma, demise of one twin, intercerebral hemorrhage, infection. There are several theories but bilateral occlusion of the supraclinoid segment of the internal carotid arteries[97] or of the middle cerebral arteries is one of the causes of subtotal defects of cerebral hemisphere.

Pathogenesis: Easy to occur when immature cerebrum has some factors with propensity of dissolution and cavitation, (high content of water, myelinated fiber bundles, deficient astroglial response). Timing of ischemic injury (maybe as early as second trimester) is strongly related to porencephaly and hydranencephaly.

Prenatal diagnosis: Recently, hydranencephaly from 11 weeks of gestation has been reported.[98]

Associated anomalies: Large head (Figure 39.58).

Differential diagnosis: Massive hydrocephalus, alobar holoprosencephaly, porencephaly.

Prognosis: Extremely poor.

Recurrence risk: Unknown.

Management: No active treatment. Shunt procedure for progressive increase of infant's head.

Intracranial hemorrhage

Incidence: Unknown, rare *in utero*.

Definition: Hemorrhage, bleeding inside of the cranium. Intracranial hemorrhage includes subdural hemorrhage, primary subarachnoid hemorrhage, intracerebellar hemorrhage, intraventricular hemorrhage, and intraparenchymal hemorrhage other than cerebellar.[99]

Etiology: Trauma, alloimmune and idiopathic thrombocytopenia, von Willebrand's disease, specific medications (warfarin) or illicit drug (cocaine) abuse, seizure, fetal conditions including congenital factor-X and factor-V deficiencies, intracranial tumor, twin–twin transfusion, demise of a co-twin, vascular diseases, or fetomaternal hemorrhage, extracorporeal membrane oxygenation (ECMO).[100]

Associated anomalies: Hydrocephalus, hydranencephaly, porencephaly, or microcephaly.

Prenatal diagnosis: Figure 39.59.

Differential diagnosis: Intracranial tumor.

Prognosis: Poor in premature infants. Apnea, seizures, and other neurological symptoms.

Recurrence risk: Depends on etiology.

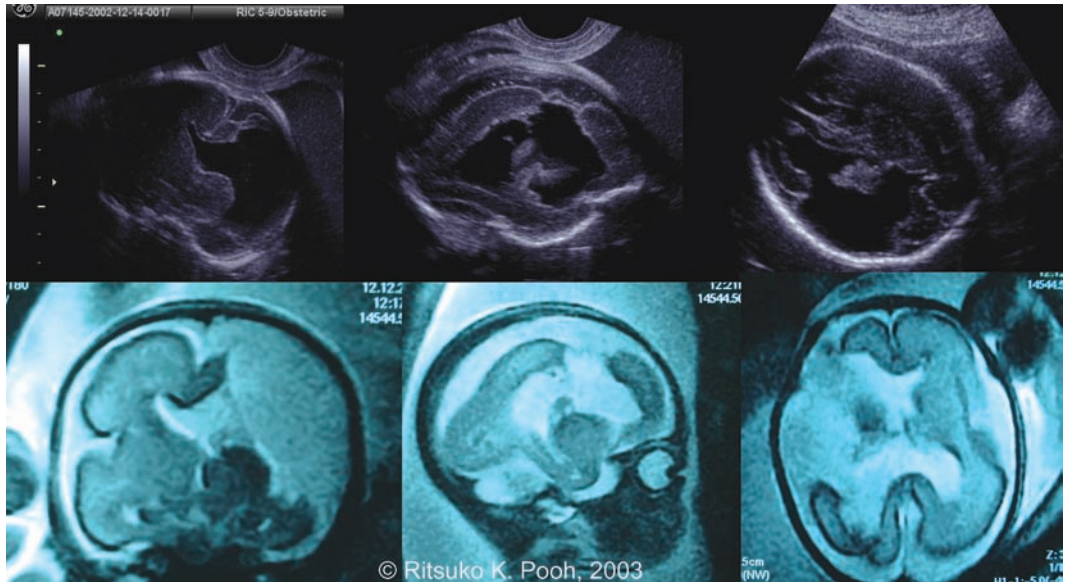

Figure 39.57 Fetal ultrasound and MR images of porencephaly at 25 weeks of gestation. (Upper left) Transvaginal ultrasound coronal image. Defect of parietolateral part of the unilateral cerebrum. This case has also absent septum pellucidum. (Upper middle) Parasagittal ultrasound image. Porencephalic part is fused with the unilateral ventricle. Echogenesity of inside ventricular wall indicates intraventricular hemorrhage. (Upper right) Transabdominal ultrasound axial image. (Lower) Fetal MR images on the same day. Coronal, parasagittal, and axial sections from the left side.

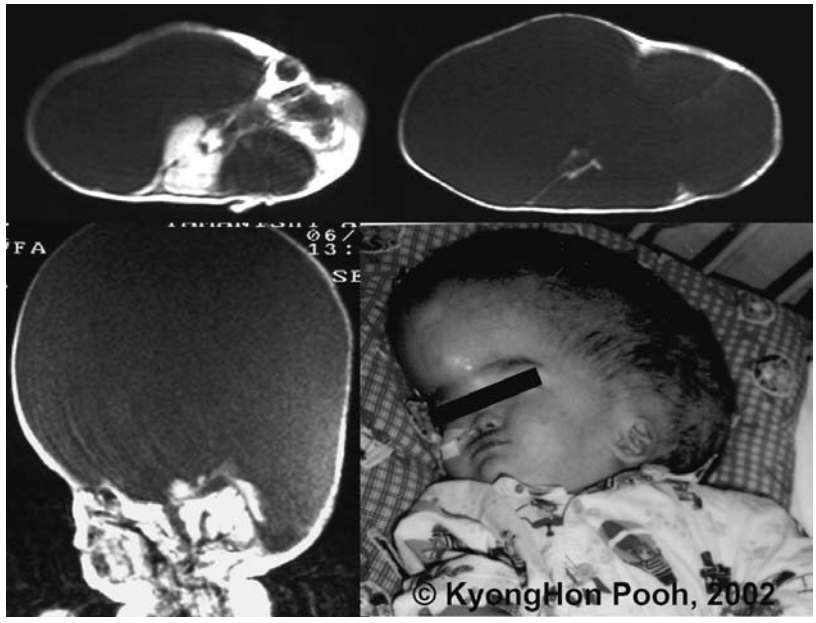

Figure 39.58 Hydranencephaly. Hydranencephaly is characterized by absence of the cerebral hemispheres with an incomplete or absent falx and a sac-like structure containing cerebral spinal fluid surrounding the brainstem and basal ganglia. In this case, tentorium and falx cerebri are recognized. Cerebral cortex is depicted in only a small part of occipital lobe. Brain stem and cerebellum are preserved to be normal. Cause of hydranencephaly may be obstruction of the bilateral internal carotid arteries. Note the remarkable increase of head circumference.

Management: Ventriculoperitoneal shunt if hydrocephalus progresses.

Fetal periventricular leukomalacia (PVL)

Incidence: 25–75% of premature infants at autopsy are complicated with periventricular white matter injury. However, clinically, incidence may be much lower; 5–10% of infants less than 1500 g birth weight. In term infants, PVL is very rare.

Definition: Multifocal areas of necrosis found deep in the cortical white matter, which are often symmetrical and occur adjacent to the lateral ventricles. PVL represents a major precursor for neurological and intellectual impairment, and cerebral palsy in later life.

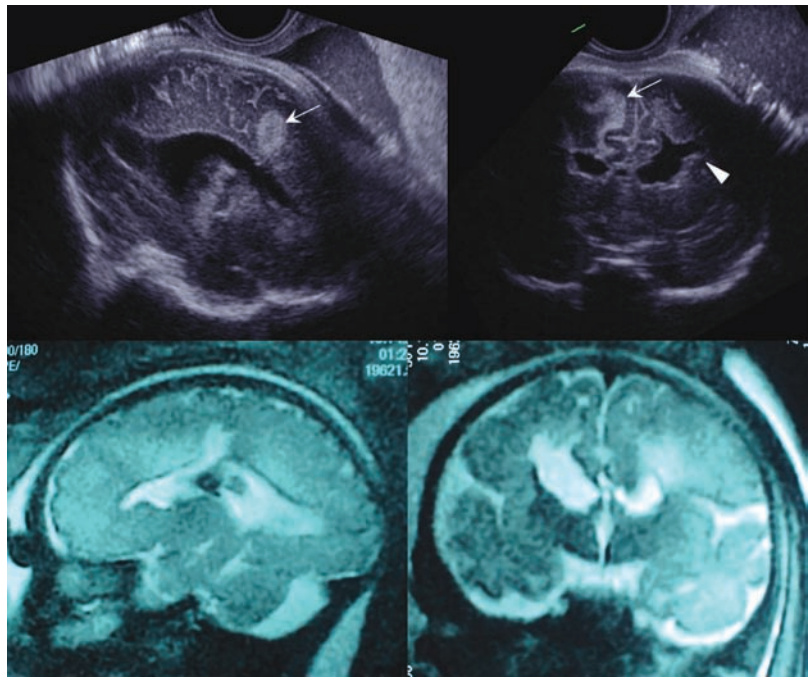

Figure 39.59 Ultrasound and MR images in a fetus with cerebral hemorrhage and mild ventriculomegaly at 35 weeks of gestation. Ultrasound parasagittal (upper left) and anterior coronal (upper right) images of the brain. Arrows indicate intracerebral hemorrhage. Arrowhead shows a porencephalic part fused with the lateral ventricle. Lower figures are MR images showing the same cutting sections as upper ultrasound images.

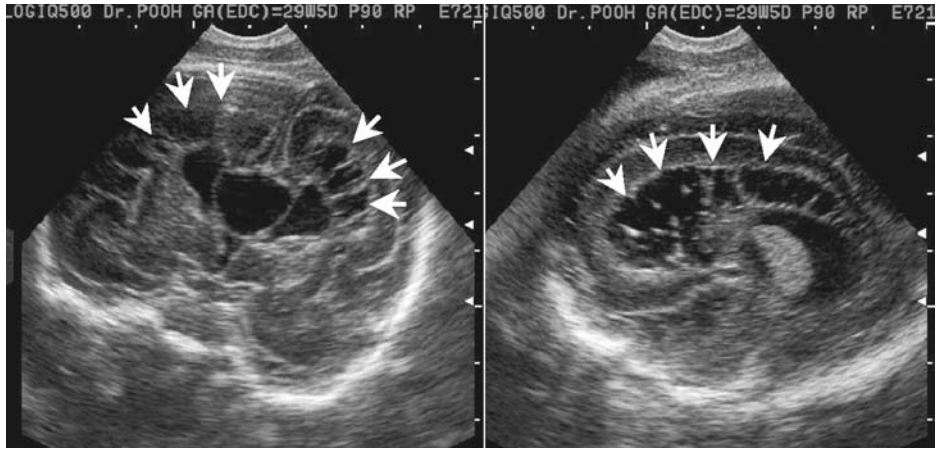

Figure 39.60 Fetal periventricular leukomalacia (PVL) at 29 weeks of gestation. Bilateral widespread type PVL (arrows) was seen. No particular maternal episode existed before and during pregnancy.

Etiology: Birth trauma, asphyxia and respiratory failure, cardiopulmonary defects, premature birth/low birth weight, associated immature cerebrovascular development and lack of appropriate autoregulation of cerebral blood flow in response to hypoxic-ischemic insults.[101]

Pathogenesis: Distinctive and consists primarily of both focal periventricular necrosis and more diffuse cerebral white matter injury. Two most common sites are at the level of the cerebral white matter near the trigone of the lateral ventricles and around the foramen of Monro. Volpe[93] describes three factors, namely (1) periventricular vascular anatomical and physiological factors, (2) cerebral ischemia, and (3) intrinsic vulnerability of cerebral white matter of premature newborn, are strongly related to PVL.

Prenatal diagnosis: Figure 39.60.

Differential diagnosis: Subarachnoid (periventricular) pseudocysts, porencephaly, other intracranial cystic formation.

Prognosis: Neurological features of PVL in neonatal period are probable lower limb weakness and as features of long-term sequelae, spastic diplegia, intellectual deficits and visual deficits are observed.[93]

Recurrence risk: Unknown.

Management: Early rehabilitation.

40 Ultrasound of the fetal thorax

A. Khurana

Technological advances in transducer and software technology have in recent years remarkably improved visualization of structures in the fetal thorax (Figures 40.1–40.4) way beyond the minimum requirement recommended by the American Institute of Ultrasound in Medicine[1] over the last few decades. Additionally, novel methods of *in utero* treatment, the evolution of neonatal surgical techniques and anesthesia, the newer understanding of the natural course of several malformations and the pressing social and legal need for informed parental counseling have placed a new responsibility on the shoulders of the practicing ultrasonologist.

There is now a pressing demand for an accurate diagnosis, the formulation of a prognosis and the institution of appropriate management whether it be expectant observation, *in utero* therapy or a referral to a tertiary care center.

This presentation reviews current concepts in the evaluation of the fetal thorax (excluding cardiac conditions).

Embryology

Knowledge of the embryology of the thoracic viscera is imperative to understand the outcome of congenital thoracic malformations and their direct bearing on fetal lung developments and ultimate fetal and neonatal outcomes.

Development of the lung begins at 5 weeks.[2] The epithelium of the respiratory system develops from the endoderm. The connective tissue, cartilage and muscle develop from splanchnic mesoderm and neural crest cells.

At 26 days the foregut evaginates to form a laryngotracheal diverticulum. This then gets separated from the foregut by longitudinal folds, which progress to form the tracheoesophageal septum. The lungs develop in four stages. From 5 to 17 weeks all elements are developed except those involved in gas exchange. This is also called the pseudoglandular period. From 16 to 25 weeks (canalicular period) the lumen of bronchi and

Figure 40.1

Figure 40.2

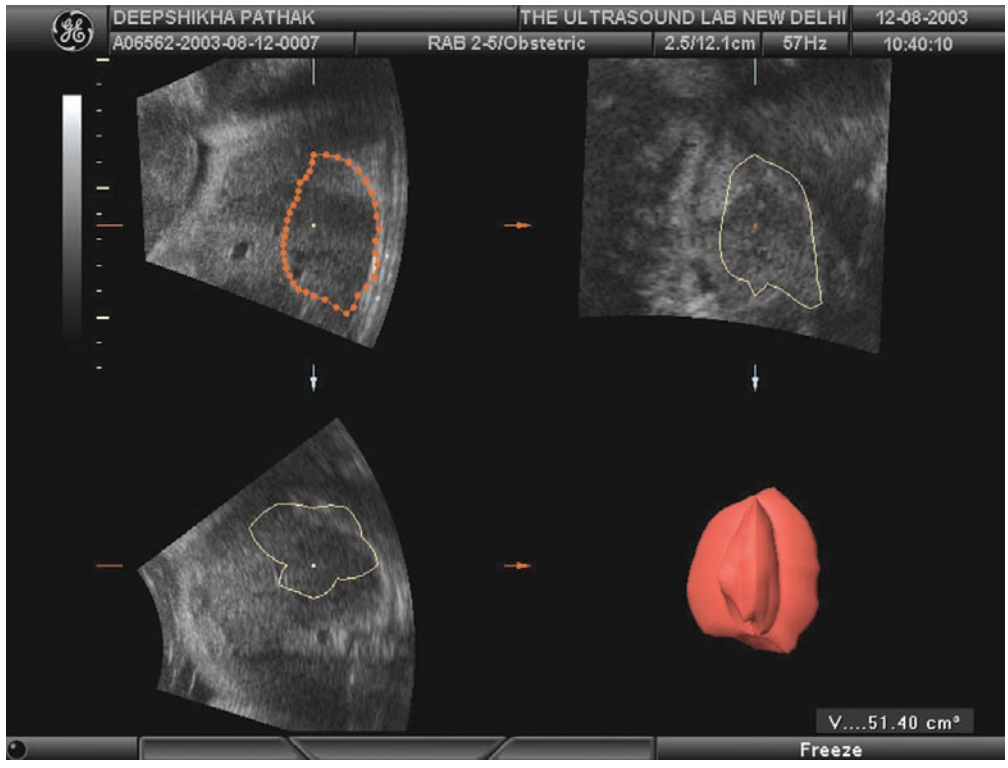

Figure 40.3

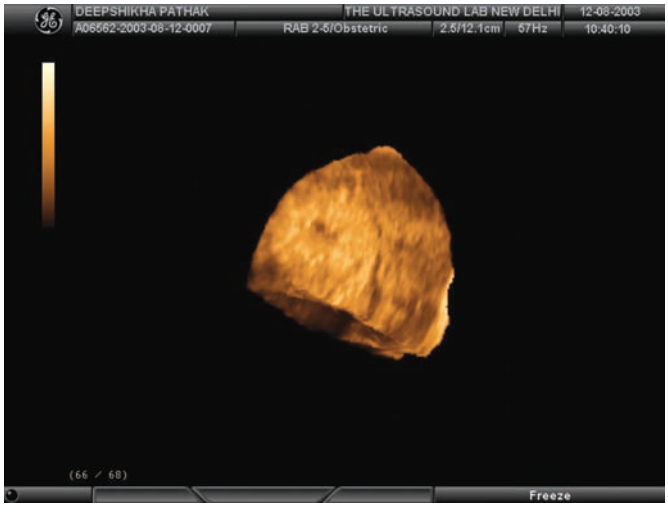

Figure 40.4

bronchioles become larger, and respiratory bronchioles and alveolar ducts develop. Some terminal sacs develop and the tissue becomes more vascular. From 25 weeks to birth, many more terminal sacs develop, the epithelium becomes very thick, capillaries bunch into alveoli, Type I alveolar cells develop and Type II alveolar cells begin producing surfactant. From late fetushood and up to childhood, squamous epithelium forms and alveoli continue to form after birth.[3]

Sonoanatomy of the fetal thorax

The fetal thorax extends from the clavicles to the fetal diaphragm. The diaphragm is continuous, thin and hypoechoic (Figure 40.5) and moves with respiratory movements in the third trimester of pregnancy. The thorax is bounded by the sternum anteriorly, the spine posteriorly and the ribs circumferentially. The heart is the most prominent structure in the thorax. The lungs are seen surrounding it. The left lung is limited in its extent by the heart (Figure 40.6). The lungs are homogenously echogenic and largely isoechoic with other mediastinal structures. The heart occupies one-third to half of the thorax and its location and axis are important to identify and evaluate non-cardiac conditions as well. Cardiac and mediastinal shifts have a tremendous bearing on the prognosis of a chest lesion. No fluid is seen in normal pleural spaces. The pleural and pericardial space should be evaluated to assess for hydrops, which again is a prognostic factor in the assessment of a chest mass. With some effort and resort to color flow mapping (Figure 40.7) and power Doppler studies, the aortic arch, pulmonary artery, ductus arteriosus, pulmonary veins, trachea, esophagus and thymus can be adequately evaluated.[4–6]

Figure 40.5

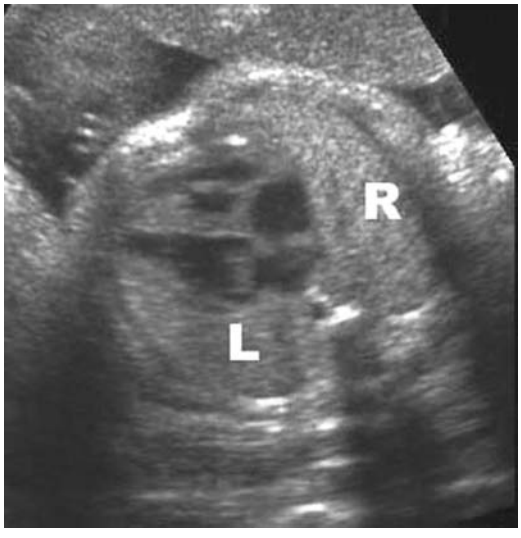

Figure 40.6

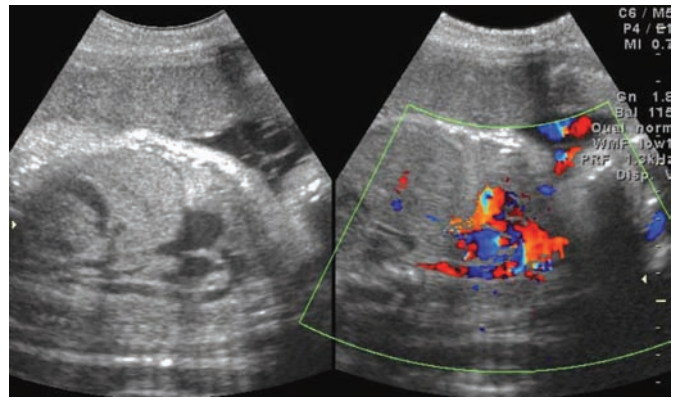

Figure 40.7

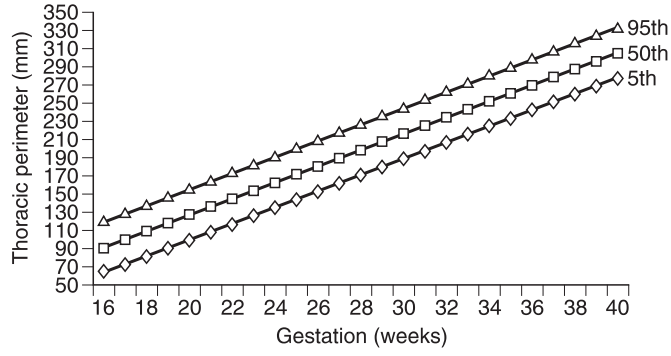

Figure 40.8

Pulmonary hypoplasia

Adequate lung development is central to fetal viability.[7,8] Hypoplastic lungs show a low lung to body weight ratio and histologically demonstrate a reduced number of alveoli.[9] Pulmonary hypoplasia is rarely primary and rarely unilateral.[10,11] It is usually secondary and consequent to any prolonged severe oligoamnios,[12–15] in skeletal dysplasias with a small bony thorax, in sizable intrathoracic masses,[16,17] consequent to neuromuscular dysfunction as in the Pena–Shokeir syndrome,[18] in trisomy 12, 18 and 21 and in conditions with decreased pulmonary artery perfusion.[19]

Thoracic perimeter measurements[20–23] (Figure 40.8) are made at the level of the four-chamber view and should exclude the soft tissue areas beyond the ribs. The thoracic perimeter/abdominal perimeter ratio[24–26] is steady through the late second trimester and in the third trimester: > 0.80. Lung lengths[27] although well studied (Figure 40.9) are not easily reproducible. Fetal lung volumes by three-dimensional reconstruction techniques (Figure 40.10) are reliable and reproducible.[28,29]

The pathogenesis of pulmonary hypoplasia commences with inadequate thoracic space for growth, inadequate breathing movements of whatever cause, inadequate fluid within the lung and suboptimal quantities of amniotic fluid.[30] Lung echogenicity does not correlate with lung maturity.

General features of chest masses

Not all lung masses can be delineated in the 18–20 weeks anomalies scan although embryologically they do

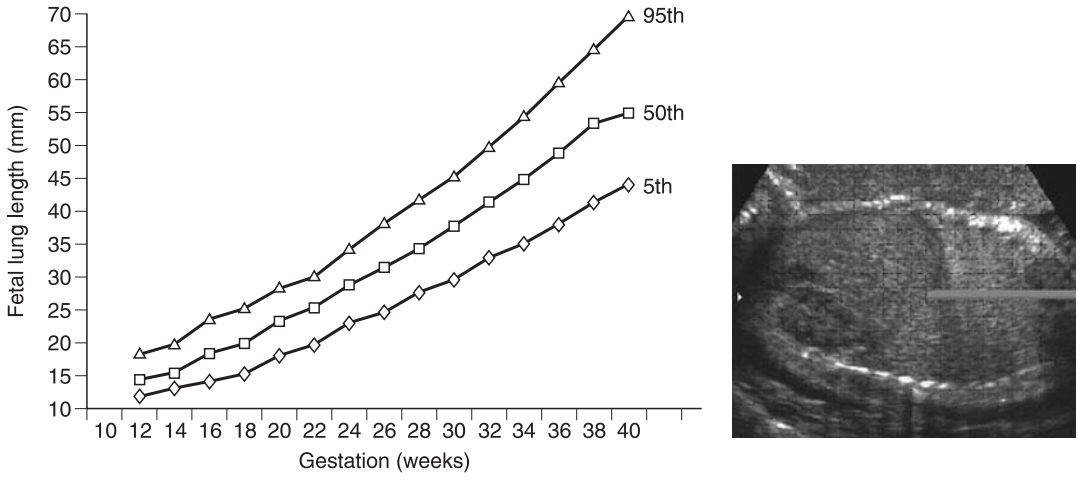

Figure 40.9

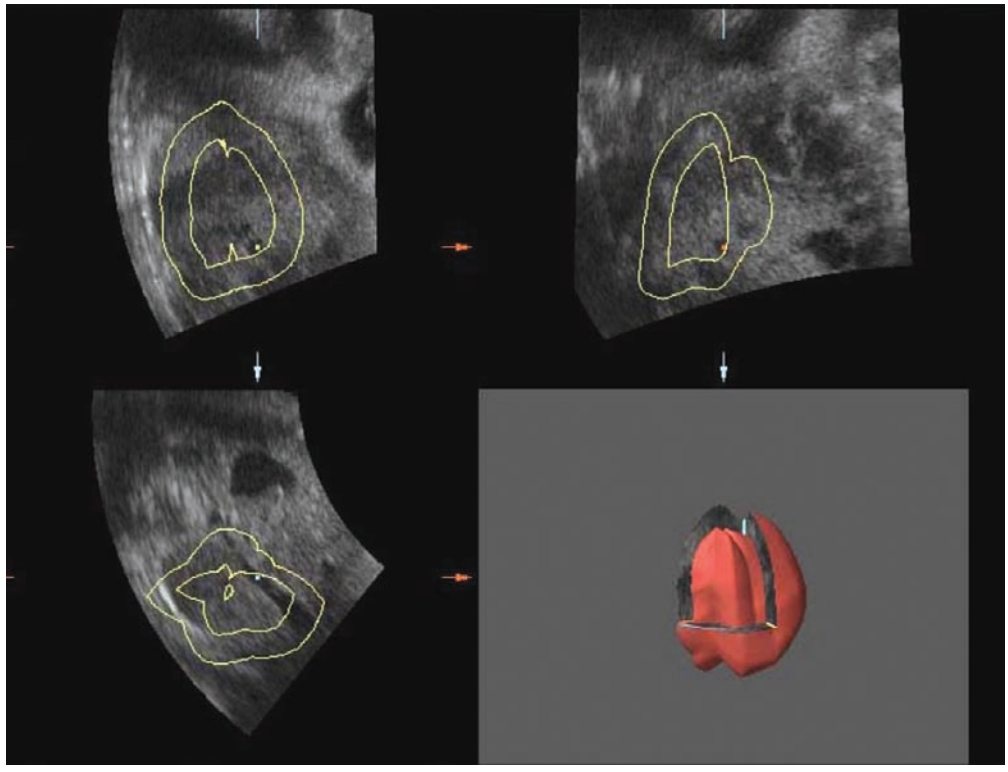

Figure 40.10

exist.[31,32] Depending on their size and growth they result in unilateral or bilateral hypoplasia of the lungs. Prognosis depends on the size of the lesion, heart and mediastinal displacements, the resence of hydrops, associated structural anomalies, underlying chromosomal abnormalities and the bearing of associated polyhydramnios on preterm premature rupture of membranes and prematurity.[33–35]

Common chest masses include congenital diaphragmatic hernia (CDH) and congenital cystic adenomatoid malformations (CCAM). Other lung masses include bronchogenic cysts, neurenteric cysts, congenital lobar emphysema (CLE), bronchial atresia, pulmonary gigantism, bronchopulmonary sequestration (BPS) and mediastinal masses. The mediastinal lesions include teratomas,[36] thymomas,[37] goiter, cardiac lesions

such as rhabdomyoma, myxoma and fibroma,[38–40] esophageal duplication cysts,[41] enteric cysts,[41] neurenteric cysts[42–44] and thoracic neuroblastoma. Mediastinal lesions are rare but important in the perspective of a differential diagnosis of a mass adjacent to the mediastinum but arising from the adjacent lung or from the abdomen.

Congenital diaphragmatic hernia

CDH has an incidence of 1–4.5/10,000 live births.[45] The incidence is higher in the fetus and a fair number are lost *in utero* or in the neonatal period prior to clinical identification. CDH is more common on the left side but not infrequently right sided or bilateral. The diaphragm forms between the 6th and 14th weeks of pregnancy by fusion of the septum transversum, pleuroperitoneal membranes, mesentery of the esophagus and the body wall. Failure of fusion especially of the pleuroperitoneal membranes results in a herniation of abdominal contents into the thorax when the gut returns to the abdomen. The disorder is progressive and the organs that herniate include the stomach, liver, spleen, small bowel and colon. Left-sided CDH usually involves the stomach. Right-sided CDH usually involves herniation of the liver. The herniation may be small, isoechoic and intermittent[46] and may therefore go unrecognized except when the problem is specifically looked for. Over four of five fetuses die in the neonatal period usually because of pulmonary hypoplasia and pulmonary hypertension. Pulmonary hypertension is consequent to the poorly understood but well documented medial wall muscular hypertrophy of the small pulmonary arteries extending up to the preacinar vessels. Newborns have a high incidence of feeding problems, gastroesophageal reflux, chronic lung disease and neurodevelopmental delays.[45,47] Sonographic signs[48] include a low abdominal perimeter, failure to visualize the fetal stomach in the fetal abdomen (Figure 40.11), visualization of the herniated viscera in the thorax (Figures 40.12 and 40.13), cardiomediastinal shift, pleural effusions and hydrops. There may also be failure to delineate the diaphragm in its entire extent. Right-sided hernias are difficult to identify because of isoechoic lung and these should be evaluated by color Doppler to confirm the location of the portal vein in the thorax (Figures 40.14 and 40.15). Although identification of the liver is not critical for a diagnosis of CDH, it has a major bearing on the prognosis.[49,50] This is so because after surgical repair the ductus venosus and umbilical vein often get kinked or compromised, thereby contributing to morbidity and often mortality. When bowel segments are not fluid-filled, as is common in the second trimester, they may appear as a non-specific chest mass (Figure 40.16). Careful

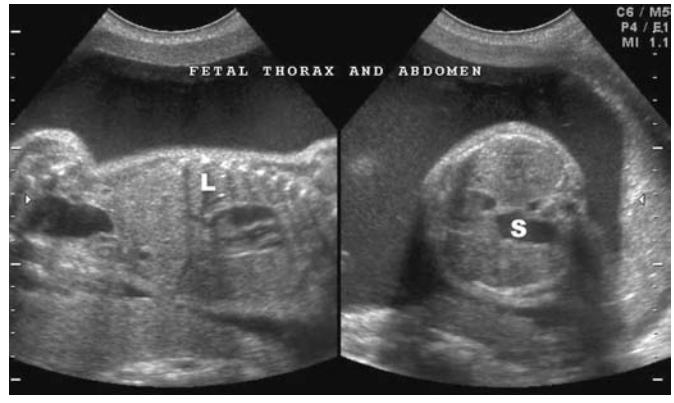

Figure 40.17

real-time scanning would reveal peristalsis in the third trimester. Occasionally, a gallbladder may be seen in the CDH. Bilateral hernias may be difficult to detect because of no cardiomediastinal shift. Ascites within a herniation may be mistaken for a pleural effusion.

Not all fetuses with a CDH have a poor prognosis.[51–54] Prognosis depends on gestational age at diagnosis, particularly if 24 weeks or earlier, large size, dilated stomach, the presence of the liver, even its left lobe in left-sided lesions, small contralateral lung, bilateral herniation (Figure 40.17) and the presence of associated anomalies (Figure 40.18). Because of the higher incidence of CDH in certain syndromes, facial and cardiac surveys merit special attention. These syndromes include trisomy 18, Fryn's, lethal pterygium, Beckwith–Wiedemann, Cornelia De Lange, Apert's and Goldenhahr.[55,56]

Fetal therapy has found a reasonable place in the treatment of CDH.[57] The aim of surgery is to prevent lung hypoplasia. Although fetal therapy initially involved reduction of the hernia by open repair *in utero*, current practice involves clipping of the trachea. Currently, videofetoscopic techniques are under evaluation. Tracheal occlusion results in increased lung volume and accelerated lung maturity similar to the pathophysiology seen in laryngeal and tracheal atresia.[58]

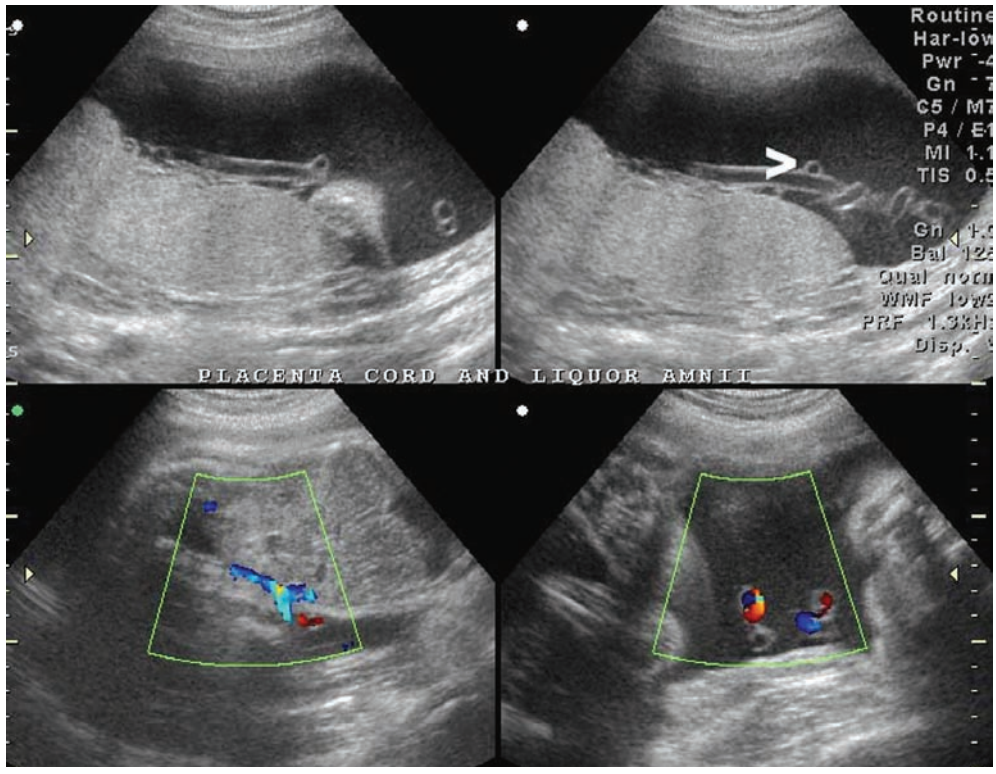

Figure 40.18

Congenital cystic adenomatoid malformations

CCAMs occur consequent to failure of induction of mesenchyme by bronchiolar epithelium. Lack of normal cellular development is considered to be consequent to focal bronchial atresia. The lesion is hamartomatous and characterized by focal abnormal proliferation of bronchiolar-like air spaces and absence of alveoli.[59] It is usually unilateral. Some may be associated with sequestration in the same lung. Diagnosis depends on the demonstration of a mass in the thorax.[60] This may be macrocystic (cysts 2–10 mm) (Figure 40.19), microcystic (cysts 0.3–0.5 mm) (Figure 40.20) or mixed[31,32] (Figure 40.21). These may cause a cardiomediastinal shift, ipsilateral and contralateral lung compression, pulmonary hypoplasia and hydrops. The lesion may regress spontaneously[61] (Figure 40.22). Prognosis depends on associated pulmonary hypoplasia, pulmonary hypertension, hydrops, associated anomalies, polyhydramnios and prematurity. Microcystic lesions are more likely to cause pulmonary hypoplasia and hydrops. The arterial supply is via a pulmonary artery and drainage into a pulmonary vein. Treatment of the lesion consists of expectant management, monitoring for hydrops or premature/term delivery followed by lobectomy if necessary.[33] Referral to a tertiary care center is important because emergency thoracic surgery is often needed. Recurrence is rare in later pregnancies. Since Klinefelter's syndrome and trisomy 18 are known for an association with CCAMs, it is appropriate to obtain a karyotype when the condition is diagnosed.

In utero aspiration of a larger cyst, thoracoamniotic shunting of a larger cyst and *in utero* resections have been attempted and are methods of gaining time to achieve viability. *In utero* resection has been tried only in fetuses with the poorest prognosis since the procedure itself carries a high morbidity and mortality.

Bronchopulmonary sequestration

Also known as pulmonary sequestration and accessory lung, BPS is a congenital malformation consisting of lung parenchyma, which is separated from normal lung. It receives arterial supply of systemic origin and does not communicate with the normal tracheobronchial tree. Sequestrations arise from a supernumerary anomalous outpouching of the foregut. If these arise prior to closure of the pleura they have no separate pleural envelope and are called intralobar

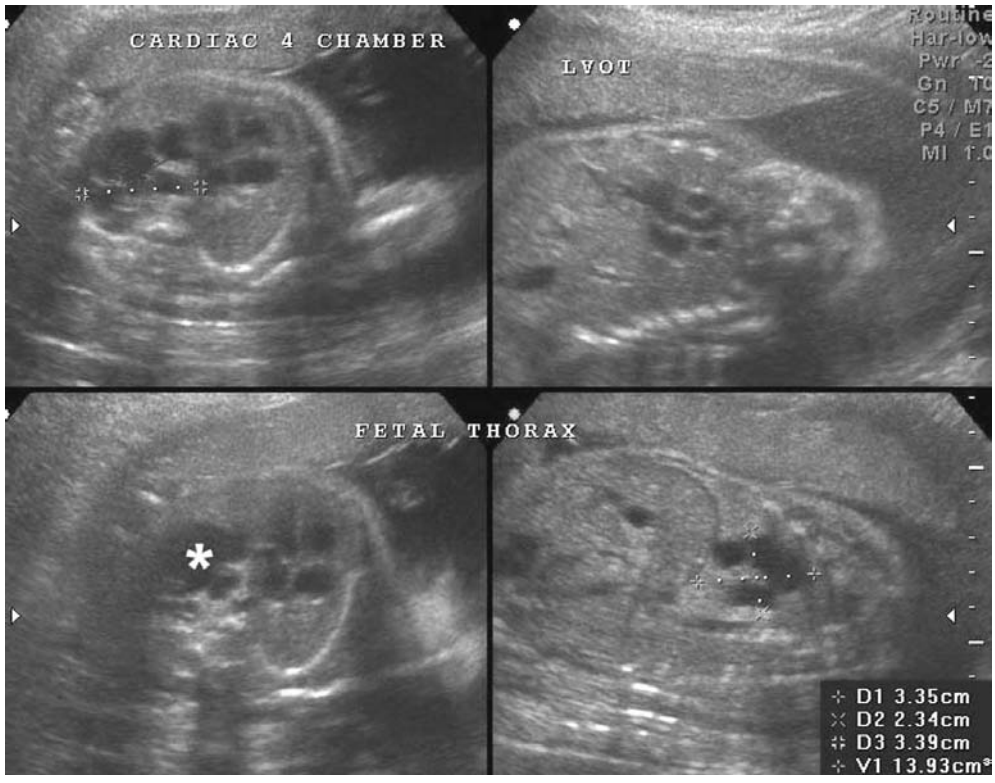

Figure 40.19

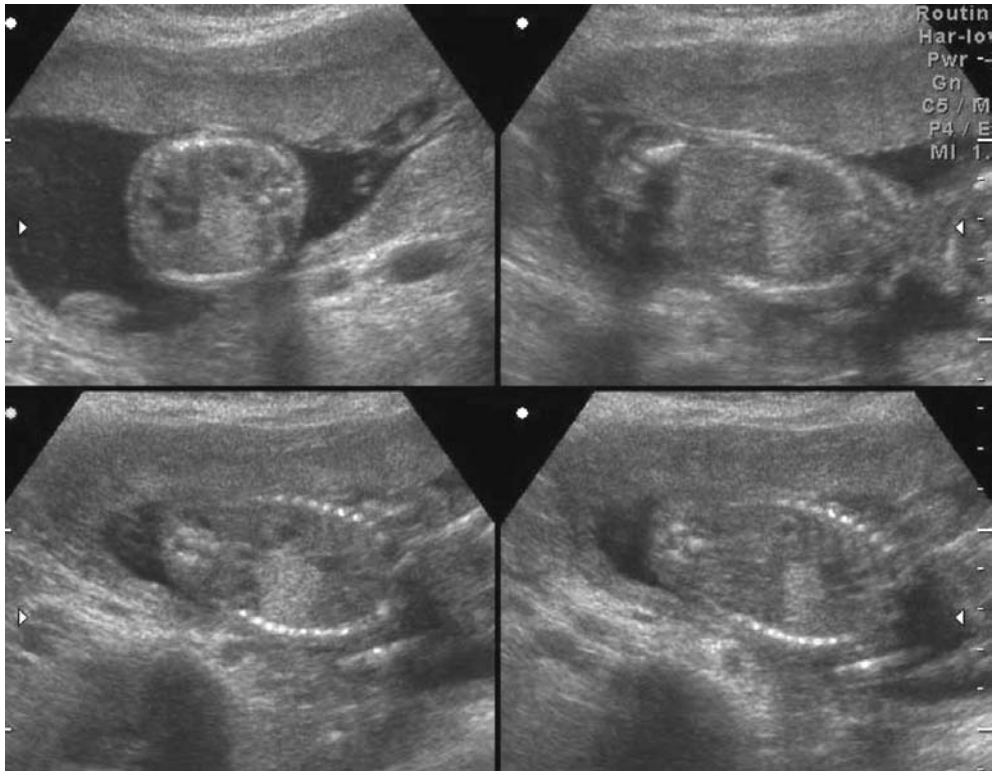

Figure 40.20

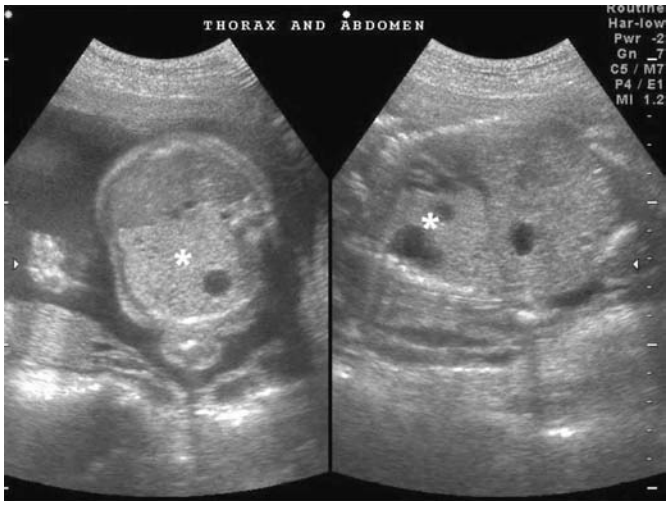

Figure 40.21

sequestrations. If these originate after closure of the pleura they are called extralobar sequestrations and have their own pleura. Intralobar sequestrations drain into pulmonary veins and extralobar sequestrations usually drain into a systemic vein, usually the azygos, hemiazygos or inferior vena cava. Extralobar sequestrations may be thoracic or extrathoracic and may even communicate with the esophagus.[62] They are occasionally associated with other thoracic and foregut anomalies such as CDH, CCAMs, bronchogenic cysts and neurenteric cysts. A wide variety of extrapulmonary anomalies including congenital heart disease, renal anomalies and hydrocephalus have been reported to coexist with sequestrations. Many sequestrations show extensive subpleural lymphatics, which account for ipsilateral pleural effusions. Typical sonographic appearances[63] include a lobar or triangular echogenic lesion in the lung base, usually left basal (Figure 40.23). Color Doppler studies reveal a systemic arterial supply[64] (Figure 40.24). There is a variable mediastinal shift and hydrops.

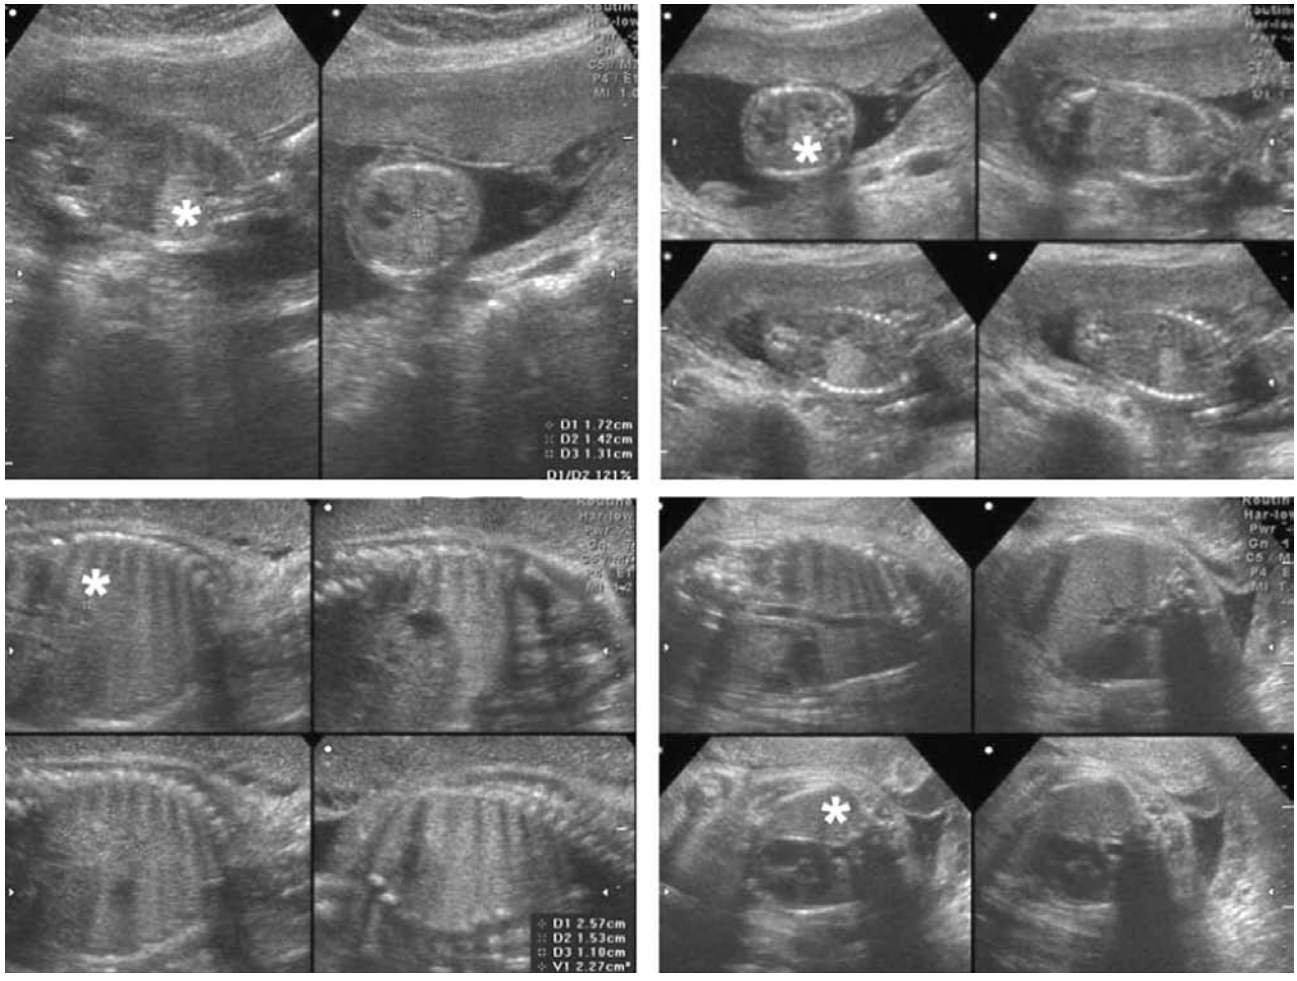

Figure 40.22

Several sequestrations regress spontaneously.[65] No specific features indicate which sequestrations are likely to resolve. Persistent sequestrations may stabilize or may need surgical resection (postnatal).

Bronchogenic cysts

These arise as a consequence of abnormal foregut budding and show variable echogenicity and variable progress. They may be mediastinal or peripheral and often show associated foregut malformations and hemivertebrae. The usual manifestation is an echogenic lesion representing fluid-filled lung beyond the stenosis. The left upper lobe is the most frequent site. Occasionally, these are multiple. These are usually innocuous and do not require specific obstetric management. Their importance lies in being one of the differential diagnoses of a fetal lung mass.[60]

Figure 40.23

Laryngeal and tracheal atresia

These are rare congenital anomalies, which are associated with demise soon after birth, unless treated antenatally. These arise consequent to subglottic laryngeal atresia, tracheal stenosis or atresia, or tracheal webs or cysts and are also known as congenital high airways obstruction (CHAOS). Embryologically, persistent fusion of the sixth bronchial arches is apparently involved. Pathologically, failure of efflux of fluid from the fetal lung results in exaggerated lung development. Ultrasound features[66,67] include symmetric enlargement of both lungs (Figure 40.25) with anterior displacement of the heart. The lungs are homogenously echogenic, often similar to autosomal recessive infantile polycystic kidneys, since the underlying lesion consists of numerous fluid-filled spaces. The diaphragm is flat or inverted and cutaneous edema is common as is hydrops. Polyhydramnios is seen consequent to esophageal compression. The distal trachea and bronchii may be identified as tubular bulging fluid-laden structures in the mediastinum. Over half the fetuses with this abnormality have renal agenesis, facial anomalies and central nervous system malformations. To salvage a fetus with this anomaly it is necessary to establish a functional airway before the fetus is removed from placental support.[68]

Congenital lobar emphysema

Although this condition has clinical manifestations in the pediatric age group, it can be seen in the fetus as a solid lung mass akin to a microcystic CCAM or an ELS. It is usually located in the upper lobe unlike ELS. There is one case report of a spontaneous regression after indometacin treatment.[69]

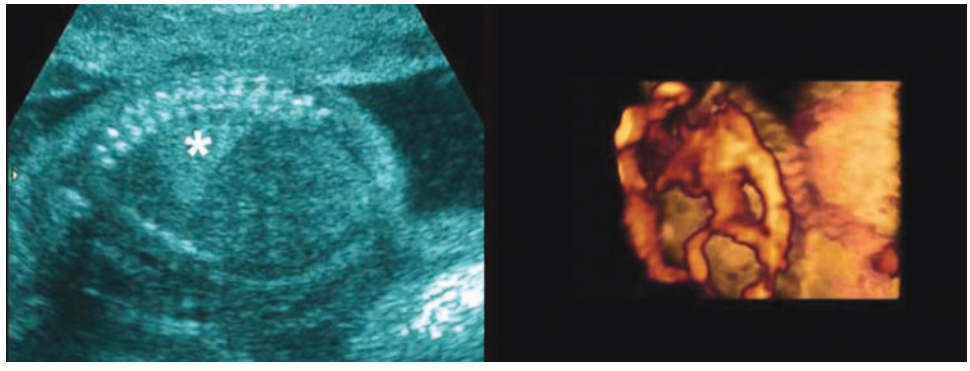

Figure 40.24

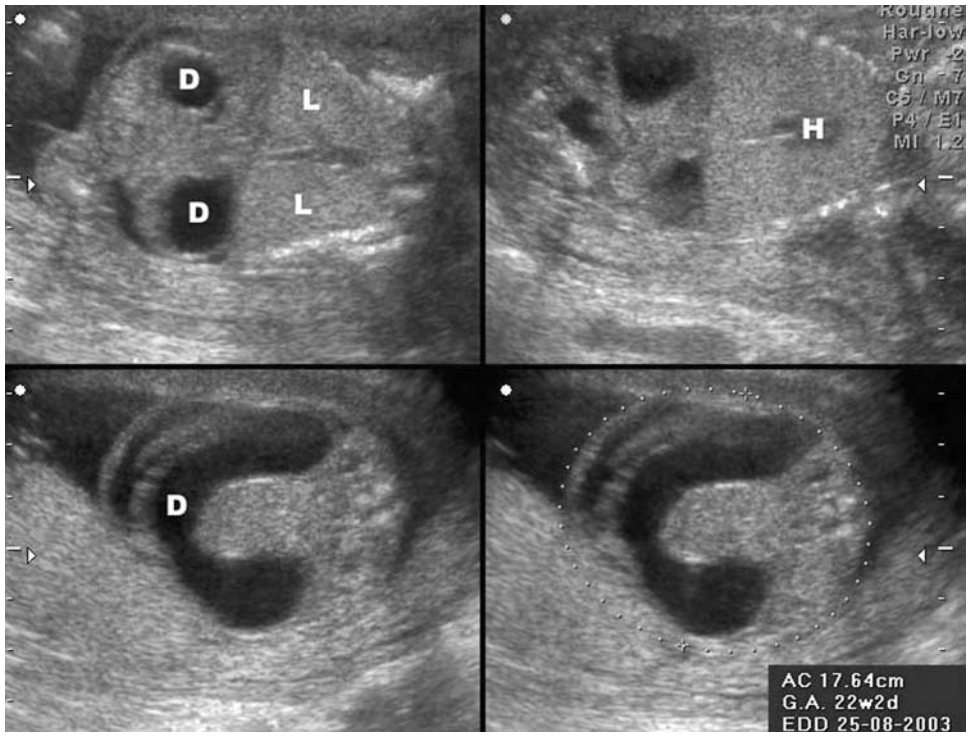

Figure 40.25

Figure 40.26

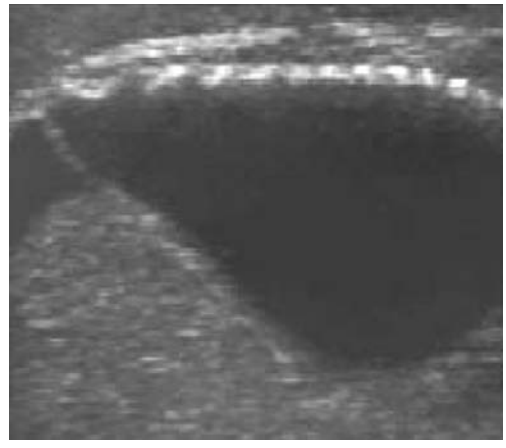

Figure 40.27

Pleural effusion

Unlike a small amount of pericardial fluid, which may be physiological, a fetal pleural fluid collection is always abnormal.

Primary pleural effusions are accumulations of pleural fluid, which may be idiopathic (Figures 40.26 and 40.27) or consequent to thoracic duct malformations[70]. They are unilateral or, if bilateral, markedly asymmetric. Mediastinal shifts are common and there are no associated findings except hydrops, which is an ominous finding. Pulmonary hypoplasia is common in large chronic effusions. The condition may resolve spontaneously and does very well after thoracentesis or thoraco-amniotic shunting.[71,72]

Secondary pleural effusions are consequent to other fetal anomalies and are often the earliest sign of immune or non-immune hydrops fetalis (NIHF).[73] The causes, therefore, include anemia, infection, cardiac anomalies, anomalies with large arteriovenous shunts, chromosomal abnormalities, skeletal dysplasias and thoracic malformations. Secondary effusions are usually bilateral and often associated with early onset of other signs of hydrops (Figure 40.28).

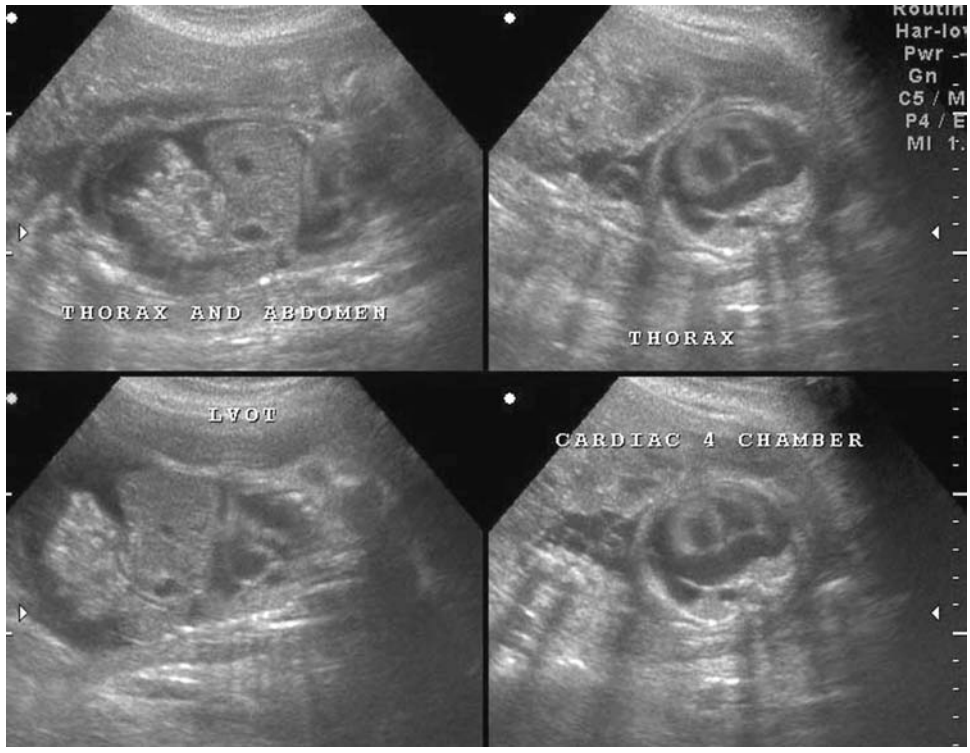

Figure 40.28

Prior to instituting any treatment procedure it is wise to exclude an abnormal fetal karyotype and assess fetal anemia.

Conclusion

The current approach to a thoracic lesion involves knowledge of sonographic features in order to make an accurate diagnosis. This should be followed by a careful evaluation for associated dysmorphic anomalies and identification of hydrops. An appropriate workup for fetal anemia and fetal karyotype should be considered next. The prognosis then needs to be formulated in the perspective of prevention of pulmonary hypoplasia, the possibility of spontaneous regression and referral to a tertiary care center. Ultrasound-guided interventions in such a fetus would include amniocentesis or cordocentesis for a complete diagnosis, and, from a therapeutic viewpoint, cyst aspiration, thoracentesis or a thoracoamniotic shunt.

41 Three-dimensional ultrasound of blood flow in the fetal cardiovascular system

R. Chaoui

Introduction

In the past 5 years three-dimensional (3D) ultrasound moved from an advertising toy with the highlight of baby facing to a new powerful diagnostic tool in prenatal medicine. This was mainly achieved by the development of fast processors enabling rapid 3D image acquisition and the advent of new software allowing new 3D image display.

The use of color and power Doppler ultrasound in the 1990s improved the prenatal diagnosis of malformations involving the cardiac and vascular systems.[1–3] Malformations of the cardiovascular system are often complex and difficult to understand when only gray-scale imaging is used. Two-dimensional color or power Doppler ultrasound can help in a better assessment of fetal abnormalities, but they generally enable the visualization of only those vessels with a straight course or lying in a 2D plane.[4–6] In most cases the examiner is reconstructing mentally a spatial image of the vessels examined.[5]

In recent years, a few case reports and studies demonstrated that the 3D power Doppler ultrasound (3D-PDU) helps in the reconstruction of the vessels of interest and thus improves the understanding of the spatial appearance of the vascular tree.[4,7,8] Images produced were very similar to results known from radiology acquired either by x-ray[9–11] or by MR-angiography. This chapter aims to present the actual possibilities of 3D ultrasound of the cardiovascular system in normal and abnormal pregnancies, looking for possible future applications of this method in prenatal diagnosis.

Technical background

The main aspects that have to be considered when evaluating a 3D imaging system are (1) the volume data acquisition and (2) the image rendering display.

Volume data acquisition

The acquisition of a volume with information on the fetal heart or the fetal vessels can be achieved either in 3D static mode, which means a volume consisting of a series of still images, or in 4D mode, which reflects the beating character of the heart. The latter can be acquired either in live real-time 3D or as off-line 4D, which was recently made possible by the advent of the new software of spatial and temporal image correlation (STIC).[12,13] In these acquisitions heart and vessels can be visualized either on gray-scale mode, or in combination with color Doppler,[14] power Doppler or B-flow. The acquisition of a volume with gray-scale information is reduced to the demonstration of the lumen of the heart or the vessels, whereas in Doppler or B-flow techniques blood flow is visualized. To acquire a volume with a potentially good 3D/4D image, the examiner should spend time in optimizing the presetting of the color and power Doppler or B-flow or increasing the contrast on the gray scale.

Image rendering

Image rendering is the process of creating a 3D visual representation of the parameters of interest. Generally the principle used is the 'planar geometric projection' of the 3D image, i.e. a 2D image representing the 3D data. For the 4D image it will be a 2D projection with cine-loop. The impression of the third dimension is generally given by the on-line rotation of the image on the screen and by different shadowing of anterior and posterior structures. Color maps can be used as well as different postprocessing means of increasing the brightness and transparency of color. The examiner can decide whether to visualize the vessels of interest alone or in combination with gray-scale information in the so-called 'glass body' rendering (Figure 41.1). Interestingly, the system also allows a gradual increase of the transparency, allowing at the beginning the visualization of the surface in gray scale

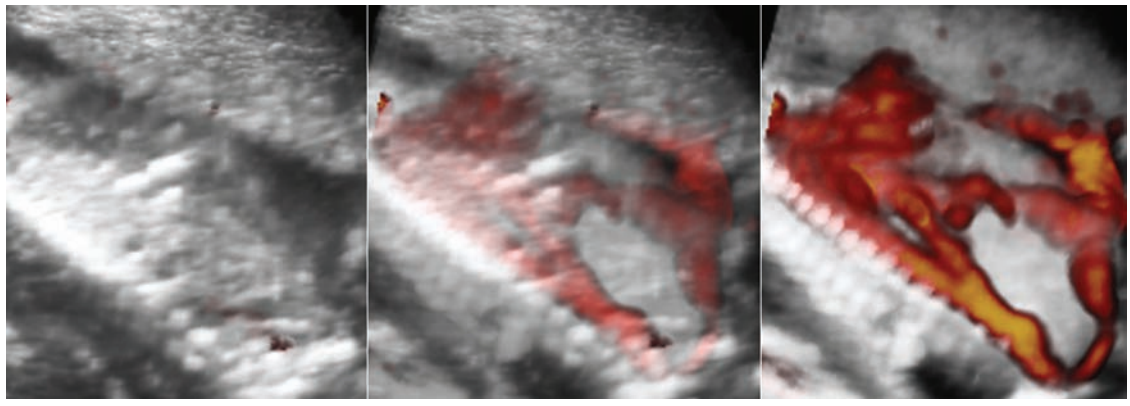

Figure 41.1 A longitudinal view of the abdomen seen from the right side in glass body mode. From left to right the transparency is gradually increased allowing a progressive visualization of power Doppler information.

but with progression of transparency, the visualization of the vessels inside the structure of interest (Figure 41.1).[7] For information using no Doppler assistance but only the gray-scale information, there are two volume rendering features permitting a 3D/4D appearance: the transparent minimum mode and the transparent inversion mode.

Most of the experience shared in this chapter was acquired with a Voluson 730 Expert system (GE Kretztechnik, Zipf, Austria) using mechanical transducers for acquisition and the 4D view software for 3D/4D volume reconstruction. The 4D of the fetal heart was achieved either with live 3D or by using the integrated STIC software as described elsewhere. Only the latter permitted a 4D of color or power Doppler information of the heart. It is expected that in the near future other companies will provide new software with new possibilities of 3D/4D acquisition and rendering, but the fields of interest will probably remain unchanged.

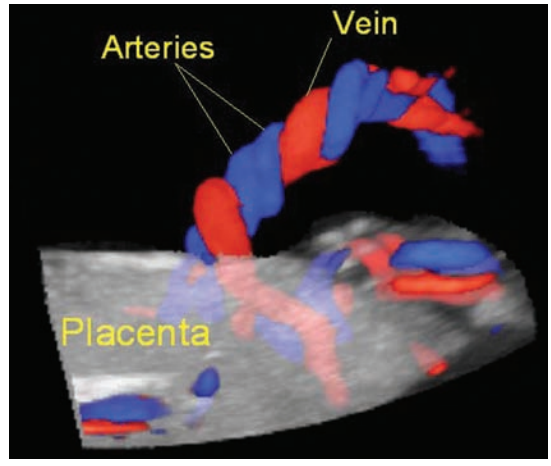

Figure 41.2 3D color Doppler ultrasound showing a posterior placenta with central insertion of the umbilical cord.

Clinical application

The clinical application of 3D/4D in prenatal visualization of the fetal cardiovascular system is closely related to the regions of interest known from the application of color and power Doppler ultrasound. We refer to reviews on the benefit of using color Doppler in fetal diseases.[2,3] Some years ago[4] we examined in a study the application of 3D-PDU in prenatal diagnosis on 45 normal and 87 abnormal pregnancies including mainly vascular abnormalities. In this study we used a prototype system and satisfactory image information was collected in only 56 out of the 87 abnormal cases examined (64%). The following eight regions were found to be of interest: vessels of the placenta, umbilical cord, abdomen, kidneys, lung, brain and fetal tumors as well as the heart and great vessels. In the following findings, the main regions of interest with the possible anomalies involving the vascular system were demonstrable on 3D ultrasound. The fetal heart will be discussed separately in the second part of this section.

Peripheral vascular system in 3D

Umbilical cord and placenta

From our experience it seems to be the structure most easily accessible to 3D throughout pregnancy. Intraplacental vessel network architecture can be visualized with this method.[15] The umbilical cord can be rendered at different places from its insertion on the placental side (Figures 41.2 and 41.3) to its attachment on the fetal abdominal wall.[4] Abnormalities like placenta previa, vasa previa[16] or velamentous insertion (Figure 41.3) can be demonstrated, as well as the single umbilical artery or less important conditions such as the connecting vessels in twin pregnancies, nuchal cord or true and false knot (Figure 41.4) or the free course of the umbilical cord (Figure 41.5).

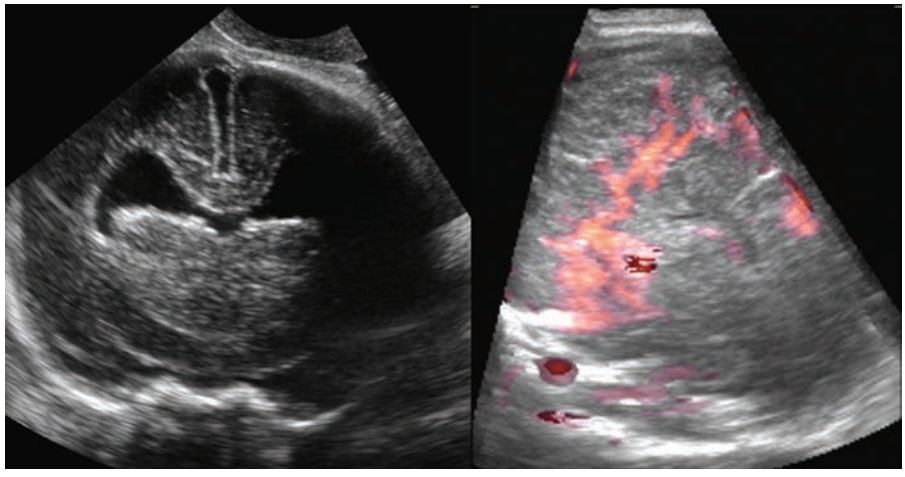

Figure 41.13 Fetus with trisomy 13 and lobar holoprosencephaly as seen by transvaginal ultrasound (left). 3D power Doppler shows the aberrant bizarre course of the anterior cerebral artery.

Intra-abdominal vessels

The vessels of interest are the umbilical vein, the ductus venosus, the portal vein system, the hepatic veins, the splenic vessels, the inferior vena cava and the abdominal aorta (Figure 41.6). The visualization of the lower abdomen gives a good orientation in visualizing the umbilical arteries around the urinary bladder in normal conditions. Since the application of color Doppler and the intensive study of the ductus venosus, abnormalities of the intrahepatic venous system were detected to be more common than expected. Conditions to study by 3D power Doppler could involve the abnormal cord insertion on the abdomen (omphalocele, gastroschisis) (Figure 41.7), abnormal umbilical vein size (varix or ectasia), but the main field of interest seems to be the absence of ductus venosus (Figure 41.8) with the different possibilities of connection of the umbilical vein. In these conditions 3D power Doppler demonstrates the spatial course of the aberrant vessel. Another interesting condition is the abnormal course of vessels in isomerism, i.e. interruption of the inferior vena cava with azygous continuity (Figure 41.9).

Renal vessels

The visualization of renal vessels is known to increase the accuracy of diagnosis of kidney malformations in the fetus. The renal vascular tree is well visualized

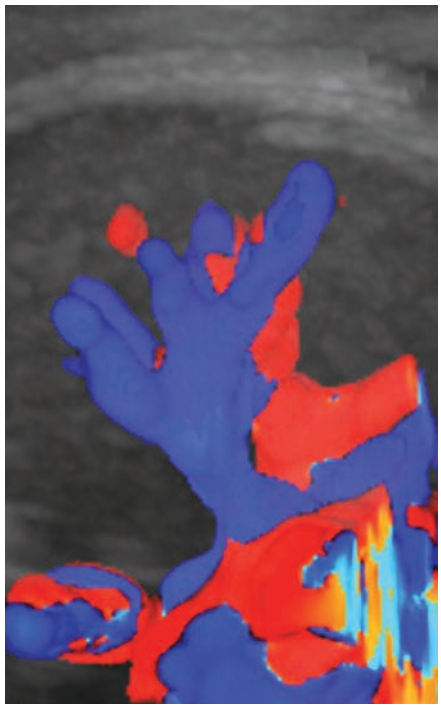

Figure 41.14 Pulmonary veins and arteries are demonstrated with 3D color Doppler ultrasound.

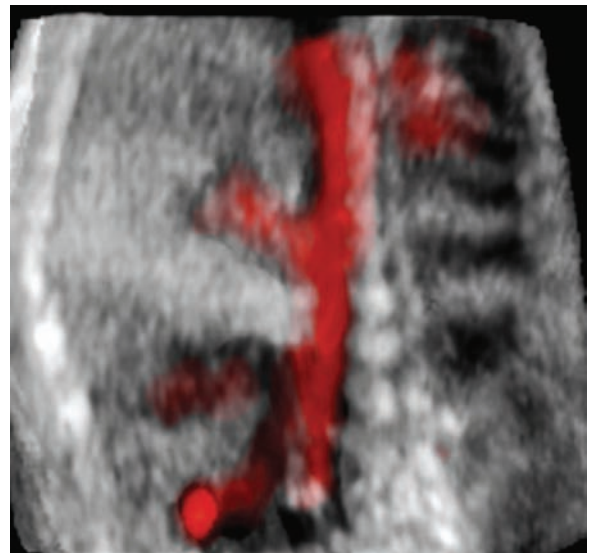

Figure 41.15 In this fetus with an echogenic lung segment the diagnosis of bronchopulmonary sequestration is supported by the demonstration of an aberrant vessel arising from the descending aorta (arrow).

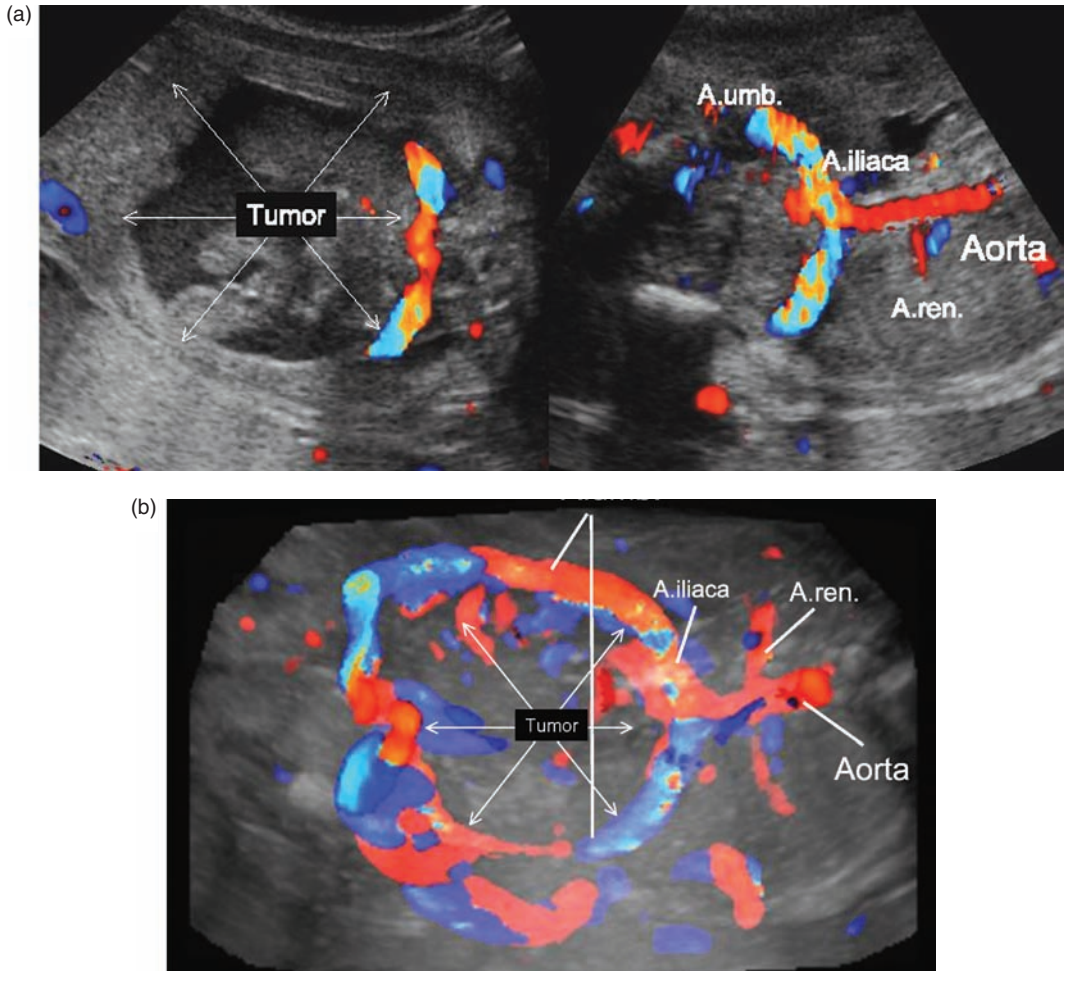

Figure 41.16 (a) In this fetus at 27 weeks with sacrococcygeal teratoma there was an intra-abdominal mass as well (arrows). In different planes one recognizes the descending aorta, one renal artery and the bifurcation of iliac arteries with the arising of umbilical arteries (A.umb). (b) The 3D rendering gives the complete aspect of the tumor and the surrounding vessels.

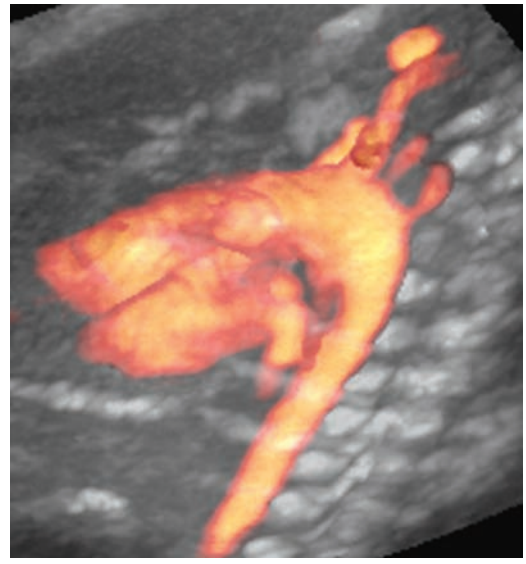

Figure 41.19 Aortic arch with the origin of the cephalic vessels. Behind the brachiocephalic artery the superior vena cava is seen.

in a coronal plane with the descending aorta showing a horizontal course. Conditions with possible benefit of 3D-PDU application are agenesis of one or both kidneys, arteries in duplex kidney, horseshoe or pelvic kidney (Figure 41.10), but the 3D rendering adds only a little information to 2D color and was probably overestimated in our few investigations.

Intracerebral vessels

The anatomy of intracranial vessel architecture became more important in recent years and is closely related to the structural anatomy of the brain. A transversal insonation allows easy reconstruction of the circulus of Willis (Figure 41.11), whereas a more sagittal approach enables the visualization of the pericallosal artery with its ramifications.[17] Choosing a lower velocity, scale flow in the cerebral veins and sagittal sinus can be imaged as well. The main fields of interest are the abnormal anterior cerebral artery in agenesis of corpus callosum, the aneurysm of the vein of Galen (Figure 41.12) and the disturbed vascular anatomy in cerebral malformations [holoprosencephaly (Figure 41.13), hydrocephaly, encephalocele, etc.]. Improved image information can be achieved by using transvaginal ultrasound of the fetal brain in fetuses with vertex position (Figure 41.13).

Lung vessels

Proximal and peripheral lung arteries and veins can be seen from their origin in peripheral pulmonary segments (Figure 41.14). Fields of interest are the analysis of the 3D vessel architecture in cystic lung malformation, congenital diaphragmatic hernia and bronchopulmonary sequestration (Figure 41.15). The

Figure 41.20 Parallel course of the great vessels in transposition of the great vessels.

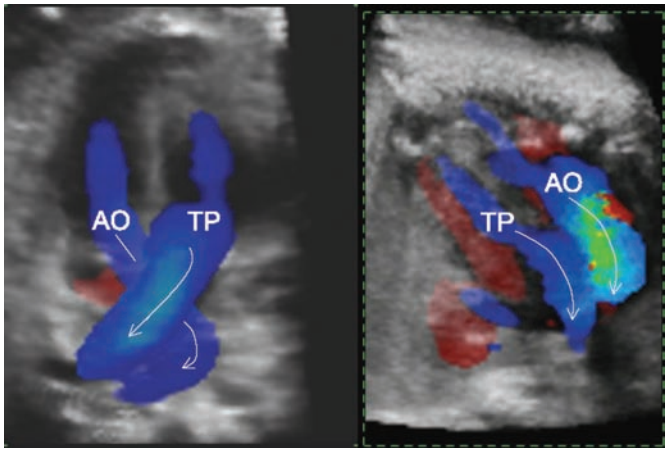

Figure 41.21 3D and 4D volume rendering with transparent gray scale and surface color Doppler of two fetuses: on the left a normal finding with the regular crossing of the great vessels, on the right a fetus with transposition of the great arteries with parallel course of both vessels.

role of color or power Doppler in predicting pulmonary hypoplasia failed and it is not expected that the 3D demonstration of the vessels could be in this field of great interest in the near future.

Fetal tumors or aberrant vessels

Aberrant vessels can be visualized in the presence of several malformations like lung sequestration, chorangioma, lymphangioma or in (sacrococcygeal) teratoma, acardiac twin, etc. Visualization of fetal tumors is of interest not only for the risk of cardiac failure due to the presence of arterio-venous fistulae, but also to assess compression of shifting of neighboring organs (Figure 41.16a and b). Some fields of

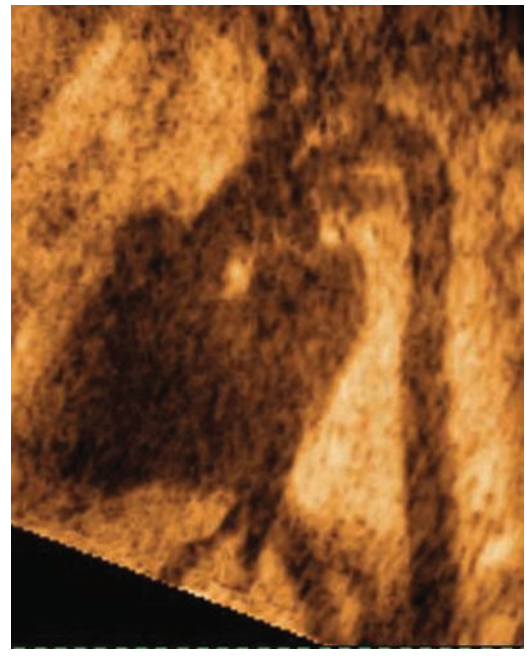

Figure 41.22 Longitudinal view of the heart, the aortic arch and the hepatic vessels in transparent minimum mode.

interest are chorangioma, teratoma, lung sequestration, acrania (TRAP), hemangioma, renal tumors, cardiac rhabdomyomas, etc.

The fetal heart in 3D and 4D

An extended fetal echocardiographic examination is achieved by acquiring and documenting different cross-sectional planes.[1,18] An examiner acquiring these cardiac cross-sectional planes during different cycles is automatically reconstructing mentally the heart in the third and fourth dimensions (3D + time). In the last decade 3D and 4D fetal echocardiography was investigated intensively in laboratories using external workstations, static volume sweep, matrix transducers and recently, a new ultrasound equipment with integrated software (STIC™) was introduced, allowing reliable 3D and 4D fetal echocardiography.[12,14]

Surface rendering can be applied to the fetal heart by using the interface between the cavities and the cardiac walls. The views are, however, either the known views from 2D ultrasound (four and five chambers) or could be new views as well, which are still to be defined.[19] Such views could focus on demonstrating the AV-valves or the interventricular or interatrial septum. The future will show which views are appropriate for clinical application. This part will not be covered in this chapter, which mainly focuses on the 3D appearance of blood flow. The first steps were acquired by combining power Doppler mode with 3D to get the image of the four cavities (Figure 41.17)[4] or the spatial arrangement of the great vessels.[11] These views could help in the demonstration

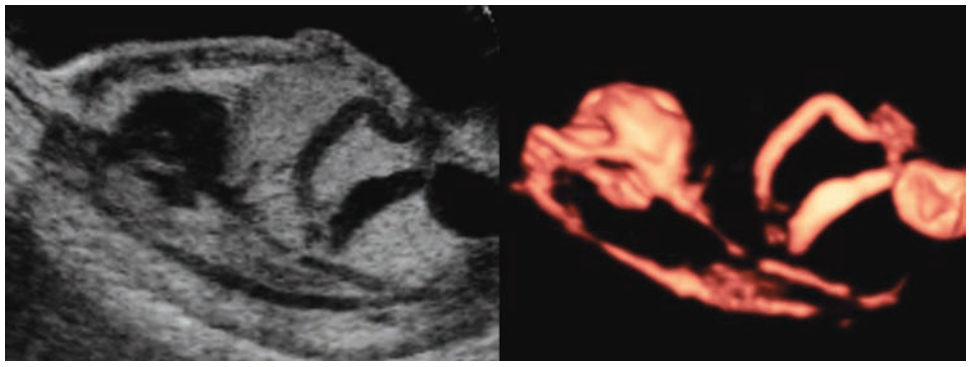

Figure 41.23 A longitudinal view of a fetal abdomen in minimum mode (left) and inversion mode (right). No blood flow is visualized but hypoechoic structures such as gallbladder and urinary bladder in addition to the usual vessels.

Figure 41.24 Crossing of the great vessels as demonstrated with the inversion mode.

of interventricular communications as a ventricular septal defect (Figure 41.18). Their main potential could be the demonstration of the crossing of the great vessels and the aortic arch under normal conditions (Figure 41.19) vs. transposition of the great arteries (Figure 41.20).[4] The application of STIC with color Doppler and 'glass body mode' allows a more precise and dynamic appearance of the relationship of the vessels to each other (Figure 41.21).[14]

An interesting rendering mode is the 'transparent minimal mode' rendering (Figures 41.22 and 41.23, left), in which blood vessels can be seen as hypoechoic structures in a projection. Especially in a longitudinal view, the aortic and ductus arch can be seen properly. The use of the new software of 'inversion mode' permits the demonstration of a negative image of the projection in minimum mode, but the image gets more plasticity and appears more 3D than the minimal mode (Figures 41.23, right and 41.24).

The breakthrough 2 years ago was achieved by the software allowing the acquisition of a STIC volume combined with color Doppler or power Doppler information. We presented extensively this technique elsewhere.[14] Using this technique the examiner is able to assess the hemodynamic spatial changes throughout the cardiac cycle. The 3D/4D volume rendering of color or power Doppler STIC provides images similar to an angiography when the feature glass body is chosen.

The potential of 3D is that it not only facilitates the understanding of the spatial arrangement of the chambers showing their size and shape, but the course of the great vessels can also be better understood. Crossing of vessels vs. parallel course, abnormal course as seen in double aortic arch, right arch with a sling[20] or simply tortuous hypoplastic aorta or pulmonary artery in different anomalies may be fields for future research.[21]

42 Specific aspects of ultrasound examination in twin pregnancies

E. Quarello and Y. Ville

Introduction

Although twins account for only 2% of all pregnancies, they are responsible for 20% of perinatal morbidity and the incidence of twinning has increased by 50% over the last 20 years. Embryologically, two-thirds of the twins are dizygotic, resulting from fertilization of two oocytes by two spermatozoids. One-third of the twins are therefore monozygotic, resulting from the splitting of one fertilized egg. Depending on the time of splitting after fecundation, one-third of monochorionic twins will be dichorionic, which occurs within the first 4 days. The majority, however, will therefore be monochorionic. It is only when splitting occurs after 8 days in 5% of these that the twins are monoamniotic. When splitting occurs after 12 days, the Siamese twins will share some organs. Among twin pregnancies, the incidence of perinatal mortality and morbidity is two to six times higher in monochorionic pregnancies. Both specific and non-specific complications justify closer surveillance by ultrasound. Indeed, ultrasound examination in twins is subjected to technical difficulties related to the presence of two fetuses in the uterine cavity and this has an impact both on biometry and on morphological and functional assessment. Specific features should also be surveyed during ultrasound examination of all twin pregnancies.

Determination of chorionicity and amnionicity (Figure 42.1)

Gestational sacs count should not be performed before 6 weeks. Indeed before that, one sac could be left unnoticed. Embryos can be counted from 7 weeks onward and yolk sacs can be identified between 8 and 12 weeks. Amnionicity should not be confirmed before 9 weeks. Prior to 9 weeks of gestation, amnionicity cannot be assessed reliably, even with the use of high-frequency vaginal ultrasound probes.[1] Chorionicity is the main determinant of both specific and non-specific complications in twin pregnancies. This is therefore the main aim of ultrasound examination in twins. Eighty percent of twin pregnancies are dichorionic. Diagnosis of chorionicity should be made in the first trimester of pregnancy, ideally between 9 and 12 weeks; however, this is still reliable until 14 weeks but it becomes uncertain thereafter when the twins are of the same sex.

Chorionicity can be established based on:

- Gestational sacs count
- Presence of the lambda sign before 14 weeks, as opposed to the T-sign in monochorionic pregnancies
- Presence of the twin peak thereafter
- Identification of two distinct placental masses
- Determination of different fetal genders
- Examination of the intertwin fetal membranes

The 'lambda' sign[2] and the 'twin peak'[3] are specific features of dichorionic pregnancies but have been described at two different gestational periods. They both appear as a thick hyper- or isoechoic triangular base of the intertwin membranes on a single placental mass. These feature the triangular projection of villous tissue at the union of two fused chorionic plates. In monochorionic placentae, a single chorionic layer cannot therefore project on the placenta; this features an abrupt junction on the placenta described as the T-sign. A lambda sign is the guarantee for a dichorionic pregnancy with a sensitivity close to 100%.[4] It can be found throughout pregnancy but the significance of its absence is reliable only before 14 weeks. Non-visualization of the lambda sign with the presence of the T-sign has a positive predictive value for monochorionicity close to 100%.

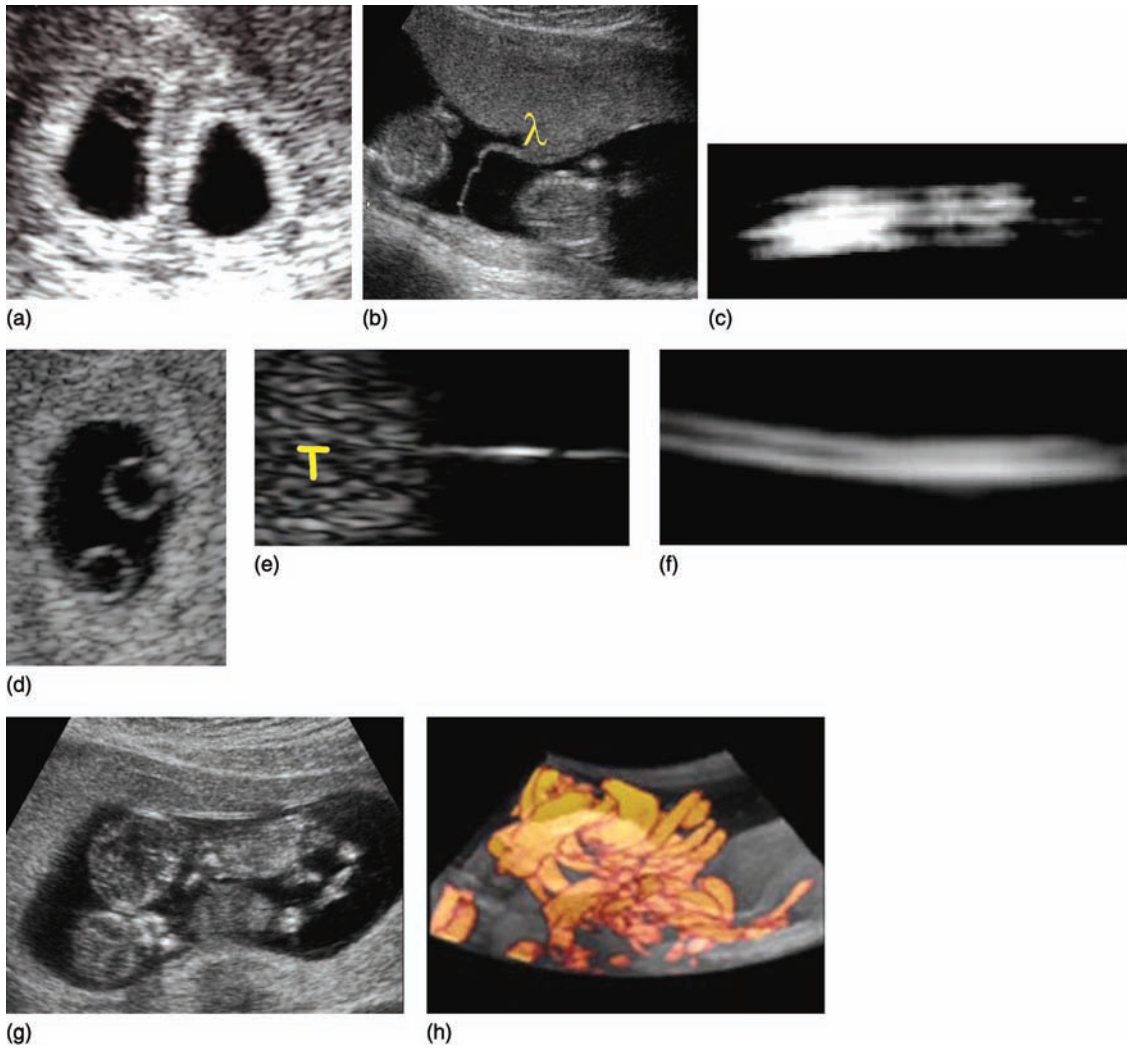

Figure 42.1 Assessment of chorionicity and amnionicity. (a) Dichorionic pregnancy (DCP) before 9 weeks showing two gestational sacs. (b) DCP showing the lambda sign of the fused chorions. (c) Interamniotic membrane in a DCP at 22 weeks counting more than two layers. (d) Monochorionic pregnancy (MCP) before 9 weeks showing one gestational sac and two yolk sacs. (e) MCP at 12 weeks showing the T-sign at the membrane attachment on the placenta without chorion interposition. (f) Interamniotic membrane in an MCP at 22 weeks counting only two layers. (g) Monoamniotic twins at 12 weeks. (h) Cord entanglement in a monoamniotic twin pregnancy at 17 weeks.

The presence of two placental masses is predictive of a dichorionic pregnancy; however, this may feature a placenta bipartita in up to 15% of these cases. Monochorionicity cannot be confirmed by the presence of a single placental mass since two separate placentae are frequently fused after 15 weeks. The presence of vascular anastomoses on the chorionic plate joining the two funicular circulations is a specific feature of monochorionicity but its detection is time-consuming and its reproducibility remains to be established.

Different fetal genders are specific of dichorionicity because they would confirm a dizygotic pregnancy. The reverse is not true.

Intertwin membrane is the result of the fusion of two amniotic and two chorionic layers in dichorionic pregnancies. This is made of only two amniotic layers in monochorionic diamniotic pregnancies. In the late second and third trimesters, ultrasound examination can assess the thickness of the intertwin membranes using cutoff measurements of 1.5 or 2 mm or, better, counting two or four layers in monochorionic and dichorionic pregnancies, respectively. Technically, this requires the use of magnification and the lowest gain possible and an angle of insonation to the membranes close to 45°. A right angle, although theoretically more suitable, is subjected to more artifactual images.

Amnionicity can be determined upon:

- Visualization of the interamniotic membrane. However, non-visualization of the membrane in a diamniotic pregnancy can arise due to technical difficulties, mainly before 8 weeks of pregnancy or in obese patients.
- Visualization of the yolk sacs and extra-amniotic spaces. The number of yolk sacs and extra-amniotic

spaces matches the number of amniotic sacs. Two yolk sacs are seen in monochorionic diamniotic pregnancies and only one in monoamniotic pregnancies.[5] These can be seen as non-contiguous in dichorionic pregnancies.
- Cords entanglement in monoamniotic twins can be best visualized using color Doppler. Doppler flow within the cord mass should also show a biphasic arterial flow.
- Conjoined twins can only be seen in monoamniotic pregnancies and can be suspected when visualizing close proximity of both twins, which also show concomitant movements.

Examination before 15 weeks is critical and a well-documented picture should be kept in the notes in order to confirm chorionicity whenever clinically relevant later on in pregnancy.

Nuchal translucency measurement in twin pregnancies

Nuchal translucency measurement can be used in twins to reliably screen for fetal aneuploidy. The false-positive rate for each dichorionic twin is 5% and is therefore similar to that in singletons. However, in monochorionic twins, nuchal translucency is measured above the 95th percentile for crown–rump length (CRL) in either twin inasmuch as 8.5% of the cases. Sebire *et al.* reported an 88% detection rate for a false-positive rate per pregnancy of around 10% and 15% in dichorionic and monochorionic pregnancies, respectively.[6] Discordance of nuchal translucency measurements between monochorionic twins is also predictive of the development of twin-to-twin transfusion syndrome (TTTS) with a sensitivity of 33% and a positive predictive value of 28%. The likelihood ratio of developing TTTS at 10–14 weeks of gestation is 4.2 (95% CI, 3.0–6.0).[6]

Specific complications of monochorionic twins

Twin-to-twin transfusion syndrome (Figure 42.2)

In all monochorionic pregnancies, a single placental mass implies that the two fetuses share some placental units with a shared vascularization of these cotyledons. An imbalance in placental sharing will arise in around 15% of monochorionic pregnancies.[6] Indeed, the natural history of monochorionic twins as observed by serial ultrasound examination suggests that up to 28% of all monochorionic twins scanned at 12 weeks will show some discrepancy either in abdominal circumference or in amniotic fluid volume, with membrane folding at 16–18 weeks, but only up to half of these (14% of the starting number) will develop TTTS in the second or early third trimester.[6,7] TTTS results from an acute hemodynamic imbalance through the vascular placental anastomoses. The donor twin becomes hypovolemic, oliguric and around two-thirds of these will also show some degree of growth restriction. Oligohydramnios develops in this sac. There is hypervolemia in the recipient twin, which is therefore polyuric leading to polyhydramnios in its sac and is exposed to high-output cardiac failure. Although a net transfer of blood is likely to initiate it, this is not the only mechanism involved in the syndrome. In order to maintain volemia, the fetal renin–angiotensin system is activated in the donor twin and suppressed in the recipient with preferential maternal–fetal transfer of fluid to the recipient.[8] A paradoxical effect of a transfer of renin toward the recipient twin through the placental anastomoses could also contribute to the development of hypertension and cardiomyopathy in this fetus. A velamentous insertion of the cord of either twin on the placenta is found in up to 30–50% of all monochorionic pregnancies and this is likely to play a significant role in creating hemodynamic imbalance between the two feto-placental circulations.

The diagnosis of TTTS requires that the pregnancy is monochorionic and relies on the association of polyuria-related polyhydramnios in the recipient twin together with oliguria-related oligohydramnios in the donor twin. Polyhydramnios is defined as a vertical deepest pool of amniotic fluid of at least 8 cm before 20 weeks and 10 cm thereafter and oligohydramnios is present when the deepest fluid is at most 2 cm. Up to 28% of all monochorionic twins seen at 12 weeks on ultrasound will develop some discrepancy in the volume of amniotic fluid and/or a discrepancy in size[6] by 16–18 weeks. This does not meet the criteria for TTTS and has led to a long-standing misunderstanding on the diagnosis and the prognosis of TTTS. It is only half of these, that is, 14% of the starting number, that will develop the polyoligohydramnios sequence. The fetal size, although the recipient is usually appropriately grown and the donor is usually smaller, is not an important criterion for the diagnosis of TTTS.

When oligohydramnios is confined to anhydramnios, the intertwin membranes are difficult to visualize and the donor twin is 'stuck' on the placenta or the uterine wall. This can lead to a false diagnosis of monoamniotic pregnancy or the suspicion of various malformations in the compressed donor twin. Pushing the abdominal wall with regard to the donor twin will demonstrate that this twin cannot move due to anhydramnios. Hypervolemia in the recipient often shows a cardiothoracic index of more than 0.55 with a thick myocardium and the presence of tricuspid regurgitation, which has no prognostic value when the recipient is not hydropic. The best first-line treatment consists of fetoscopic surgery to coagulate the anastomotic chorionic plate vessels.[9]

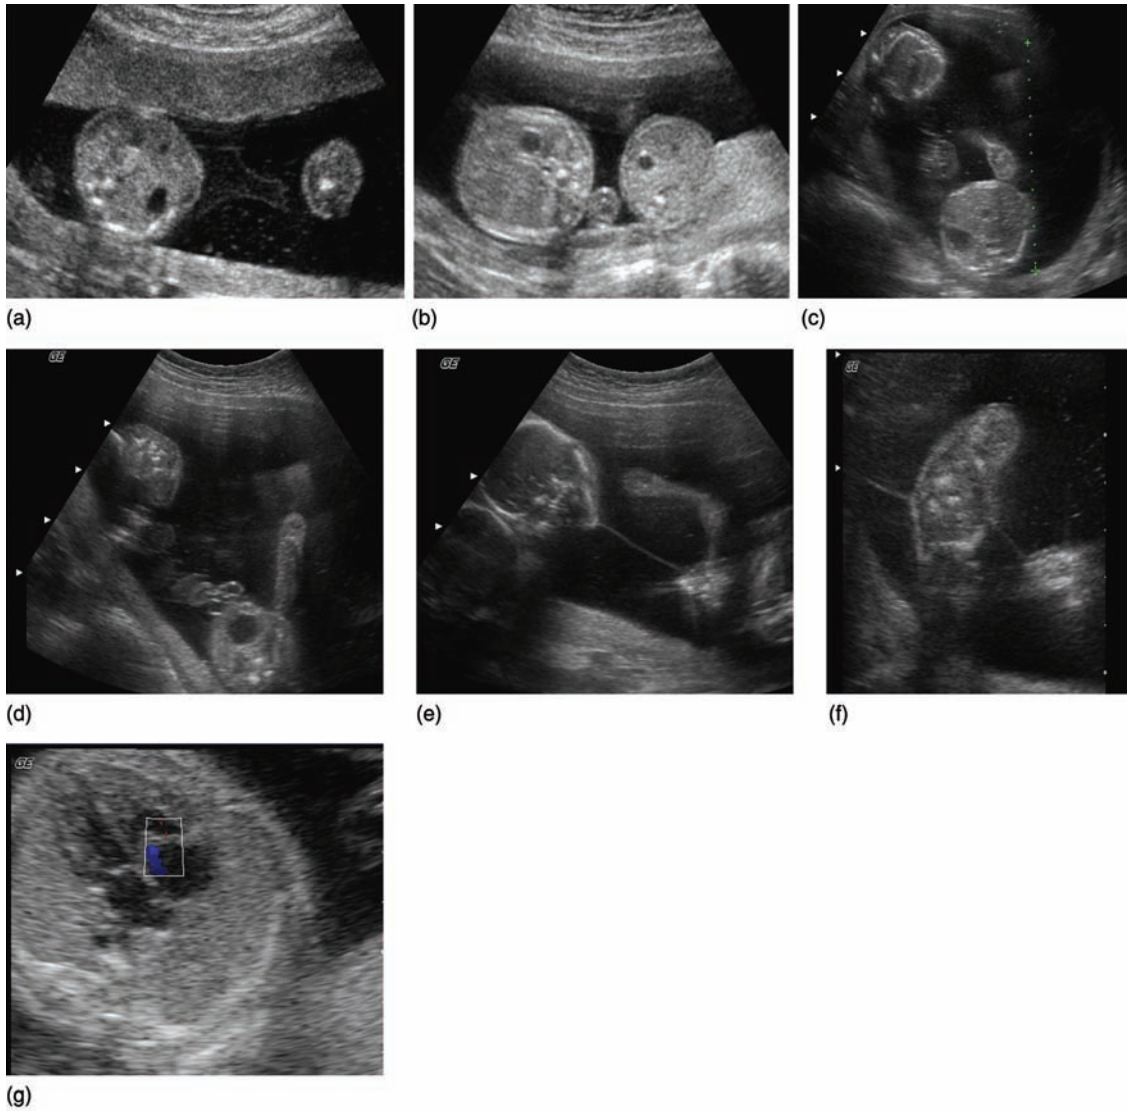

Figure 42.2 (a) Folding of the membranes (arrow) in a monochorionic twin pregnancy at 17 weeks. (b) Cross-section through the fetal abdomen of two monochorionic twins discordant for growth at 20 weeks. (c) Cross-section through the fetal abdomen of the stuck donor twin in anhydramnios against the uterine wall (d) and the recipient twin in polyhydramnios (r) in twin-to-twin transfusion syndrome. (d) Cross-section through the fetal pelvis of the stuck donor and the recipient showing absent and distended bladder, respectively. (e) The donor in anhydramnios is wrapped in its membranes as shown in a sagittal plane (f) and in a cross-section through the pelvis showing an empty bladder. This 'sling-sign' could lead to the false impression that the amniotic fluid volume is normal on both sides of a floating intertwin membrane. (g) Examination of the recipient's four-chamber view of the heart with color Doppler showing tricuspid regurgitation.

Arterial and venous fetal Doppler can be normal or show absent or reverse end diastolic flow in the umbilical arteries. Absent or reverse flow in the a-wave of the ductus venosus usually corresponds to severe hypoxemia or cardiac overload in the donor or the recipient twin, respectively. Peak systolic velocities in the middle cerebral artery are sensitive to anemia and to polycythemia showing values above 1.5 MoM or below 0.7 MoM, respectively.[10] However, a difference in hemoglobin is unusual *in utero* in most cases of TTTS.[11]

Quintero[12] has proposed a classification of TTTS in four stages, which has the advantage of homogenizing the diagnostic criteria. Stage 1 corresponds to the association of polyhydramnios in the recipient and oligohydramnios in the donor, where the bladder is visible. Stage 2 is similar but the bladder cannot be visualized in the donor. In Stage 3, Doppler examination shows marked abnormalities with absent or reversed end diastolic flow or absent or reversed a-wave in the umbilical arteries or in the ductus venosus, respectively. Stage 4 is characterized by the presence of hydrops in either twin. Stage 5 is when one or both twins have died *in utero*.

TTTS can also develop into monoamniotic pregnancies. Polyuric polyhydramnios is then seen together with a small or unseen bladder in its co-twin.

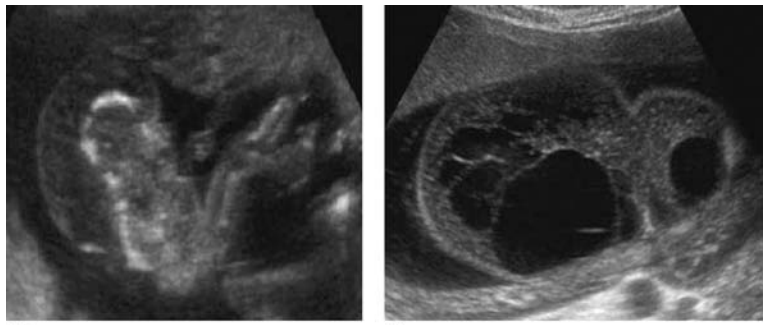

Figure 42.3 (a) Monochorionic twin pregnancy showing an acardiac twin at 13 weeks showing rudimentary head, spine and lower extremities. (b) Edematous acardiac mass at 25 weeks.

Acardiac twin

An acardiac twin is defined by the presence of one monochorionic twin without a clearly anatomically defined heart; the co-twin is usually normal. Vascularization of the monochorionic placenta almost invariably shows the presence of two superficial anastomoses between the two cord insertions: one artery-to-artery and one vein-to-vein anastomose flowing in opposite directions. There is usually a single umbilical artery in the cord of the acardiac twin and this sets the basis for an increased cardiac workload in the normal twin, also named the pump twin. The acardiac mass can grow and develop to various degrees, increasing the mass of tissue that the normal twin heart has to bear (Figure 42.3). This can therefore lead to the development of high-cardiac output hydrops in up to 50% of pump twins. The bigger the acardiac mass, the higher the likelihood of hemodynamic decompensation of the pump twin.[13] The acardiac twin usually bears several major malformations, allowing for embryological classification,[13] the most frequent being the acardiac acephalus; however, rudimentary organs, especially limbs and spine, are often present. Early in the pregnancy, this is often mistaken for either an early embryonic demise or a placental tumor. The key to the diagnosis is the use of color Doppler showing retrograde perfusion of the acardiac mass, and eventually demonstrating the placental anastomoses.

Monoamniotic pregnancies

The fetuses will be seen in close proximity and both crossing of their limbs and cord entanglement as seen by color Doppler will establish the diagnosis.

Conjoined twins

These are 4–5% of all monochorionic monoamniotic twins. The embryological classification refers to the part of their body through which they are attached, the most frequent type being thoracopagus.[14] Organ sharing can be symmetrical or asymmetrical. The extreme form of the latter constitutes the fetus-in-fetu, where a rudimentary fetal mass can be found as a hyperechogenic tumoral mass into an otherwise usually normal fetus, child or even adult.

There is a clear benefit for an early diagnosis of a unique embryonic mass often characterized by the presence of two beating hearts. Embryonic/fetal movements are always simultaneous and a single umbilical cord with more than three vessels can be identified.

Amniotic fluid volume in twin pregnancies

Oligohydramnios, anhydramnios and the 'stuck-twin phenomenon'

All causes of oligohydramnios in the singleton can affect one or both twins and should be investigated in the same way. The stuck-twin phenomenon can therefore affect both monochorionic and dichorionic pregnancies to the same extent. However, when oligohydramnios affects only one twin, the twin with a normal amount of fluid is often unduly credited for having polyhydramnios and a wrong diagnosis of TTTS is often suspected. It is therefore critical to use an objective measurement of the amniotic volume, mainly using the deepest pool measurement.[15] Another important pitfall is to consider that the two layers of membranes tightly wrapped around the stuck-twin, featuring the 'sling-sign'[16] could be mistaken as free-floating membranes separating two cavities with a normal amount of fluid in each sac. Etiologies that are more prone to affect twins include low urinary tract obstruction, severe intrauterine growth retardation and preterm prelabor rupture of the membranes.

Polyhydramnios in twins

All malformations seen in singletons, such as anencephaly, bowel atresia, are more frequent in twins. Monochorionic twins, however, are the only ones to

see acute polyhydramnios developing polyhydramnios due to TTTS.

Cervical changes in twin pregnancies

Although twin pregnancies are 1% of all pregnancies and 2% of all deliveries, twins account for 15% of all maternal morbidity and mortality. This is mainly due to preterm delivery with 12% of all preterm neonates being twins.

The advantage of cervical ultrasound over digital examination has also been clearly shown in twins. Relative risk of preterm delivery within a week of cervical ultrasound examination has been reviewed by Ong *et al.*[17] as 4.1 (95% CI, 1.10–15.47) and 11.7 (95% CI, 4.23–32.17), respectively, for values lower than the thresholds of 25 and 20 mm.

Growth discordance in twins

This is the second most frequent complication in twins and the second contributor to neonatal mortality and morbidity. Conflict of interest may arise between twins so as to define the optimal timing for delivery. In the second and third trimesters of pregnancy, the cutoff value for EBW estimate is at least 20%.

Malformations in twins

The presence of two embryos/fetuses increases the risk as compared to singletons. A recent series[18] has gathered data on 260,000 twin pregnancies among 12 million births. Five thousand and five hundred twin pregnancies carry at least one malformed twin outside specific risks associated with monochorionicity representing 2.14% vs. 1.72% for singletons. A total of 101 malformation sequences have been reported, 37 of which are more prevalent in twins. The prevalence of fetal malformations in twins is therefore around 25% with relative risks of 8–60%. Dizygotic twins only carry non-specific malformations. Monochorionic twins will bear malformations both non-specific and specific to monochorionicity. Specific malformations include those arising from a delay in zygotic splitting or midline abnormalities as well as those resulting from a sequence of events following severe hemodynamic imbalance through placental anastomoses. Furthermore, only 5–20% of monozygotic pregnancies are concordant for fetal malformations.[19] These differences can also arise from postzygotic genetic abnormalities, different susceptibility to their exposure to environmental factors.

Intrauterine fetal death of one twin

Perinatal mortality in twins is up to sevenfold higher than in singletons.[20] Intrauterine death of one twin can result from non-specific fetal complications such as those seen in singletons, including cord compression and severe growth restriction, as well as from specific complications related to hemodynamic imbalance, including TTTS and collapse. In monochorionic twins, the death of one fetus will threaten its co-twin by causing an abrupt and profound drop in systemic blood pressure subsequent to the exsanguinations of the survivor in its dead co-twin and its placenta through the intertwin anastomoses. Peak systolic velocities in the midcerebral arteries of the survivor measured above 1.5 MoM within 24 h of the co-twin's death will predict anemia/hypovolemia in this twin (sensitivity 90% for a 10% false-positive rate).[10] Exsanguination will lead to fetal death or severe ischemic sequelae in the survivor in 25% and 25% of the cases, respectively. Ischemia-related malformations include cerebral lesions such as periventricular leukomalacia, porencephaly, hydrocephalus and migrational anomalies, renal ischemia and mesenteric ischemia leading to bowel atresia. These lesions will only be amenable to prenatal diagnosis from 2 to 3 weeks following the acute event.

In dichorionic pregnancies, the co-twin will only be exposed to a persistent cause of death and prematurity.[21,22]

43 Echocardiography in early pregnancy: a new challenge in prenatal diagnosis

C. Comas, J. M. Martínez, A. Galindo, O. Gómez, C. Millán and G. Azumendi

Summary

Within the last decade, two significant events have contributed to the increasing interest in early fetal echocardiography: first, the introduction of high-frequency vaginal ultrasound probes that allow detailed visualization of cardiac structures at an early stage of gestation, making early detection of fetal malformations possible, and second, the close relationship observed between some first-trimester sonographic and Doppler markers and congenital heart defects, which allows early identification of a high-risk group at 11–14 weeks of gestation. In this context, from the early 1990s, many authors have examined the potential role of the transvaginal (TV) approach to obtain earlier diagnosis of fetal cardiac malformations. Further studies have appeared in the literature showing that early TV echocardiography in experienced hands is a fairly sensitive investigative tool. Although some malformations are detected as early as 11 weeks' gestation, the optimal gestational age to perform the early scan is at least 13 weeks' gestation. TV ultrasound is the preferred approach, although most of the authors agree that results can be improved if transabdominal ultrasound is also incorporated. The further application of color Doppler enhances visualization. The sensitivity and specificity of early fetal echocardiography for the detection of heart anomalies are acceptable compared to those obtained by midgestational echocardiography, showing a slight reduction in detection rates and an increase in false-positive and -negative rates. The cardiac anomalies detected at this early stage of pregnancy are mainly defects involving the four-chamber view, indicating that defects solely affecting the outflow tracts are difficult to diagnose in the first trimester of pregnancy. Heart defects diagnosed early in pregnancy tend to be more complex than those detected later with a higher incidence of associated structural malformations, chromosomal abnormalities and spontaneous abortions. The neonate follow-up or postmortem examination in case of termination of pregnancy is essential to assess the actual role of early fetal echocardiography. At present, early fetal echocardiography is a promising technique, which can be of considerable value for patients at high-risk. This technique is, however, currently limited to a few specialized centers.

The aim of this review is to explore the possibilities of examining the fetal heart at this early stage of pregnancy. This article also presents our experience in the first multicenter trial in early fetal echocardiography performed in Spain. In accordance with other studies, this experience stresses the usefulness of early echocardiography when performed by expert operators on the fetus, specifically at risk for cardiac defects. Our review of these 48 additional cases contributes to the expanding literature on the ability of TV ultrasonography to detect fetal heart defects in early pregnancy.

Introduction

Prenatal detection of fetal congenital heart defects (CHD) remains the most problematic issue of prenatal diagnosis.[1] Major CHD are the most common severe congenital malformations with an incidence of about 5 in 1000 live births, whenever complete ascertainment is done and minor lesions are excluded.[1,2] Congenital heart anomalies have a significant effect on the affected children's life with up to 25–35% mortality rate during pregnancy and the postnatal period, and it is during the first year of life that 60% of this mortality occurs. Moreover, major CHD are responsible for nearly 50% of all neonatal and infant deaths due to congenital anomalies, and it is likely to be significantly higher if spontaneous abortions are considered. Although CHD used to appear isolated, they are frequently associated with other defects, chromosomal

anomalies and genetic syndromes. Their incidence is six times greater than chromosomal abnormalities and four times greater than neural tube defects.[1–3]

Most major CHD can be diagnosed prenatally by detailed transabdominal second-trimester echocardiography at 20–22 weeks' gestation.[1,3–6] The identification of pregnancies at high risk for CHD needing referral to specialist centers is of paramount importance in order to reduce the rate of overlooked defects.[6,7] However, the main problem in prenatal diagnosis of CHD is that the majority of cases take place in pregnancies with no identifiable risk factors. Therefore, there is wide agreement that cardiac ultrasound screening should be introduced as an integral part of the routine scan at 20–22 weeks. When applied to the low-risk population, scrutiny of the four-chamber view allows only the detection of 40% of the anomalies, while additional visualization of the outflow tracts and the great arteries increases the rate up to 60–70%.[3–5]

Recently, the finding of an increased nuchal translucency (NT)[8,9] or an altered ductus venosus (DV) blood flow[10,11] at 10–14 weeks' gestation has been associated with a high risk for CHD and their prevalence increases exponentially with the thickness of NT[8] regardless of the fetal karyotype. Since earlier diagnosis of congenital malformations is increasingly demanded, the option of an early fetal echocardiography must be taken into account.[12–14] The use of high-frequency vaginal ultrasound probes along with substantial improvements in magnification and processing of the imaging, together with the introduction of color Doppler, has extensively contributed to the development of the technique, allowing better visualization of cardiac structures earlier in pregnancy.[12,15,16] Although most of the groups perform early fetal echocardiography between 13 and 16 weeks' gestation, we can name it as so when performed before the 18th week of gestation. Despite several studies that stated that fetal heart examination could be incorporated in first- or early second-trimester examinations, its use is currently still limited to a few specialized centers.

Technical issues

Regarding early fetal echocardiography, some institutions use predominantly the transvaginal (TV) approach,[14,17–22] while others prefer the transabdominal one.[23–26] Most of the authors reporting early fetal echocardiography prefer the TV approach because of its increased resolution associated with higher-frequency transducers and also because given that equivalent transducers frequencies, the TV probes provide better-quality images.[27] However, most importantly, authors with background training as pediatric cardiologists are more likely to use the transabdominal approach in contrast with most of the obstetricians, who are well used to the TV route. The superiority of TV sonography is usually well accepted before the 14th week. Between the 15th and the 18th weeks both transabdominal and TV routes seem to offer similar advantages and disadvantages, and beyond the 18th week the transabdominal echocardiography seems to achieve better results.[1,5,16,27,28]

The combination of two-dimensional echocardiography with color Doppler flow imaging proved generally helpful, in particular by visualization of blood flow on both great arteries and of two divided ventricular inflows. The addition of color Doppler flow studies provides substantial improvement in the diagnostic accuracy of early echocardiography, as was also shown by DeVore for transabdominal sonography in the second half of pregnancy.[29]

When performing early fetal echocardiography, we first recommend scanning by the TV route, following the examination by the transabdominal probe when a complete study is not possible. The highest frequency must always be used, whatever the route chosen. Obviously, a high-resolution real-time ultrasound has to be used. For color Doppler evaluation, the energy output levels have to be lower than 50 mW/cm^2 spatial peak-temporal average. Since color Doppler is dissipated over a wide area of interest, thermal effects resulting from Doppler insonation should not be a matter of concern, unlike pulsed Doppler in which the whole energy of the beam is focused at a specific location. Besides, the embryonic development of the heart has been completed by the time the scan is performed.

Ultrasound anatomy of the normal heart

Embryonic heartbeat can be detected as early as the 5th week of gestation, and normal development of its function shows an increasing heart rate from 80–90 beats/min at 5 weeks' gestation to 170–180 beats/min at the end of the 9th to 10th week. As pregnancy progresses, the control of the heart rate matures with increasing vagal dominance, and the baseline rate declines to 145–155 beats/min with the appearance of beat-to-beat variation, most likely resulting from the functional adaptation to the development of the heart and autonomic nervous system maturation, and remains more or less constant during the rest of intrauterine life.[30,31]

The structural development of the heart begins on day 16 and is completed by the 10th week. Early fetal echocardiography has the same goals as the standard one, and we advocate performing it in a segmental approach. The first objective of the examination is to assess the normality of the four-chamber view through a transverse section of the fetal chest: normal situs solitus; normal size and axis of the heart in relation to the chest; both atria equal in size, with the foramen ovale flapping within the left atrium; both ventricles equal in size and contractility; atrial and ventricular septa of normal appearance; tricuspid and

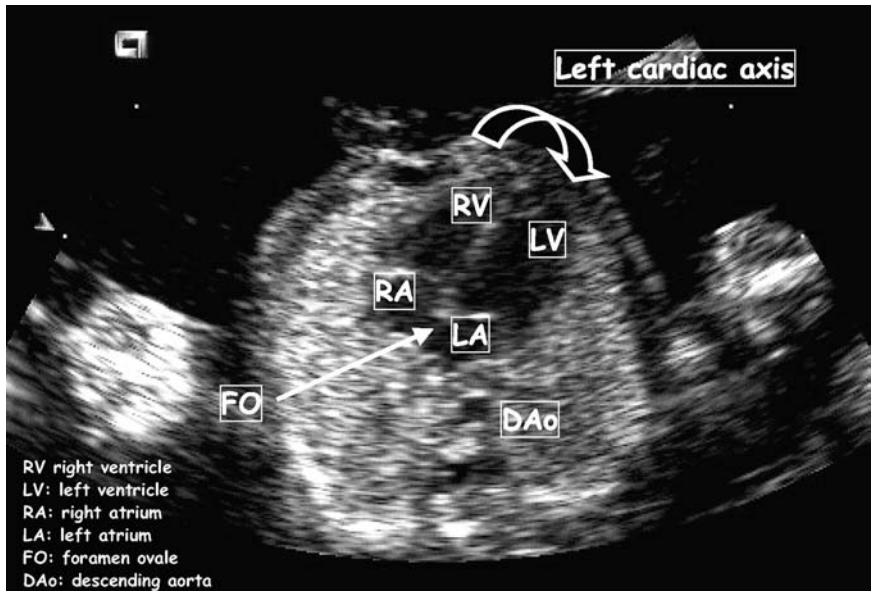

Figure 43.1 Early fetal echocardiography by 2D in a structurally normal heart. The four-chamber view: normal situs solitus; normal size and axis of the heart in relation to the chest; both atria equal in size, with the foramen ovale flapping within the left atrium; both ventricles equal in size and contractility; atrial and ventricular septa of normal appearance; tricuspid and mitral valves normally inserted.

mitral valves normally inserted, opening and closing together. Color and pulsed Doppler are particularly useful to confirm normal inflow to the ventricles and to detect turbulent flow or jets suggesting valve regurgitation. It is useful to assess the four chambers in different views, apical, basal and long axis, with the interventricular septum perpendicular to the ultrasound beam in order to visualize better the integrity of the septum. Then, the origin and double crossing of the great arteries must be correctly identified: the left ventricle outflow tract, with the continuity between the interventricular septum and the anterior wall of the ascending aorta; the right ventricle outflow tract, more superior, anterior, almost perpendicular to the axis of the ascending aorta and connecting to the descending aorta in the three vessels view. Color Doppler is also of help to better visualize the outflow tracts to confirm anterograde flow through the semilunar valves and great arteries, and makes easier the examination of both aortic and ductal arches and their confluence. Pulsed Doppler may be used to assess blood flow through the aortic and pulmonic valves in order to confirm the normal anterograde flow and to detect very high velocities suggesting valve stenosis. Finally, color and pulsed Doppler are also very useful to identify normal systemic and pulmonary venous return. Figures 43.1–43.10 illustrate images obtained at early fetal scan by two-dimensional echocardiography and color Doppler in a structurally normal heart. In our experience, the average duration of the complete fetal cardiac scan is over 15 min. It essentially depends on the gestational age at the examination, and can be even shorter if there is a favorable fetal lie. In our setting, a subsequent transabdominal

echocardiography is scheduled for all our patients at 20–22 weeks' gestation.

Most of the authors agree that the best window of time to perform the early echocardiography is between 13 and 16 weeks of gestation, since a complete cardiac examination is rarely achieved before the 13th week of gestation.[14,17,18,20–22,26] Articles on early fetal echocardiography demonstrate an increase

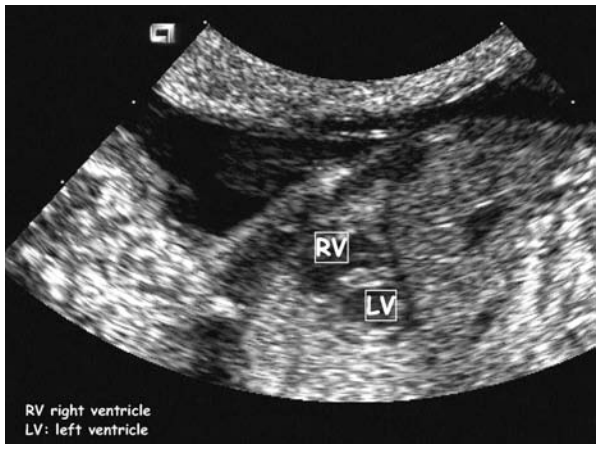

Figure 43.3 Early fetal echocardiography by 2D in a structurally normal heart. The short axis view showing an anterior right ventricle and a posterior left ventricle.

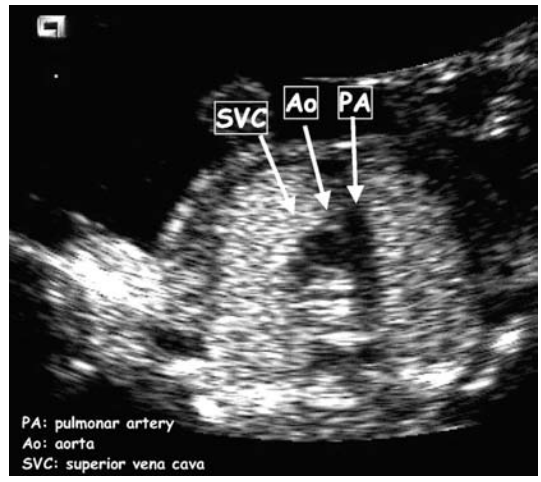

Figure 43.4 Early fetal echocardiography by 2D in a structurally normal heart. The three-vessel view: cross sections of the pulmonary artery, ascending aorta and superior vena cava in a transverse view of upper mediastinum. In normal conditions, the structures in the three-vessel view are in descending order of size from the left to the right.

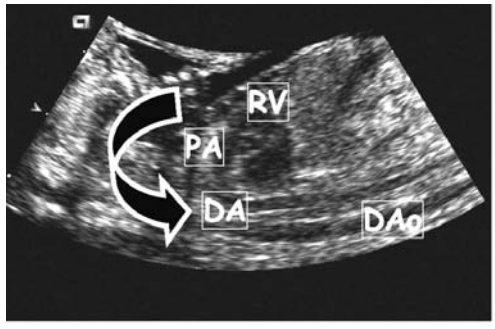

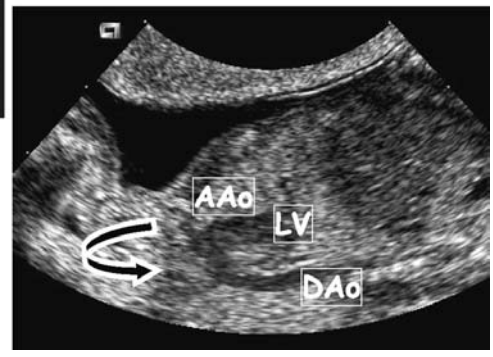

RV: righ ventricle
LV: left ventricle
PA: pulmonar artery

in visualization rates of the four-chamber view and the outflow tracts in the last decade, with visualization rates greater than 90% at 13 weeks' gestation.[28] To maximize the reduction of uninterpretable examinations, early fetal echocardiography should be preferably performed at 13 completed weeks' gestation. Using current technology, the four-chamber view and the outflow tracts are often demonstrated by two-dimensional echocardiography only, but color Doppler imaging enhances and makes the identification of the structures faster, increasing the success rate of the examination, and allows even earlier identification of the structures.

Diagnosis of CHD

The first diagnosis of CHD by early echocardiography was reported by Gembruch *et al.*[32] in 1990. A complete atrioventricular canal defect, with complete heart block and atrioventricular valve regurgitation, was diagnosed at 11 weeks + 4 days' gestation using a 5-MHz TV probe. The same year, Bronshtein *et al.*[33] reported the diagnosis of a ventricular septal defect (VSD) with overriding aorta and a further case of an isolated VSD with pericardial effusion, both cases at 14 weeks' gestation. Since then, an increasing number of case reports and series on the early diagnosis of CHD have been reported,

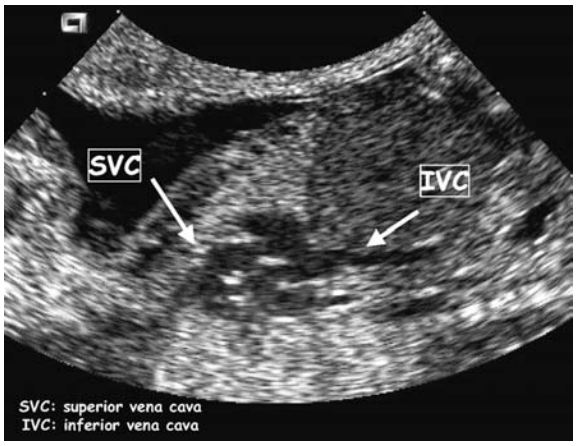

Figure 43.6 Early fetal echocardiography by 2D in a structurally normal heart. Systemic venous return to the right atrium through the superior and inferior venae cavae.

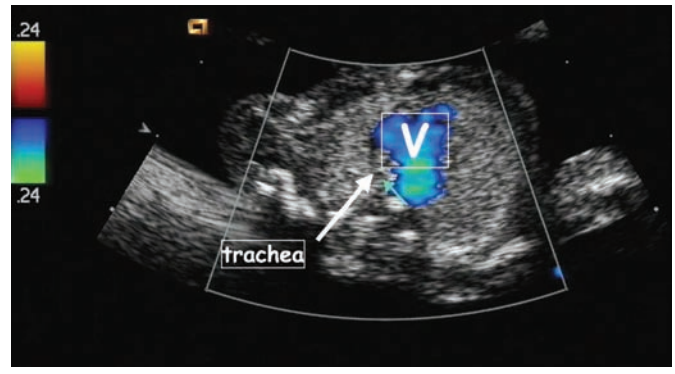

Figure 43.9 Early fetal echocardiography by 2D and color Doppler in a structurally normal heart. Color Doppler is particularly useful to demonstrate the normal V confluence of the ductal and aortic arches (V sign). Note that normally the trachea is located behind the aortic arch.

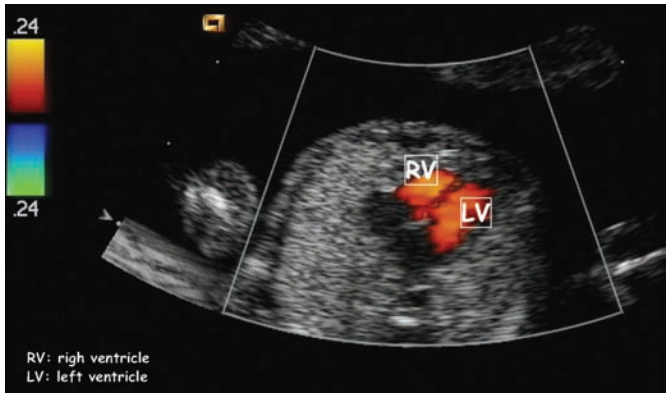

Figure 43.7 Early fetal echocardiography by 2D and color Doppler in a structurally normal heart. Color Doppler in the four-chamber view is particularly useful to confirm normal inflow to the ventricles and to detect turbulent flow or jets suggesting valve regurgitation.

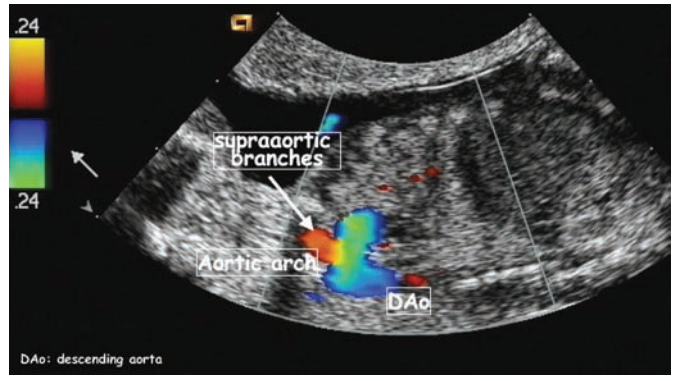

Figure 43.10 Early fetal echocardiography by 2D and color Doppler in a structurally normal heart. Color Doppler is particularly useful to demonstrate the aortic arch.

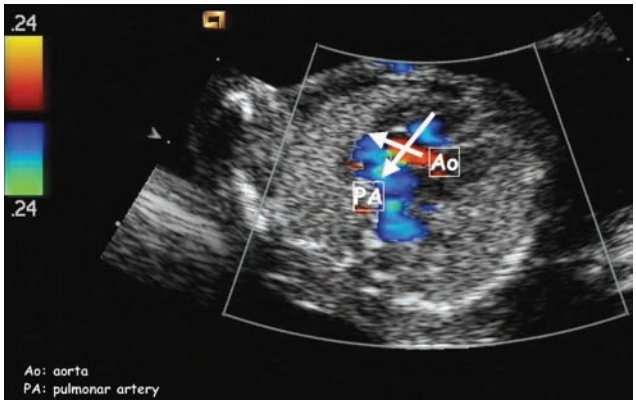

Figure 43.8 Early fetal echocardiography by 2D and color Doppler in a structurally normal heart. Color Doppler is particularly useful to demonstrate the crossing of the great arteries.

in both high-risk and low-risk populations. Tables 43.1 and 43.2 summarize some of the largest and the most significant studies on the detection of CHD using early fetal echocardiography in high-risk and low-risk pregnancies.[14,17–22,24–26,34–39] Obviously, studies in unselected population report less encouraging results with lower visualization rates and detection rates. The largest series so far is the one published by Bronshtein *et al.*[20] They report the diagnosis of 173 cases of CHD over 36,323 fetuses evaluated by TV ultrasound at 11–17 weeks' gestation over a 14-year period of time, with 99% of the scans performed at 14–16 weeks' gestation and 86% of them in low-risk population. Recently, two institutions went further and reported their experience performing the echocardiography as early as between 10 and 13 weeks' gestation.[22,26]

Bronshtein[20]	11–17	99	Low	30148	127	97%	99%

GA, range of gestational age at scan (weeks); Success, visualization success rate for the extended cardiac examination (four chambers outflow tracts); Normal, total number of pregnancies screened; Cases, total number of cardiac defects (pre- and postnatally); 11–16 weeks, percentage of cardiac defects identified at early scan; 20–22 weeks, percentage of cardiac defects identified at midtrimester scan

The most frequent fetal heart anomalies diagnosed at early echocardiography are summarized in Table 43.3 (true-positive cases).[14,18–21,24–26,34,35,37,39] Note that only the main anomaly for each fetus is presented in the table, even though some fetuses had several cardiac anomalies. It should be noted that defects such as small, isolated VSD or valvular stenosis are not reported in these studies. Table 43.4 summarizes the published cases of cardiac anomaly not detected in early pregnancy (false-negative cases).[14,19–21,24–26,34–37,39]

The results of these studies support the use of early fetal echocardiography to detect the majority of major CHD in both low-risk and high-risk populations during the first and the early second trimesters of pregnancy. The cardiac anomalies detected at this early stage of pregnancy are mainly the defects involving the four-chamber view, such as large VSDs, atrioventricular septal defects (AVSDs) and malformations resulting in asymmetry of the ventricles, indicating that defects solely affecting the outflow tracts are

difficult to diagnose in the first trimester of pregnancy. Heart defects diagnosed early in pregnancy tend to be more complex than those detected later, with a higher incidence of associated structural malformations, chromosomal abnormalities and spontaneous abortions. It is widely accepted that the spectrum of CHD diagnosed during prenatal life is different from that observed in postnatal series, with a higher incidence of associated extracardiac lesions and a significant relationship with chromosomal abnormalities in comparison with postnatal life.[3–5,17] Furthermore, when the cardiac defects are detected during early pregnancy, they are even more complex, probably corresponding to the most severe spectrum of the disease,[21,25,26] and cause more severe hemodynamic compromise in the developing fetus. A common finding is the presence of a hygroma or hydrops associated with CHD, whereas this is not so when the diagnosis is done later in pregnancy.[1,5,21] As a result, many of these fetuses are not going to survive long into the second trimester, but this does not argue against early diagnosis. Indeed, when the intrauterine demise of the fetus occurs days or weeks before the delivery, the pathological examination is certainly more difficult to perform. All these considerations should be taken into account when counseling the parents about complex CHD.

This review presents our experience in the first multicenter trial in early fetal echocardiography performed in Spain.[21] In accordance with other studies, this experience stresses the usefulness of early echocardiography when performed by expert operators on the fetus specifically at risk of cardiac defects. Our review of these additional 48 cases contributes to the expanding literature on the ability of TV ultrasonography to detect fetal heart defects in early pregnancy.

Our experience in early prenatal diagnosis of congenital heart anomalies

Methods

A multicenter study was made of 334 fetuses from 330 selected high-risk pregnant women, including four twin pregnancies. The women were attending the prenatal diagnosis units of Institut Universitari Dexeus in Barcelona (Group I), Hospital 12 de Octubre in Madrid (Group II) or Institut Clínic d' Obstetrícia, Ginecologia i Neonatologia del Hospital Clínic in Barcelona (Group III) for ultrasound examination because of an increased *a priori* risk of heart anomalies. These are referral centers for prenatal diagnosis of CHD. Fetal echocardiography was performed combining TV and transabdominal probes between 12 and 17 weeks' gestation. When possible, we selected the 14th week of gestation as the optimal time for TV scan because the visualization of heart structures is better at this time. This is a prospective design study, performed from September 1999 to May 2001, where the overall group was reviewed focusing on the feasibility of diagnosing fetal CHD by early echocardiography. Informed consent was obtained from each patient and the study was approved by our ethics committees.

Epidemiological data are summarized in Table 43.5, for the overall group and according to the reference unit. Maternal age ranged from 17 to 46 years (mean 33 years with 36% of women over 34 years). The median gestational age at scan was 14.2 weeks (range 12–17 weeks). The distribution of gestational ages was as follows: 23 cases at 12 weeks, 76 cases at 13 weeks, 101 cases at 14 weeks, 72 cases at 15 weeks, 54 cases at 16 weeks and 8 cases at 17 weeks.

Fetal echocardiography was performed in a population with an increased *a priori* risk of CHD. Criteria for inclusion were a family history of CHD ($n=37$), ultrasound markers for chromosomal abnormalities ($n=186$), such as increased NT (>99th centile) or abnormal DV flow (pulsatility index for veins in the DV 95th centile), suspected cardiac or extracardiac anomalies at the early second-trimester scan ($n=43$), maternal pregestational diabetes ($n=33$), pregnancy affected by a chromosomal abnormality ($n=8$), exposition to teratogens ($n=3$), genetic sonography ($n=22$) and a screening test ($n=2$). The last two cases refer to two twin pregnancies in which the main indication for the echocardiography was an ultrasound marker for chromosomal abnormality in one fetus, but the echocardiographic examination was performed to both the fetuses for practical reasons. For NT and DV assessment, measurements were made between 10 and 16 weeks' gestation. NT was systematically assessed in all cases, while DV blood flow was only measured in Groups I and II. We have used our own published nomograms to define increased NT or abnormal DV.[40] Genetic sonography was offered to a high-risk population refusing invasive karyotyping test.

For each fetus, visualization of the four-chamber view (with both atria, atrioventricular valves and ventricles), the origin and double crossing of the great arteries, aortic and ductal arches and systemic venous return, was attempted in a segmental approach. Two-dimensional mode and color/pulsed Doppler flow imaging were used in all cases, while M-mode was occasionally performed. The operators kept a record of optimal visualization (complete visualization of heart structures) or partial visualization (incomplete visualization of heart structures). In cases of partial visualization, only when an anomaly was suspected was a second scan arranged 2 weeks later. Ultrasound examinations were performed using a multifrequency real-time vaginal probe (5.0–7.5 MHz) and convex abdominal probe (3.0–6.5 MHz) on a Toshiba ultrasound system (Toshiba SSH-140A, Toshiba Co., Tokyo, Japan), Acuson 128 XP or Aspen (Acuson Inc., Mountain View, CA) and General Electric Logic 400 or Logic 500 (GE Medical Systems, Milwaukee, WI). The ultrasound examination was mainly performed transvaginally, completed nearly always by the transabdominal route. For color Doppler evaluation, the energy output levels were lower than 50 mW/cm^2 spatial peak-temporal average. The duration of complete heart examination was less than 30 min. All the examinations were made by three experienced operators (CC, JMM and AG).

When indicated, fetal karyotyping by chorionic villus sampling or amniocentesis was offered. According to the policy of our institutions, invasive testing was recommended as a result of advanced maternal age (>35 years), family history of aneuploidy, biochemical screening for Down's syndrome higher than 1/270 or ultrasound anomalies (including malformations or NT >95th centile). Fluorescence *in situ* hybridization (FISH) studies to test for 22q11 deletion were also offered when a heart malformation affecting the great arteries was suspected. When possible, in those who continue their pregnancies, a follow-up detailed ultrasound scan was carried out at 20–22 weeks' gestation. When karyotyping was not performed, chromosomal abnormalities were excluded at neonatal examination.

Reliability was assessed by conventional transabdominal echocardiography at 20–22 weeks, by postnatal follow-up in the first 3 months of life and/or by autopsy in cases of termination of pregnancy (TOP). Minor cardiac anomalies described in the literature as difficult or impossible to diagnose early (atrial septal defects or patent ductus arteriosus) were not considered when calculating the validity of the early echocardiography.

Results

The rate of optimal visualization of the fetal heart was 94.6% (316/334). In 48 out of 334 (14.4%) fetuses the final diagnosis was abnormal, including 48 cases of structural heart abnormalities (Table 43.6). In 38 out of 48 cases with heart defects the diagnosis was suspected at early echocardiography. These true-positive cases were as follows: 13 cases of abnormal outflow tracts, 8 cases of atrioventricular defect, 4 cases of hypoplastic left heart (HLH), 5 cases of tricuspid atresia or dyspasia, 3 cases of isolated VSD, 3 cases of ectopia cordis, 1 case of aortic coartation and 1 severe complex heart defect. True positive diagnoses are summarized in Table 43.7. Figures 43.11–43.15 illustrate some examples of detected CHD early in pregnancy.

There were 10 false-negative cases (2 cases of HLH, 3 cases of atrioventricular defect, four cases of VSD and 1 case of tetralogy of Fallot) (Table 43.8). There were no false-positive diagnoses. When considering the validity of the early echocardiography, we have excluded one case of isolated pericardial effusion, two cases of significant tricuspid regurgitation within a structurally normal heart, a child affected by an ostium secundum atrial septal defect, a structural normal heart in a Down's syndrome affected by a patent ductus arteriosus who had neonatal surgery.

Karyotyping was performed in 290 cases of our series (86.8%), including all cases with cardiac abnormalities. In the whole series, 51 cases had an abnormal karyotype. These chromosomal abnormalities included trisomy 21 ($n = 28$), 45XO ($n = 7$), trisomy 18 ($n = 6$), trisomy 13 ($n = 2$), 22q11 microdeletion ($n = 1$), triploidy ($n = 1$), trisomy 7 ($n = 1$), partial trisomy 15 ($n = 1$), rearrangement ($n = 1$) and others ($n = 3$). Among the heart defects, 27 cases (56.3%) had an abnormal karyotype (13 trisomy 21, 5 trisomy 18, 3 Turner' syndrome, 2 trisomy 13, 1 trisomy 7, 1 partial trisomy 15, 1 rearrangement and 1 with a 22q11 microdeletion detected by FISH), and 31 cases (64.6%) showed additional sonographic extracardiac anomalies, including mainly cystic hygroma, congenital diaphragmatic hernia (CDH),

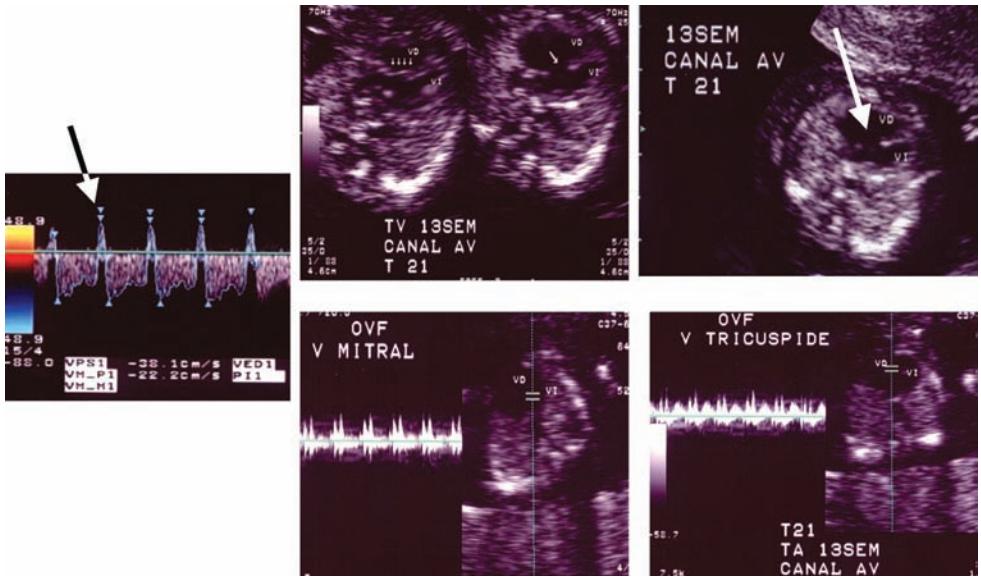

Figure 43.11 AVSD detected at 13 weeks' gestation in a fetus affected by cystic hygroma and trisomy 21. Note the abnormal reversed A wave in the DV.

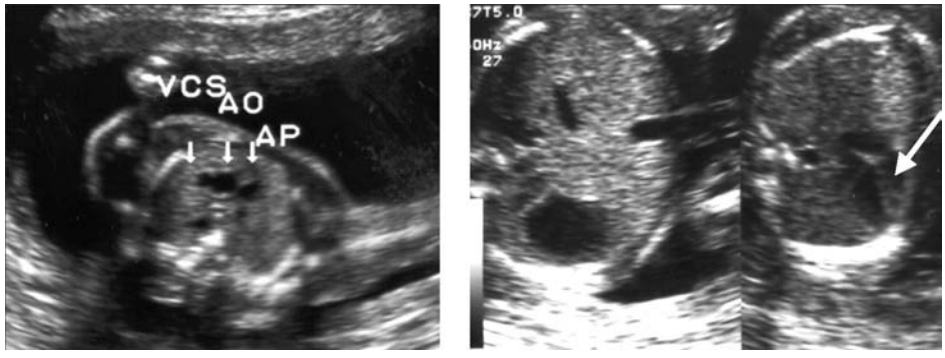

Figure 43.12 Tetralogy of Fallot detected at 16 weeks' gestation in a fetus affected by cystic hygroma and normal karyotype. Note the left cardiac deviation and the dominance of the aorta compared with the small pulmonary artery at the three-vessel view in the upper mediastinum.

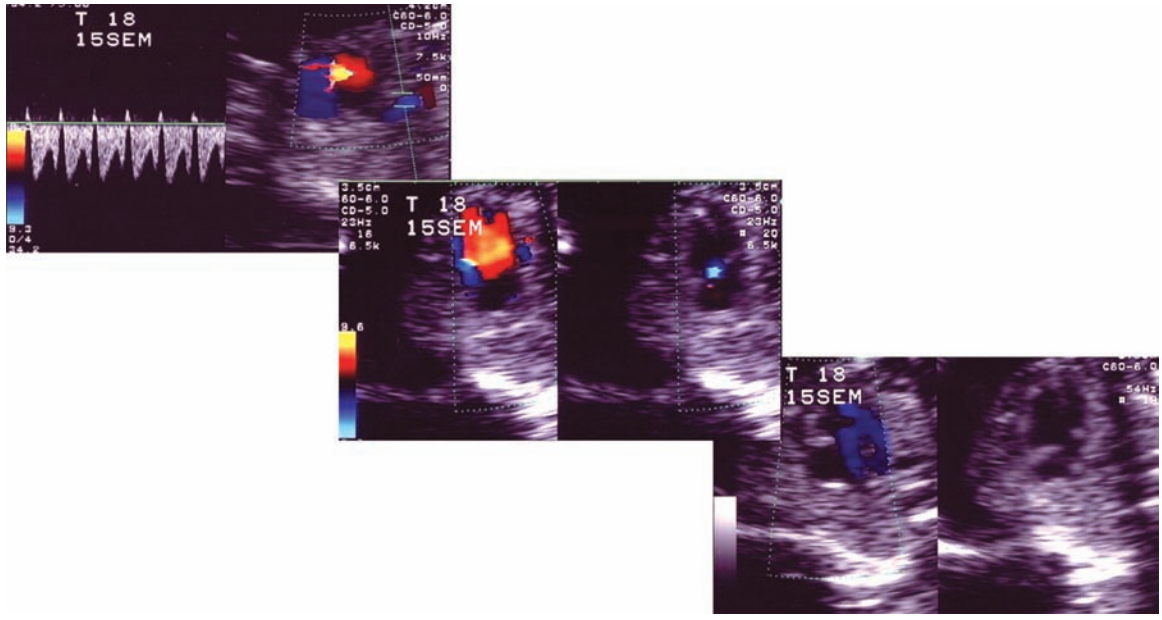

Figure 43.13 AVSD with unbalanced right ventricle dominance and double-outlet right ventricle at 15 weeks' gestation. Note the abnormal reversed A wave in the DV.

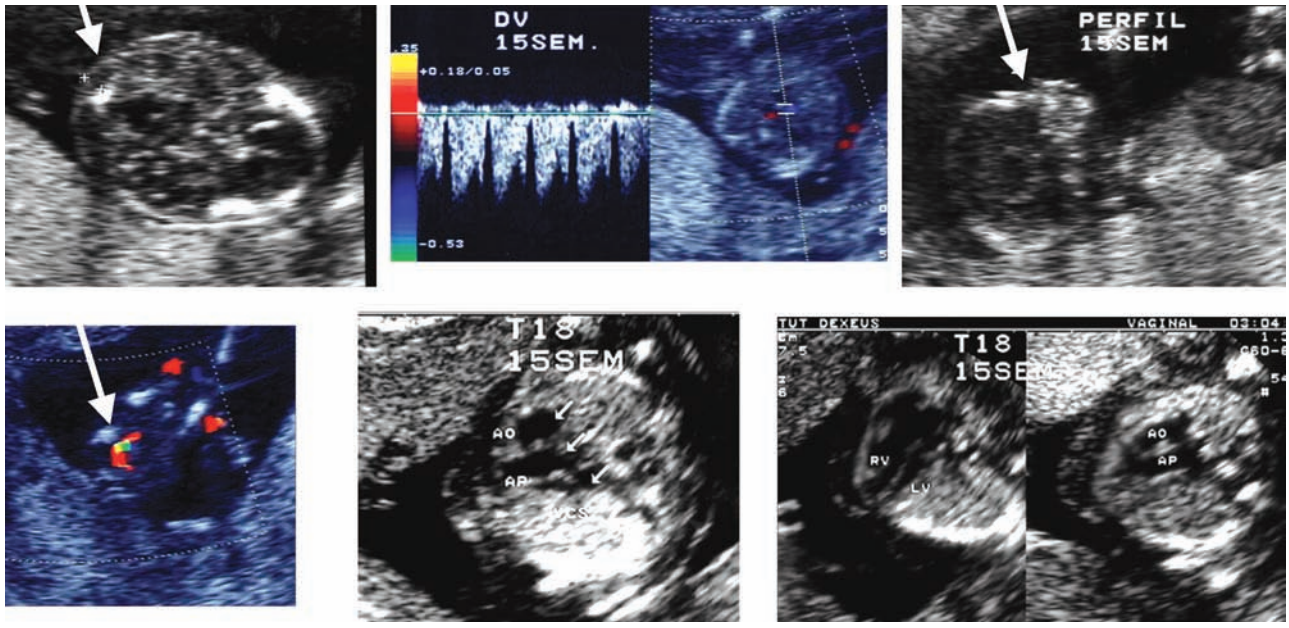

Figure 43.14 HLH and double-outlet right ventricle at 15 weeks' gestation in a trisomy 18. Note the identification of multiples markers of chromosomal abnormality (increased NT, abnormal DV flow, absent nasal bone, single umbilical artery).

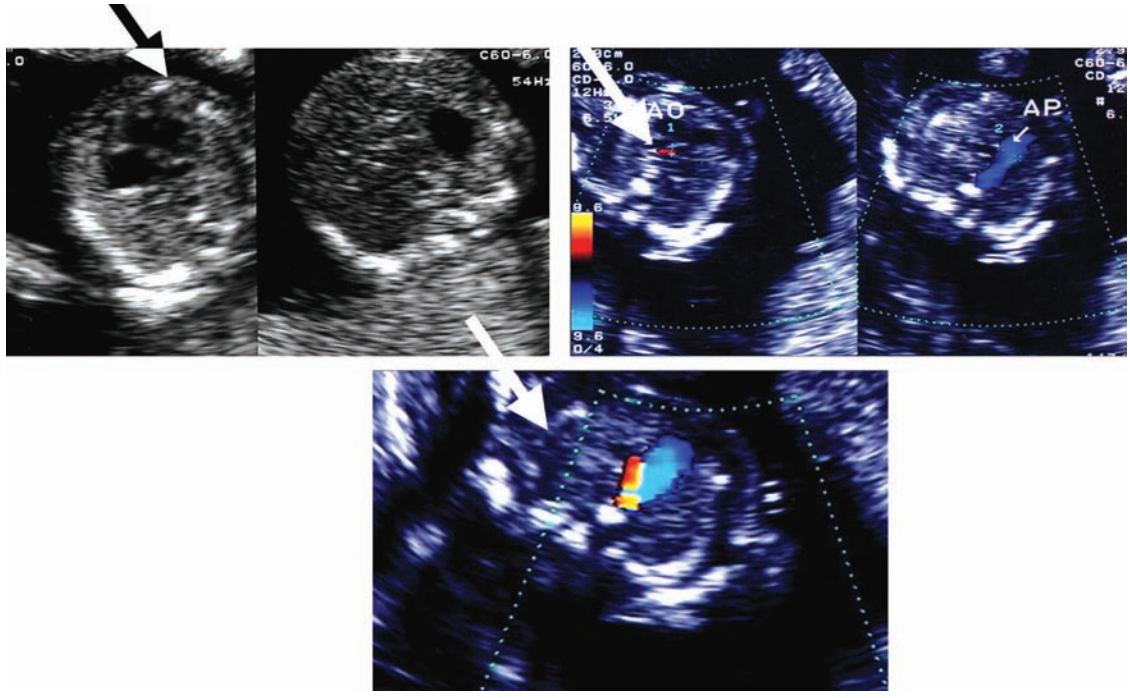

Figure 43.15 HLH and aortic stenosis at 17 weeks' gestation in a Turner syndrome. Note the left cardiac axis deviation, the opposite color flow in the V sign at the upper mediastinum level and the severe reduction of the aortic outflow tract compared to the main pulmonary artery.

abnormal situs visceralis, single umbilical artery, bilateral dysplastic kidneys, hydrops, limb–body wall complex, omphalocele, exencephaly, holoprosencephaly, pyelectasis, choroid plexus cysts, hemivertebra and pleural effusion.

In the CHD group, increased NT at 10–16 weeks' gestation was noted in 21 fetuses (43.8%), while abnormal DV blood flow was found in 18 out of 37 fetuses with DV assessment (48.6%).

The outcome of fetuses with a CHD was poor. In 37 cases a TOP was performed at the parents' request before 20 weeks' gestation and in one case a selective feticide was offered in a twin pregnancy discordant for a CHD. The outcome of the surviving fetuses was

Table 43.6 Our experience: CHD (from Comas *et al.*[21])

	Overall (Groups I + II + III)
Prevalence	48/334 (14.4%)
True positive	38/48 (79.2%)
False negative	10
False positive	0
Chromosomal abnormalities	27/48 (56.3%)
Extracardiac abnormalities	31/48 (64.6%)
Increased NT	21/48 (43.8%)
Abnormal DV	18/37 (48.6%)
Outcome	37 TOP
	One selective feticide
	Two postnatal death
	Eight surviving
Follow-up	33/48 (68.8%)
Autopsy available	25/41 (61.0%)

NT, nuchal translucency; DV, ductus venosus; TOP, termination of pregnancy

poor, with two cases of neonatal death (one VSD and one HLH) and eight surviving children [one VSD, three atrioventricular defects, one pulmonary stenosis, one VSD diagnosed of Noonan's syndrome, one case of tetralogy of Fallot and one single ventricle with transposition of great arteries (but the child died 3 months after palliative surgery)]. Pathological examination was performed in 25 cases. In 16 cases, the autopsy was not available, because of the selective feticide in a twin pregnancy or because the termination was performed in another hospital without fetal necropsy, or due to the unavailability of an adequate material for pathological exam (fragmentation) or because the parents declined the examination.

In our series of early echocardiography, a complete follow-up was possible in 281 cases (84.1%), 61.1% in Group I, 83.1% in Group II and 97.8% in Group III. When a heart defect was detected, a complete follow-up was possible in 33 out of 48 cases (68.8%).

Fetal heart rate

The diagnosis of fetal arrhythmia early in pregnancy may give rise to the suspicion of a fetal chromosomal abnormality,[34–36] an increased risk of a later miscarriage[35,37,38,41] or the presence of CHD.[42] The factors that control fetal heart rate in the first trimester are

CHD, congenital heart defect; GA[1], gestational age of the echocardiographic examination in early pregnancy (weeks); GA[2], gestational age at diagnosis (weeks); TOP, termination of pregnancy; HLH, hypoplastic left heart; TA-echo, transabdominal echocardiography; ASD, atrial septal defect; AVSD, atrioventricular septal defect; VSD, ventricular septal defect; NTD, neural tube defects

*Twin pregnancy

uncertain, so the underlying cause of the abnormal pattern in chromosomally abnormal fetuses remains obscure. A delay in maturation of sympathetic and parasympathetic systems as well as an abnormally developed and responsive myocardium have been proposed.[30,43] An alternative explanation could be that fetal arrhythmias are a reflection of an underlying structural heart disease, and are a common feature in trisomic fetuses.[35,42,44,45] Baschat *et al.*[46] reported four cases of severe CHD associated with bradycardia (likely to be atrioventricular block) during early echocardiography at 11–14 weeks' gestation. All cases had either increased NT or generalized edema and complex CHD. Most authors find a high correlation between abnormal heart rate and increased NT in chromosomally abnormal fetuses, thus supporting the hypothesis that cardiac defects may be involved in the physiologic basis of NT.[35,36,47]

NT and DV

NT measurement at 10–14 weeks' gestation is a widely accepted method to screen for chromosomal abnormalities. Recent studies have suggested the potential role of an increased NT thickness [8,9,11,48–51] or an abnormal DV flow pattern [10,11,52,53] at early pregnancy as a screening tool for CHD, in addition to its role in screening for chromosomal defects. The risk of CHD after the finding of an increased NT seems to vary between 4% and 9%.[24,54] Recently, Galindo *et al.* have examined the prevalence, distribution and spectrum of cardiac defects in 353 chromosomally normal fetuses with increased NT, with a complete follow-up in 97% of the cases.[55] This multicenter Spanish study presents an overall prevalence of heart defects of 9.1%, increasing significantly from 5.3% in those with NT >95th centile to 24% when thickness >6 mm. Interestingly, most of the cardiac defects can be prenatally detected. A wide range of cardiac anomalies were observed in this series, with the most common being AVSDs and tricuspid atresia. Hyett *et al.* reported that about 55% of the major CHD were associated with a fetal NT thickness above 95th centile at 10–14 weeks of gestation.[8] However, others have failed to demonstrate such a strong association,[49,50,53,54,56–58] suggesting that the routine assessment of the four chambers and great vessels at

mid-second trimester remains the most important screening tool for the detection of major CHD.[56,59] Theoretically, both types of screening used in combination should improve the overall sensitivity of prenatal diagnosis of the major cardiac defects.

The physiopathogenic mechanism of this relationship is not easy to explain.[11,44,45,53,59,60–63] Pathological examination of fetuses with increased NT thickness at 10–14 weeks have demonstrated a high prevalence of cardiac defects and abnormalities of the great arteries and of subtle defects, such as widening of the aortic valve and ascending aorta, narrowing of the aortic isthmus and persistence of the left superior vena cava. Another proposed mechanism to explain the increased NT is an early cardiac function impairment suggested by an abnormal DV flow pattern. However, Matias *et al.*[10] reported that most of the chromosomally normal fetuses with increased NT but normal DV flow did not have CHD. This finding might contradict a cardiac involvement in the pathogenesis of the increased NT in most of the fetuses, and suggest that only fetuses with abnormal DV blood flow are those at high risk of CHD. On the other hand, in cases with CHD and both enlarged NT and abnormal DV, because the type of cardiac defects cannot always explain the hemodynamic changes found in these fetuses, some other mechanisms seem to be involved.[53]

Based on ultrasonographic and postmortem morphological studies, the findings in increased NT fetuses can be classified into three categories.[64] First, an association between increased NT and cardiac anomalies, combined with an abnormal DV flow pattern, has been described in some cases, leading to the theory that cardiac failure causes NT enlargement. Second, various types of abnormalities have been found in the extracellular matrix of the nuchal skin of fetuses with increased NT. Third, abnormal lymphatic development has been demonstrated in fetuses with increased NT. Many hypotheses on NT enlargement are based on associations and speculations. Therefore, within this context, it is not clear whether all these cardiovascular anomalies are the cause of the increased NT or both events are the result of another pathophysiologic mechanism.

Chromosomal abnormalities

The detection of CHD may be the first clue to the diagnosis of a chromosomal abnormality or a genetic syndrome. The incidence of chromosomal defects in CHD diagnosed prenatally may be as high as 30–40%, and 15% when the CHD is presented isolated. These figures increase up to 40–60% when the CDH is diagnosed during the first trimester.[20-22,26] This is much higher than the incidence in live borns. Also, the high rate of spontaneous abortion loss in early pregnancy suggests a higher rate of chromosomal abnormalities in first-trimester fetuses with CHD. Therefore, whenever CHD are diagnosed, karyotype evaluation is mandatory, including FISH test to rule out 22q11 deletion.[65–68]

Recently, the early finding of isolated tricuspid regurgitation or disproportion of the cardiac chambers and/or outflow tracts, has been regarded to be highly associated with fetal chromosomal abnormalities, even in the absence of structural heart disease, as it had been previously described during the second trimester.[26,69,70] The chromosome defect most frequently found to be associated with tricuspid regurgitation was trisomy 21, but all types of karyotype anomalies were seen in association.[69] In view of these results, the authors propose to assess the four-chambers view and the outflow tracts for disproportion and to use color Doppler to rule out tricuspid regurgitation in each first- or early second-trimester ultrasound to screen for chromosomal anomalies.[26,27] Since these unexpectedly good results were obtained in particularly high-risk fetuses, they remain to be confirmed in an unselected population.

Advantages and limitations

The first benefit of performing early fetal echocardiography would be an early reassurance of normality in order to relieve anxiety and reduce emotional trauma to the parents at high risk of CHD. Early prenatal diagnosis of CHD will allow us to optimize the genetic counseling to the parents by permitting further testing, such as fetal karyotyping, and in those cases with severe defects it may provide the parents with the option of an earlier and safer TOP.[13,14,17] In selected cases, there is the possibility of pharmacologic therapy. Furthermore, the correct timing and place for delivery may be planned and arranged well in advance.

However, there are certain disadvantages of the early scanning, which reduce its diagnostic accuracy compared with the conventional examination at 20–22 weeks' gestation.[1,5,13,14,17] The TV technique requires a substantial amount of operator experience, yet it cannot be learned from the second-trimester examination as the early transabdominal scan. Unfavorable fetal position or limited angles of insonation due to the less mobile capacity of the TV probe may not be overcome. Also, spatial orientation can be challenging by the TV scan. In such cases, we recommend a transabdominal scan that will help us to quickly assess the situs and obtain a good spatial orientation. The small size of the fetal heart is an important limiting factor to obtain an optimal sonographic visualization, and also to obtain a successful pathological examination, particularly before the 13th week of gestation. At 13–14 weeks of gestation the transverse diameter of the heart at the four-chambers view ranges between 5 and 8 mm, and the great artery diameter at the level of the semilunar valves ranges between 0.8 and 1.8 mm[5]. Moreover, this exploration is more time-consuming and requires a high level of training of the examiner. Finally, the

biggest disadvantage of first-trimester echocardiography is the later manifestation of structural and functional changes in some CHD. Some cardiac lesions are progressive in nature, such as mild pulmonary and aortic stenosis or coarctation and even HLH syndrome. Some obstructive lesions, as a result of a reduced blood flow, may increase the severity of the lesions, resulting in restricted growth in the chambers or arteries. This may be the biggest disadvantage of performing the early scan. Progression usually is toward a more severe form of lesion that may be sometimes discernible only in the second or even in the third trimester, although in some rare cases a regression to a less severe form may be observed. In this sense, the false-negative cases published in the literature are particularly instructive demonstrating these limitations (Table 43.4). Another disadvantage of early fetal echocardiography is the possible detection of defects that could resolve spontaneously in later pregnancy, such as muscular ventricular septal defects, resulting in unnecessary anxiety in the parents.

Therefore, a normal early examination does not preclude a subsequent abnormal heart development at the second-trimester ultrasound, or even in the third trimester or the postnatal period. After a normal early fetal echocardiography, a conventional transabdominal echocardiography at 20–22 weeks of gestation is strongly recommended.

Pathological confirmation

Pathological confirmation in the case of an early TOP or perinatal death is particularly important in those areas where ultrasound diagnosis is the most challenging. Only a complete diagnosis will make an individual genetic counseling possible and will validate the accuracy of early fetal echocardiography as a diagnostic technique. Therefore, we recommend that a precise pathological report has to be compulsory for an adequate assessment of the reliability of early fetal echocardiography. This is still a major drawback in most of the studies.[1,5,21,26]

TOP is an option only before 22 weeks of gestation in our country. Whenever a termination takes place, it is of vital importance to obtain permission for autopsy in order to confirm the diagnosis and to search for any other associated malformations. Ideally, this should be performed by a pathologist who is familiar with the small size of the specimen and with special examination techniques, such as dissection microscopy.[5,21,22,45] Current methods of terminating early pregnancies other than using prostaglandins are less recommended because they do not usually allow the retrieval of suitable specimens for appropriate examination to correlate ultrasound and pathological findings.[45] This method allows a more gentle extraction of the embryo or fetus so that a pathological examination for verification of the prenatally diagnosed malformation can be performed. A pathological investigation after TOP following the diagnosis of a CHD should be always recommended, preferably in referral laboratories, being of paramount importance to validate early echocardiography. In particular, semilunar valve and aortic arch defects are usually underdiagnosed. We are aware of some cases in which Doppler findings, such as turbulent flow and very high velocities, are more reliable to diagnose valve stenosis than pathological examination, even during the second trimester. Indeed, this is a problem and a major challenge not only for ultrasonographers but also for pathologists.

Indications of early fetal echocardiography

Since most CHD are detected in low-risk pregnancies, and knowing the high prevalence of heart defects in a non-selected population (incidence of CHD in low-risk population 1/238),[20] some authors suggest that an early detailed cardiac examination should be performed in all pregnant women.[17,20] Indeed, very few cardiac defects have been identified in the pregnancies in which a family history was the main indication for the early fetal echocardiography, which is consistent with the recurrence rate of 2–3% for siblings. The main value of the early scan in such family-risk cases lies in the reassurance that it gives to the parents. As we have previously stated, in most of the studies the early echocardiography is somewhat less reliable and may result in higher false-negative and false-positive results in comparison with the 20–22 weeks' transabdominal echocardiography. Besides, early echocardiography is the most time-consuming and requires a high level of expertise of the examiner. Therefore, it is difficult to offer this scan as a screening test to the general population. In this context, the identification of a high-risk collective is of paramount importance.

Currently, the importance of the aforementioned limitations of early fetal cardiac examination justifies restriction of its use to fetuses at high risk of having cardiac anomalies.[5,10,14,18,21,22,26] The indications proposed for early fetal echocardiography are:

- Increased NT (greater than 95th or 99th centile) is the main indication of referral in all recently reported studies.
- Abnormal DV blood flow, regardless of the measurement of the NT.
- Fetuses affected by other structural malformations: hygroma, hydrops, omphalocele, situs inversus and arrhythmia.
- Suspected cardiac anomalies at screening ultrasound.
- Pregestational diabetes of the mother.
- High-risk family, with a previously affected child, a first-degree relative affected by a congenital heart

disease or a genetic disease in which CHD are common.
- Women at high risk of chromosomal abnormality declining invasive test for karyotyping.
- Pregnancies affected by a chromosomal abnormality.

Currently, as long as the sensitivity, specificity and predictive value of early echocardiography is still unclear, this examination should be generally reserved for patients at high risk of CHD. However, only the accumulation of results from carefully collaborative studies such as the present series will clearly define the role of early TV echocardiography.

Conclusions

Fetal echocardiography performed by expert operators is reliable for an early reassurance of normal cardiac anatomy

(1) Transvaginal sonography enables good visualization of fetal heart earlier in gestation. The four-chamber view and the extended examination to the great vessels can be imaged in almost 100% at 13–14 weeks of gestation. Less than 5% of patients will need a repeated scan because of inadequate visualization.
(2) The combination of TV and transabdominal routes and the application of color Doppler enhances visualization.
(3) Most CHD are detected in a low-risk population. As we cannot perform a targeted fetal echocardiography as a screening test, we need to improve the identification of high-risk group pregnancies. Increased NT at 10–14 weeks' scan and, maybe, DV blood flow assessment seem to be the newest and the most promising risk factors for fetal CHD, and may be particularly useful during the first trimester.
(4) Currently, early fetal echocardiography should be offered to high-risk pregnancies. Some authors advocate routine early-extended cardiac examination in low-risk pregnancies. At present, as long as the sensitivity, specificity and predictive value of early echocardiography are still unclear, this examination should be generally reserved for patients at high risk of CHD.
(5) Whenever a normal heart is diagnosed in the early scan, it has to be supplemented with the conventional transabdominal examination at 20–22 weeks' gestation.

Fetal echocardiography performed by expert operators is reliable to diagnose most major structural heart defects in the first and early second trimesters of pregnancy

(1) Cardiac defects diagnosed early in pregnancy tend to be more complex than those detected later on and cause more severe hemodynamic compromise in the developing fetus.
(2) Many CHD can be detected at the beginning of the second trimester.
(3) The incidence of associated structural malformations, chromosomal abnormalities and spontaneous abortions is significantly high.
(4) A complete workup including pathological and karyotype evaluation should be warranted in order to provide the parents with proper genetic counseling, which is extremely difficult to obtain if spontaneous loss of pregnancy occurs.
(5) The small size of specimens at this time of gestation renders pathological examination difficult and requires high expertise and careful inspection, irrespective of the technique used for termination.
(6) Clinical follow-up in the neonate and post-mortem examination if TOP is undertaken are essential to assess the actual role of early fetal echocardiography.

44 Prenatal diagnosis of fetal cytomegalovirus infection

Y. Ville, O. Picone, G. Makridemas and M. Leruez-Ville

Congenital cytomegalovirus (CMV) infection is likely to have become the most prevalent infection-related cause of congenital neurological handicap as rubella vaccination has become universal in developed countries.[1] However, prenatal diagnosis and screening policies have been rather incoherent for the last 25 years and obstetricians have shown great reluctance to tackle this issue.[2] Indeed, although the infection is frequent in 1–2% of all neonates excreting CMV in their urine, 90% of these will remain asymptomatic.[3] However, among symptomatic neonates, half will be severely infected and one-third of these will die, while 60% will develop significant neurological and developmental sequelae. Among the moderately symptomatic neonates, 65–75% will develop normally, whereas 25–35% will have some degree of handicap at long-term follow-up. Furthermore, between 5% and 15% of the asymptomatic cases will also develop long-term developmental abnormalities, mainly sensorineuro hearing loss, which can be bilateral in up to 50% of the cases.[1,3,4] Epidemiological risk factors have been extensively reviewed elsewhere.[5] Maternal age below 25 years, low socioeconomic status and presence of children of age 1–3 years in the home are the most constantly quoted factors.[5] Preconceptional maternal immunity [relative risk (RR) 0.31; 95% CI 0.17–0.58] and maternal age of 25 years or older [RR 0.19; 95% CI 0.07–0.49] are highly protective against congenital infection.[6]

The possibilities for prenatal diagnosis have emerged more rapidly than those for establishing the prognosis of an infected fetus[2] and the possibilities of treatment are still experimental. In this chapter, we will address the possibilities and limits of prenatal imaging and biology in assessing both the diagnosis and the prognosis of fetal CMV infection.

Prenatal ultrasound examination

Overall, less than half of fetal infections are diagnosed by ultrasound[7–16] and multiple organ system involvement is present in more than 50% of the cases[17] at the time of prenatal diagnosis, ranging from 15% to 100% (Table 44.1), and is very likely subjected to reporting bias.

Indeed, a review of the pediatric literature suggests that most symptomatic congenitally infected neonates obviously escaped ultrasound screening and one should be aware that ultrasound alone is not a sensitive test for fetal infection or affection. Longitudinal observational surveys of intrauterine infection cases are lacking because the other half of prenatally diagnosed cases were recognized as a result of maternal screening. The majority of these cases reported to date were terminated on the basis of proven fetal infection without ultrasound findings or before they could eventually develop.[10,18] However, three small prospective series reported a 15–25% sensitivity for antenatal ultrasound.[14–18]

The predictive value of ultrasound, like that of any other diagnostic test, increases with the prevalence of the disease and therefore works better in a population preselected by screening for maternal seroconversion. However, even in such a high-risk population, at least 90% of infected fetuses are expected to be asymptomatic.[17] The ultrasound features of this progressive disease will also vary significantly with time and serial ultrasound follow-up is likely to perform better than routine cross-sectional examination at any fixed gestation.[2]

The pathophysiology of fetal CMV infection allows one to expect progressive and sometimes only subtle or transient findings on ultrasound in cases of fetal infection (Figure 44.1). Indeed, irrespective of the mode of transmission to the mother, CMV is a viremic herpes virus with a prolonged latency within maternal monocytes, which will eventually reach the fetus via the umbilical circulation.

The placenta, where the virus replicates, will act not only as a barrier against CMV but also as a reservoir, which may release the virus into the fetal circulation at any stage of the pregnancy, irrespective of the time of seroconversion.[55,56] Within 4–8 weeks

IUGR, *in utero* growth restriction; US, ultrasound

*Isolated abnormality

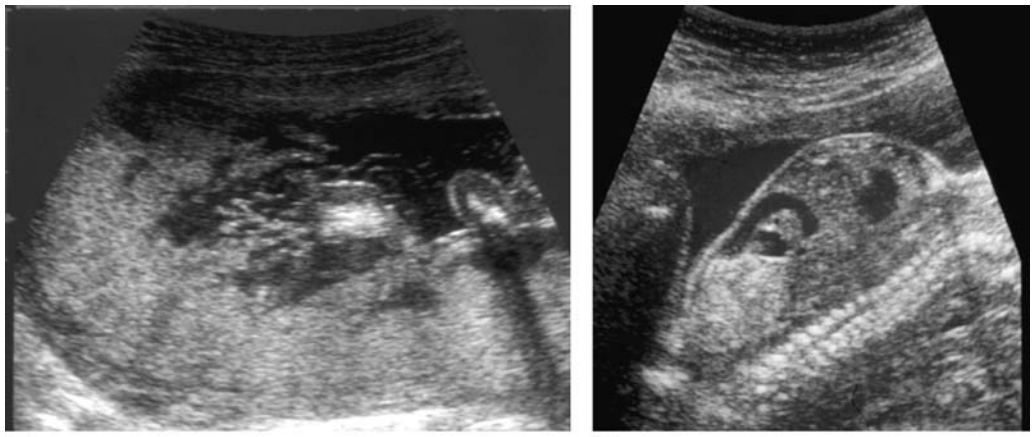

Figure 44.1 Placentitis showing a thick and heterogenous placenta (a). Hyperechogenic bowel and hepatomegaly (b) are not specific features of systemic fetal infection.

following maternal viremia, an early but inconstant sign of vertical infection is therefore likely to be placentitis, as defined by a thickness of 4 cm or more and a heterogenous appearance typically with calcifications coexisting with hypoechoic areas[13].

Once the virus reaches the fetal circulation, the fetal kidney is hit early and preferentially, which may cause transient oligohydramnios and, less often, renal hyperechogenicity. This appears to be more frequent than polyhydramnios.[13] Viral enterocolitis often shows with the transient or persistent appearance of at least grade-2 hyperechogenic bowel as an early ultrasound finding, which may be accompanied by high human chorionic gonadotropin and alpha-fetoprotein levels in maternal blood.[32,47,48,57] This usually represents meconial ileus or bowel perforation and meconial peritonitis.[58,59] Several weeks can elapse until other features of fetal infection, if any, show up on antenatal ultrasound, and some of the former may have disappeared by then.

Overt systemic disease will appear as hepatosplenomegaly and possibly ascites in the fetus as a result of cholestatic hepatitis and liver insufficiency.[41] Less often, generalized edema and ascites will suggest anemia-related hydrops due to the combined effect of liver failure and marrow infection. This spectacular presentation has also proven to be eventually transient with both ultrasound and biological normalization at follow-up.[54] Cardiomyopathy, expressed as cardiomegaly with a thick myocardium, which may contain punctuate calcifications, is a rare finding that could also participate in the development of fetal hydrops, eventually associated with tachyarythmia.[13,41] Calcifications of the fetal liver, spleen and even lungs could appear and remain as a result of a systemic disease.[60]

Intrauterine growth restriction (IUGR) may develop as a result of fetal infection or placental infection or both. It can therefore be advisable to screen for CMV as a part of the assessment of any IUGR fetus below the fifth percentile. Indeed, this could be a completely isolated finding irrespective of placental or fetal Doppler values.[61,62]

Affection of the fetal brain shows mainly late and multiple suggestive and heterogenous ultrasound features of fetal infection and fetal affection[21] (Table 44.2). These can be present when the previously described features have resumed, therefore, weeks or months after the onset of maternal and even fetal infection.

Microcephaly is a major form of the disease; however, this may prove to be a very difficult diagnosis to establish, especially in a growth-retarded fetus.[72,73]

Ventriculomegaly, unilateral or bilateral, is a common entry to the diagnosis as around 5% of all ventriculomegaly diagnosed *in utero* is of infectious origin.[74] It can be of two types. Destructive ventriculomegaly is often moderate and will often precede microcephaly, showing even subtle enlargement of pericerebral spaces (Figure 44.2) as an early sign of microencephaly. Obstructive ventriculomegaly can occur as a result of obstruction of the foramen of Monroe and/or of Magendie and Lushka by ventriculitis-related edema or intraventricular hemorrhage.[46] The same mechanisms can lead to less common presentations such as mega cisterna magna, cerebellar hypoplasia or hemorrhage, pseudo-Dandy Walker malformations and schizencephaly.[21,66]

More subtle anomalies can be identified as associated findings with any of the features described above or as isolated findings, making the diagnosis more difficult. Non-specific vasculitis in the fetal thalami and basal ganglia,[67] described as candle-stick images, punctuate echogenicity within the brain parenchyma or underlying the rim of the lateral ventricles together with strands across the lateral ventricles.[40,75] Germinolysis-related subependymal cysts can also be overlooked by routine fetal ultrasound examination when fetal infection is not known).[21,40,64] Rare cases of corpus callosum abnormalities have also been described *in utero* and postnatally.[21,69]

Abnormal myelinization and gyration of the fetal brain is another pitfall for fetal brain ultrasound examination and the development of fetal MRI is a recent and definite asset in the complete assessment of high-risk fetuses.[21,51,63] Lissencephaly could reflect injury before 16 or 18 weeks whereas polymicrogyria could reflect injury at 18–24 weeks. Cases with normal gyral patterns have probably been injured during the third trimester showing diffuse heterogeneity in the white matter.[63] Both T1 and T2 sequences are therefore useful.

It is noteworthy that although the relationship between the ultrasound features described above and fetal CMV infection is well established, CMV is rarely reported in series of cases bearing these anomalies. This further emphasizes the poor performance of ultrasound in diagnosing fetal CMV infection in the general population.

Maternal and fetal biology

When the presence of CMV infection is suspected on the basis of any of the ultrasound findings described above, it can be excluded only if maternal serology shows negative immunoglobulin G (IgG) and negative IgM. Indeed, IgM, which can be present both in primary and non-primary infections, is often negative at the time of a positive fetal ultrasound examination several weeks or months following maternal infection. At that time, both maternal viruria and viremia are also likely to be negative although they have been found positive for 3–12 months following maternal infection.[76]

The diagnosis of fetal infection is made by recovery of the virus or by amplification of its genome in the amniotic fluid (AF) retrieved by amniocentesis.[5,77] Indeed, the AF is colonized once the virus has infected the fetal kidneys and replicates in the tubular epithelium to be passed in the urine. Viral DNA therefore accumulates in the AF as it does in the urine of infected individuals postnatally. This provides with clear guidelines for performing amniocentesis in CMV infection during pregnancy. Following seroconversion or reactivation, the process leading to CMV excretion in the fetal urine will take an average of 6–8 weeks and this interval should be recognized in order to avoid false-negative prenatal diagnosis.[77] This should also be performed when fetal urination is well established, and therefore not before 22 weeks.

Detection of infectious CMV in AF may be performed by the use of rapid virus isolation in cell cultures ('shell vial culture')[77,78] as well as CMV DNA detection by polymerase chain reaction (PCR) amplification. Sensitivity varies between 45% and 100% for both PCR and culture, the lowest figures being obtained when amniocentesis was performed before 21 weeks, and less than 6–8 weeks from maternal seroconversion.[7,19,21,42–44,79–81] However, the free interval can be even longer depending on the placental ability to contain infection.[55] The overall false-negative rate of amniocentesis is around 12% (52/365) [0–25%][8–10,14,15,18,24,43–45,77,80–84] and has been reported to be much lower and even down to 0% when the conditions of sampling were ideal.[14,15,20]

The variation in sensitivity may also account for the differences in PCR methods used. Each PCR method reported in the literature has its own protocol (e.g. single-round PCR, nested PCR or commercial tests) and tests different volumes of fetal specimen, leading to variable sensitivities. Moreover, the CMV genome sequences amplified in these PCR tests varied with various fragments of the immediate early protein gene or of the glycoprotein B gene being most frequently used. Genetic diversity in those two genes is well recognized,[85] but the design of primers and probes did not always account for this.

False-positive PCR results have also been reported when the neonate was not infected in 9/179 (5%) (0–30%), questioning the quality of the technique.[9,11,14,15,18,43–45,80,83,84] False-positive diagnosis may be explained by contamination of the AF with the maternal blood during amniocentesis, if the mother had a positive CMV DNAemia at the time of sampling. Indeed, Revello *et al.* showed that CMV DNA may be recovered in the blood of nearly 50% of immunocompetent patients up to 3 months after CMV primary infection.[76] Another explanation could be laboratory contamination occurring during PCR testing. Indeed, in some of these studies a nested CMV PCR was used, which is known to be a very sensitive technique but at high risk of contamination. Generalization of semiautomated real time PCR might help to overcome the risk of contamination and achieve absolute specificity for prenatal diagnosis of CMV infection. These results, however, establish PCR as a reliable technique in reference laboratories. The question of performing a second amniocentesis when the result of the first examination is negative remains unanswered. However, to date, information available on 13 cases with a false-negative result[9,24] did not show any symptom at the age of up to 36 months, although one neonate was growth restricted.

Another question without an answer today is that of the risk of fetal iatrogenic infection when maternal viremia is positive at the time of amniocentesis. However, the commonly understood pathophysiology of vertical transmission of CMV to the fetus makes this possibility unlikely.

Prenatal diagnosis in fetal blood

There are few data available on the prenatal diagnosis of CMV infection in fetal blood.

The sensitivity of IgM detection in fetal blood is around 50%.[10,77] The sensitivity of CMV rapid or classic culture is even lower, ranging from 0% to 40%.[10,11,77,80] This is probably due to the small volume

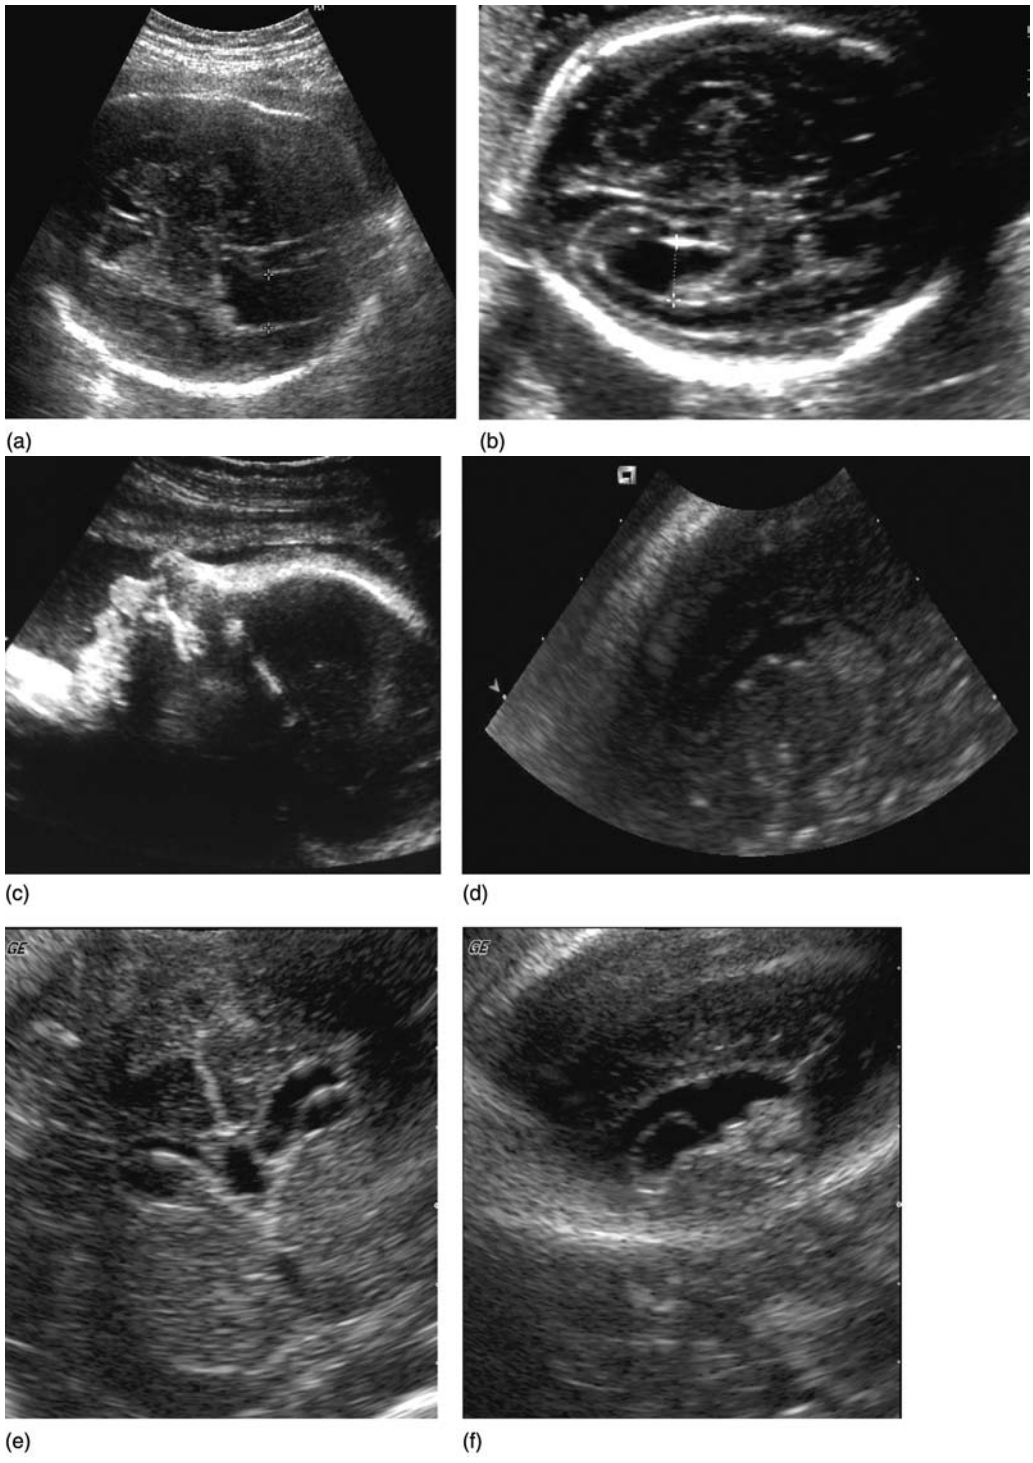

Figure 44.2 Cerebral features include ventriculomegaly (a) often preceding microencephaly (b), which in turn can precede microcephaly as illustrated by a sloping forehead on the profile view of the face (c). More subtle features include parenchymal punctiform calcifications (d), subependymal cyst (e) and hyperechogenicity of the germinal matrix (f).

retrieved by cordocentesis, and PCR methods should be preferred. However, the sensitivity achieved by PCR in fetal blood varied greatly in three studies published, ranging from 40% to 92%.[9,10,77] Enders *et al.*[9] reported a 100% sensitivity when combining amplification of CMV DNA in AF and in fetal blood.

To date, CMV detection in fetal blood is, therefore, generally considered to be unsuitable for prenatal diagnosis. However, the value of viral quantification (DNA and IgM) in fetal blood to identify fetuses at risk of developing severe congenital infection is emerging and this issue will be discussed in a later chapter.[9,14,15,77]

Conclusion

CMV infection in pregnancy is not only diagnosed from suggestive ultrasound features but also often suspected as a result of an individual or population-based screening. Interpretation of maternal serology and indication for invasive and non-invasive testing require some knowledge of the natural history of CMV transplacental infection.

Amniocentesis remains the gold standard invasive test to diagnose fetal infection, and in the absence of ultrasound features this should be performed after 22 weeks and at least 6 weeks following maternal seroconversion.

45 Fetal hydrops

T. Marton and P. M. Cox

Fetal hydrops

Fetal hydrops is a combination of generalized soft tissue edema and fluid (effusion) in one or more body cavity.

Hydrops still has a high mortality causing fetal demise in more than 50% of the detected cases and postnatal mortality following live birth is also around 50%.[1] There may be many causes. According to the traditional classification, the hydrops can be divided into immune and non-immune types. A more clinically (fetal medicine) oriented approach could be to divide cases into those due to fetal anemia- and non-anemia-related hydrops. The practical reason for this categorization is that fetal anemia is still the most common cause of hydrops and in most cases fetal anemia is easily detectable *in utero*. It can often be treated with intrauterine transfusion and thus anemia-related hydrops has a better prognosis than other forms.

In different parts of the world, there are different causes of hydrops. For example, in underdeveloped countries, rhesus (Rh) isoimmunization still remains a major cause; whereas in southern China, fetal α-thalassemia is the main causative factor. In contrast, in the developed world structural and chromosomal anomalies and parvovirus B19 infection are the most frequent causes of hydrops.

This chapter aims to be a comprehensive library of the various fetal conditions that play a role in fetal hydrops and presents a few characteristic features.

Anemia-related hydrops

It is well known that fetal anemia can be readily detected with the help of ultrasound/Doppler, measuring the middle cerebral artery velocity. For details see the relevant chapter of this book. The causes of fetal anemia should be subdivided, as they affect the prognosis for the pregnancy and fetus.

Immune hydrops

Historically, immune hydrops (due to maternal anti-D isoimmunization) was the commonest cause of fetal anemia and hydrops. Fortunately, these severe cases of anti-D isoimmunization are now very rarely seen, as a result of anti-D immunoglobulin (Ig) prophylaxis for rhesus-negative mothers. In the absence of prophylaxis, the disease still occurs. Immune hydrops is the result of a maternal IgG-mediated hemolytic disease of the fetus, the severest form of which is erythroblastosis fetalis.

There are further antigens that can cause immune-mediated fetal hemolytic disease including Rh anti-C, -c, -E, -e, anti-Kell, anti-MNS, anti-Duffy and anti-A or anti-B.

Isoimmunization due to the non-Rh groups such as Kell, MNS and Kidd have assumed increasing importance as the incidence of Rh-D sensitization has decreased.

Anti-Kell disease has a particularly poor prognosis, probably because the anemia is partly hemolytic and partly the result of suppressed erythropoiesis.[2] A significantly higher incidence of polyhydramnios was found among fetuses with Kell isoimmunization and the maternal serum titer is much lower than in the Rh-D group.[3]

Genetically determined hemolytic disease of the fetus

There are a number of genetically determined hemolytic diseases of the fetus, which can rarely lead to fetal hydrops (see Box 45.1).

Box 45.1 Genetically determined hemolytic anemias causing fetal hydrops

Glucose phosphate isomerase deficiency [autosomal dominant (AD) in adult cases, neonatal and fetal form most likely autosomal recessive (AR)][4] causes hemolytic crisis, very rarely fetal anemia and hydrops

Glucose-6-phosphate dehydrogenase (G6PD) deficiency (X-linked dominant) hemolytic episodes

Pyruvate kinase deficiency of erythrocyte (AR)[5]

Non-infectious disorders of erythrocyte production

α-Thalassemia (AD) is a common cause of fetal hydrops in the Chinese population.[6] Thalassemias are a group of inherited abnormalities of the hemoglobin synthesis. Hemoglobin has an α and a β chain. Homozygous α-thalassemia (deletion of both α-chain alleles of the corresponding region of chromosome 16) is responsible for the fetal hydrops (Bart syndrome). Clinical classification, such as thalassemia major, intermedia and minor refers only to the clinical severity of the disease. It is also apparent that, at least in some cases, compound heterozygosity is responsible for the hydropic change of the fetus. Anemia in thalassemia is the result of short turnover time of erythrocytes with a reduced hemoglobin content.

Other inherited forms of dyserythropoiesis are listed in Box 45.2. These represent rarities.

Box 45.2 Inherited dyserythropoietic conditions associated with fetal hydrops

Congenital dyserythropoietic anemia (AD)[7] is characterized by ineffective erythropoiesis and multinuclear erythroblasts

Congenital erythropoietic porphyria (AR)[8]

Diamond–Blackfan syndrome (AD)[9] causes congenital hypoplastic anemia

Leukemia (associated with Down's syndrome)[10]

Fetal anemia as a consequence of fetal blood loss

Internal fetal hemorrhage may lead to severe anemia due to blood loss. The commonest site of hemorrhage is the brain, but intrathoracic and intra-abdominal hemorrhages may also occur. Spontaneous fetal hemorrhage should always prompt a search for maternal antiplatelet antibodies to exclude alloimmune thrombocytopenia.[11,12]

Placental subchorial/intervillous hemorrhage can also originate from the fetus.

Fetomaternal hemorrhage (i.e. hemorrhage from the fetal into the maternal circulation) is common. Tiny hemorrhages are probably universal. Massive hemorrhage may be acutely fatal but smaller or recurrent bleeds may lead to an anemic, hydropic fetus. A maternal Kleihauer–Betke test is an essential part of the investigation of hydrops.[13]

Hemorrhage can also occur into a necrotic congenital tumor.

Human parvovirus B19 infection

Parvovirus is one of the most important factors causing anemia and hydrops.

In pregnant women, it can cause miscarriage (6.5%),[14] hydrops and intrauterine death, although most infected women give birth to healthy neonates without any intervention.[15] In a meta-analysis of 165 reported cases of antenatal human parvovirus B19 (HPVB19) cases, there was a 10.2% excess risk of fetal death. Transplacental transmission was confirmed in 69 (24.1%) of 286 reported maternal infections. According to a separate meta-analysis HPVB19 infection was present in 57 out of 299 (19.1%) non-malformed cases of non-immune hydrops fetalis.[16] Parvovirus not only affects the erythroid cell lines, inhibiting erythrocyte production, but also infects the cardiac myocytes. In most cases, the hydrops is a consequence of severe anemia, though at least in some chronic cases it appears that a direct effect on the heart cannot be excluded.

Infections in which anemia plays a role in the hydrops are seen below.

Non-anemia-related hydrops

Infection-induced fetal hydrops[17]

The most common infections causing fetal hydrops are parvovirus B19 (see earlier section), cytomegalovirus,[18] Herpes simplex virus, *Toxoplasma gondii*, *Treponema pallidum*, Coxsackievirus type B and adenovirus. Congenital Chagas' disease is also reported to be associated with hydrops.[19]

The mechanism by which the different infections cause hydrops varies. For example, Herpes simplex virus causes liver damage, whilst Coxsackie- and adenoviruses lead to myocarditis and fetal tachyarrhythmia.[20,21]

Congenital syphilis results in generalized chronic infection,[22] with anemia, thrombocytopenia and, later, ascites. In congenital syphilis, the mother can be seronegative with an infected fetus,[23] and this may also be true for parvovirus (personal observation).

Structural anomalies

(1) Tumors or tumor-like/hamartomatous lesions within the body cavities may cause hydrops with compression or obstruction of the major vessels of the systemic venous return. The lesions that belong to this group are shown in Box 45.3. Fetal lung lesions associated with hydrops are almost always lethal.[24]

Occlusions of the superior or inferior venae cavae and ductus venosus are also reported to result in hydrops.

Box 45.3 Obstruction of systemic venous return

Thorax

Congenital cystic adenomatoid malformation of the lung[25,26]

Pulmonary extralobar sequestration[27]

Large diaphragmatic hernia

Intrathoracic teratoma

Intrathoracic lymphangioma[28]

Cardiac or pericardial tumor[29]

Laryngeal atresia

Abdominal tumor or tumor-like lesion

Abdominal teratoma

Cystic kidneys

Obstructive uropathy

Hepatoblastoma

Ovarian cyst

Other tumor

(2) Cardiac disease, including developmental abnormalities, tachyarrhythmia and bradycardia may cause fetal hydrops. A list of these conditions is given in Box 45.4.

Box 45.4 Congenital heart conditions in fetal hydrops

Congenital heart disease[30]

Atresia of the aortic or pulmonary trunk

Various malformations of the great arteries

Atrioventricular septal defect

Right or left ventricular hypoplasia, divided right ventricle[31]

Cardiomyopathy[32]

Fetal bradycardia

Congenital heart block[33]

Maternal systemic lupus erythematosus

Lupus anticoagulant

Fetal tachycardia with myocarditis

Adenovirus

Coxsackievirus

Parvovirus

Chagas' disease

Wolff–Parkinson–White syndrome[34,35]

(3) Vascular shunts result in high-output cardiac failure and subsequent hydrops.

This occurs in fetal sacrococcygeal teratoma[36–38] and in arteriovenosus malformations at various locations in the body. In the head, vein of Galen aneurysm, intracranial arteriovenosus malformation and intracranial teratoma have been described.[39] Cervical, abdominal,[40] or cutaneous hemangiomas, arteriovenuous malformations of the liver and lung, large placental chorangioma and angiomatosis of the fetus are also rare causes of hydrops.

Hydrops can occur as a complication of monochorionic twinning, often because of high-output cardiac failure of one twin.[41] In twin-to-twin transfusion syndrome, volume overload in the recipient leads to failure and hydrops, while in TRAP sequence reversed perfusion of a large acardiac co-twin by the pump-twin is the cause. There are also reported cases with myocardial infarct of the recipient in twin-to-twin transfusion syndrome[42] and transient hydrops of the donor after amniocentesis.[43]

(4) Other circulatory problems.

It has been suggested that long and/or overcoiled umbilical cord with increased vascular resistance may, in some instances, cause circulatory failure and consequent hydrops.[44]

Chromosome abnormality (including Turner syndrome)

X monosomy (45,XO – Turner syndrome) is the most common chromosome aneuploidy related to hydrops. It appears that failure of the lymph vessel development causes the hydropic change.[45] It is also apparent that in 90% of the hydropic Turner syndrome fetuses the heart weight is under the 2.5th percentile and it has been suggested that this is a major cause of fetal demise in Turner syndrome fetuses.[46]

Trisomy 21 hydrops or nuchal swelling was diagnosed in approximately 40% [cystic hygroma and increased nuchal fold thickness (30.5%), hydrops (9.6%)] according to a large series.[47]

Other karyotypic abnormalities associated with hydrops include trisomy 18, trisomy 13, trisomy 15 and trisomy 10 mosaicism.

Metabolic and storage disease

Metabolic and storage disease represents less than 1% of all hydrops cases. These are individually rare, but important because of autosomal recessive inheritance, and thus have 25% recurrence risk. The relevant enzyme defects are listed in Box 45.5.

Box 45.5 Lysosomal and glycogen storage diseases that cause hydrops

Lysosomal storage disease[48]

Mucopolysaccharidosis type VII[49]
Mucolipidoses I (sialidosis III)[50]
Mucolipidosis II (I-cell disease)
Gaucher disease[51]
Farber disease[52]
GM1-gangliosidosis[53]
Niemann–Pick disease[54]
Moroquio disease[55]

Glycogen storage disease

Type IIb (glycogen storage disease limited to the heart)[56]
Type IV[57]

Further genetic causes

Box 45.6 contains the most frequent genetic syndromes that cause hydrops. Osteochondrodysplasias are important because of the inheritance, and the number of recognized syndromes is growing.

Box 45.6 Osteochondrodysplasias and other genetic syndromes causing hydrops

Osteochondrodysplasias

- Blomstrand-type chondrodysplasia [(AR) short limbs, polyhydramnios, hydrops fetalis, facial anomalies, increased bone density and a remarkable advanced skeletal maturation]
- Greenberg dysplasia [(AR) radiological features: 'moth-eaten' appearance of the markedly short long bones, bizarre ectopic ossification centers and marked platyspondyly with unusual ossification centers][58]
- Conradi–Hunermann, chondrodysplasia punctata [(X linked – D) disorganization of the spine, premature echogenity of femoral epipheses and frontal bossing with depressed nasal bridge, polyhydramnios][59]
- Osteogenesis imperfecta congenita (AD)
- Achondrogenesis type IA [(AR) polyhydramnios, subgaleal edema, microcephaly, a narrow thorax, pericardial effusion and a severe short-limbed dwarfism with unossified tubular bones and vertebral bodies][60]
- Achondrogenesis type IB [(AR) sulfate transporter gene mutation, severe rhisomelia, narrow chest, flat face, polyhydramnios, possible umbilical hernia]
- Achondrogenesis type II [(AD) Marked micromelic dwarfism, barrel shaped, small chest, polyhydramnios]
- Short rib polydactyly syndrome type II [(AR) short ribs, polydactyly (pre- or postaxial), possible polycystic kidneys, median cleft lip][61]
- Short rib polydactyly syndrome type IV [(AR) markedly narrow ribs, micromelia, shortened limbs with postaxial heptasyndactyly polycystic renal dysplasia]
- Fibrochondrogenesis (AR)
- Kniest-like dysplasia (AR)
- Campomelic dysplasia (AR)

Other genetic syndromes associated with hydrops

- Arthrogryposis multiplex
- Lethal multiple pterygium syndrome
- Fetal akinesia
- Beckwith–Wiedemann syndrome
- Simpson–Golabi–Behmel syndrome[62]
- Smith–Lemli–Opitz syndrome
- Tuberous sclerosis
- Congenital arteral calcification

Miscellaneous

According to recent studies, fetal hemochromatosis appears to be the result of fetal liver disease and in the late second trimester of pregnancy results in severe panhypoproteinemia with non-immune hydrops.[63,64]

Maternal indometacin therapy mainly in the third trimester has been reported causing early closure of ductus arteriosus and consequent fetal hydrops.[65]

One case of iatrogenic intrauterine hypothyroidism and subsequent fetal hydrops has also been published, which was caused by maternal propylthiouracil medication for maternal Grave's disease.[66] In another case report, fetal hyperthyreosis and hydrops were caused by a hyperthyroid mother with Grave's disease by antithyroid antibodies.[67] Mother also had a history of three prior perinatal deaths between 26 and 28 weeks' gestation, all associated with fetal hydrops. After maternal therapy with propylthiouracil, resolution of non-immune hydrops was documented and a healthy neonate subsequently delivered to term.

Investigations in hydrops[68,69]

Pathologic examination of fetuses with non-immune hydrops requires a multidisciplinary approach. The first and most important is the macroscopic description and identification of structural abnormalities. Developmental abnormalities may draw attention to

the possibility of a chromosome abnormality; thus, cytogenetic studies are essential. (If cytogenetic culture fails, fluorescence *in situ* hybridization studies should be performed to exclude common trisomies.) The pathologist has to be careful to save living cells for further biochemical studies in case of suspicion of a metabolic disease. Osteochondrodysplasias cannot be diagnosed without proper x-ray documentation and, if necessary, involvement of an experienced radiographer. Molecular biology and DNA investigation are also important. Microbiology with bacterial, viral cultures and, if necessary, PCR investigation may also be useful. Light microscopic examination is essential, and in a significant proportion of the cases is enough to make a diagnosis. Fortunately, CMV, parvovirus and adenovirus antibodies are available to prove infection in paraffin-embedded blocks of the fetal tissues. According to published figures, a meticulous examination, including clinical studies, such as Kleihauer–Betke test and maternal autoantibodies, leaves approximately 10–20% of cases unexplained.[68,69]

The proverb that a *good clinical history is half the diagnosis* is very true with regard to the pathologist's work while undertaking an autopsy of a hydropic fetus. Nowadays, fetal hydrops is generally investigated prenatally. Clinical data can draw attention to subtle signs (which would otherwise be missed, especially in autolytic fetuses) and make the pathologist widen the investigation in the relevant direction. Samples are taken that cannot be taken later, such as frozen tissue for metabolic studies or DNA, frozen sections for immunohistochemistry, specially fixed tissue for electron microscopy, instruction to the cytogenetic or histochemistry laboratory to save cells for biochemical studies, etc.

It is essential to seek and document any prenatal finding, as it is an important feedback to the clinician and provides the parents with information.

In summary, because of the wide spectrum of causes of hydrops, a multidisciplinary approach to diagnosis is recommended based on proper communication and exchange of information between the clinician and the pathologist.

46 3D/4D color and power Doppler ultrasound in obstetrics

G. Bega and S. Weiner

Introduction

Two-dimensional ultrasound (2DUS)-derived color and power Doppler imaging is commonly used in fetal imaging. The information derived from 2DUS color and power Doppler images is displayed in a cross-sectional image plane. It is from these cross-sectional ultrasound planes that we develop a 3D perception of the vascular anatomy. Nevertheless, the ability to visualize, fully understand and differentiate between normal and abnormal vascular anatomy with 2DUS is often limited. These limitations become especially important in complex anatomical abnormalities. Recent developments in digital signal processing and transducer design have made possible the acquisition of volume ultrasound data with color and power Doppler, which can also be interactively manipulated through the volume. In three-dimensional ultrasound (3DUS) or volume ultrasound, a volume (rather than a slice) of ultrasonographic data is acquired and stored. The stored data can be analyzed and displayed in numerous ways and new and more sophisticated tools are being introduced at a very fast rate. Although these new and relatively complex applications are not widely known or understood in the field of ultrasound, there seems to be little doubt that these tools will become a routine part of our diagnostic imaging toolset. One of the most significant advantages of acquiring a volume ultrasound data is the ability to navigate through the saved volume and demonstrate any arbitrary plane and, most importantly, even planes that are otherwise impossible to be obtained by the conventional 2DUS. In the multiplanar display, three perpendicular planes are displayed simultaneously. Correlation between these three planes is used to confirm the given desired plane, such as the midsagittal or midcoronal plane. This process generally involves placing the planar center point at the point of interest in one of the planes and observing the location of the corresponding center points in the other two planes.[1,2]

In this chapter, we intend to review the current and potential future applications of 3DUS and four-dimensional ultrasound (4DUS) color and power Doppler ultrasound in obstetrics. In the section Technical Considerations, the reader will be introduced to the basics of 3DUS volume acquisition, display, analysis, volume calculation and perfusion studies. The main clinical applications will be presented with a special section on techniques of 3D color and power Doppler in fetal echocardiography. The somewhat limited literature as related to 3D color and power ultrasound will be reviewed as well. Last but not least, networking capabilities will be discussed.

Technical aspects of acquisition and display

3DUS acquires 2D planar ultrasound data in a volume and as such represents an extension of the conventional 2DUS imaging. Considering this, 3DUS does not necessarily replace 2DUS but rather extends its capabilities in time and space. Being a 2DUS-based technique makes 3DUS vulnerable to all drawbacks and limitations of 2DUS. As such, problems related to image resolution, penetration, depth, artifacts and body habitus are also present in 3DUS and are even made worse and compounded across a volume of data. Consequently, image and color and power Doppler setting optimization plays a huge role in acquiring adequate information that could be used clinically. Using 3DUS, color and power Doppler techniques generally require an additional investment of time, which in experienced hands typically goes anywhere from 5 to 20 min and at times, depending on the complexity of the case and the experience of the examiner, significantly more. This additional time is not so much related only to scanning and acquiring the data, which is only a portion of the learning curve, but also to exploring the saved volume data afterward in a meaningful way. The fact that this information can be digitally saved, either temporarily in the hard disk of the equipment or permanently in a removable

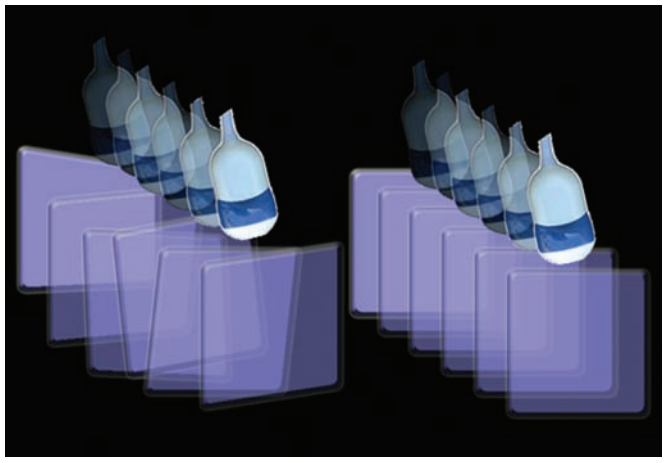

Figure 46.1 This image illustrates the principle of image registration and the effect of a dedicated 3D volume transducer with a built-in position-sensing device in it. The images on the right represent a volume acquired with a free-hand transducer and the images on the left represent a volume acquired with a dedicated volume transducer and appear well registered. The controlled acquisition and reliable registration are prerequisites for obtaining clinically useful ultrasound volumes with color or power Doppler.

disk, such as CD-ROMs or DVD-ROMs, makes the exploration of the saved volume data after the patient is discharged a real possibility.

It is important to understand the concept of volume data and how they are acquired. The acquisition of one single volume of ultrasound data is called a 3DUS acquisition and the volume is commonly called a 3D volume. The introduction of dedicated transducers in the mid-1990s made possible the continuous acquisition of 3D volumes and on the fly display of either multiplanar or rendered views. This continuous acquisition displaying motion views of moving targets, such as the fetus or the fetal heart, was called the fourth dimension and the imaging technique 4D. There are basically three methods of acquiring volumes of ultrasound data for 3DUS imaging. The first and the oldest one is the free-hand method, which utilizes a normal 2DUS transducer with a position-sensing device mounted that can acquire multiple 2DUS images as the probe is manually swept through the region of interest. This method typically acquires one 3DUS volume and in principle cannot acquire 4D data, as that would require the operator to continuously move his/her hand at fast acquisition speeds, which is impossible in reality. The second method is the acquisition of volumes with a dedicated 3DUS transducer (Figure 46.1). A mechanical device moves the transducer elements at a preselected speed and a preselected angle automatically in a fan shape through the region of interest.[3,4] While color and power Doppler ultrasound volumes can be reliably obtained with mechanically swept dedicated transducers, their acquisition time is typically slow as there simply is more information to acquire and process. There is a special fetal heart package that displays heart volumes with either color or power Doppler data in 4D, called spatiotemporal image correlation (STIC). This technique, which will be discussed in more detail at the fetal echocardiography section, is an exception to the fact that currently mechanically swept transducers cannot display 4D color and power data. The third method is the volume acquisition through matrix array transducers. These newly introduced dedicated volume transducers have a very high number of transducer elements (typically, as of this writing from 3000 to 4000 elements) and produce a thick ultrasound beam in all directions. All elements of the matrix array transducer transmit and receive. Interestingly, the first imaging and data processing take place in the transducer itself as it contains a built-in data processor. These transducers are electronically steered and have no need for mechanical sweeping. As such, they can produce very high acquisition speeds even with color or power Doppler.[5,6] These transducers are the future in volume imaging and will make a revolution in our capabilities of investigating fetal and/or placental vasculature with 3D/4D color and power Doppler. For the time being, matrix array technologies are mainly being investigated in adult echocardiography, but slowly studies are being conducted in obstetrics as well.[7] All of these methods rely on specialized 3D software, which allows processing of the acquired volumes either on-line through a built-in computer or off-line on a workstation.

In this chapter, we will present work with the dedicated mechanical volume transducers (the second method) as for the moment this is the best and the most commonly used technique of acquiring clinically useful data in obstetrics.

Image optimization

One of the most common problems practitioners encounter in their learning curve of acquiring 3D color and power Doppler is optimization of the settings. While there is no fixed recipe for every occasion, there is a set of principles and techniques that if understood well should be helpful in obtaining adequate information. First, we start with the 2D color or power Doppler information. Normal 2DUS principles of visualizing vessels with color and power Doppler should be followed (and the following work better in a 3D volume acquisition as well), such as:

(a) Be as parallel to the vessel or vessels of interest as possible.
(b) Adjust the gain to avoid 'bleeding' in the vessel wall by decreasing the gain at the minimally acceptable level, typically no more than 50–70%.
(c) Adjust the wall filter – usually the medium settings work better.
(d) Set the dynamic motion differentiation to avoid background noise signals.
(e) Sensitivity works better in medium scale.

(f) Priority set on high generally brings a better signal.
(g) Pulse repetition frequency (PRF) should be adjusted according to the particular vessel size and blood flow, typically a higher PRF is needed for higher-velocity vessels (i.e. intracardiac flow) and a lower PRF is needed for small and/or branching vessels (i.e. brain), especially placental or retroplacental (venous) vessels.
(h) Start in 2D gray-scale image with the highest frame rate possible. This translates into a volume with the highest quality, as there will be more frames in a volume. Factors that affect the frame rate are the angle opening in the 2D beam (use the narrowest angle you can), the number of focal zones and the amount of depth (the less the better). Harmonic imaging helps significantly in imaging in the near field but not much in the far field, but it is important to know that it does slow down the frame rate.

The 2D power and color Doppler ultrasound principles above should be incorporated to adequate 3D volume acquisition principles such as:

(a) Start with the slowest acquisition speed that is practically possible in order to leave time for the transducer to acquire the maximum amount of information. Typically, the slower the speed of acquisition the higher the quality of the volume obtained.
(b) Ask the mother to hold still for the expected time frame that the acquisition takes place, that is, anywhere between 5 and 15 s depending on the size of the volume box and the angle of acquisition.
(c) Try to acquire volumes at quiet fetal states to avoid motion artifacts.

Analyze the volume right after acquisition for possible acquisition-related artifacts due to fetal breathing, respiration or movement. Explore the B or the C window as those are the computer-generated views where the hidden artifacts can be depicted. Window A is the acquisition plane and as such may or may not show artifacts.

Flow volume and perfusion studies

For the first time 3DUS allows very accurate volume measurements. Multiple studies have shown that volume measurements are feasible and nomograms of several different organ systems in the fetus have been generated.[8–12] A very interesting aspect of obtaining power and color Doppler volumes is that this information can give an overall estimation of the blood supply of a given anatomical area. Many efforts have been made by the industry to further postprocess this information with the purpose of quantifying the amount of blood supply. One of the most useful programs is the so-called 3D-shell imaging method. In this method, a 3D volume is acquired with power Doppler, then a volume of interest (VOI) inside the initial acquired volume can be traced. Inside the VOI the gray scale and color histograms can be evaluated together or separately and expressed as a mean value. The expected clinical value of these power and color Doppler volume quantification methods is better estimation of blood flow within the area of interest (i.e. tumor). For this purpose, four indices have been proposed: (1) average gray value of non-color voxels (MG); (2) vascularization index (VI): ratio of number of color voxels to total number of voxels inside VOI; (3) flow index (FI): ratio of sum of color intensities to number of color voxels inside VOI and (4) ratio of sum of color intensities to total number of voxels outside VOI (VFI). Importantly, while these measurements provide a useful method in quantifying blood flow and vascularity in the acquired volumes, their information is based on digitized color voxel information. The accuracy of this information may change (i.e. improve) as software updates or better probes emerge that improve color or power Doppler sensitivity. Published nomograms for vascularity cannot be used for imaging with other types of machines or with different generations of the same probe because of variable color sensitivity. Nevertheless, the information obtained can provide important qualitative assessment of vascularization and blood flow changes in different normal and abnormal physiologic states. While a few studies have been conducted in gynecology, no studies have been reported in obstetrics yet.

Clinical applications

Color and power Doppler information in a volume have shown to be very useful in visualizing the fetal anatomy (Figures 46.2–46.10). Several authors have reported their positive experiences with the use of 3D Doppler.[13,14] Studies have shown that 3D color and power Doppler, as used with a free-hand 3D ultrasound system, was useful in imaging tumors (chorioangioma, teratoma, hygroma, lung sequestration), the fetal brain (vein of Galen aneurism, corpus callosus agenesis, vascular malformations), kidneys (agenesis of the kidneys, renal arteries), fetal abdominal vessels, umbilical cord anomalies and placental disorders.[14] Lee *et al.* demonstrated that 3D color and power Doppler, as acquired with an automated 3D probe, could visualize placental angiogenesis as early as 7.1 weeks of gestation, cerebral and neck vessels as early as 12.9 weeks of gestation, brain vessels, cord insertion, placenta and vasa previa.[15] In an interesting study, Kalache described the use of 3D power Doppler ultrasound to identify vascular congenital anomalies of the fetal portosystemic and umbilical venous system. He found 8 out of 310 fetuses with portosystemic venous malformations. When an umbilical vein or ductus venosus anomaly is suspected, the operator has to construct the 3D orientation of the vessels from cross-sectional 2D images. Power Doppler in 3D allows visualization of low-velocity

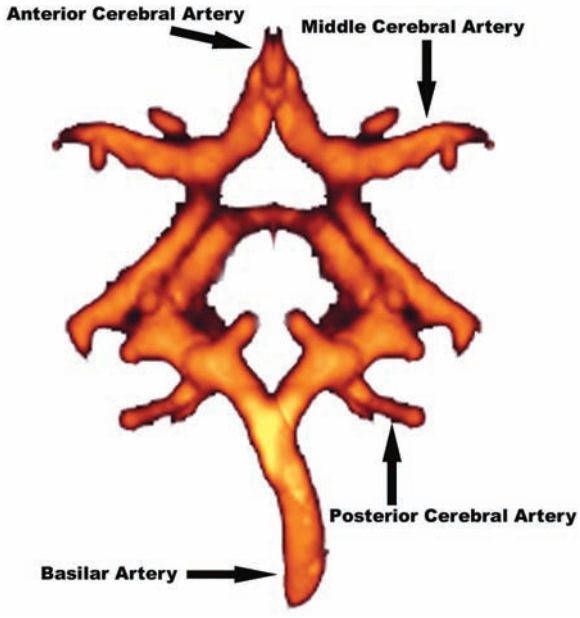

Figure 46.2 This is a 3D power Doppler (without the gray scale) display of the Circulus of Willis at 26 weeks' gestation. Note the anterior, middle and posterior cerebral arteries as well as the basilar artery.

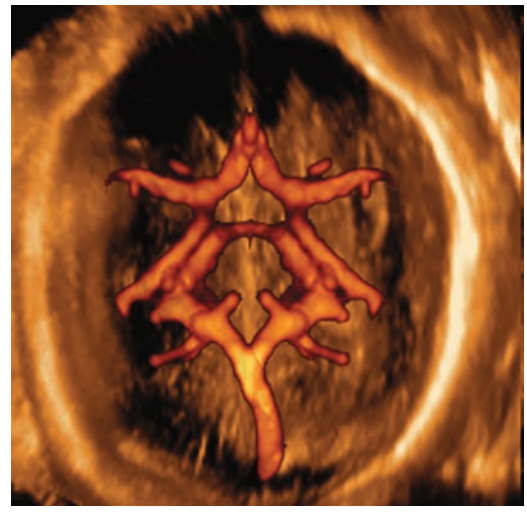

Figure 46.3 The same case as Figure 46.2. A volume rendered in transparent mode in gray scale and 3D power Doppler information in the same display. This display is generally used to display the brain vasculature in power Doppler as well as the brain gray-scale information simultaneously for better orientation and correlation. Typically, the color Doppler rendering can be combined with the gray scale at different percentages to the liking of the operator.

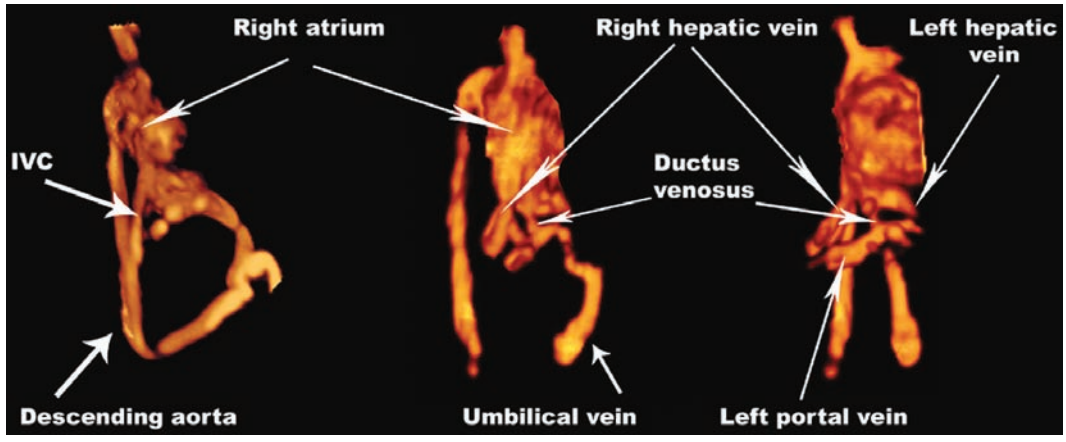

Figure 46.4 This is a 3D power Doppler rendered volume of the fetal cardiovascular system of a normal 23-week-gestation fetus. This volume has been rendered only with the 3D power Doppler without the presence of any gray-scale information. As this is the volume data, it can be rotated to depict different views of the anatomy. Note the detailed visualization of the descending aorta, inferior vena cava (IVC), right atrium, umbilical vein, right hepatic and left veins, left portal vein and ductus venosus.

flow; blood flow is displayed independent of its velocity and the vessels are visualized throughout the volume, ensuring spatial orientation.[16] Figures 46.5–46.7 demonstrate how 3D color and power Doppler can have an important role in visualizing the complex anatomical arrangements otherwise quite difficult with 2D ultrasound.

Hull *et al.* reported their experience in using 3D color and power Doppler in imaging the placenta.[17] They found that 3D ultrasound with color Doppler imaging allowed a more accurate diagnosis of placenta percreta. They had seen several patients in whom the use of 3D ultrasound with color flow and power Doppler imaging allowed refinement of the diagnosis of placental invasion, correctly predicting placenta percreta with bladder invasion. They feel that the multiplanar capability is the key to 3D ultrasound utility. Other useful applications of 3D color and power Doppler reported by this group are placental cord insertion and vasa previa visualization.[17]

Fetal echocardiography

3D volume acquisition speed has been improved significantly over the last 5 years. In the past, it was generally believed that increases in acquisition speeds

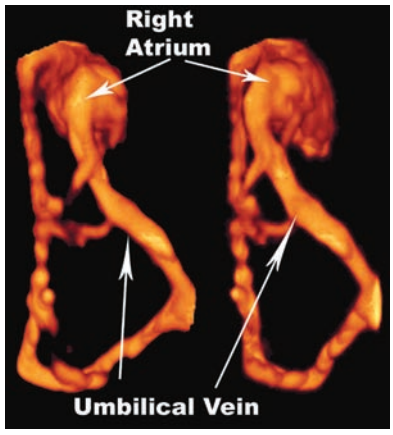

Figure 46.5 Power Doppler rendered volume of a fetus at 20 weeks' gestation with Noonan syndrome. Note the absence of ductus venosus and the umbilical vein draining directly to the right atrium. Note the distorted angio-architecture as compared to the normal fetus in Figure 46.4.

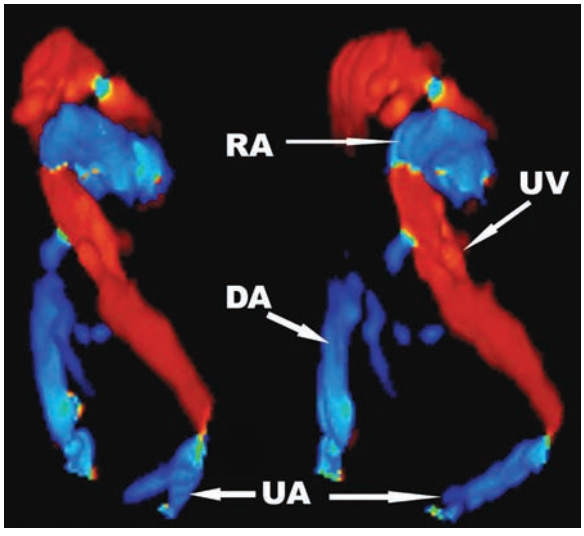

Figure 46.6 The same patient as in Figure 46.5, but the volume has been rendered in a 3D color Doppler again without the gray-scale information. The information provided from 3D color Doppler is similar to the one provided by 3D power Doppler, but in color Doppler we have additional information regarding the direction of flow. RA, right atrium; DA, ductus venosus; UV, umbilical vein; UA, umbilical arteries.

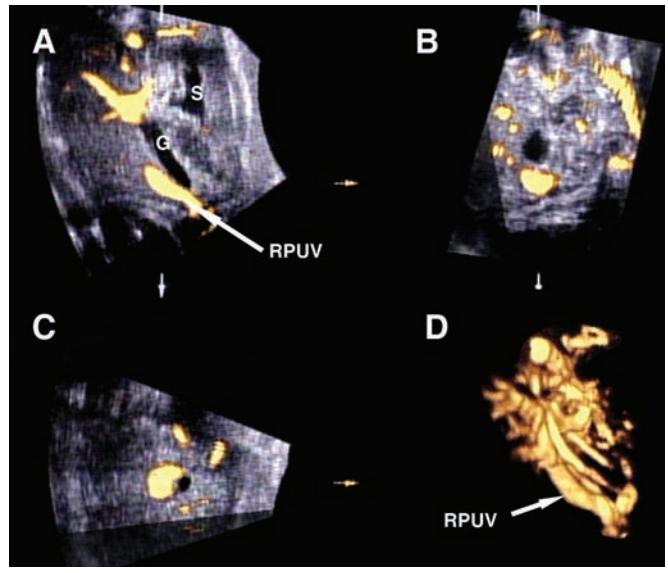

Figure 46.7 Multiplanar display and a rendered display of a fetus at 25 weeks' gestation with persistent right umbilical vein. (A) Transverse plane through the fetal abdomen at the level obtained to measure the abdominal circumference: S, stomach; G, gallbladder; RPUV, right persistent umbilical vein. The right umbilical vein passes lateral and to the right side of the gallbladder connecting the left portal vein. This is the intrahepatic form of the right umbilical vein. (B) A perpendicular view to plane A. (C) A coronal view to plane A. (D) The rendered 3D power Doppler view with the arrow pointing at the persistent right umbilical vein. Note that all these four windows are interactive with each other. Windows A and D can be correlated to identify the right umbilical vein both in cross-sectional and in rendered view.

will have a great impact in 3D fetal echocardiography. While the Voluson 730 Expert (GE MEDICAL, Milwaukee, WI, USA) can achieve speeds of acquisition up to 32 frames/s, in acquiring fetal heart volumes these high speeds do not necessarily translate into higher-quality volumes. Indeed, the opposite is true. Slower volumes yield higher-quality information as there are more 2D frames incorporated in the volume. To overcome this obstacle, a new volume acquisition technology was introduced. This technology is called STIC. With STIC, an extra slow (by 3DUS standards) acquisition from 7.5 to 15 s is performed over a preselected area of the fetal heart, typically at the level of the four-chamber view. The acquisition angle varies from 15° to 40° and again is user selectable. The same image optimization criteria apply just as the ones mentioned above. After the acquisition, postprocessing of spatial and temporal data is performed so that the 2D acquired images are correlated in time and space. This information is displayed in a classic multiplanar view and/or in a cine sequence depicting heart motion with total control on interactive reslicing and/or rendering the same as you would in a static 3D volume. Typically, in gray scale, this acquisition has a very high b-mode frame rate (approximately 150 frames/s) due to the relatively small region of interest.

STIC technique was initially introduced only in gray scale but later the acquisition of fetal heart volumes with STIC could be achieved with color and/or power Doppler information. This development opened up a whole new area in evaluating the fetal heart with 3DUS. STIC represents the first significant development in 3D fetal heart scanning that has the potential to perform a full fetal echo exam out of a single fetal heart volume at the level of the four-chamber view. Studies done before and after the introduction of STIC were able to demonstrate that a volume of the fetal heart can provide all the standard imaging views for a fetal echo[4,18] (Figures 46.13–46.15).

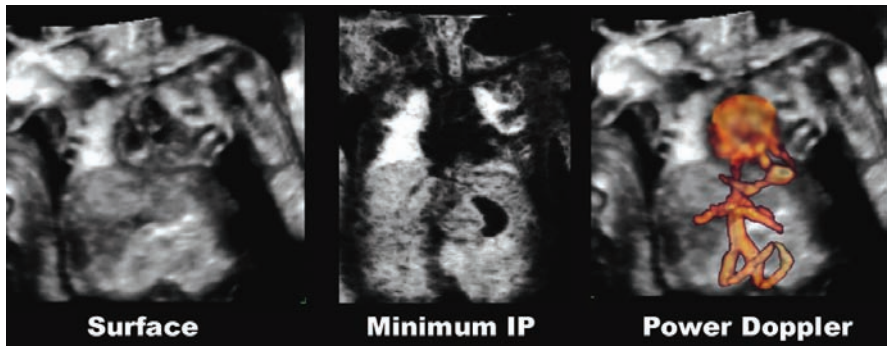

Figure 46.8 A composite image of a frontal view through the fetal body of a normal fetus at 20 weeks' gestation. The volume was acquired with and without power Doppler. The volumes are displayed in 3D surface rendering to visualize tissue interfaces of heart, lung, liver and bowel (first to the right), minimum intensity projection to visualize fluid-filled structures, such as heart and stomach, and surface and 3D power Doppler to visualize the relationships between vascular orientation and fetal body.

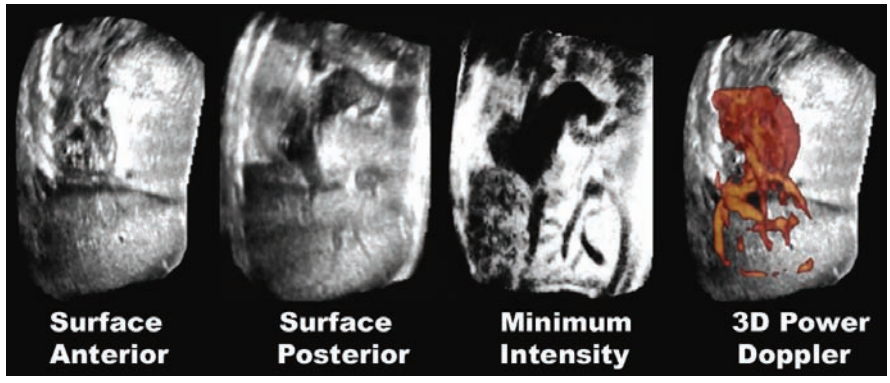

Figure 46.9 A composite image of several different volumes of a frontal view through the fetal body of a fetus at 22 weeks' gestation with congenital diaphragmatic hernia. In surface anterior view, the volume has been rendered with surface rendering settings at a very anterior level right behind the sternum to show the fetal liver, the diaphragm and the heart displaced in the right. In surface posterior view the volume has been rendered again with surface rendering settings, but at a posterior level to show the fetal stomach up in the chest, the disappearance of the diaphragm posteriorly and to the left as well as the left lobe of the liver going up in the chest. In minimum intensity view, the volume has been rendered with minimum intensity settings (good for fluid-filled structures) at a posterior level to better display the fetal stomach up in the chest as well as the left lobe of the liver vessels up in the chest. In 3D power view, the volume has been rendered with both surface and 3D power Doppler to better visualize the fetal heart and liver vessels in relationship to the chest wall and the diaphragm. Note the distorted angio-architecture as compared to the normal fetus in Figure 46.8.

Several reports have been demonstrating the value of STIC to the evaluation of the fetal heart with 3DUS.[20–24] Recently, Chaoui published a comprehensive prospective study in which he examined the potential of color Doppler STIC in the evaluation of normal and abnormal fetal hearts. He included 35 normal fetuses and 27 fetuses with congenital heart defects (CHD) examined between 18 and 35 weeks of gestation. Volume acquisition was achieved by initiating the image capture sequence from the transverse four-chamber view. Volumes were stored for later off-line evaluation using a personal computer-based workstation in a multiplanar mode and as spatial volume rendering. Successful acquisition was possible in all 62 cases. Spatial volume rendering was attempted in 18 fetuses with CHD. Four normal fetuses had inadequate visualization using color Doppler STIC, as the region of interest was perpendicular to the ultrasound beam. In two fetuses with CHD, inadequate visualization was related to an enlarged heart in late gestation, in which the entire cardiac volume could not be acquired. The third case was an 18-week fetus with complex CHD and transposed great vessels in which artifacts were related to confluent color signals as a result of low resolution in the reconstructed plane. He concluded that STIC in combination with color Doppler ultrasound is a promising new tool for multiplanar rendering of the fetal heart.[24]

While the potential of this technique is clear, there are a number of potential pitfalls that are worth mentioning. The acquisition is still relatively slow, from 7.5 to 15 s and as such fetal breathing and gross body

Figure 46.10 A 3D volume of the fetal heart and vessels of a normal fetus at 22 weeks rendered with minimum intensity projection. This is a unique and very helpful view that visualizes the vessels in gray scale without any color or power Doppler information. This rendering parameter can be employed in all acquisition modes (3D, 4D and STIC) and can be a useful addition to the information provided by the 3D color or power Doppler.

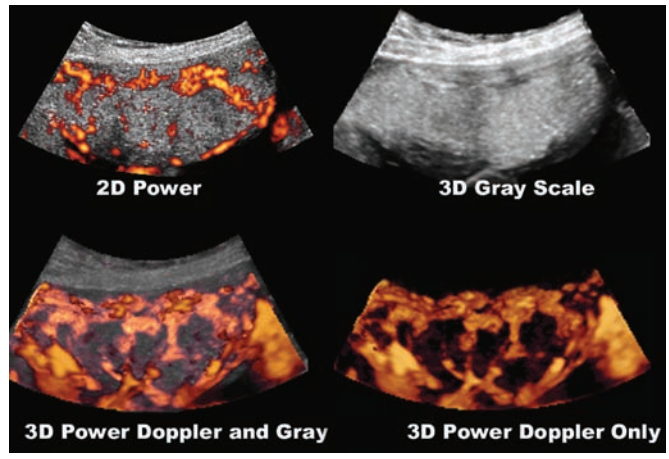

Figure 46.12 A composite image of four different image displays of the placenta. In 2D power Doppler view in the upper right we see scattered power Doppler signal in a thin 2D ultrasound slice. In 3D gray scale we see a rendered view through the placenta in gray scale. In 3D power Doppler and gray scale we see the great depth perception and detail of placental vasculature provided by 3D power Doppler in a 3D volume. In 3D power Doppler only we can see more clearly the vascular anatomy of the placenta without the gray scale superimposed on it.

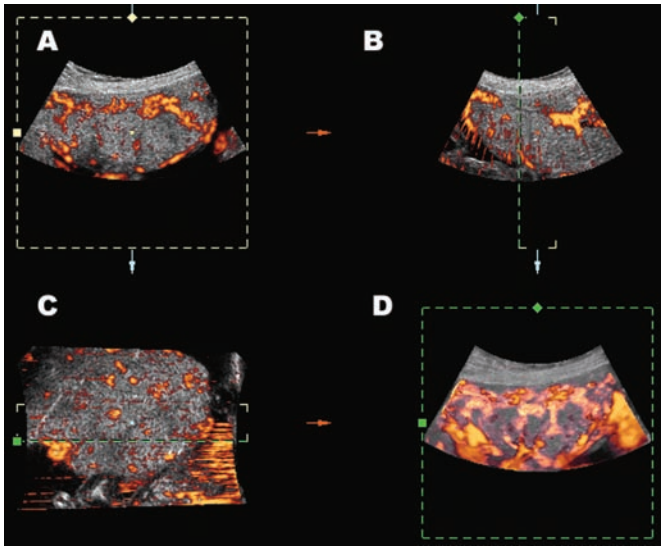

Figure 46.11 Multiplanar and rendered display of a placental volume acquired with 3D color Doppler at 20 weeks' gestation: (A) the acquisition plane, in this case along the long axis of the placenta; (B) the short axis; (C) the coronal view and (D) the 3D color Doppler and gray-scale rendered view of the placenta. Note that the rendered view represents a rather thin slice through the placenta and not the whole placental volume. The thickness of this particular volume can be judged and appreciated at (B), where you can see the green interrupted lines.

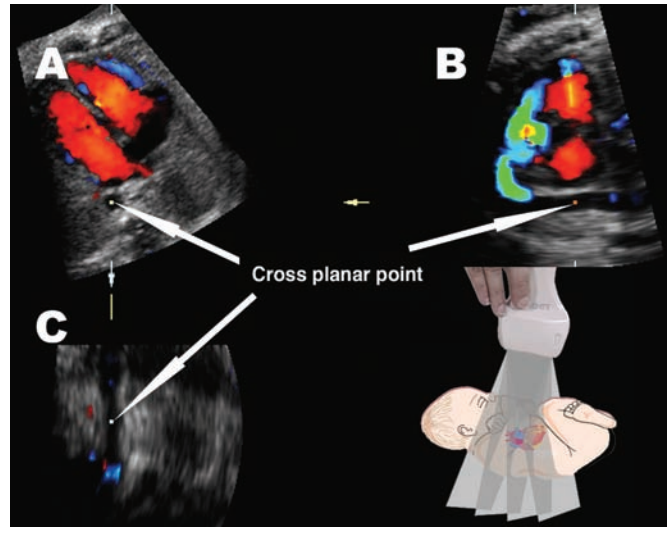

Figure 46.13 A composite image of a multiplanar view of the fetal heart acquired with 3D STIC color Doppler at the four-chamber view level. In the lower left, there is a diagram illustrating the acquisition of a fetal heart volume with a dedicated volume transducer where the transducer is kept stationary and the mechanically steered transducer elements sweep through the volume of the heart at a predetermined angle and speed. After the acquisition of the volume, the cross-planar center point is placed at the descending aorta in plane (A) and oriented at the 6 o'clock position. This rotation will ensure that we can obtain the ductal arch at (B) and the descending aorta in (C). A STIC volume with color Doppler depicts in red the atrioventricular flow (A) and in blue the outflow tracts (B).

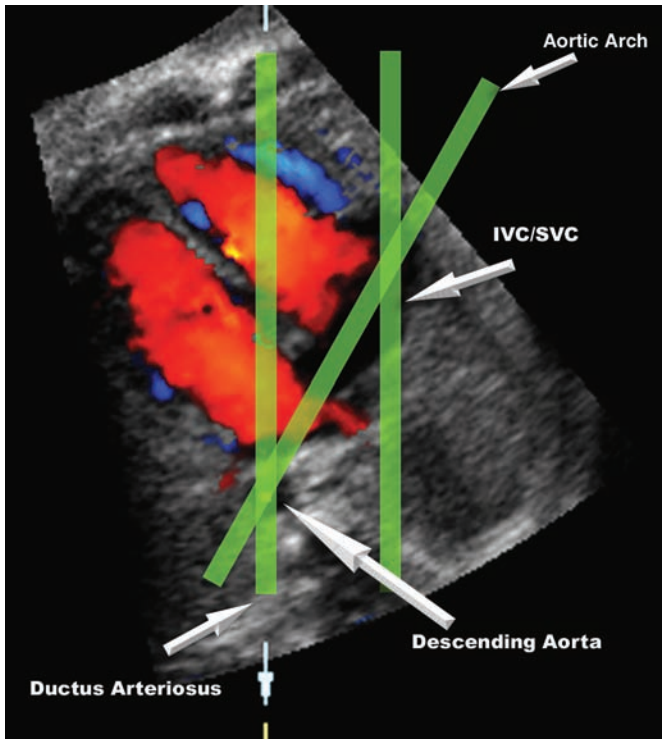

Figure 46.14 This image shows the four-chamber view image with color Doppler extracted from a STIC 3D color Doppler volume. The green lines represent the scan planes where the additional views of the heart, such as IVC/superior vena cava (SVC) or aortic arch, can be obtained. The vertical axis of the display can be aligned with these scan planes by rotating the image plane and simultaneously maintaining the descending aorta as the pivot point by placing the cross-planar point in it. Typically, the ductus arteriosus plane is the plane that goes through the descending aorta (placed at 6 o'clock) upward, intersecting the left atrium, right ventricle and sternum. The IVC/SVC plane is a plane parallel to the plane of the ductus arteriosus and to the right of it close to the level of the right atrium. The aortic arch is a plane that can be found by rotating the four-chamber view plane around 35–40° from the ductus arteriosus plane and maintaining the descending aorta as the pivot point by keeping the cross-planar point there.

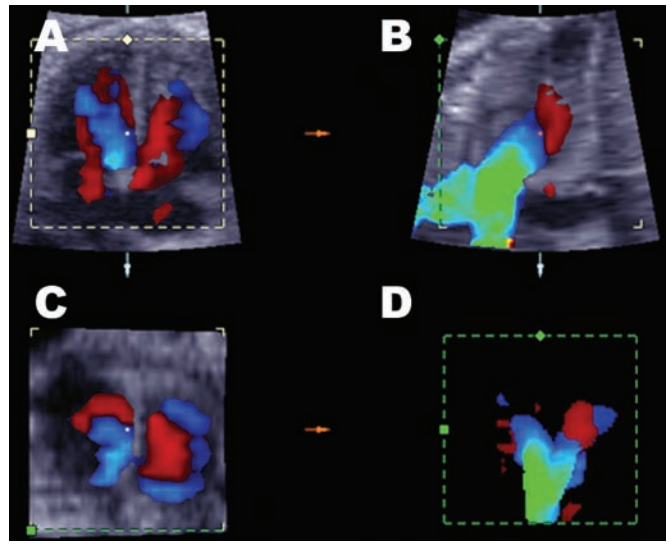

Figure 46.15 This image is a multiplanar and rendered view of a fetal heart volume obtained with STIC and color Doppler at the level of the four-chamber view in a patient with transposition of the great arteries. In (A) the heart is seen at the level of the four-chamber view and the atrio-ventricular flow is seen in red. In (B) we see a plane through the fetal heart that is perpendicular to (A) that shows a cross section of the outflow tracts in blue. In (C) we see a cross-sectional view of the heart right under the atrio-ventricular valves. In (D) there is a rendered view of the outflow tracts (in blue color). Note the fact that the outflow tracts do not crisscross as normally expected to, but they exit the ventricle in a parallel fashion indicative of a d-transposition of the great vessels.

movement do commonly occur. Careful evaluation of the windows B and C in the multiplanar display after the acquisition is crucial to ensure that no artifacts are present. Adjusting the volume box tightly around the region of interest helps, as it generally increases the frame rate. The best frame rates recommended are the ones above 15 Hz, typically with higher rates in smaller hearts and slower rates in bigger hearts. An important adjustment is the acquisition angle, as the default settings tend to be very narrow. Optimal angles vary from 15° to 30° and are related to the gestational age. The earlier the gestational age the narrower the angle.

Networking

A potential benefit of 3DUS lies in ultrasound documentation, storage and networking. Digitally saved volumes of patient data can be readily transferred to a remote site for interpretation or second opinion consultation. Further research is needed to define the indications, the potential advantages and limitations of volume data transfer across networks, but it is clear that this is a better method for sharing ultrasound information as one does not have to rely only on still 2D images or videotapes, but has the whole anatomy, which can be manipulated at any plane. Using this technology, one would expect that in the future, primary clinical sites in remote areas would have access to expert consultation and off-line interpretation, enabling high-quality and cost-effective medical care. The digitally stored patient volumes can be accessed and analyzed by physicians and sonographers in facilitating training in ultrasound. As this information is digital, it can be encrypted for patient data safety considerations, and efficiently compressed with loss-less algorithms to be shared across hospital networks.

Summary

It is important to emphasize that 3DUS color and power Doppler information is based on acquisition and reformatting of conventional 2DUS data. Therefore, it is not surprising that 3DUS is prone to

the same problems that affect 2DUS, such as unfavorable body habitus, motion and shadowing artifacts and poor scanning technique. Although 3DUS with color and power Doppler may improve the overall comprehension of the vascular anatomy, it does not make up for poor scanning technique. Poor resolution in 2DUS will very likely result in suboptimal image quality in the volume data as well. Imaging the vessels in perpendicular planes with the beam will also result in poor imaging as the best results are achieved with parallel vessel orientation to the ultrasound beam. The resolution of the three perpendicular planes in the multiplanar display varies according to their deviation from the plane during acquisition. Typically, the coronal reconstructed plane, which is unique to 3DUS, has the lowest resolution of the three planes in the multiplanar display. There definitely is a learning curve associated with the adequate use of this technology. Professionals contemplating the introduction of this modality into their practices should consider dedicating time and effort for additional training in its principles. As this technology improves and becomes more widely available, clinical indications for its use will continue to emerge. There is a great need for comprehensive and rigorous research studies that would hopefully standardize optimal acquisition and analysis of 3D color and power Doppler studies for specific fetal indications.

47 Non-invasive detection of fetal anemia by Doppler ultrasonography

L. Pereira

Introduction

Cases of hemolytic disease of the newborn were described as early as 1609 in France;[1] however, it was not until 1932, over 300 years later, that the association of erythroblastosis with fetal hydrops, jaundice and hemolytic anemia was characterized by Diamond *et al.*[2] Shortly thereafter, the discovery of the Rhesus (Rh) blood group by Landsteiner and Weiner in 1940, and their demonstration of agglutination when rhesus monkey red blood cell antiserum was mixed with Rh-positive, but not Rh-negative blood, stands as one of the most important hematologic discoveries of the 20th century.[3] From this landmark achievement, treatment of hemolytic disease of the newborn with transfusion therapy and ultimately prevention of Rh sensitization with anti-D immune globulin became possible. However, despite the availability of postnatal transfusion therapy, the medical practice of this era was limited by an inability to screen for hemolytic disease antenatally.

The discovery that Rh sensitization could be quantified by assessing the spectral absorption curve of amniotic fluid at 450 nm (ΔOD_{450}) was first described by Bevis and Walker and then further characterized by Liley in 1961.[4–6] From this important observation, successful antenatal management strategies were developed for Rh alloimmunized patients and for those alloimmunized with non-Rh antigens as well.

Years of experience have taught us that amniocentesis ΔOD_{450} assessment is a reliable predictor of fetal anemia in most cases of alloimmunization. However, because amniocentesis ΔOD_{450} assessment is limited to hemolytic causes of fetal anemia and because it has the potential to cause fetal–maternal hemorrhage and worsen sensitization, active research for nearly 30 years has focused on attempts to detect fetal anemia non-invasively.

Ultrasonographic evaluation of fetal anemia

Serial ultrasound evaluations for fetal hydrops in cases of suspected anemia have become a routine component of perinatal medicine. The observation of hydrops on ultrasound is highly specific for severe anemia, with most hydropic fetuses having hemoglobin levels that are less than 5 g dl^{-1}. The finding of fetal hydrops in cases of suspected anemia should lead directly to therapeutic interventions aimed at restoring blood volume. However, basing treatment on the presence of hydrops alone may miss over 50% of fetuses with hemoglobin concentrations below 6.0 g dl^{-1}.[7]

Partly because of this shortcoming, many investigators have attempted to detect fetal anemia prior to the onset of hydrops. Rightmire *et al.* published one of the first successful endeavors at non-invasive diagnosis of fetal anemia in non-hydropic fetuses in 1986. The authors developed a model of combined Doppler measurements of the fetal aorta, inferior vena cava, and umbilical vein, which was able to predict fetal anemia with a mean error of only 3.8 hematocrit units in a retrospective study.[8] Nicolaides *et al.* prospectively measured six different ultrasonographic parameters, including umbilical vein diameter and placental thickness, but concluded that in the absence of hydrops, none of these successfully distinguished mild from severe fetal anemia.[9] This observation was confirmed by Whitecar *et al.* who reported on a variety of parameters including amniotic fluid volume, intrahepatic and extrahepatic umbilical vein diameters, hepatic length, and splenic perimeter.[10] Most of these parameters have proven unreliable clinically. Attempts to accurately predict fetal anemia by measurement of the mean blood velocity in the fetal aorta have likewise not been clinically applicable.[11]

Measurement of peak systolic velocity as opposed to mean blood velocity seems to have improved the

clinical utility of Doppler velocimetry. One author has reported on the utility of measuring peak systolic velocity in the splenic artery for the detection of fetal anemia in cases of Rh factor alloimmunization[12] and no fewer than seven prospective studies have reported on the reliability of peak systolic velocity measurements in the middle cerebral artery for detection of fetal anemia in pregnancies complicated by red cell alloimmunization (including Kell sensitization) and parvovirus B19 infection.[13–19]

Evidence supporting middle cerebral artery peak systolic velocity measurements for fetal anemia

In 1995, Mari *et al.* reported that middle cerebral artery peak systolic velocity Doppler measurements could accurately predict fetal anemia in a prospective series of 16 pregnancies complicated by maternal red cell alloimmunization.[13] This report was followed in 2000 by a larger multicentered study in which 111 fetuses at risk for anemia were followed prospectively.[15] In this cohort, 23 fetuses had moderate to severe anemia without hydrops and in all 23, middle cerebral artery peak systolic velocities were above 1.5 multiples of the median (MoM). In this study, 83 women were RhD alloimmunized, 18 were Kell sensitized, and another 9 were alloimmunized to non-RhD antigens. The authors also published reference tables for fetal hemoglobin levels and middle cerebral artery peak systolic velocities, which have served as the basis for further research studies and are useful reference guides for current clinical management (Tables 47.1 and 47.2).

In 2000, Teixeira *et al.* published results from a prospective cohort study of 26 fetuses (24 cases of RhD and 2 cases of RhC alloimmunization), and using a peak systolic velocity above 1 standard deviation (SD), reported a sensitivity of 73% and specificity of 93% for fetal hematocrit values below 3 SD.[14] A large prospective, intent to treat trial of 125 cases of red cell alloimmunization was published by Zimmermann *et al.* in 2002 and confirmed the findings of previous authors.[17] This trial reported that for the detection of moderate to severe fetal anemia, middle cerebral artery peak systolic velocities over 1.5 MoM had a sensitivity of 88% and specificity of 87%.

Further studies have provided evidence that middle cerebral artery peak systolic velocity Doppler can be used to estimate actual hemoglobin concentrations[18] and to predict the timing of a second *in utero* blood transfusion.[20]

In addition to cases of red cell alloimmunization, two studies have found that, in a total of 42 cases of parvovirus B19 infection, middle cerebral artery peak systolic velocity assessment could detect fetal anemia with sensitivity between 94% and 100% and specificity between 93% and 100%.[16,19]

Table 47.1 Middle cerebral artery peak systolic velocity (MCA-PSV) as a function of gestational age (from Mari *et al.*[15])

Weeks of gestation	MCA-PSV (cm s^{-1}) (multiples of the median)			
	1.00	1.29	1.50	1.55
18	23.2	29.9	34.8	36.6
20	25.5	32.8	38.2	39.5
22	27.9	36.0	41.9	43.3
24	30.7	39.5	46.0	47.5
26	33.6	43.3	50.4	52.1
28	36.9	47.6	55.4	57.2
30	40.5	52.2	60.7	62.8
32	44.4	57.3	66.6	68.9
34	48.7	62.9	73.1	75.6
36	53.5	69.0	80.2	82.9
38	58.7	75.7	88.0	91.0
40	64.4	83.0	96.6	99.8

Table 47.2 Fetal hemoglobin (Hgb) as a function of gestational age(from Mari *et al.*[15])

Weeks of gestation	Fetal Hgb (g dl^{-1}) (multiples of the median)				
	1.16	1.00	0.84	0.65	0.55
18	12.3	10.6	8.9	6.9	5.8
20	12.9	11.1	9.3	7.2	6.1
22	13.4	11.6	9.7	7.5	6.4

38	15.8	13.6	11.4	8.9	7.5
40	16.0	13.8	11.6	9.0	7.6

Technique for measuring the middle cerebral artery peak systolic velocity

Measurement of peak systolic velocity in the middle cerebral artery should be technically straightforward in most cases. Obtain an axial view of the fetal

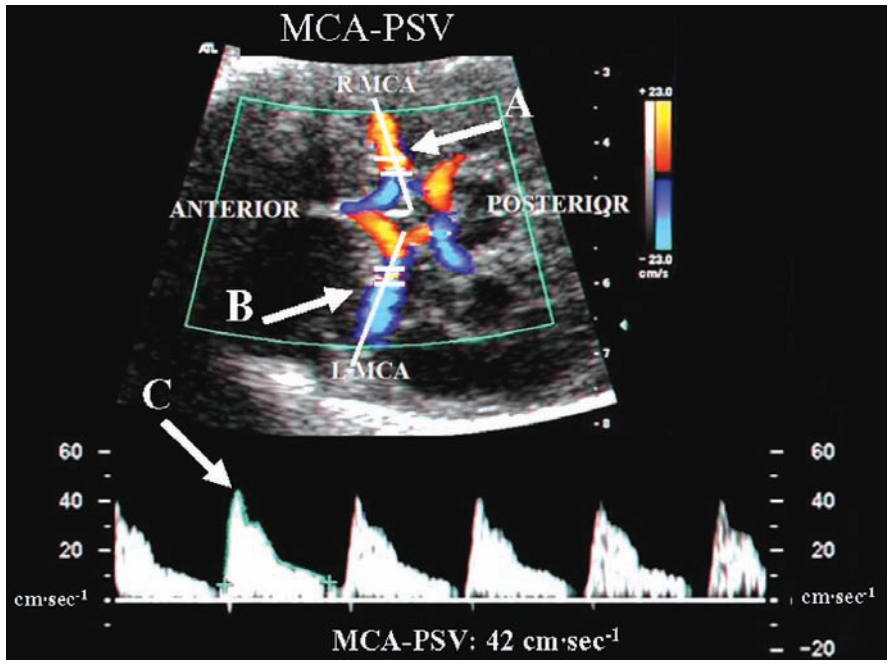

Figure 47.1 Doppler assessment of the fetal MCA. (A) Correct position of Doppler cursor over anterior MCA. (B) Correct position of Doppler cursor over posterior MCA. (C) Correct measurement of the PSV. MCA, middle cerebral artery; PSV, peak systolic velocity.

calvarium, as if one were measuring the biparietal diameter. Center and magnify the image until the fetal calvarium fills the image window. Following identification of midbrain structures, including the thalami and cavum septum pellucidum, move the transducer in a slight caudal direction and identify the circle of Willis using color Doppler. The bilateral middle cerebral arteries should then be visualized flowing anteriorly and outward just behind the orbits. The sample volume line should be parallel to the walls of the vessel, as close to a 0 angle of insonation as possible (Figure 47.1). Either the ipsilateral or the contralateral middle cerebral artery can be measured, but angle correction should not be used. The peak systolic velocity should be measured in the proximal middle cerebral artery, 2 mm after its origin from the internal carotid artery. Placement of the sample volume line in the proximal MCA is crucial since systolic velocity decreases with distance from the point of origin of the MCA.[15,21]

The sample volume should be made relatively small so that the Doppler signal does not incorporate the internal carotid artery. The peak systolic velocity should be measured at the highest point of the Doppler waveform. The measurement should be repeated several times during periods of fetal apnea, while the fetus is relatively stationary. The highest Doppler measurement obtained should be recorded. With this procedure, multiple sources have previously reported low intraobserver and interobserver variability rates between 2.3% and 4.0%.[13,21,22]

Management with middle cerebral artery peak systolic velocity compared to conventional management with amniocentesis ΔOD_{450}

Based on the results of the previously mentioned studies,[13–19] clinical reliance upon serial middle cerebral artery peak systolic velocity Dopplers is becoming more common. However, few studies have compared Doppler velocimetry to conventional management with amniocentesis. At the time of publication of this chapter, only two published trials had compared the two management strategies.

The first study, published by Nishie *et al.* followed 28 non-hydropic fetuses and found that conventional management and middle cerebral artery peak systolic velocity Doppler were both accurate predictors of fetal anemia in cases of red cell alloimmunization.[23] The authors suggested in their conclusion that management with middle cerebral artery peak systolic velocity Doppler could decrease the number of invasive procedures performed in their population.

A second study, by Pereira *et al.*, also reported outcomes on 28 cases of red cell alloimmunization followed by both middle cerebral artery peak systolic velocity Doppler and conventional management with amniocentesis.[24] In this study, management by middle cerebral artery peak systolic velocity Doppler

compared favorably to conventional management, with a sensitivity of 91% and a specificity of 100% for moderate to severe fetal anemia. The authors concluded that compared to conventional management, management by middle cerebral artery peak systolic velocity Doppler may have a better predictive value for moderate to severe anemia in red cell alloimmunization, eliminate the need for amniocentesis, and reduce the number of percutaneous umbilical cord blood samplings (PUBS) performed on non-anemic fetuses.

The main benefit of management with middle cerebral artery peak systolic velocity Doppler is a reduction in invasive procedures and avoidance of potential complications. Transplacental fetal hemorrhage, which may worsen sensitization, occurs following 2–11% of amniocenteses.[25–27] Another 1–2% of amniocenteses are complicated by rupture of amniotic membranes, premature labor, vaginal bleeding, or infection, while fetal loss occurs in approximately 0.5% of cases.[28] Complications associated with PUBS are even more common, with at least 50% of procedures complicated by umbilical cord vessel bleeding and a procedure-related loss rate of 2–3%.[29]

In the USA, there are approximately 14,000 cases of alloimmunization annually.

Extrapolating from published trends, management with middle cerebral artery peak systolic velocity Doppler could avoid 24,500 amniocenteses and over 1500 PUBS per year in the US population.[24] With a complication rate of 0.5% for amniocentesis and a conservative estimate of 2% for PUBS, one pregnancy loss or preterm delivery per 100 patients (over 140 annually) could be avoided by using middle cerebral artery peak systolic velocity Doppler over conventional management – and these would likely occur in mildly anemic or non-anemic fetuses. Furthermore, an additional benefit would occur from avoiding procedure-related bleeding complications that increase sensitization and worsen disease.

Limitations of middle cerebral artery peak systolic velocity

Management of suspected fetal anemia by middle cerebral artery peak systolic velocity Doppler has limitations. The accuracy of middle cerebral artery peak systolic velocity Doppler appears to diminish after 35 weeks' gestation, leading to higher false-positive rates for prediction of anemia.[17,30] Furthermore, multiple intrauterine transfusions increase fetal blood viscosity, which may alter the predictive accuracy of middle cerebral artery peak systolic velocity Doppler.[20,31] The reliability of middle cerebral artery peak systolic velocity Doppler in predicting fetal anemia after three or more transfusions has not been tested prospectively, and false-negative cases have been reported.[17,20] At present, serial amniocenteses for ΔOD_{450} assessment should be considered in fetuses greater than 35 weeks' gestation and in those who have received three or more *in utero* transfusions. The use of amniocentesis after 35 weeks' gestation also allows for concomittant fetal lung maturity testing, which can impact the timing of delivery.

The predictive accuracy of middle cerebral artery peak systolic velocity Doppler in fetuses with compromised left-sided cardiac output from structural heart disease has not yet been established. Anomalies such as mitral stenosis or hypoplastic left heart syndrome that compromise left ventricular cardiac output may result in decreased middle cerebral artery peak systolic velocities. Amniocentesis ΔOD_{450} measurements should not be affected by the presence of congenital heart disease and may be superior to Doppler in this setting.

Another limitation of middle cerebral artery peak systolic velocity Doppler occurs in the setting of fetal hydrops. The middle cerebral artery peak systolic velocity in hydropic fetuses may be diminished by compromised cardiac output. In these cases, the fetus may not be able to maintain adequate cardiac output, resulting in a lower middle cerebral artery peak systolic velocity than would be expected for the degree of anemia. False-negative middle cerebral artery Dopplers have been previously reported in hydropic fetuses with severe anemia.[17,32]

Potential pitfalls in measuring middle cerebral artery peak systolic velocity

Serial middle cerebral artery peak systolic velocity Doppler measurements must be conducted in strict adherence with proper technique as previously discussed to maintain diagnostic accuracy. Measurements taken in the distal middle cerebral artery or with an angle of insonation above 20° may underestimate the peak systolic velocity and decrease sensitivity.

Intermittent vascular constriction of the middle cerebral artery can occur and may explain several reported cases where an elevated middle cerebral artery peak systolic velocity measurement has not been reproducible.[17,19]

Multiple factors influence fetal cerebral hemodynamics and can influence middle cerebral artery Doppler studies. Variations in fetal heart rate, both bradycardia[33,34] and tachycardia,[35] alter flow through the middle cerebral artery. Fetal behavioral state and activity level also result in dynamic changes in middle cerebral artery perfusion.[36] For these reasons, the middle cerebral artery peak systolic velocity should be measured during periods of fetal apnea and when fetal activity is minimal.

Alterations in middle cerebral artery Doppler waveforms should be anticipated during active labor and in fetuses with severe intrauterine growth restriction (IUGR). The reliability of middle cerebral artery peak systolic velocity in detecting anemia during active labor has not been established, and Yagel *et al.* reported a 40% reduction in middle cerebral artery

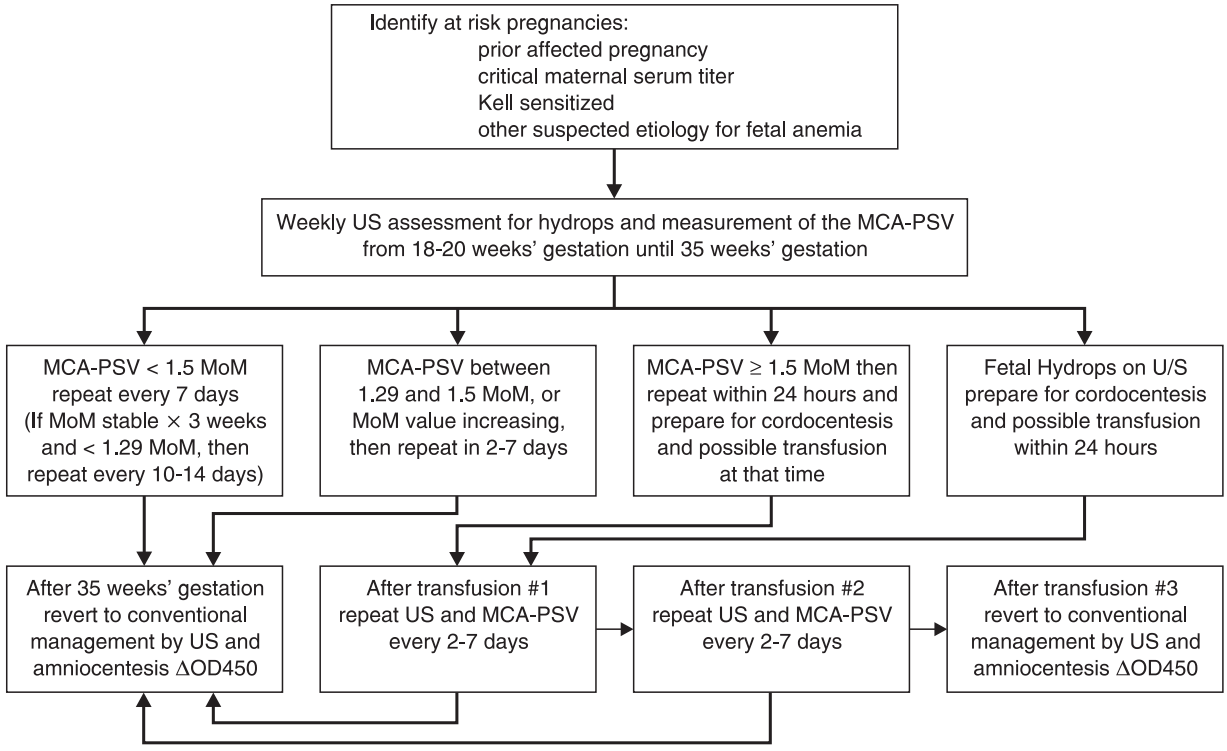

Figure 47.2 Antenatal surveillance for fetal anemia using MCA-PSV. MCA, middle cerebral artery; PSV, peak systolic velocity; US, ultrasound; MoM, multiples of the median.

blood flow impedence during labor.[37] Fetuses with severe IUGR display similar reductions in cerebral blood flow impedence independent of hematocrit.[38,39] This is likely due to 'brain-sparing', which has been characterized by a decrease in the middle cerebral artery pulsatility index as a cephalization of blood flow in response to fetal hypoxemia.[39–41]

Algorithm for fetal surveillance using middle cerebral artery peak systolic velocity

For clinical purposes, a sample algorithm for management of suspected fetal anemia using middle cerebral artery Doppler velocimetry is shown in Figure 47.2 and can be summarized as follows:

Identify pregnancies at risk for fetal anemia such as patients with prior affected pregnancies, antibody titers that have reached a critical threshold level, anti-Kell antibodies, congenital parvovirus, suspected fetomaternal hemorrhage (e.g. strongly positive Kleihauer–Betke test or unexplained elevated maternal serum alpha-fetoprotein level). Beginning at 18–20 weeks of gestation, perform weekly sonograms to measure the middle cerebral artery peak systolic velocity and evaluate for evidence of fetal hydrops. If the middle cerebral artery peak systolic velocity is less than 1.5 MoM, then repeat it weekly for the next 3 weeks. If over that time, the middle cerebral artery peak systolic velocity remains stable and is under 1.29 MoM, then it is probably safe to follow the middle cerebral artery peak systolic velocities every 10–14 days.

If serial middle cerebral artery peak systolic velocities remain between 1.29 and 1.5 MoM or are increasing in MoM values, then repeat the middle cerebral artery peak systolic velocity measurement in 7 days or less. If at any time the middle cerebral artery peak systolic velocity is $\geq$1.5 MoM, then plan to repeat the measurement in 12–18 h and plan for a cordocentesis with preparations for a possible *in utero* transfusion at that time.

If there is a sonographic evidence of fetal hydrops, then plan for a cordocentesis and transfusion even if the middle cerebral artery peak systolic velocity is $<$ 1.5 MoM.

Continue to follow at-risk fetuses as outlined above until the fetus reaches 35 weeks of gestation or has received three or more *in utero* transfusions, then revert back to conventional management by amniocentesis ΔOD_{450} measurements.

Areas for future research with middle cerebral artery peak systolic velocity

Areas for future research include studies to determine how well middle cerebral artery Dopplers predict anemia in fetuses with genetic syndromes

(thrombocytopenia-absent radius, Fanconi syndrome), hemoglobinopathies (alpha-thalassemia), or viral infections that can cause a myocarditis as well as an anemia. There have been case reports of fetuses with hydrops due to parvovirus B19 that were not anemic at the time of umbilical cord sampling and recovered without transfusion.[42,43] In these cases, hydrops may be due to myocarditis caused by the tropism of parvovirus B19 for myocardial cells. Perhaps in these cases, middle cerebral artery peak systolic velocity will prove a valuable modality for avoiding an unnecessary cordocentesis.

The possibility of measuring middle cerebral artery peak systolic velocity Dopplers in fetuses with platelet or neutrophil disorders, such as neonatal alloimmune thrombocytopenia, should be explored remembering that the basis for elevated middle cerebral artery peak systolic velocities is not actual hematocrit but decreased blood viscosity.

Suspected fetal hemorrhage

Acute or chronic fetomaternal hemorrhage may lead to anemia, hydrops, and intrauterine death. In suspected cases, the diagnosis of fetomaternal hemorrhage is typically made by demonstration of fetal erythrocytes in maternal circulation by Kleihauer–Betke acid-elution stain. Measurement of the maternal serum alpha-fetoprotein level may also be useful in cases of suspected fetomaternal hemorrhage.

As in cases of red blood cell alloimmunization, the appearance of hydrops in the setting of fetomaternal hemorrhage remote from term should generally be treated with intrauterine transfusion as these fetuses are at risk for *in utero* demise.[44–46] Based on limited data, it appears that middle cerebral artery peak systolic velocities may be useful for detection of fetal anemia in these cases. Baschat *et al.*, in 1998, reported a case of acute fetomaternal hemorrhage in which the middle cerebral peak systolic velocity was elevated at presentation (hematocrit < 11%) and then normalized after *in utero* transfusion (hematocrit 27%).[47]

Some authors have reported that intraplacental Dopplers may be useful in predicting adverse pregnancy outcomes (IUGR, pre-eclampsia) in cases of fetomaternal hemorrhage. In 1996, Jaffe and Woods reported results from 32 patients followed due to abnormal first-trimester Doppler studies. In these patients, an abnormal ratio of intraplacental resistive index (RI) to umbilical artery RI (defined as > 1) between 22 and 25 weeks' gestation was associated with adverse pregnancy outcomes in 17/21 women compared to 2/11 controls.[48] A second study in 1997 by Haberman and Friedman compared intraplacental pulsatility index (PI) to umbilical artery PI and reported a higher rate of IUGR and pre-eclampsia when the intraplacental PI to umbilical artery PI ratio was over 1.[49]

In rare cases, fetal anemia may be due to fetal intracranial hemorrhage, usually subdural hematomas.[50,51] Coagulation deficiencies such as neonatal alloimmune thrombocytopenia should be suspected when a fetal intracranial hemorrhage is identified in the absence of antecedent trauma.[52] The reliability of middle cerebral artery Doppler assessment in the setting of intracranial hemorrhage has not been established at this time.

Summary

The clinical management of fetuses at risk for anemia is currently evolving. Based on the results of several prospective trials, the accuracy of middle cerebral artery peak systolic velocity Doppler has been established for the prediction of fetal anemia in cases of red cell alloimmunization. Limited evidence seems to support its accuracy in cases of parvovirus B19 infection as well. When conducted in strict adherence with proper technique, the reliability and accuracy of middle cerebral artery peak systolic velocity Doppler is high, and intraobserver variability uniformly low. In the near future, evidence may support the application of middle cerebral artery peak systolic velocity Doppler to a broad spectrum of conditions that may cause fetal anemia. At the present time, however, reliance solely on middle cerebral artery peak systolic velocity Doppler should be limited to cases where its accuracy has been established and normal left ventricular cardiac output preserved. In cases where the accuracy of middle cerebral artery peak systolic velocity Doppler has not been established, and in centers in which middle cerebral artery peak systolic velocity Dopplers are not performed regularly, simultaneous management by conventional amniocentesis ΔOD_{450} measurements should probably be continued. Exciting research in the field of Doppler velocimetry is ongoing, and in the near future further advances in our ability to detect fetal anemia non-invasively are certain to emerge.

48 Doppler ultrasound studies of the fetal pulmonary circulation

D. C. Wood Jr. and J. P. Räsänen

The fetal lungs may be quickly evaluated for size and function by observation using real-time ultrasound: there should be adequate amniotic fluid but there should be no thoracic fluid spaces, cysts or echo dense areas. The size of the lungs should occupy about 2/3 the area of the thoracic cavity in a transverse plane at the level of the four-chamber view of the heart. The heart should have a normal 45° axis from the sternal/spine axis in the levocardia position and occupy the other third of the chest cavity. The pulmonary outflow tract should emerge from the heart aiming toward the left shoulder and cross anteriorly over the aortic outflow tract that aims toward the right shoulder. While these observations of normality in the first half of the second trimester will typically rule out most forms of congenital heart disease, pulmonary obstructions and anomalous venous connections will typically be missed at anatomic fetal ultrasound. In the second half of pregnancy, diaphragmatic fetal breathing movements may reassure the observer of normal physiologic growth of the lungs, but this does not rule out lethal pulmonary hypoplasia. However, changes in lung size and heart position may be signs of potential neonatal pulmonary hypoplasia and hypertension problems (Figure 48.1).

The fetal pulmonary circulation consists of the pulmonary arteries, ductus arteriosus and pulmonary veins, all of which may be identified with ultrasound by 16 weeks' gestation. However, subtle differences in the circulation of the fetal lungs and the vascular connections to the heart require interrogations of the venous and arterial Doppler color and spectral flow patterns. These investigations may be both difficult and time consuming because of fetal lie and movement, maternal habitus and the presence of fetal breathing and may require an advanced ultrasound system. It is important to remember that normal appearing fetal lungs and normal cardiac situs can be seen with any major structural cardiac abnormality including pulmonary atresia and totally anomalous pulmonary venous connection.

Pulmonary angiogenesis

The cardiovascular system is the first organ developed in the embryonic period: primitive blood vessels are in place to accommodate the output of the heart, which begins to beat in the human fetus as early as 19 gestational days. Endothelial cells are the earliest specialized cells. They form endothelial tubes and recruit precursors to smooth muscle cells that form the arteries, arterioles, veins and venules. Proliferation, migration, matrix production and contractile protein

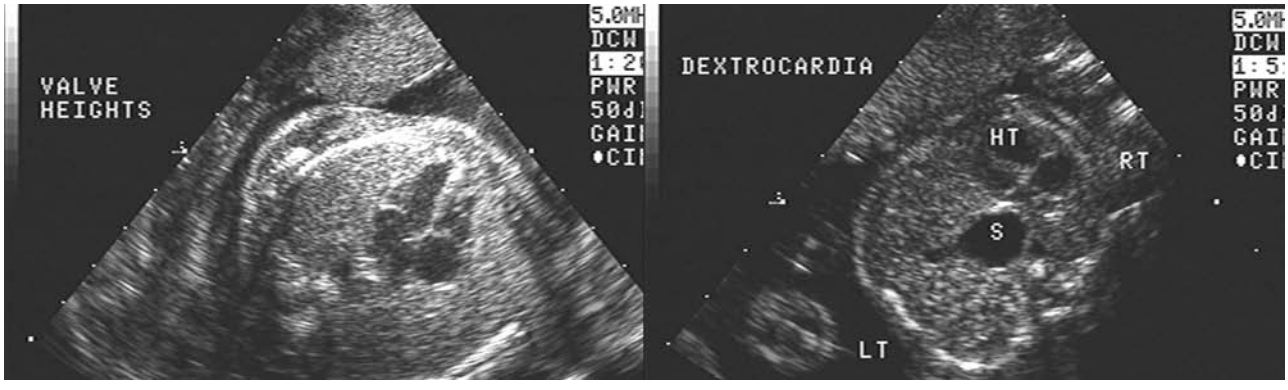

Figure 48.1 Four-chamber heart in the transverse thorax view with normal size lungs and diaphragmatic hernia with small lungs.

expression characterize early circulatory development.[1] Vasculogenesis within the primitive lungs may be considered to be of constant capillary production, fusion and regression. During the embryonic period, the lung appears as a ventral diverticulum of the foregut that becomes separated in a caudo-cranial direction from the future esophagus by the laryngyotracheal grooves. By day 26, that developing bud divides and grows into the surrounding mesenchyme into right and left lungs.[2] Blood is pumped from the heart into the common truncus arteriosus which divides into paired right and left branches which connect to the dorsal aorta via various arches, most of which will regress and disappear. The sixth or most proximal arch connection to the distal aorta is maintained throughout fetal life, typically on the left side, as the ductus arteriosus. The sixth arch vessel gives rise to the main branches of the pulmonary arteries, and, with the helical division of the truncus and muscular division of the conotruncus, becomes the main pulmonary artery, the anterior vessel originating from the right ventricular outflow tract. At the same time, a bud develops from the dorsal surface of the sinoatrial part of the heart, which divides and connects with the pulmonary plexus. As the atria expand, this single pulmonary vein is carried into the right atrium but eventually becomes absorbed into the left atrium as four separate ostia. Therefore, the pulmonary veins actually drain into the systemic venous system until about day 30, when they become the proximal pulmonary veins of the left atrium. In anomalous migratory patterns, the pulmonary veins can continue with their connection as a common venous sack, draining to the ascending vein of Marshall to the innominate vein to the superior vena cava, to a connection below the diaphragm to the hepatic veins, or continue in part or completely attached to the right atrium or the vena caval connections to the right atrium.

Pulmonary development in the postembryonic fetus has been studied extensively in various animal models and has generally divided into three overlapping morphological stages: the pseudoglandular lung, the canalicular lung and the sacular stage of the viable lung.[3] Development of the human pulmonary vasculature is closely timed to cardiac development. In the human embryo at 5 weeks, it has been shown that the upper poles of the right and left lungs are supplied by primitive pulmonary arteries, which arise from the sixth aortic arch between the pulmonary trunk and the dorsal aorta. The lower poles are supplied from the dorsal aorta via intersegmental arteries that penetrate through the diaphragm. Anomalous growth at this connection leads to pulmonary sequestration. As the branching bronchi develop, so do the aligned pulmonary veins and arteries.

During the early pseudoglandular period (5–17 weeks), the bronchial system has formed such that at each airway generation, there is an accompanying artery, in addition to supernumerary bronchial arteries which supply the major airways and pulmonary arteries.[4] The lung therefore possesses two vascular systems: a low pressure pulmonary system and a high pressure bronchial system. By the end of the pseudoglandular period, Kitaoka *et al.* counted 20 generations of airways with their accompanying arteries; the adult human lung averages 24 generations.[5] During this period, the growth in veins and arteries is enormous, not in total length or volume, but in the number of generations.

The canalicular stage (16–26 weeks) represents the development of the gas exchange tissues. During this period, pulmonary capillary expansion corresponds to epithelial cell differentiation that permits the formation of thin air–blood barriers and surfactant production. The tremendous growth of the capillary system into the lung parenchyma gives rise to the concept of 'canals' and gives the lungs a spongy appearance. Arteries and veins develop both in length and diameter as they follow the growth of the preacinar airways.

The saccular stage of lung development (24 weeks to birth) is demarcated by the expansion of the alveolar spaces. The interstitium between the airspaces contain the capillary system and the development of a network of elastic fibers where the postnatal interalveolar wall will be located. The arterial pathways increase in length and diameter. It has been shown that the diameter of the artery is a function of the distance from the previous branching such that the diameters are constant at a given distance from the end of the alveolar tree.[6] Arterial growth is faster centrally than in the periphery. Distally, the number of additional branches grows exponentially. The intrapulmonary veins begin to grow the circular muscular layer of mature vessels during the saccular period. The function of the lung tissue changes dramatically with birth but the structure is not radically altered (Figure 48.2).

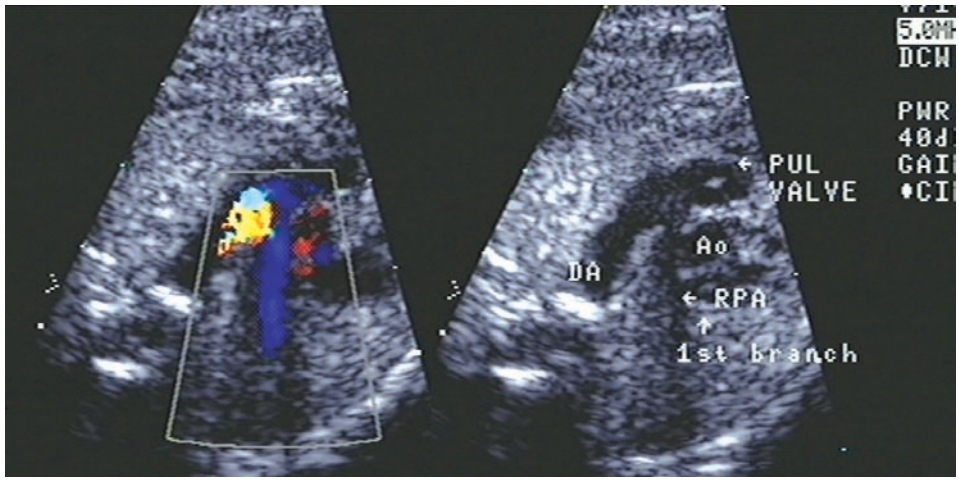

Figure 48.3 Site of pulmonary Doppler imaging.

Pulmonary vascular resistance (impedance)

Fetal pulmonary arterial vascular impedance decreases significantly during the second half of pregnancy. The linear decrease in the vascular impedance during the second trimester and in the beginning of the third trimester may be related to the growth of the lung and to the increase in the number of resistance vessels. During the latter part of the third trimester pulmonary vascular impedance does not decrease further. In a cross-sectional study of 100 uncomplicated singleton pregnancies we evaluated human fetal pulmonary blood flow by Doppler techniques to analyze the relationships between proximal and distal pulmonary arterial blood velocity waveforms and to determine normal pulmonary arterial vascular impedance and physiologic parameters in proximal and distal branch pulmonary arteries. We found that high resistance, high pressure and low blood flow characterize the fetal pulmonary circulation throughout pregnancy.[7]

Using color Doppler to identify and align the vessel in a position parallel to the pulsed Doppler beam, a narrow sample volume was placed into the proximal part of the branch pulmonary artery immediately after the bifurcation of the main pulmonary artery. Using color Doppler guidance in a high resolution magnification imaging mode, distal pulmonary arteries beyond the first bifurcation of the branch pulmonary artery were identified and waveforms were obtained during fetal apnea and in the absence of fetal body movements (Figure 48.3). Waveforms were also measured at the aortic and pulmonary valve levels and at the ductus arteriosus. Proximal left and right pulmonary artery diameters were measured from captured real-time images. In each fetus, a sagittal section right lung length was measured from the tip of the apex to the base of the lung on the dome of the diaphragm during fetal apnea, as described by Roberts and Mitchell.[8] Proximal right pulmonary artery Doppler measurements were obtained successfully in 98% of cases and proximal left pulmonary artery Doppler measurements in 96% of cases, respectively. In the distal pulmonary artery, success rate on the right side was 88% and on the left side 94%.

During the second half of pregnancy the pulsatility index (PI) values in both proximal and distal left and right pulmonary arteries decreased and the systolic peak velocities and time to peak velocity (TTP) intervals increased significantly. In the proximal branch pulmonary arteries, a near linear decrease in the PI values was detected until 34–35 weeks of gestation, while in the distal pulmonary arteries, after 31 weeks of gestation there was no significant decrease in the PI-value. Respectively, peak systolic velocities in the proximal branch pulmonary arteries increased in a linear fashion until 30 weeks of gestation and remained unchanged until term. Proximal and distal pulmonary arterial TTP-intervals were significantly shorter at 18–22 weeks of gestation and at term (36–40 weeks) than at the pulmonary valve. The TTP-interval at the ductus arteriosus was shown to be significantly longer than at the pulmonary or aortic valves. TTP-intervals at the aortic valve were significantly longer than at the pulmonary valve. In this study population, the fetal heart rate did not change significantly during the second half of pregnancy. There were no significant differences in PI values, peak systolic velocities, TTP-intervals or pulmonary artery diameters between right and left proximal and distal pulmonary arteries. Both proximal right and left pulmonary arterial diameters, as well as the right lung length, increased significantly during the second half of pregnancy, demonstrating a 2.5-fold increase in their respective measurements.

In the proximal pulmonary arteries the PI-values and peak systolic velocities were significantly higher

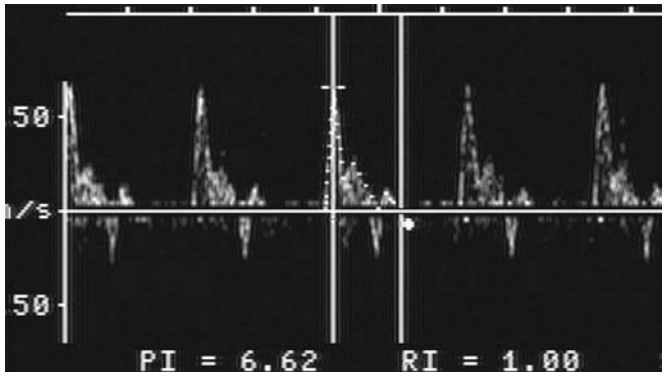

Figure 48.4 Distal pulmonary artery waveforms.

and TTP-intervals were significantly longer when compared with the distal pulmonary arteries. The ratio between the peak systolic velocities in proximal and distal pulmonary arteries decreased significantly with advancing gestational age. However, the ratio between the proximal and distal branch pulmonary artery PI values did not vary significantly during the study period. This study demonstrated that ultrasound techniques may be used to evaluate human fetal pulmonary circulation as early as 18 weeks of gestation.

The shape of the proximal branch pulmonary arterial Doppler velocity waveform profile is unique in the fetal circulation (Figure 48.4). It is characterized by rapid initial flow acceleration followed by a very early and rapid deceleration phase, producing a needle-like systolic peak followed by a short, but relatively stable systolic flow segment culminating in a gradual decay in systolic flow. At the beginning of diastole, proximal branch pulmonary artery blood flow patterns demonstrate a short reverse flow interval following either no or a small amount of diastolic flow. The fetal branch pulmonary artery Doppler tracing is similar to that obtained by direct invasive blood flow recordings in fetal lambs.[9] Fetal growth during the second half of pregnancy is characterized by a 2.5-fold increase in the lung length, as well as in the diameters of proximal pulmonary arteries. The significant decrease in the PI values in both proximal and distal pulmonary arteries during the study period suggests a significant decrease in the pulmonary vascular impedance. There is no difference in changes in the pulmonary vascular impedance between the right and left lungs during the second half of pregnancy.

The PI patterns in the distal and proximal pulmonary arteries during the second half of pregnancy are different. In the distal pulmonary arteries the decrease in the PI values reaches the plateau stage around 31 weeks of gestation, while in the proximal pulmonary arteries the PI values decrease in a linear fashion until 34–35 weeks of gestation. In fetal lambs, a 40-fold increase in the total number of the fifth and sixth generation vessels and a fourfold increase in the lung weight characterize the latter part of gestation.[10] The medial width of these vessels remains unchanged throughout the gestation. In our study, distal pulmonary arteries represent at least the third generation vessels, and in these segments, the linearly decreasing vascular impedance during the latter part of the second trimester represents the increase in the number of resistance vessels. The vascular impedance does not decrease markedly during the third trimester of pregnancy.

It is assumed that the phenomenon of wave reflection in a vascular bed is closely related to impedance. From the heart to the periphery, the pulsatility of pressure waves progressively increases while the flow velocity waves decline. This explains the difference between the proximal and distal branch pulmonary artery PI values. The forward propagating waves of pressure and flow demonstrate the same configuration, but after wave reflection, the retrograde flow waves are inverted, while the retrograde pressure waves are not. Wave reflections occur mainly in arterial system at the level of arterial–arteriolar junctions.[11]

Vasodilatation decreases the wave reflection and impedance while increasing flow.[12] The changes in the branch pulmonary arterial vascular impedance are similar to changes in the fetoplacental vascular impedance during the same pregnancy period. The continuing angiogenesis in both the fetoplacental unit and fetal lung causes diminished wave reflections associated with progressively declining vascular impedance. If the angiogenesis or angiomorphology is abnormal in the fetoplacental unit this vascular pathology results in increased vascular impedance associated with enhanced wave reflections (increased systolic to diastolic ratio).[13] We speculate that the failure of angiogenesis in fetal lungs could cause similar changes in vascular impedance, increasing the pulsatility of the Doppler waveform. The plateau stage, especially in the distal pulmonary artery vascular impedance during the third trimester, could be explained by acquired vasoconstriction in the pulmonary circulation, even though the number of resistance vessels is increasing in a linear fashion during this period according to animal studies.[14] However, other factors affect the regulation of the pulmonary circulation. For example, prostaglandin I_2 production is increased after lung distention, distortion or spontaneous ventilation of fetal lungs without changes in O_2 environment producing pulmonary vasodilatation.[15]

The changes in the peak systolic velocities support the concept that during the last trimester, the decrease in pulmonary vascular impedance reaches the plateau stage. Fetal lamb studies have revealed that an increase in the pulmonary vascular resistance due to hypoxia reduces the magnitude and duration of the forward flow in pulmonary arteries, while acetylcholine, which is a potent pulmonary vasodilator, produces a marked increase in the magnitude

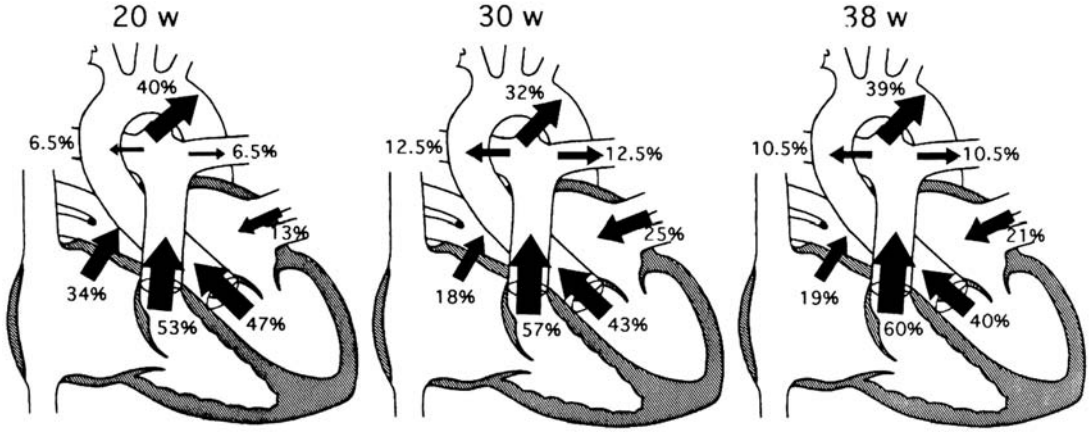

Figure 48.5 Distribution of fetal cardiac output.

and duration of systolic flow and reduces or eliminates backflow.[16] However, peak systolic velocities are not only affected by changes in afterload or vascular impedance, but also by fetal cardiac contractility, compliance, size of the vessels, and the distance between the point of measurement and the fetal heart will affect peak systolic velocities.

TTP-intervals increased significantly from 18 to 22 weeks of gestation to term in all the vessels examined, while the fetal heart rate was unchanged. At the pulmonary valve level the TTP-interval was significantly longer than in the proximal and distal pulmonary arteries and significantly shorter than in the aortic valve level and ductus arteriosus. These findings are partially in agreement with Machado *et al.*, concerning difference between aortic and pulmonary TTP-intervals[17] and with Choi *et al.* and Hata *et al.* demonstrating significant increases in aortic, pulmonary and ductal TTP-intervals with increasing gestation.[18,19] Invasive animal studies have shown significant increase in both mean systemic and pulmonary arterial pressures with advancing gestation. Mean pulmonary arterial pressure is higher than mean systemic pressure throughout gestation.[20] These findings parallel significant increases in cardiac output, peak systolic velocities, vessel size and by significant decrease in the placental vascular impedance. The difference in the mean arterial pressures and TTP-intervals may therefore be explained by the differences in end organ impedance: the placenta for the systemic circulation and the lung parenchyma for the pulmonary circulation. There is a structural obstruction in the ductus arteriosus that accelerates outflow into the descending aorta and increase the PI above that of the main pulmonary artery.[21] We speculate that during the latter part of the second trimester and in the beginning of the third trimester, the decrease in the vascular impedance may be related to the growth of the lung and especially to the increase in the number of resistance vessels. During the latter part of the third trimester, the pulmonary vascular impedance does not decrease further.

Pulmonary blood flow effects on fetal combined cardiac output

The human fetal pulmonary circulation has an important role in the distribution of the cardiac output.[22] The latter part of the second and the beginning of the third trimester is characterized by a decrease in the pulmonary vascular resistance and an increase in the proportion of pulmonary blood flow of the fetal combined cardiac output. This proportion is higher in human fetuses than suggested by previous animal studies. The proportion of blood flow across the foramen ovale decreases. Later during the last trimester, the pulmonary vascular resistance increases again. The proportion of pulmonary blood flow of the fetal combined cardiac output remains about 20% during this period, and is proportionate to that of the foramen ovale blood flow. Right ventricular dominance persists and even increases towards the end of pregnancy (Figure 48.5).

We studied 63 normal singleton fetuses in uncomplicated pregnancies referred for fetal echocardiography in a cross-sectional manner between 19 and 39 weeks of gestation (median 28 weeks) to establish the relative outputs of the left and right ventricles. The normal distribution of human fetal combined cardiac output from the left and right ventricles was determined and the weight-indexed pulmonary (*R*pi) and systemic (*R*si) vascular resistances and the changes during the second half of pregnancy were established.

Volumetric blood flow was calculated by using the formula: $Q = \text{fetal heart rate} \times \text{valve area} \times \text{time velocity integral}$. Left ventricular cardiac output

(LVCO) equals the blood flow through the aortic valve. Right ventricular cardiac output (RVCO) equals the blood flow through the pulmonary valve. Combined cardiac output (CCO) is the sum of LVCO and RVCO. Total pulmonary artery blood flow (Q_P) was calculated by combining right and left pulmonary artery blood flows. We calculated blood flows across the aortic and pulmonary valve annuli, right and left pulmonary arteries and ductus arteriosus. Foramen ovale blood flow was estimated by the formula $Q_{FO} = LVCO - Q_P$.

Biometric weight-indexed pulmonary and systemic vascular resistances were calculated by using the formula: $R_i = P/Q_i$, where P is the blood pressure (mmHg) and Q_i is the weight indexed volume blood flow (ml/min/kg). These indexes were analyzed at 20, 30 and 38 weeks of gestation. Systemic blood flow (Q_{Si}) was calculated by pulmonary volume blood flow from CCO. The mean transpulmonary pressure gradient was assumed to be equal to mean systemic blood pressure. At 20 weeks of gestation human fetal blood pressure is about 30–35 mmHg.[23] At 30 and 38 weeks of gestation fetal blood pressure values were assumed from values in newborns at the same gestational age.[24]

From 20 to 30 weeks of gestation the proportion of pulmonary blood flow (Q_P) of the CCO doubled (from 13 to 25%), while the proportion of flow across the foramen ovale (Q_{FO}) decreased by half (from 34 to 18%). After 30 weeks of gestation the proportions of Q_P and Q_{FO} remained unchanged. At 38 weeks of gestation, the proportion of RVCO (60%) was higher than that of LVCO (40%). The proportion of flow across the ductus arteriosus (Q_{DA}) did not change significantly. The correlation between RVCO calculated from blood flow across the pulmonary valve to the combined Q_{DA} and Q_P was excellent. $R_P i$ decreased from 20 to 30 weeks of gestation but increased from 30 to 38 weeks of gestation. However, $R_S i$ continuously increased from 20 to 38 weeks of gestation. Thus, the R_{Pi}/R_{Si} decreased from 20 to 30 weeks of gestation and later remained unchanged.

The area and TVI of aortic and pulmonary valves, ductus arteriosus and branch pulmonary arteries increased significantly with advancing gestational age as did right and left ventricular stroke volumes. RVSV/LVSV ratio was greater at term of pregnancy than at 20 weeks of gestation. Fetal CCO, RVCO and LVCO increased more than 10-fold from 20 weeks to term, and Q_{DA}, Q_{FO} and Q_P also increased significantly with advancing gestation. The PV area, RVSV and RVCO were greater than AV area, LVSV and LVCO. The ratio between diameters of the pulmonary valve and the ductus arteriosus increased significantly from 20 weeks of gestation toward the term of pregnancy. The DA area was always greater than LPA or RPA area, but the ratio of LPA or RPA to DA area increased significantly with advancing gestation. There were no significant differences in the area, TVI or volume blood flow between right and left pulmonary arteries. The proportions of Q_P and Q_{FO} of the CCO remained unchanged from 30 to 38 weeks of gestation.

During the third trimester, the proportion of Q_P of the LVCO is about 50% suggesting that the Q_P contribution to the LVCO increases with advancing gestation. These measurements concur with previously published estimates.[25] Our results show that the proportion of Q_P of the human fetal CCO is clearly higher than suggested in previously published animal studies, where the proportion of Q_P of the CCO was estimated at less than 10%.[26,27]

Volume blood flow across the FO is very difficult to assess directly. The cross-sectional area of the FO is difficult to calculate accurately because of the shape and relative size and position of the flap tissue of the septum primum and the fact that the blood velocity waveform is multiphasic during the cardiac cycle.[28] However, our measurements correlated with published diameters of the FO and showed linear increase with advancing gestation.[29] In our study, the Q_{FO} increased fourfold, but its proportion of the CCO decreased by half from 20 weeks to term. At 20 weeks of gestation it represents about 73% of the LVCO, but after 30 weeks of gestation its proportion has decreased to about 50% of the LVCO. In the human fetus, the Q_{FO} has an important role, because highly oxygenated blood returning from the placenta is directed via the ductus venosus across the FO to the left atrium.[30] Thus the most oxygenated blood from the placenta is supplied to the fetal coronary and cerebral circulations. Our findings suggest that during the third trimester, the FO becomes relatively restrictive and therefore unable to increase its proportion of the CCO. This supports proportional right ventricular dominance in the human fetus during the last trimester of pregnancy. After 20 weeks of gestation, the right ventricular output becomes dominant. At 38 weeks of gestation RVCO (60%) significantly exceeds LVCO (40%) as a proportion of the CCO, which may explain the appearance of relative RV > LV disproportion seen in late third-trimester fetuses.

Effects of indomethacin treatment on pulmonary circulation

Maternally administered indomethacin used as tocolysis is transferred across the placenta to the fetus.[31] Maternal and fetal serum levels of indomethacin are identical after few hours of maternal oral administration of indomethacin.[32] Indomethacin is known to reduce fetal urine output leading to decreased amniotic fluid volume.[33] Another well-known effect of indomethacin on the fetus is the constriction or even occlusion of the ductus arteriosus.[34] It is evident that the prevalence of indomethacin-induced fetal ductal constriction increases with advancing gestational age.[35,36] These

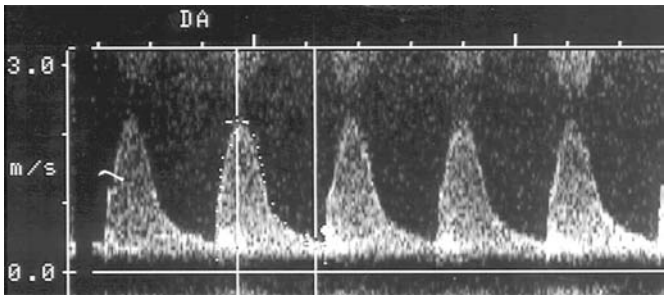

Figure 48.6 Ductal constriction with high velocity and increased diastolic flow.

fetal side effects of indomethacin are usually reversible after either reducing the indomethacin dose or stopping the indomethacin therapy.[37] Maternal indomethacin therapy affects human fetal pulmonary arterial vascular impedance.[38]

In a cross-sectional study, we compared Doppler echocardiographic findings in three groups of fetuses between 24 and 34 weeks of gestation. Fifty-two normal fetuses were without maternal medication, while 33 fetuses without constriction of the ductus arteriosus, 15 fetuses with mild to moderate and 8 fetuses with severe ductal constriction occlusion during maternal indomethacin therapy. The indication for maternal indomethacin therapy was preterm labor; the daily indomethacin dose varied between 50 and 200 mg. Blood velocity waveforms across the ductus, aortic and pulmonary valves, and proximal right or left pulmonary artery were obtained. The constriction of the ductus arteriosus was defined as mild to moderate when the pulsatility index of the ductus arteriosus varied between 1.0 and 1.9. The ductal constriction was defined as severe if the PI value was less than 1.0. During the second half of pregnancy normal values for the PI of the ductus arteriosus are between 1.9 and 3.0.[39] Occlusion of the fetal ductus arteriosus was diagnosed when no blood flow across the ductus arteriosus could be identified by color, continuous or pulsed Doppler techniques but tricuspid regurgitation was identified (Figure 48.6).

Pulsatility indices were measured in the peripheral pulmonary arteries and left and right ventricular outflows. Combined cardiac outputs were calculated. The pulsatility of the peripheral pulmonary arteries was constantly greater in the indomethacin fetuses than in the control group. After 26 weeks gestation, the values in the mild to moderate group were significantly higher than in the control group. In the study groups I and II, LVCO, RVCO and CCO were similar to the control group. In the study group III, RVCO and CCO were lower than in the control group. Only LVCO did not differ from the control group. Human fetal pulmonary arterial vascular impedance is increased by maternal indomethacin therapy even without ductal constriction. In the presence of mild to moderate DC the magnitude of the increase in the vascular impedance is related to the gestational age. In the group with severe ductal constriction or occlusion of DA pulmonary vascular impedance is similar to the control group. In this group, decreased RVCO and CCO without significantly increased LVCO show that these fetuses were unable to redistribute the cardiac output from the right to the left ventricle. Interestingly, the newborns with ductal occlusion in utero did not show any signs of pulmonary hypertension during the neonatal period.

Prostaglandins are potent vasoactive substances, which have a role in the pulmonary vascular changes occurring after birth. Prostaglandins D2, E1 and I2 have been shown to be fetal pulmonary vasodilators in near term animal models.[40] Indomethacin, which is a prostaglandin synthetase inhibitor, may affect fetal pulmonary function by decreasing lung liquid production and altering pulmonary hemodynamics. During rhythmic distention of the lungs in the fetal lambs, prostaglandin synthetase inhibitors have been demonstrated to abolish the fourfold decrease in pulmonary vascular resistance seen without prostaglandin inhibitors.[41,42] However, indomethacin has not been shown to change the pulmonary vascular response to increased oxygen tension in fetal lambs.[43] In the presence of indomethacin-induced ductal constriction in fetal lambs, the smooth muscle has been found to be significantly increased and the external diameter decreased in the fifth generation resistance vessels in the lung tissue compared to control fetuses.[44] Also, in fetal lambs the acute mechanically induced occlusion of the ductus arteriosus decreases the total fetal cardiac output by about 34%.[45] We have earlier demonstrated that pulmonary vascular impedance decreases significantly during the second half of pregnancy until 34–35 weeks of gestation and thereafter it remains unchanged. Likewise, weight-indexed pulmonary vascular resistance decreases significantly from 20 to 30 weeks of gestation and increases again from 30 to 38 weeks of gestation.[22]

Maternal indomethacin therapy without constriction of the fetal ductus arteriosus is associated with higher PI values in the branch pulmonary arteries than in the control fetuses. This finding suggests that prostaglandins have a role in the regulation of the human fetal pulmonary circulation. In fetuses with mild to moderate ductal constriction, the PI values were higher and the average weekly change in the PI values was significantly different from the control group. This suggests that after 27–28 weeks of gestation the human fetus is able to regulate branch pulmonary arterial vascular tone in response to increased pulmonary arterial pressure. In the group with severe constriction or occlusion of the ductus arteriosus the PI values of the branch pulmonary arteries were not different from the control group showing that further increase in the pulmonary arterial pressure overcomes the regulatory capacity of the pulmonary circulation. In these fetuses

right ventricular and combined cardiac outputs were less than in the control group, while the left ventricular cardiac output remained similar to the control group demonstrating that these fetuses were not able to redistribute the cardiac output from the right to the left ventricle.

The effects of right ventricular loading conditions on pulmonary circulation

The equation for ventricular ejection force estimates the energy transferred from the ventricular myocardial shortening to work done by accelerating blood into the circulation. This information can be used for the assessment of the ventricular systolic function. Ventricular ejection force does not require estimation of ventricular volumes and is independent of ventricular configuration. Newton's second law of motion defines force as the product of mass and acceleration: force = mass × acceleration. The mass of blood accelerated across the aortic and pulmonary valves over a time interval is calculated by multiplying the density of blood, which is 1.055, with the cross-sectional area (CSA) and the TVI at the valve. The acceleration component is calculated by dividing peak systolic velocity by the time to peak velocity interval.[46] Ventricular ejection force (EFo) is calculated by using the formula: $EFo = (1.055 \times CSA \times TVI_{ac}) \times (PSV/TTP)$. In adults, a close correlation has been found between the mean left ventricular ejection force and ejection fraction suggesting that Doppler echocardiography can be used for the noninvasive assessment of right and left ventricular performance. The mean left ventricular ejection force has been shown to be more sensitive for the diagnosis of mild to moderate left ventricular systolic dysfunction than the peak aortic blood velocity or mean acceleration.[47]

Human fetal right and left ventricular ejection forces both increase 10-fold during the second half of gestation.[48,49] There is no significant difference between the right and left ventricular ejection forces *in utero*. Right ventricular performance is modified by abnormal loading conditions: it is increased by a chronic volume overload and decreased by an acute pressure overload. These findings demonstrate that the human fetal right ventricle is able to adapt its systolic function when it is facing chronically increased volume load. Pressure overload against the right ventricle must be dramatically increased as in severe ductal constriction or occlusion before the right ventricular ejection force (RVEF) decreases demonstrating the capability of the right ventricle to maintain its systolic performance.[50] In growth-retarded fetuses both ventricular ejection forces are reduced compared to normal fetuses as related to the severity of fetal compromise. Animal studies have suggested that early systolic flow is less affected by changes in afterload and preload than flow during late systole.[51,52]

To determine whether abnormal loading conditions can modify human fetal right ventricular ejection force, we studied 73 normal fetuses, 27 fetuses with hypoplastic left heart syndrome, 14 fetuses with mild to moderate constriction of the ductus arteriosus and 7 fetuses with severe constriction or occlusion of the ductus arteriosus. In the normal and ductal constriction/occlusion groups, blood velocity waveforms were recorded at the level of the aortic and pulmonary valves, and in the group with hypoplastic left heart syndrome (HLHS) at the level of the pulmonary valve. The ventricular ejection forces were calculated. In the HLHS group, seven patients terminated the pregnancy after diagnosis and there was one stillborn fetus. Except for one newborn, who had a heart transplant operation, others underwent three-stage palliative cardiac surgery. All the fetuses in the HLHS group had a normal karyotype. In the ductal occlusion or constriction groups there were no perinatal or neonatal deaths.

In the normal group, right and left ventricular ejection forces increased and were equal during the second half of gestation. The average weekly increases were greater in the hypoplastic left heart syndrome group than in the normal group. In the group with mild to moderate ductal constriction, both ventricular ejection forces were similar to those of the normal group. The average weekly increase was lower in the group with severe ductal constriction or occlusion than in the normal group, but the LVEF did not differ from that of the normal group. This study showed that chronic volume overload increases and relatively acute pressure overload decreases human fetal RVEF.

Increased chronic volume load (HLHS group) was associated with increased ejection force developed by the right ventricle. This demonstrates the capacity of the right ventricle to adapt its systolic performance and to maintain adequate cardiac output. This also shows that chronic volume overload the right ventricular ejection force rises with other parameters of ventricular size, i.e. mass, end-diastolic volume and stroke volume. In fetuses with anemia due to red cell alloimmunization, intravascular transfusion, which represents acute volume overload transiently, decreases fetal cardiac output with a recovery to baseline levels by the day following the correction of the anemia.[53,54] It has been proposed that relative hyperviscosity secondary to the acute correction of anemia during the transfusion increases the afterload. The transient decrease in the cardiac output could also represent the time period needed for the adaptation of the ventricles to the acute volume overload.

Severe ductal constriction or occlusion significantly decreased right ventricular ejection force, possibly because of tricuspid regurgitation in this group. However, right ventricular ejection force was similar in fetuses with holosystolic tricuspid regurgitation to those without tricuspid regurgitation. Rizzo *et al.*[55] showed that in fetal intrauterine growth

restriction secondary to uteroplacental insufficiency, both ventricular ejection forces were symmetrically decreased. A direct relationship was present between ejection force and umbilical vein pH values, suggesting that decreased ejection force was primarily caused by myocardial dysfunction. In ductal constriction or occlusion groups, there were no signs of placental insufficiency and the growth of the fetuses was appropriate for gestational age in all cases. Also during fetal ductal constriction the umbilical artery PI is similar to or even significantly less than without constriction suggesting that fetal ductal constriction and indomethacin therapy itself are not detrimentally affecting placental impedance.[56,57] It seems that the human fetus with normal placental function is able to maintain right ventricular ejection force development until there is a dramatic increase in the right ventricular afterload. This demonstrates the capability of the right ventricle to maintain its systolic function, which seems to be disturbed only after the pulmonary artery diastolic pressure is significantly increased. We believe that in cases of severe ductal constriction or occlusion, which develops in a short time interval, the right ventricular systolic pressure is increased without myocardial hypertrophy leading to increased systolic wall tension and myocardial oxygen consumption. During that period, the FO becomes relatively restrictive because its fixed dimension and ability to increase blood flow is limited, which results in a decreased combined cardiac output.

Effects of maternally administered oxygen on fetal pulmonary circulation

Maternal hyperoxygenation decreases human fetal pulmonary arterial vascular impedance and increases pulmonary blood flow between 31 and 36 weeks of gestation. Earlier in pregnancy, between 20 and 26 weeks of gestation, maternal hyperoxygenation does not alter human fetal pulmonary circulation. These findings show that the reactivity of the human fetal pulmonary circulation to oxygen develops between these two study periods and oxygen tension in the fetus has a role in the regulation of the fetal pulmonary circulation. Fetal oxygen tension has a role in the regulation of the pulmonary circulation and in the distribution of fetal cardiac output during the latter part of the third trimester when the human fetal pulmonary arterial bed is under acquired vasoconstriction, directing right ventricular cardiac output from the pulmonary circulation to the systemic circulation. Maternal hyperoxygenation, at least after 31–36 weeks of gestation, mimics the changes in the fetal central hemodynamics, which occur after birth.[58]

To determine the role of oxygen tension on the human fetal pulmonary arterial circulation during the second half of gestation we studied 20 women between 20 and 26 weeks of gestation and 20 women between 31 and 36 weeks of gestation with normal singleton pregnancies. They were randomized to receive either 60% humidified oxygen or medical compressed air (room air) by face mask. Fetal aortic and pulmonary valve, ductus arteriosus, and right, left and distal pulmonary artery blood velocity waveforms were obtained by Doppler ultrasound before, during and after maternal administration of either 60% oxygen or room air. Left and right ventricular cardiac outputs, and DA (Q_{DA}), RPA and LPA (Q_P) volume blood flows were calculated. Foramen ovale blood flow was estimated. PI values of DA, RPA, LPA and DPA were calculated. Maternal hyperoxygenation did not change any of the measured fetal parameters between 20 and 26 weeks, while between 31 and 36 weeks the PI values of RPA, LPA and DPA decreased and the PI of DA increased. Q_P increased, and Q_{DA} and Q_{FO} decreased. LVCO and RVCO were unchanged. All changes returned to baseline after maternal hyperoxygenation were discontinued. Reactivity of the human fetal pulmonary circulation to maternal hyperoxygenation increases with advancing gestation.

The mean increase in the Q_P was 24.5% and the mean decrease in the Q_{DA} was 17.1% from the baseline values. One fetus at 36 weeks of gestation developed a reversal of diastolic blood flow in the DA during maternal hyperoxygenation (from the aorta to the pulmonary artery). The estimated Q_{FO} remained stable in groups 1, 2 and 4 during the study period whereas maternal hyperoxygenation after 30 weeks gestation decreased foramen ovale blood flow significantly. The FO blood flow decreases because the pulmonary volume blood flow increases significantly without any change in the LVCO. In fetal lambs, the FO blood flow decreases by an average of 50% during maternal hyperbaric oxygenation at near term gestation.[59] Both distal and proximal pulmonary arteries showed a similar decrease in the PI values during maternal hyperoxygenation suggesting that both sampling sites gave the same information about the pulmonary vascular reactivity.

This study supports the concept that in the human fetus the reactivity of the pulmonary arterial bed to changes in the fetal oxygen tension develops after 21–26 weeks of gestation and is detectable by noninvasive Doppler ultrasound techniques between 31 and 36 weeks of gestation. This suggest that human fetal pulmonary circulation is under acquired vasoconstriction at least after 31–36 weeks of gestation with blood flow directed from the pulmonary circulation to the systemic circulation. The reactivity of the pulmonary arterial circulation to oxygen with advancing gestation has been explained by an increasing amount of smooth muscle in small pulmonary arteries.[14] The decrease in the pulmonary vascular resistance is mainly caused by the release of endothelium derived nitric oxide, which leads to vasodilatation of the pulmonary arterial bed.[60,61]

The decrease in the pulmonary vascular impedance and the increase in the pulmonary blood flow by maternal hyperoxygenation between 31 and 36 weeks of gestation were accompanied by opposite changes in the fetal ductus arteriosus. The decrease in the DA PI has been associated with the constriction of the DA and the increase in the DA PI has been found in the cases with increased right ventricular cardiac output.[39] This study shows that the changes in the DA PI may also reflect fetal pulmonary vascular impedance. The decrease in the pulmonary vascular impedance directs blood flow from the systemic circulation to the pulmonary circulation. This mainly affects the diastolic flow component in the DA by decreasing it or even reversing the direction of the blood flow during diastole. This leads to increased PI in the DA, because the end-diastolic velocity and the mean velocity during the cardiac cycle decrease. In normal circumstances, the direction of the blood flow in the human fetal DA during the diastole is from the pulmonary artery to the aorta. This study supports previous animal data that the increase in the pulmonary blood flow and the decrease in the pulmonary vascular impedance during maternal hyperoxygenation are not caused by the constriction of the ductus arteriosus.[7,27,62] In the presence of the ductal constriction peak systolic, end-diastolic and mean velocities across the ductus arteriosus are increased in the human fetus leading to decreased PI value. These findings agree with those of Burchell *et al.* where children and adults with patent ductus arteriosus and pulmonary hypertension when breathing of a low oxygen mixture either initiated or increased the blood flow from the pulmonary artery to the aorta whereas the breathing of 100% oxygen caused opposite changes.[63]

Pulmonary hypoplasia

Pulmonary hypoplasia is a term that describes lungs that are sufficiently small enough to impede the exchange of respiratory gases leading to severe neonatal pulmonary disease or death.[64] It occurs secondarily to other fetal anomalies that restrict volumetric lung expansion. It can be associated with mediastinal shift or cardiac malposition. However, pulmonary hypoplasia is different from pulmonary agenesis where there is complete absence of a lung and from pulmonary aplasia where there is absence of a broncus or bronchiolar pathway as survival is likely with either of those two malformations. As gas exchange does not occur in the fetal lung, it is difficult to prove that fetal lungs may be functionally hypoplastic. Pulmonary hypoplasia is defined as incomplete or underdevelopment of lung tissue present at autopsy as determined by the wet lung to body weight ratio, reduced alveoli count or by reduced lung DNA content.[65] Fetal detection of pulmonary hypoplasia is based on ultrasound imaging techniques based on a reduced chest size for gestational age. The thoracic to abdominal ratio of 0.89 is relatively constant throughout gestation and a ratio of less than 0.77 is consistent with pulmonary hypoplasia.[66]

The association between pulmonary hypoplasia and reduced amniotic fluid volume was first observed in infants with bilateral renal agenesis.[67] Abnormalities that result in olighydramnios include renal agenesis, renal dysplasia and those that restrict urinary flow into the amniotic sac. Urethral atresia or stenosis, urethral valve and bladder outlet obstructions also restrict urinary flow. In pregnancies with prolonged leakage of amniotic fluid or premature rupture of the membranes may also be subject to pulmonary hypoplasia. With these conditions, it has been proposed that compression or forced flexion of the fetal trunk secondary to restricted movement.[68] It has been shown that fetal lung expansion becomes restricted within 48h of diminution of amniotic fluid but that process may be reversed by amnioinfusion.[69] A reduction in fetal breathing patterns in patients with reduced amniotic fluid may also contribute to pulmonary hypoplasia, although there are conflicting reports.[70–72]

Fluid in the fetal thorax either as primary hydrothorax or from hydrops fetalis is one of the most common causes of pulmonary hypoplasia with overall mortality reported at over 50%.[73] If fluid is drained from the chest in fetal hydrothorax by catheter or needle aspiration, lung growth may be restored.[74] Other 'space occupying lesions' of the fetal thorax include cardiomegaly (mitral valve insufficiency associated with giant left atrium and aortic stenosis, Ebstein's anomaly of the tricuspid valve and tricuspid valve dysplasia), pericardial effusion and neuroblastoma.

The incidence of congenital diaphragmatic hernia is estimated at 1 in 3000–5000 births. As a result of incomplete closure of the pleuroperitaneal membranes, the abdominal contents may enter the thorax and result in a mediastinal shift. This may effect the growth of the effected side and the contralateral lung, and may cause esophageal obstruction resulting in polyhydramnios. Postnatal survival is approximately 50% depending upon the degree of pulmonary hypoplasia.[75] In the absence of a congenital closure defect, the diaphragm may be affected by abnormal development of function as in phrenic nerve agenesis and Pena–Shokeir syndrome leading to an elevation or eventration of the dome of the diaphragm.[76] Central neural defects that as associated with absent fetal breathing movements may also lead to pulmonary hypoplasia including anencephaly, microcephaly and encephalocele.[77]

Congenital cystic adenomatoid malformation (CCAM) of the lung is a failure of maturation of certain bronchial structures during the pseudoglandular stage of development. The lesion is typically unilobar and

consists of cystic areas that may be identified on ultrasound. Type I lesions have a single or multiple large cysts and represent 50% of CCAMs. Type II has multiple smaller cysts and may be associated with gastrointestinal or renal anomalies. Type III lesions are large with cysts often too small to measure and carry a poor prognosis. When associated with developing hydrops fetalis, preterm surgical intervention has been offered.[78]

Pulmonary hypoplasia is also associated with skeletal dysplasias because of a narrowed or constricted fetal thorax.[79,80] These anomalies may include Jeunes syndrome (asphyxiating thoracic dystrophy), achondrogenesis, achondroplasia, osteogenesis imperfecta, thanatophoric dwarfism and hypophosphasia. Ultrasound measurements of fetal lung or chest size as a ratio to normal gestational biometric measurements have been advanced as predictors of pulmonary hypoplasia.[81–84] Yoshimura *et al.* analyzed several methods of prediction for fetal lung hypoplasia, concluding that the lung area against gestational age and the ratio of the thoracic circumference to the abdominal circumference were the most clinically useful.[85] Recently, estimates of lung volumes from three-dimensional ultrasound have been used in an attempt to estimate lung maturity and predict hypoplasia.[86–89] We and others believe that a method that evaluates function as well as relative size may prove to be a more reliable predictor of post natal pulmonary dysfunction from pulmonary hypoplasia. Pulmonary blood flow parameters may be measured by the methods previously mentioned. We have seen in the fetus later found to have lethal pulmonary hypoplasia that the proximal and distal pulmonary artery flow patterns are reduced in peak velocity while pulsatility indices are increased. Those patients with space occupying lesions such as diaphragmatic hernias may have a blunted or no response to a maternal hyperoxia test after 32 weeks gestation.[90] One of the more easily obtained waveform patterns recorded during these studies has been the proximal pulmonary venous flow, which normally increases significantly with maternal hyperoxia. Mitchell *et al.* showed a high resistance pattern quite different from that of normal fetuses in the peripheral pulmonary arteries in 10 fetuses with bilateral multicystic dysplastic kidney disease all of whom died from associated pulmonary hypoplasia.[91] Yoshimura *et al.* made similar observations in the proximal pulmonary artery flow patterns with lethal pulmonary hyperplasia in hydrops fetalis, thanatophoric dwarfs and Potter syndrome.[92] Roth *et al.* have found an association with lethal pulmonary hypoplasia with the lack of pulmonary artery flow patterns with power color Doppler techniques.[93] Chaoui *et al.* have shown that abnormal pulmonary artery flow patterns may be seen as early as 19–23 weeks gestation in fetuses with lung hypoplasia.[94]

A test for the prediction of lethal pulmonary hypoplasia

To determine the predictive accuracy of our test for neonatal death from pulmonary hypoplasia, we measured the Doppler changes in fetal pulmonary artery blood flow in room air and during maternal hyperoxygenation. Women carrying fetuses with those congenital anomalies as illustrated above or with prolonged olighydramnios often associated with pulmonary hypoplasia were offered participation in the study as part of a comprehensive fetal echocardiogram. Each fetus at $\leq$30 weeks gestation had the Doppler blood flow pattern in the first branch of either the right or the left pulmonary artery measured before and again during at least 10 min exposure to maternal breathing of 60% oxygen by mask. An increase in the relative fetal pulmonary blood flow with oxygen (a decrease of at least 25% of the PI) was considered a reactive test. A change of less than 20% in the flow pattern during maternal hyperoxygenation was a nonreactive test and suggested pulmonary hypoplasia. The primary outcome for this study was neonatal outcome of death from pulmonary hypoplasia. In the 29 pregnancies that met criteria for our study, 14 fetuses who had a nonreactive hyperoxygenation test, 11 (79%) died of pulmonary hypoplasia. Of the 15 that had a reactive hyperoxygenation test, only 1 (7%) died in the neonatal period. Sensitivity, specificity, positive, and negative predictive values were 92%, 82%, 79% and 93%, respectively, with an odds ratio of 51 (95% CI 4.6–560).[95] We have now performed over 100 of these oxygen challenge tests with excellent results in sensitivity and specificity.

The oxygen challenge method evaluates fetal pulmonary function and therefore may prove to be a more reliable predictor of postnatal pulmonary dysfunction from pulmonary hypoplasia as compared to those that evaluate relative anatomic size. Maternal hyperoxygenation increases fetal pulmonary blood flow by decreasing pulmonary arterial vascular impedance. The changes we have observed between 31 and 36 weeks of gestation mimics the changes in the fetal hemodynamics after birth.[15] During normoxia, when the human fetal pulmonary arterial bed is under acquired vasoconstriction, right ventricular cardiac output is directed away from the lungs and into the systemic circulation via the ductus arteriosus. Increased blood oxygen content decreases pulmonary vascular resistance and thus increases pulmonary blood flow in the normal fetus. The reactivity of the pulmonary arterial circulation to oxygen with advancing gestation has been explained by an increasing amount of smooth muscle in small pulmonary arteries.[14] The decrease in the pulmonary vascular resistance is mainly caused by the release of endothelium-derived nitric oxide, which leads to vasodilatation of the pulmonary arterial bed.[60,61]

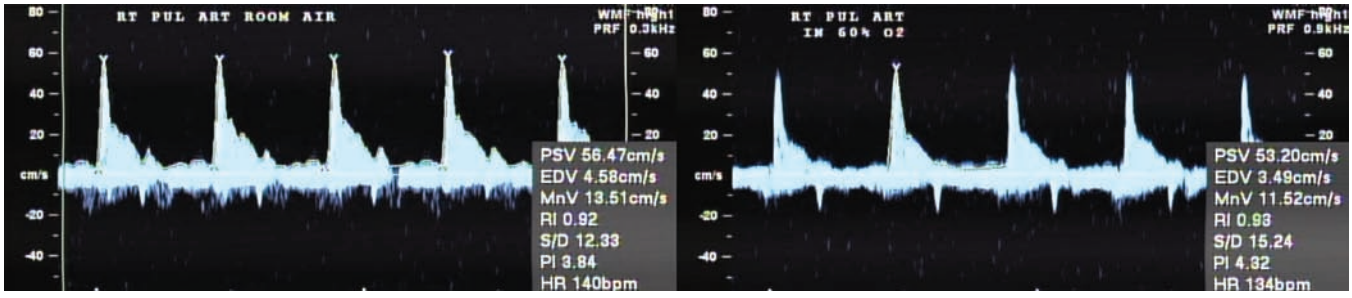

Figure 48.8 Negative change in Doppler flow patterns of pulmonary vascular reactivity with oxygen.

The method to accurately predict those fetuses who will die from pulmonary hypoplasia is important for parental counseling and subsequent decision-making regarding obstetric and neonatal management. As the oxygen challenge is an extension of our comprehensive fetal echocardiogram, we also measure the cardiac circumference to thoracic circumference ratio (CC/TC) and the thoracic circumference to the biometric abdominal circumference ratio (TC/AC) as well as M-mode measurements of the ventricles in systole and diastole. These measurements typically show normal size heart for gestational age, but the CC/TC and TC/AC are widely divergent relative to the cause of the small lungs. For example, oligohydramnios may show a relative cardiomegaly whereas a diaphragmatic hernia will have a relatively small heart to thoracic size. Likewise, we have seen exaggerated fetal breathing movements in fetuses that have lethal pulmonary hypoplasia and an absence of such movements in fetuses with long standing oligohydramnios who have a normal physiologic response to maternal oxygen and go on to a normal neonatal course. Difficulty in performing the examination occurs, especially in the fetus with diaphragmatic hernia, who has hard to image lungs and who typically increases both its gross body movements and breathing movements when exposed to an increased oxygen environment.

Intrauterine growth restricted (IUGR) fetuses with oligohydramnios can have a negative response to maternal hyperoxygenation. Those fetuses may present in extremis with abnormal Doppler measurements in the MCA, FLUA and DV, suggesting redistribution of cardiac output by cephalization, placental insufficiency and congestive heart failure with increased central venous pressure. The blunted or absent response to oxygen appears to be an extension of redistribution of cardiac output as these fetuses, who were delivered within hours of their oxygen tests, did reasonably well in the newborn period and were eventually discharged home (Figures 48.7 and 48.8).

Cystic adenomatoid malformation

Probably the most common lung lesion detected *in utero* by ultrasound is cystic adenomatoid malformation. This appears as an echo bright portion within a lobe of the lung and maybe associated with large, small mixed or micro cysts, appearing as a solid mass. It is characterized by dysplastic or hamartomatous tissue often mixed with normal tissue and typically confined to a single lobe. Regression is common, but when large and/or associated with hydrops it may be lethal because of pulmonary hypoplasia. As it is likely to be the result of early maldevelopment of terminal brochiolar structures, color or power Doppler in the area of the lesion may show pulmonary arterial flow around but not into the lesion (Figure 48.9).

Pulmonary sequestration

Pulmonary sequestration is a rare anomaly identified *in utero* by a difference in echo density of a particular

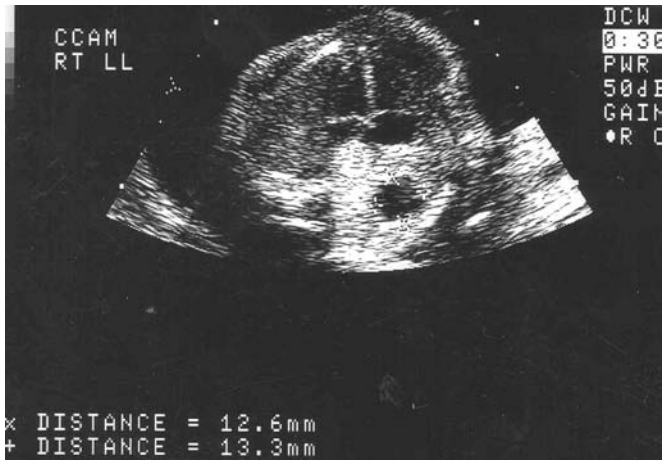

Figure 48.9 Cystic adenomatoid malformation.

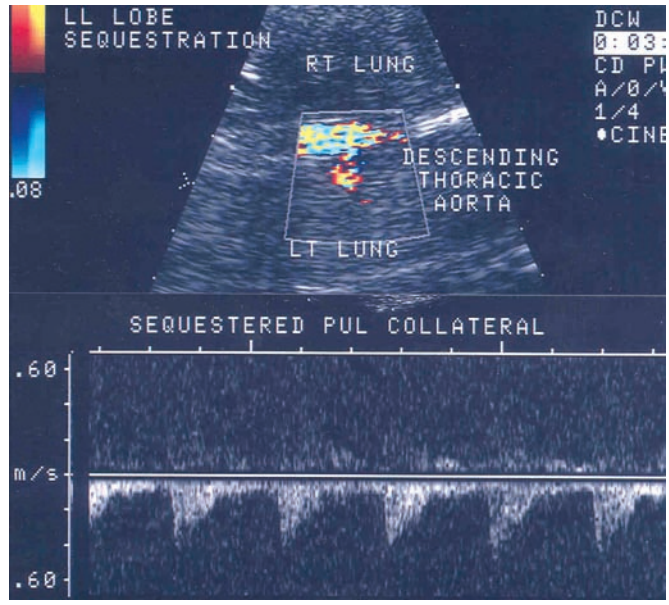

Figure 48.10 Color Doppler of sequestration flow pattern.

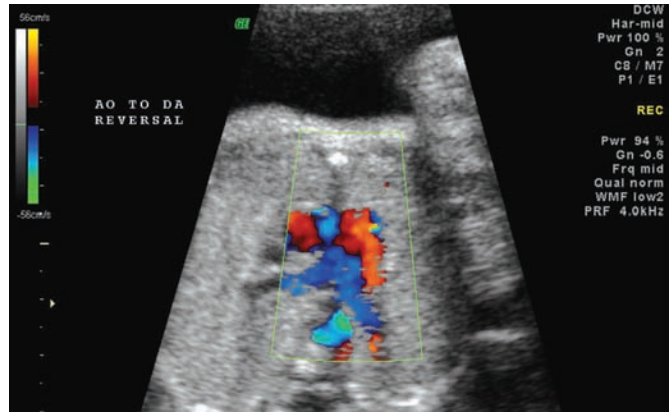

Figure 48.11 Color Doppler of normal pulmonary artery bifurcation with pulmonary valve atresia and reversed ductus arteriosus flow pattern.

lobe of the lung. It is seen as either above or below the diaphragm and is defined as either intrapulmonary or extrapulmonary depending on its position relative to the visceral pleura. It may present with mediastinal shift or cardiac malposition and occasionally with hydrops from impingement or torsion of the inferior vena cava. The sequestered lobe receives its blood supply from the aorta rather than the pulmonary artery with venous return usually to the right atrium via the inferior vena cava. The majority of sequestrations are extrapulmonary and occupy the lower portion of either hemi-thorax. Color directed pulsed Doppler may be used to identify the arterial origin from the descending aorta and thereby differentiate sequestration from cystic adenomatoid malformation. Most subdiaphragmatic sequestationas identified *in utero* regress and may not require neonatal surgical resection (Figure 48.10).

Congenital pulmonary blood flow abnormalities

Observable abnormalities of fetal pulmonary circulation may be related to structural congenital heart disease or to thoracic space occupying lesions. The pulmonary artery should be superior and anterior to and slightly larger than the aorta in the four-chamber view of the fetal heart. The pulmonary artery blood flow is directed toward the fetal left shoulder and ductus arteriosus. Likewise, the normal connections of the pulmonary veins are easily identified from the four-chamber image just as the LVOT comes into view. Anomalous connection of the pulmonary veins should be ruled out when major structural congenital heart defects are identified. By combining high-resolution ultrasound magnification with the color flow and narrow sample size pulsed Doppler techniques we have described, blood flow connection abnormalities of the veins and arteries including sequestered lobes of the fetal lung may be identified. However, hydrothorax, cystic masses and diaphragmatic hernias may impede pulmonary blood flow to the extent that the flow may be difficult or impossible to observe or measure in one or both of the fetal lungs. Congenital malformations of pulmonary circulation should be considered in the presence of other forms of congenital heart disease. Direction of the fetal ductus arteriosus should be evaluated with both color and pulsed Doppler when arterial connection or obstruction is suggested in order to identify a ductal dependent lesion (Figure 48.11).

Major pulmonary venous abnormalities can generally be ruled out by imaging the right and left venous ostia as they connect into the left atrium on either side of the descending aorta when seen in the four-chamber view of the heart in a transverse image of the thorax (Figure 48.12). Exceptions to expect are when there is visceral heterotaxy when the stomach

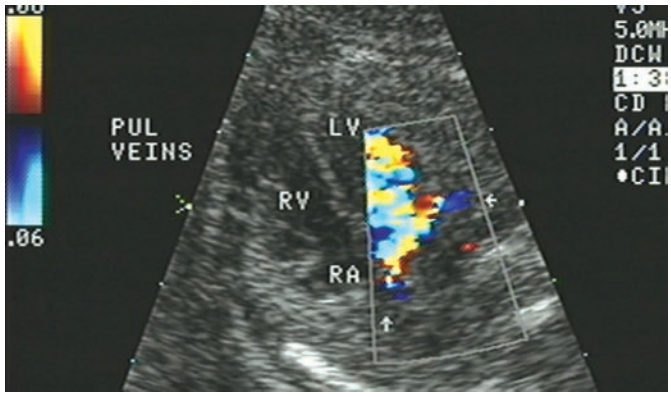

Figure 48.12 Color Doppler of normal pulmonary venous connections.

and heart may be on opposite sides of the fetus and/or when there is a common atrium or large atrial septal defect. Ipsilateral venous connections may be seen in these diagnoses but may be difficult to identify by fetal echocardiography. Both partially anomalous and totally anomalous pulmonary venous connections are typically associated with a disproportion of right-sided chambers larger than the left-sided structures. More obvious is total anomalous pulmonary venous connection (TAPVC) to the coronary sinus where a dilated coronary sinus can be identified as an eccentric line parallel to the mitral valve annulus in the four-chamber view. However, a dilated coronary sinus may also be seen with normally connected pulmonary veins when the left superior vena cava drains into the coronary sinus behind the lower left corner of the left atrium. The extra line in the left atrium may also signify the membrane in cortriatriatum (triatrial heart) where the common pulmonary venous sack is attached to the posterior left atrial wall but may drain anomalously into the right atrium or via restricted fenestrations into the left atrium. The most common type of TAPVC is when the common pulmonary venous sac is not attached to the left atrium but to a vein that ascends to join the innominate vein which then flows into the right superior vena cava and right atrium. The form of TAPVC most likely to become obstructed in the early newborn period is when the common pulmonary venous sack is attached to a vein that descends below the diaphragm and connects to a hepatic venous structure. Partially anomalous pulmonary venous veins are difficult to identify as they may enter the right atrium, coronary sinus, the right or left superior vena cava, the inferior vena cava or into the azygous venous system as single attachments with otherwise normally connecting pulmonary veins. In cases of hypoplastic left heart syndrome, the pulmonary veins may appear dilated for gestational age, but may be anomalously connected and associated with pulmonary venous stenoses. Stenosis of pulmonary veins may be difficult to identify in fetal life from ultrasound because of the relative paucity of pulmonary blood flow. Pulmonary venous dimensions can usually be measured successfully after 22 weeks' gestation. Pulmonary venous blood flow is best measured with color directed pulsed Doppler techniques in a lateral approach to the four-chamber view.

We believe that all fetal ultrasound anatomic survey examinations should include identification and relative quantification of the outflow tracts of the heart. The pulmonary artery should arise above the anterior right ventricle aiming toward the left shoulder at the ductus arteriosus, while the aorta arises centrally from the left ventricle aiming toward the right shoulder in a 90° crossing fashion relative to the main pulmonary artery. The ascending aorta and the main pulmonary artery should be about the same size. Pulmonary outflow obstructions may not become obvious on fetal ultrasound until the third trimester. A form of hypoplastic right heart where there is pulmonary atresia with intact ventricular septum may have a normal four-chamber view in the second trimester and normal sized pulmonary arteries at birth. In these cases, the pulmonary valve may acquire more severe obstruction with fetal growth resulting in a reversal of flow through the ductus arteriosus. We have seen this in the recipient twin in twin-to-twin transfusion syndrome as well as in singleton pregnancies. In these situations, the left ventricle begins to become disproportionately larger than the right ventricle during the second trimester as blood flow patterns change. Color Doppler is useful in proving a normal pulsed Doppler flow pattern into the main pulmonary artery. Normally, the forward flow pattern from the right ventricle into the pulmonary artery is a hollow envelope rarely exceeding 0.7 m/s. Pulmonary stenosis can be recognized by a course spectral flow pattern measuring greater than 1.0 m/min and often associated with tricuspid valve regurgitation. Pulmonary outflow obstruction should be considered with presumptive fetal diagnoses of Ebstein's malformation of the tricuspid valve, double outlet right ventricle (DORV), transposition of the great arteries (d or l-TGA), ventricular septal defect, tetralogy of Fallot and in cases of early diagnosis of transient cystic hygroma associated with Noonan's syndrome. In those cases with the physiology of tetralogy of Fallot with pulmonary atresia, color Doppler is useful in identifying collateral arterial vessels feeding the lungs from the aorta. It is important to differentiate this disease from truncus arteriosus. Collateral vessels can also be seen using color Doppler in cases of pulmonary sequestration.

We use a team approach of prenatal counseling by the perinatologist, neonatologist, pediatric cardiologist and cardiothoracic surgeon for the family of any fetus with congenital heart disease that may require prenatal or early neonatal intervention. Any suggestion of a fetal anomaly of venous or arterial connection or obstruction must be confirmed after delivery by newborn echocardiography or at cardiac catheterization.

49 Uteroplacental and umbilical circulation: physiologic changes in pregnancy

A. K. Ertan, H. A. Tanriverdi and W. Schmidt

Doppler sonography in obstetrics is a widely accepted functional method of examining the uteroplacental and fetal unit. It is a noninvasive method and became almost a standard technique in antenatal care. This method became an important tool for qualifying high-risk pregnancies. Color Doppler ultrasound represents blood flow changes as a color image, superimposed on the real-time ultrasound image being examined. In this way different vessels of the uteroplacental circulation can be accurately identified. Also, by identifying the vessel at a fixed point, e.g. where the uterine artery crosses the external iliac artery, it is possible to examine the same point in the circulation. Endovaginal color Doppler transducers allow easy and quick visualization of even the smallest vessels in the uteroplacental and fetal circulation. This, in turn, has enabled us to build a picture of the physiological changes in uteroplacental and fetal blood flow before and during the early stages of pregnancy.[1]

One of the first steps toward realizing the potential of Doppler ultrasound is to gain a clear understanding of the physiological changes that occur in the uteroplacental circulation during normal pregnancy. With this knowledge, we can obtain a clearer understanding of the pathophysiological changes that occur in the presence of disease.

Indices

Although measurement of volume flow changes in an organ would be ideal, *in vivo* the current methods for determining true flow are too inaccurate for deriving meaningful conclusions that can be of clinical value. Consequently, we rely on indices of resistance and velocity derived from the flow velocity waveforms (FVW) of a vessel.

Blood flow velocity in the fetal circulating system depends on the type of vessel. The arteries always have a pulsatile pattern (Figure 49.1), whereas veins have either a pulsatile or a continuous pattern (Figure 49.2).

Analyzing Doppler sonographic FVWs quantitatively is more difficult than analyzing them qualitatively. Qualitative analysis also overcomes erroneous measurements in small vessels. There are plenty of indices for qualitative analysis. The following are the most frequently used indices:

- systolic/diastolic ratio (S/D ratio, Stuart 1980)
- resistance index (RI, Pourcelot 1974)
- pulsatility index (PI, Gosling and King 1977).

In analyzing sonographic results and calculating indices, the following characters are used:

S = temporal peak of maximum frequency
D = end-diastolic maximum frequency
C = temporal average of maximum frequency, F_{mean}
I = instantaneous spatial average frequency
E = temporal average of spatial average frequency.

Calculations of formulas are as follows (Figure 49.3):

$$\text{S/D ratio} = S/D$$
$$\text{RI} = (S-D)/S$$
$$\text{PI} = (S-D)/C$$

The indices presented above also overcome a very serious problem involved with the angle between the ultrasound beam and the direction of blood flow (insonation angle). These indices are relatively angle independent and are therefore easily applied in clinical practice.

In practice, none of the indices is superior to the other[2–4] and any index may be used. Although S/D ratio is easily calculated, RI is the easiest to interpret. RI values approach 0 if resistance decreases and 1 if resistance increases. If end-diastolic flow is absent,

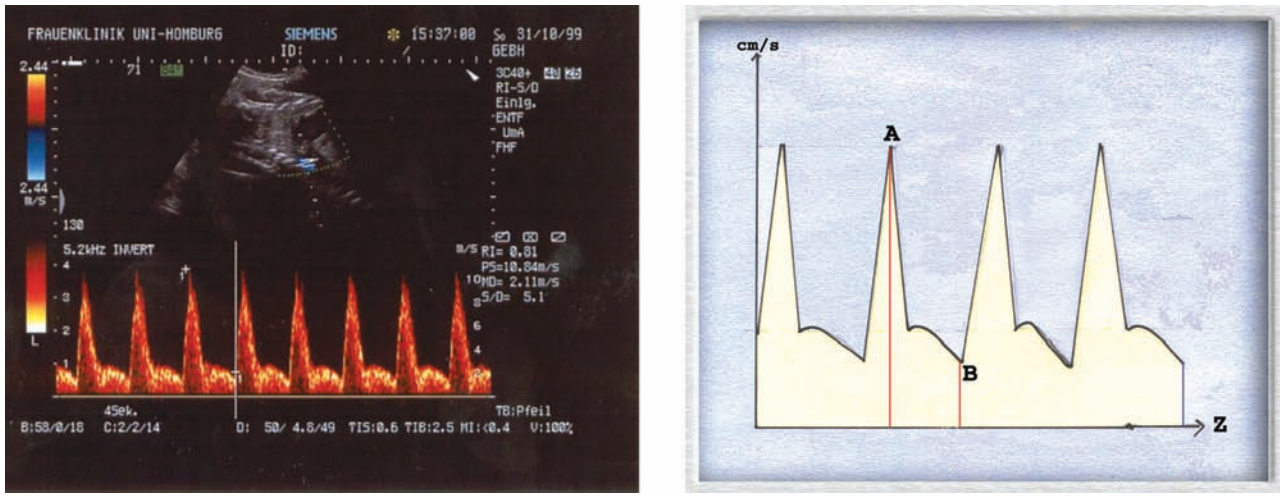

Figure 49.1 Doppler sonography of fetal aorta with a pulsatile pattern.

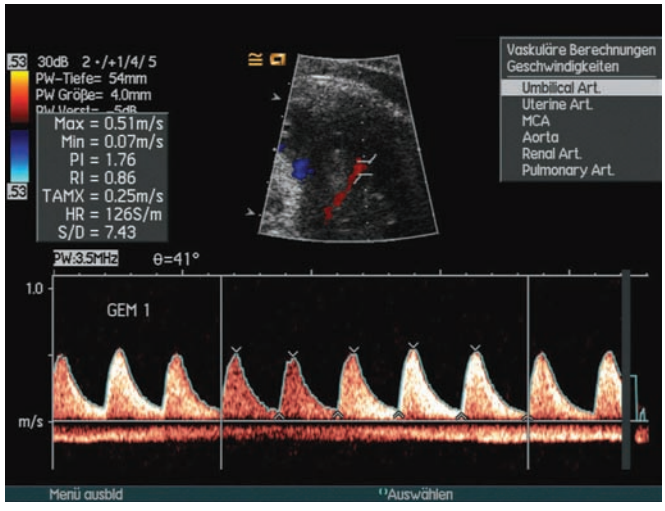

Figure 49.2 Umbilical artery with a pulsatile (upper line) and umbilical vein with a continuous pattern (lower line).

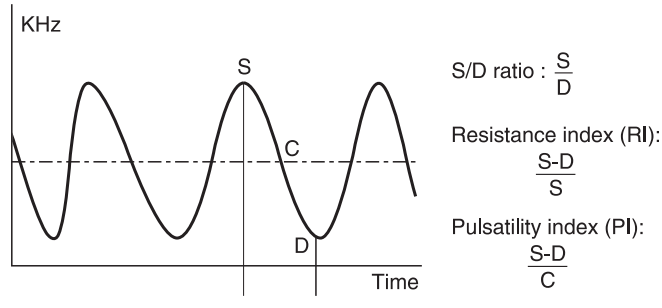

Figure 49.3 Scheme of the Doppler curve (a). *S*=systolic, *D*=diastolic, *C*=temporal average of maximum frequency. Calculation of formulas of the main Doppler sonographic indices (b.)

PI is the only index making evaluation of blood flow possible, because in this situation S/D will equal to infinity and RI to 1. The PI is more complex because it requires the calculation of the mean velocity, but modern Doppler sonographic devices provide those values in real time.

Physiologic color Doppler sonographic changes of the embryonic and uteroplacental vessels in early pregnancy

The results of a recent study performed by Ertan *et al.*,[5] evaluating the uteroplacental and fetal circulation during early pregnancy in non-complicated pregnancies, showed that vascular impedance to blood flow in all the examined vessels decreased significantly throughout the first gestational trimester. Resistance to flow was highest in the main uterine artery and decreased toward the spiral artery. When the FVW patterns of the arteries under investigation were analyzed, specific changes were observed. In all of the cases during early gestational development, an early diastolic notching was determined in the uterine arteries. The FVWs of the fetal aorta and umbilical arteries were similar: until week 10 the arteries were typically without a diastolic flow. From week 16 onward, diastolic velocities were present in all signals at the fetal aorta and umbilical arteries.

Changes in uterine artery circulation in early pregnancy

The uterine artery FVW was characterized by an early diastolic notch and a gradually increasing flow

velocity during early pregnancy. The peak systolic velocities (PSV) increase, whereas the S/D ratio and RI decrease progressively during early pregnancy. The end-diastolic velocity increases progressively. In all of the cases during early gestational development, an early diastolic notching was determined, but there was a gradually flattening in the depth of the notch (Figure 49.4). At the third trimester of pregnancy this notch disappeared. The RI of the uterine arteries decreased gradually, which means that the resistance of the arteries lessens during pregnancy progression.

Changes in umbilical circulation in early pregnancy

The color signal of the umbilical artery was recorded for the first time at 7 weeks' gestation.

From week 10 onward it was possible to show the end-diastolic velocity and from week 16 onward diastolic signals were present in all cases (Figures 49.5 and 49.6). The PSV between weeks 7 and 9 remained constant and from week 9 onward it increased, while the S/D ratio and RI decreased progressively during the first 16 weeks of gestation.

Changes in fetal aorta circulation in early pregnancy

It was possible to record the color signal of the fetal aorta for the first time at 7 weeks' gestation. The main problems in achieving Doppler signals of the aorta were fetal body movements and trying to make measurements with a correct angle, less than 60°.

The FVW was similar to the umbilical artery. Until week 10 of gestation the FVW was typically without a diastolic flow (end-diastolic zero flow). From week 16 onward, diastolic velocities were present in all aortic signals (Figure 49.7). The PSV increased and the S/D ratio and RI decreased progressively during the first 16 weeks of gestation.

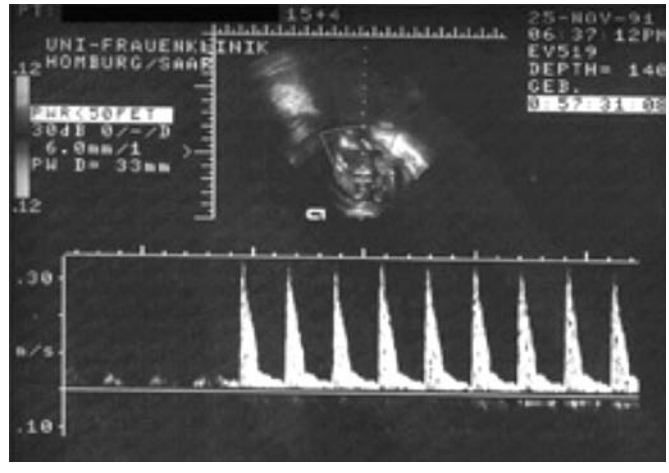

Figure 49.7 Doppler velocity waveforms of fetal aorta with an end-diastolic flow in 15+4 weeks of pregnancy.

Uteroplacental and fetal circulation after midpregnancy

The maternal side: uterine circulation

The uterine artery is a branch of the internal iliac artery. It courses along the lateral wall of the pelvis before crossing the external iliac artery and reaching the uterus at the level of the cervix. After giving off a cervical branch, it ascends along the lateral wall of the body of the uterus in a tortuous manner, before anastomosing with the Fallopian branch of the ovarian artery. As it passes along the body of the uterus it gives off the arcuate arteries, which encompass the uterine body. These in turn give off radial arteries that penetrate into the inner third of the myometrium, where they become the basal arteries. The spiral arteries, a continuation of the basal arteries, supply the endometrium, their coiled form allowing contraction during menstruation[1] (Figure 49.8).

Using transvaginal color Doppler sonography, it is possible to identify the uterine artery in early pregnancy at the level of the cervical os, as it enters the uterus, and as it ascends into the uterine body (Figure 49.9). It is possible to examine the uterine artery by the transabdominal approach after 12 weeks' gestation, when the uterus becomes an abdominal organ. The FVWs obtained from the uterine artery do not significantly change from when it enters the cervix up to the point that it reaches the body of the uterus. It is important to measure at this level, before the uterine artery enters the uterus and branches into the arcuate arteries. An arcuate artery can exhibit a relatively low resistance pattern even when the uterine artery has high resistance with persistent notching present (Figure 49.10). It is therefore necessary to ensure that the uterine artery is examined as it reaches the uterus at the level of the cervix, if the changes in the uterine circulation are to be interpreted as a whole. Similarly, if the sample site is too low on the cervix, the cervical branch of the uterine artery will be examined; this can show high resistance when the main uterine artery waveform is normal.[1]

Blood flow velocities in the uterine artery depend on the localization of the placenta and the gestational age.[6] If the placenta is laterally located, blood flow velocities in the ipsilateral uterine artery are more important than the flow velocities of the contralateral vessel. Differences between flow velocities of the right and left uterine arteries are evident in the early stages of pregnancy. But in the third trimester, the difference between the S/D ratio of the vessels decreases to 0.3–0.4.[2] If an abnormal flow pattern is observed in the uterine arteries in midpregnancy, it most probably indicates the defective perfusion of the fetoplacental unit, which predicts a high probability of developing pre-eclampsia and/or intrauterine growth retardation (IUGR).[7]

In the early stages of pregnancy end-diastolic flow velocities in placental arteries are low, but systolic

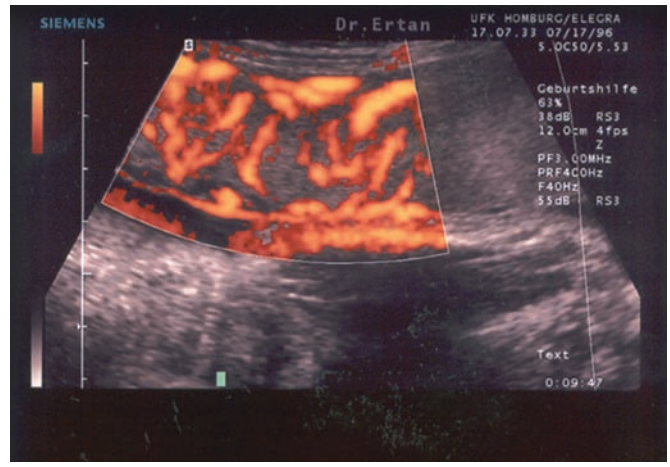

Figure 49.8 Power Doppler of arcuate and intraplacental arteries.

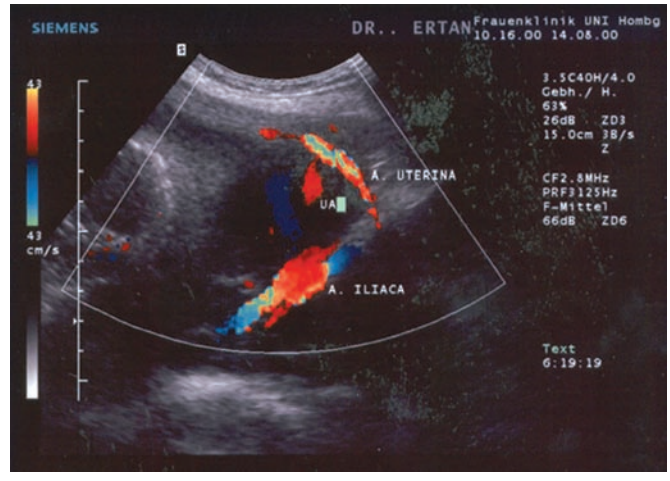

Figure 49.9 Color Doppler sonographic view of the main uterine artery crossing the iliac artery.

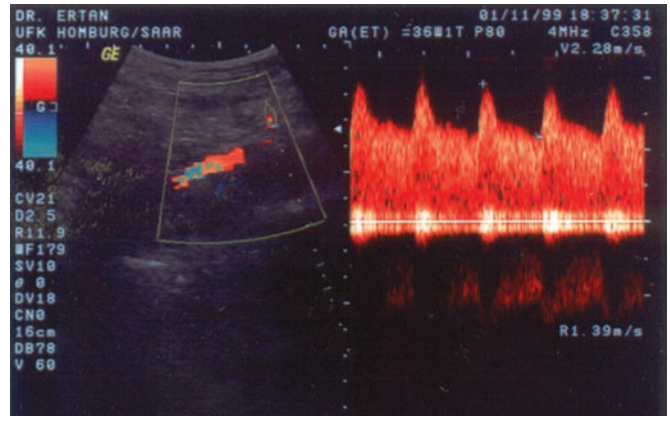

Figure 49.10 Flow in different parts of the uteroplacental circulation can be measured with color Doppler technology, here the relatively low resistance pattern of the uteroplacental arteries.

flow is evident.[2] With trophoblastic invasion and maturation of the uteroplacental vessels, beyond the second trimester the high-pressure system is converted to a low-pressure system, and vascular resistance declines.[8] The biologic variability after the middle of the second trimester becomes almost stable.

Before 24 weeks' gestation early diastolic notching, due to the immature uteroplacental vascular system, is normally observed. Beyond this gestational age, persistent early diastolic notching is associated with pre-eclampsia[9–11] (Figures 49.11 and 49.12).

The fetal side: umbilical arteries, fetal aorta and middle cerebral artery (MCA)

Umbilical arteries

Blood flow velocity in the umbilical arteries increases with progressive gestational age (Figure 49.13). As a result, the S/D ratio continuously decreases due to increasing arterial blood flow. With progressive gestational age, end-diastolic flow becomes evident during the whole heart cycle, matching with the previous longitudinal studies of Fogarty *et al.*[2] and Huneke *et al.*,[12] as with many cross-sectional studies.[13–16]

Trudinger *et al.*[17] put forth the following mechanisms to explain this development:

- continuous maturation in placental villi
- continuous widening of placental vessels causing a continuous decrease in vascular resistance
- continuous increase in fetal cardiac output
- continuous changes in the vessel compliance
- continuous increase in fetal blood pressure.

Especially in the third trimester of pregnancy, depending on the above factors, normal values become scattered on nomograms. This scattering is more prominent in the S/D ratio than the PI. RI is not affected by the above factors after 28 weeks' gestation.

Descending fetal aorta

Beside the umbilical arteries, routine Doppler sonographic measurements on the descending fetal aorta are possible. As the gestational age increases, the S/D ratio of fetal aorta decreases insignificantly, paralleling the results of Hecher *et al.*[18] The FVW of the fetal aorta shows a continuous forward stream during the whole heart cycle, but when compared to the FVW of the umbilical arteries, the end-diastolic flow is less than the systolic component. Because of this, the S/D ratio in the fetal aorta is greater than the S/D ratio in the umbilical arteries. As pregnancy progresses, the diameter of the vessel gets wider and as a result peripheral resistance decreases, and diastolic flow increases. Nevertheless, this does not cause a significant decrease in the S/D ratio in the fetal aorta. RI and PI are not affected significantly, and show a similar course as in the umbilical arteries.

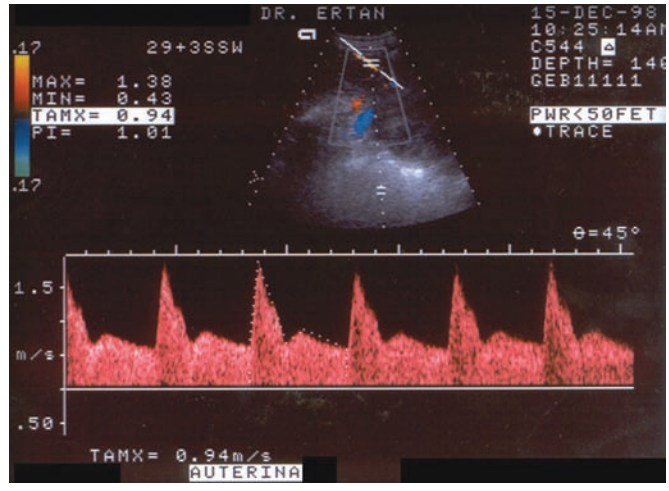

Figure 49.12 Pathological waveforms of uterine artery in 29 + 3 weeks of pregnancy with IUGR and pre-eclampsia.

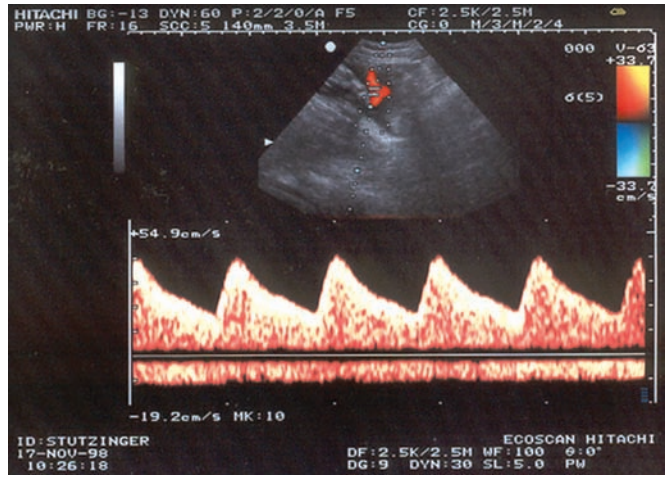

Figure 49.13 Blood velocity waveform in umbilical artery in late pregnancy.

Middle cerebral artery

The most favorably positioned vessel for Doppler sonographic examination of the fetal brain perfusion is the MCA. Biologic variability of vessels perfusing the fetal brain is excessive due to the fetal activity status. As pregnancy progresses, the vascular resistance decreases.[19] During the early stages of pregnancy, end-diastolic flow velocities in cerebral vessels are weak, but velocities increase toward the end of gestation. Hyperactivity of the fetus, increase of intrauterine pressure (e.g. polyhydramnios) and external pressure to the fetal head (e.g. by the probe) might erroneously increase end-diastolic flow velocities.[20] Different investigators have undertaken studies utilizing data obtained from the umbilical arteries and MCA to develop indices for evaluation of intrauterine risk.

Dependency of Doppler FVWs on gestational age

The amount of perfusion in trophoblastic tissue is related to gestational age. For this reason, in interpreting the Doppler sonographic findings, gestational age should be taken into account as well. In general, the accepted time for starting Doppler sonographic examinations is the beginning of the second trimester. This is the right time to allow for modifications in antenatal care in a high-risk pregnancy. For specific conditions, earlier timing of measurements may be considered.[21]

The main objective in using fetomaternal Doppler sonographic nomograms is to improve perinatal outcome in high-risk pregnancies. The curves presented below depict normal fetal and maternal Doppler sonographic values standardized according to gestational age, and can be used in routine practice (Figures 49.14–49.25).

Doppler sonographic nomograms are used for differentiation of normal and abnormal blood FVWs, which helps to determine high-risk pregnancies. By taking threshold values of pathologic pregnancies into consideration, nomograms are capable of differentiating between the normal and the abnormal.[22] While using these nomograms, it must always be kept in mind that the values on these nomograms should not be taken as mathematical equations, and that limitations of sensitivity and specificity exist.

Using nomograms in practice

Just like the defense mechanism of peripheral vasoconstriction in an adult in the face of hemorrhagic shock, the 'brain sparing' mechanism (brain sparing effect) becomes active in a fetus with hypoxia or chronic placental insufficiency. As a result of the brain sparing effect, resistance either in the umbilical artery or in the fetal descending aorta increases. As a consequence, Doppler indices related to these vessels

increase. The end-diastolic blood flow increases in the MCAs by the same effect. Doppler indices for this vessel decrease consequently.

Some points should be considered while using Doppler sonographic nomograms:

(1) Among the measurements performed on the umbilical artery and the fetal descending aorta, values between the 90th and 95th percentiles should be considered as borderline and repeat follow-ups should be planned. Values exceeding the 95th percentile are considered abnormal.
(2) Doppler values between the 5th and 10th percentiles in the MCA should be considered as borderline and repeat follow-ups should be planned. Values below the fifth percentile are considered abnormal.
(3) Measurements taken after 24 weeks' gestation from the uterine arteries are more valuable. The early diastolic notching and values exceeding the 95th percentile are considered as abnormal. One point to remember is that notching by itself predicts an elevated risk of pre-eclampsia.

Conclusion

In normal pregnancies, uteroplacental flow velocities become almost stable after the middle second trimester; meanwhile, fetal blood flow velocities also alter. With advancing gestational age, the S/D ratio in the umbilical artery and MCA decreases. Although the S/D ratio in the descending aorta is almost stable during pregnancy, advancing gestational age narrows the biologic variability of the flow spectrum. Accordingly, it is recommended to use gestational age-matched nomograms to define threshold values, and to differentiate and predict pathologic pregnancies.

The key points relating to physiological changes in the uteroplacental and fetal circulation can be summarized as follows:

(1) The technique of Doppler ultrasound is a non-invasive method of examining the uteroplacental and fetal circulation. Color Doppler sonography allows the uteroplacental and fetal circulation to be investigated throughout pregnancy.
(2) The main changes in FVW in the fetal and uteroplacental vessels occur in the first trimester of pregnancy and go on slowly in the remaining periods. Fetal and uteroplacental velocities increase gradually during early pregnancy and velocimetric indices show a progressive decrease of the uteroplacental resistances. In early pregnancy the umbilical artery and fetal aorta FVWs are initially of high resistance, with absent end-diastolic flow. Resistance falls rapidly toward the end of the first trimester; and end-diastolic flow is usually present by the 16th week of gestation. Resistance continues to fall throughout the remainder of the pregnancy.
(3) In normal pregnancy there is a gradual fall in resistance, an increase in diastolic flow and a disappearance of the diastolic notch in the uterine artery FVW.
(4) Pre-eclampsia, IUGR and placental abruption are associated with inadequate placentation/function, and a relationship exists between these complications and the failure of physiological change in the uteroplacental circulation.

50 Doppler sonography in high-risk pregnancy

A. K. Ertan, H. A. Tanriverdi and W. Schmidt

One of the main aims of routine antenatal care is to identify the 'at risk' fetus in order to apply clinical interventions which could result in reduced perinatal morbidity and mortality.[1] Doppler sonography in obstetrics is a widely accepted functional method of examining the utero-fetoplacental unit.

Doppler ultrasound is a noninvasive technique whereby the movement of blood (usually in a vessel) is studied by detecting the change in frequency of reflected sound. Doppler ultrasound has been used in obstetrics since 1977 to study the fetoplacental (umbilical) circulation,[2] and since the 1980s to study the utero-placental (uterine) circulation[3] and fetal circulation.[4] Recently, this method has become an important tool for qualifying high-risk pregnancies.

Information obtained with Doppler sonography helps obstetricians in managing patients in situations like pregnancies complicated by intrauterine growth restriction (IUGR), Rhesus alloimmunization, multiple pregnancies, and anamnestic risk factors. Examination of the uteroplacental and fetomaternal circulation by Doppler sonography in the early second trimester helps predicting pregnancy complications like preeclampsia, IUGR and perinatal death.[5–13]

This chapter aims to introduce Doppler sonographic examinations in high-risk pregnancies. Doppler blood flow velocity waveforms (FVWs) of the fetal side (umbilical artery, descending aorta, and middle cerebral artery) are discussed.

The safety of Doppler ultrasound in obstetrics

The safety of Doppler ultrasound in obstetrics remains a concern. The data available to date suggest that diagnostic ultrasound has no adverse effects on embryogenesis or fetal growth. In addition, ultrasonographic scanning has no long-term effects on cognitive function or noted changes of visual or hearing functions. However, although B and M mode scans are safe during pregnancy, color, power and pulsed Doppler procedures should be performed with caution due to possible thermal effects. Lastly, a new method, the three-dimensional technique, was introduced. While there are no studies regarding the safety of this new technique, the short acquisition time and the postprocessing analysis may decrease exposure and thus reduce the risk of possible effects of the ultrasound waves on fetal development.[14]

In particular, the use of pulsed Doppler involves the use of higher intensities compared to diagnostic ultrasound, and hence may cause significant tissue heating and thermal effects. However, these thermal effects depend on the presence of a tissue/air interface and may therefore not be clinically significant in obstetric ultrasound examinations.[15] Clearly, while there is continuing concern regarding the safety of Doppler ultrasound, it should only be used in cases of proven value or controlled investigational circumstances.

Indications of Doppler sonography in obstetrics

Prospective randomized studies of fetal vessels and their collective evaluation have shown no benefit of Doppler sonography in screening the nonselected population.[16] In high-risk pregnancies, however, there is definitive evidence that the use of Doppler studies can significantly reduce the number of antenatal examinations and the number of necessary inductions of labor and cesarean deliveries for fetal distress. Doppler sonography reduces the perinatal mortality, the number of elective deliveries, the incidence of intrapartum distress, and the occurrence of hypoxic encephalopathy.[17] A definite benefit has been established for Doppler sonography in selected cases (Table 50.1).

Table 50.1 Indications for Doppler sonography in obstetrics

Suspicion of intrauterine growth restriction (IUGR)
Pregnancy-induced hypertension (PIH)/preeclampsia/eclampsia
Suspicion for a fetal malformation or disease
Multiple pregnancy with discordant growth
Investigation of fetal cardiac anomaly or heart disease
Fetal heat rate abnormalities/arrhythmia
Preexisting maternal diseases with vascular relevance
Prior history of IUGR or intrauterine fetal death
Prior history of PIH/pre-eclampsia/eclampsia

Changes in Doppler sonographic results during the course of pregnancy and complicated pregnancies

During the course of pregnancy and in some specific pregnancy complications, Doppler sonographic results of fetomaternal vessels display changing values. Chronic placental insufficiency is a major research application for Doppler sonography in high-risk pregnancies. Various fetal vessels are examined to determine/diagnose perinatal problems.

Umbilical artery

It has been shown in a longitudinal, observational study that Doppler ultrasound of the umbilical artery (UA) is more helpful than other tests of fetal well-being (e.g., heart rate variability and biophysical profile score) in distinguishing between the normal small fetus and the 'sick' small fetus.[18] However, its exact role in optimizing management, particularly timing of delivery, remains unclear, and is currently being investigated by many study groups. The optimal timing of delivery in pregnancies complicated by highly pathological Doppler flow findings is still an issue to be resolved. The established approach to resolve this question and to improve the perinatal morbidity and mortality by the use of Doppler examination is being investigated in multicenter clinical trials,[19] e.g., the trial of umbilical and fetal flow in Europe Group (TRUFFLE-Protocol, unpublished data).

Blood flow velocity in the UA increases with the advancing gestation. As a result impedance to blood flow continuously decreases due to increasing arterial blood flow in the systole and diastole. End-diastolic velocity is often absent in the first trimester[2,20] and the diastolic component increases with advancing gestation[21] (Figure 50.1). With advancing gestational age end-diastolic flow becomes evident during the whole heart cycle (Figure 50.1). This has been proven by previous longitudinal studies of Fogarty *et al.*[22] and Hünecke *et al.*,[23] as with many cross-sectional studies.[21,24]

Trudinger *et al.*[25] explained this phenomenon with the following mechanisms:

- Continuous maturation in placental villi
- Continuous widening of placental vessels cause a continuous decrease in vascular resistance
- Continuous increase in fetal cardiac output
- Continuous changes in the vessel compliance
- Continuous increase in fetal blood pressure.

Especially in the third trimester of pregnancy, depending on the above factors normal values become scattered on nomograms. This scattering is more prominent in the S/D ratio than the pulsatility index (PI). Resistance index is not affected by the above factors after 28 weeks' gestation.

FVWs of the UA are slightly different at the abdominal wall and the placental site, with indices higher at the fetal abdominal wall than the placental insertion.[26] The difference, however, is minimal, and therefore in clinical practice it is not important to obtain the FVWs always at the same level. FVWs must always be obtained during fetal apnea periods because fetal breathing affects the waveforms.

In case of an abnormal test, clinical experience and randomized controlled trials showed significant association with an adverse perinatal outcome.

Intrauterine growth restriction

The IUGR fetus is a fetus that does not reach its potential growth. Environmental factors responsible may be

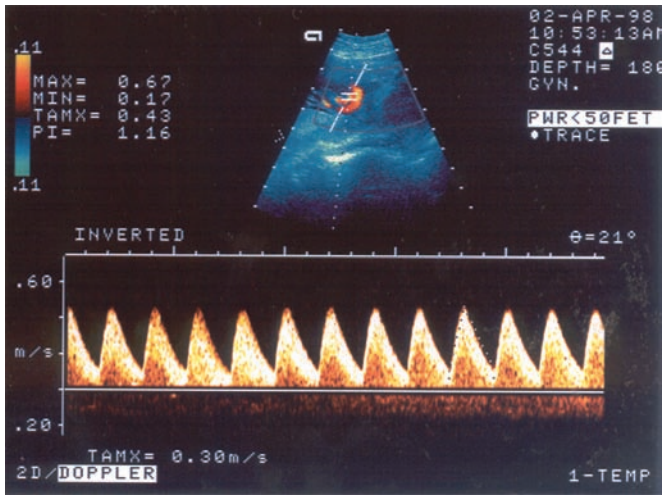

Figure 50.2 Abnormal flow velocity waveforms of the umbilical artery in the third trimester (high resistance index).

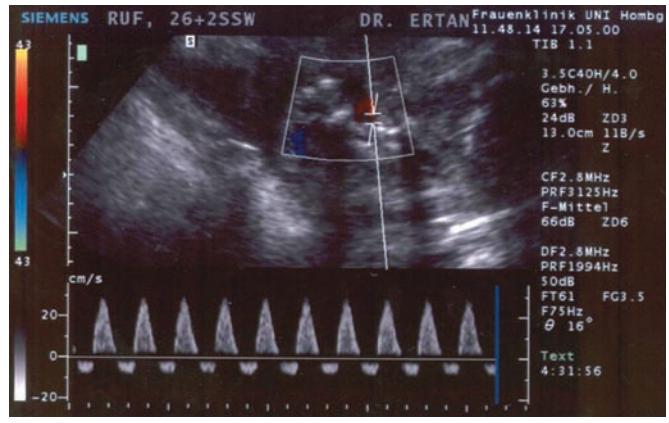

Figure 50.4 Reverse flow (RF) of the umbilical artery.

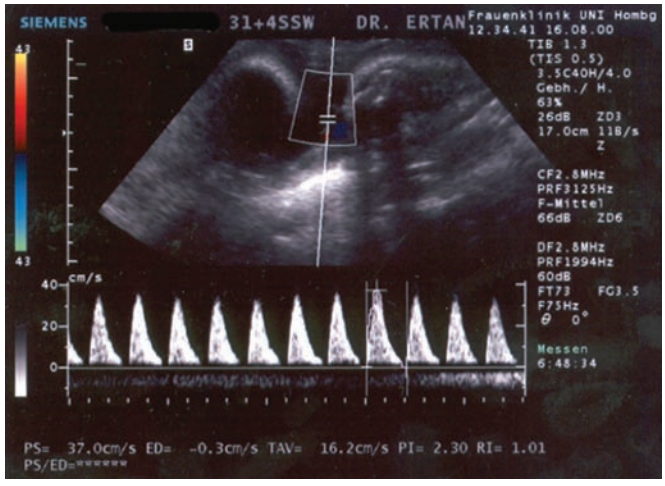

Figure 50.3 Absent end-diastolic flow (AEDF) of the umbilical artery in the third trimester.

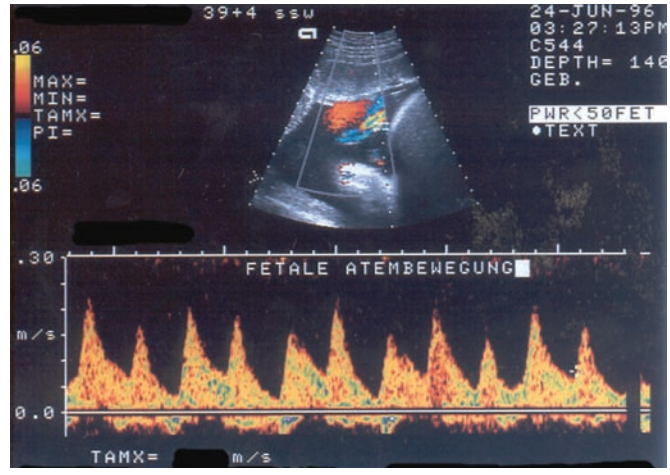

Figure 50.5 Pitfalls in umbilical artery Doppler velocimetry (fetal breathing).

due to maternal, uteroplacental and fetal factors. Many authors have reported on the association between an abnormal UA Doppler FVW and IUGR.

Differentiating the fetus with pathologic growth restriction that is at risk for perinatal complications from the constitutionally small but healthy fetus has been an ongoing challenge in obstetrics. Not all infants whose birth weight is below the 10th percentile have been exposed to a pathologic process *in utero*; in fact, most small newborns are constitutionally small and healthy. Doppler sonography has become the most important investigation method to differentiate between these fetuses.

It should be noted that Doppler sonography is not suitable for the primary diagnosis of fetal growth restriction, but it provides an excellent adjunctive method for risk differentiation in suspicious cases.

Pathophysiology of abnormal FVWs in placental insufficiency[27]

In the presence of placental insufficiency, there is greater placental resistance, which is reflected in a decreased end-diastolic component of the UA FVWs.[28–32] An abnormal UA FVW has an S/D ratio above the normal range. As their placental insufficiency worsens, the end-diastolic velocity decreases (Figure 50.2), then become absent (Figure 50.3), and finally it is reversed (Figure 50.4). Some fetuses have decreased end-diastolic velocity that remains constant with advancing gestation and never become absent or reversed, which may be due to a milder form of placental insufficiency (Figure 50.2). Pitfalls can be caused because of, e.g., fetal breathing (Figure 50.5).

Abnormal UA Doppler studies, but not normal results were found to be associated with lower

arterial and venous pH values, an increased likelihood of intrapartum fetal distress, more admissions to the neonatal intensive care unit (NICU), and a higher incidence of respiratory distress in IUGR fetuses.[33] Therefore, intensive antenatal surveillance in fetuses with suspected IUGR if the UA Doppler FVWs are normal was not recommended by the authors. Conflicting data were presented by McCowan *et al.*[34] They confirmed that abnormal UA Doppler studies are associated with a poor perinatal outcome in IUGR fetuses but also concluded that the perinatal outcome in small for gestational age fetuses with normal UA Doppler studies is not always benign (i.e., low ponderal index, postnatal hypoglycemia, admission to the NICU). Recently, Ertan *et al.*[35] suggested that reversed flow should be seen as a particular clinical entity with higher incidences of perinatal and overall mortality, and severe intrauterine growth restriction compared to absent end-diastolic flow (Figures 50.3 and 50.4).

In our clinical experience, when an IUGR fetus is suspected, the UA, fetal descending aorta (FDA), and middle cerebral artery (MCA) are the first fetal vessels to be assessed. The ductus venosus (DV), umbilical vein, inferior vena cava Doppler examinations are secondary vessels to be examined, only when an abnormal FVW is detected on the arterial vessels. Adding serial Doppler evaluation of the UA, MCA, and DV to IUGR surveillance will enhance the performance of the biophysical score in the detection of fetal compromise and therefore optimizing the timing of intervention.[36]

Table 50.2 Antenatal complications of the reversed ($n=30$) and absent end-diastolic flow cases ($n=30$)

Type of complication	Reverse flow, *n* (%)	Absent flow, *n* (%)
Pregnancy-induced hypertension	19 (63.3)	19 (63.3)
HELLP syndrome	1 (3.3)	6 (20)
Gestational diabetes	1 (3.3)	2 (6.7)
Fetal Infection	1 (3.3)	0
Abruptio placenta	0	4 (13.3)
Birth weight in g (M ± SD)	1071 ± 112	1214 ± 82
Intrauterine growth retardation* (< 5 percentile)	25 (83.3)	19 (63.3)
Oligohydramnios*	21 (70)	13 (43.3)

HELLP: hemolysis, elevated liver enzymes, low platelets.

* $p < 0.05$.

Comparison of perinatal outcome in fetuses with reverse or absent end-diastolic flow in the umbilical artery/fetal descending aorta[35]

An abnormal FVW is a good predictor for poor perinatal outcome in high-risk pregnancies.[37–41] The absence or reversal of end-diastolic flow in the umbilical artery (UA) and fetal aorta is widely accepted as an ominous sign of fetal compromise, with a very high perinatal mortality (35–100%) and morbidity.[27,39,42,43]

The incidence of absent end-diastolic flow is low, and of reversed flow it is even lower (reverse flow/absent end-diastolic flow ratio = 1:10).[27,42,43] Studies so far analyzed the fetal outcome in reversed and absent end-diastolic flow cases together as one clinical entity. The difference between the prognosis of fetuses with reversed flow and absent end-diastolic flow is still unknown.

We undertook a study, in which the highly pathologic flow profiles, consisting of absent end-diastolic flow and reverse flow at the UA and fetal aorta were compared for perinatal outcome. The aim of this study was to clarify whether reverse flow at the UA and fetal aorta worsens perinatal outcome more than absent end-diastolic flow at the same vessels and to assess the possibility of making predictions about the further course of pregnancy.

Materials and methods

During a 10-year period 30 cases with reverse flow in the umbilical artery and/or fetal aorta (group I) were detected. We selected matched pairs of 30 cases with absent end-diastolic velocities (group II). The selection criterion into the groups was an absent or reverse flow at the time of delivery. Fetal malformations and chromosomal anomalies were excluded from both groups. For matching of the absent end-diastolic flow group fetuses to the reversed flow group same gestational ages, estimated fetal weights and gestational ages at delivery were stipulated.

Results

Maternal complications were similar in bothgroups. Intrauterine growth retardation and oligohydramnios incidences were significantly more common ($p < 0.05$, Table 50.2) in the reverse flow group (83% and 70% versus 73% and 43%).

The median time interval between the registration of reverse flow and death of fetuses was 2.5 days. After diagnosis of reverse flow, 11 fetuses (91.7%) died within a week (three on the same day, two on the next day, three on the second day, and the remaining four cases on days 3–8).

Table 50.3 Perinatal and neonatal parameters of the reverse ($n=18$) and absent end-diastolic ($n=29$) flow cases (live-born)

	Reverse flow, *n* (%)	Absent end-diastolic flow, *n* (%)
5 Apgar ≤7	7 (39)	13 (45)
pH ≤7.2	6 (33)	9 (31)
Cerebral hemorrhage	5 (27.8)	5 (17.2)
Infections	8 (44.4)	8 (27.6)
Anemia	8 (44.4)	9 (31.0)
Hypocalcemia*	3 (16.7)	0
Hyaline membrane syndrome	12 (67)	19 (66)
Icterus	8 (44.4)	12 (41.4)
Shock lung	3 (16.7)	2 (6.9)
Lung emphysema	2 (11.1)	0
Retinopathy	1 (5.6)	3 (10.4)
Muscle hypotony	1 (5.6)	3 (10.4)

* $p < 0.05$.

The mean gestational age at live birth was 31 weeks in both groups. Of the 18 survivors in group I, 17 (94.4%) were delivered by cesarean section. This was not significantly different from group II. The main indication for the cesarean section was fetal distress. The mean birth weight, 1071 (112 g) vs. 1214 (82 g) was not statistically different between the groups.

The mean values and the frequency of pathological Apgar scores (7) at 1, 5, and 10 min, the arterial cord blood pH values, and the mean values of umbilical arterial PO_2, PCO_2 and HCO_3 were not different among the groups.

All the fetuses with absent and reversed end-diastolic flow were admitted to the NICU, and there was no difference in the duration of NICU treatment required. The rates (83% vs. 86%, respectively, for groups I and II) and duration of mechanical ventilation were not different among the groups.

Neonatal cerebral hemorrhage occurred more often in group I, but without statistical significance (27.8% vs. 17.2%). Neonatal morbidity (Table 50.3) included infections, hyaline membrane syndrome, icterus, and anemia and shock lung, without statistical difference between the groups. Only hypocalcemia was found more often in group I ($p < 0.05$).

There was a significantly higher overall and perinatal mortality in the reversed end-diastolic flow group (53% and 27%) as compared to the absent end-diastolic flow group (10% and 7%) ($p < 0.05$).

Discussion

Reverse flow in umbilical velocimetry is associated with dismal perinatal outcome. Perinatal mortality ranges from 35% to 100%, and postnatal morbidity is significant.[37,43–45] The above presented study[35] confirmed the adverse fetal outcome in fetuses with reversed end-diastolic flow in the UA and/or fetal aorta with a high overall mortality (53.3%) and perinatal mortality (26.8%).

Because of the low incidences of reverse flow cases, most authors have studied the effect of both reverse flow and absent end-diastolic flow velocity, often referred to an 'ARED-flow', on the fetal outcome together as one entity.[46] Reverse flow was considered to be the last phenomenon preceding fetal death.[37,47,48]

Absent or reversed end-diastolic flow in the UA or fetal aorta, is closely associated with intrauterine growth retardation due to uteroplacental insufficiency and higher rates of pre-eclampsia.[39,40,43] On the other hand, fetuses with intrauterine growth retardation have a high risk of developing absent or reversed end-diastolic flow.[44]

These fetuses with reverse flow had a very high incidence of oligohydramnios, intrauterine growth retardation and maternal pregnancy induced hypertension. Therefore, pregnant women with these complications should be evaluated with Doppler sonography to detect the compromised fetuses.

Several authors found an increasing association between reversed flow of the umbilical artery and the rate of fetal malformations, especially congenital heart anomalies, ranging from 12% to 50%.[43,49] These malformations of fetuses were associated with a low growth potential, not only for the fetus (intrauterine growth retardation) but also for the placenta, regardless of whether the placenta/neonatal weight was normal or below normal.[39] For a better understanding of this correlation, an additional study of subgroups with fetal malformations including more cases would be required.[49]

A close association between the reversed flow and neonatal cerebral hemorrhage has been reported.[44] The inappropriate autoregulation of the cerebral blood flow which is induced by extreme prematurity is the major risk factor for intracerebral hemorrhage.[50]

Normal fetal blood velocity values are considered reassuring and are generally believed to characterize a normal fetal oxygenation.[51] Absent or reversed end-diastolic flow velocity in the UA is associated with fetal hypoxia.[47,52,53] Although normal results of blood-gas analysis from umbilical vessels were observed in some cases with reversed or absent end-diastolic flow velocities, infants with this severe Doppler flow pathologies are at a high risk for neonatal asphyxia.[51] It was further suggested that fetuses with reverse flow should immediately be delivered after diagnosis.[48] 'Once the diastolic component of umbilical artery flow velocity waveforms becomes absent or reversed, the fetus is in a state of hypoxia and acidosis, and fetal

death is impending'.[49] Our results showed almost the same frequency of neonatal acidosis in 33% ($pH \leq 7.2$) in the reverse flow group, compared to 31% in cases with absent end-diastolic flow velocities. As significant reduction in the proportion of villous tissue occupied by the peripheral villi in pregnancies with absent or reversed end-diastolic flow was well documented previously,[54,55] in our presented cases the higher intrauterine death rates in the reverse flow group denotes an extreme placental insufficiency.

The incidence of infection, hyaline membrane syndrome and icterus was not influenced by reverse or absent end-diastolic flow. The incidence of anemia and shock lung was especially high, and hypocalcemia occurred statistically more frequent in the neonates with reversed end-diastolic flow. There was no difference in NICU admission and mechanical ventilation rates and duration of NICU stay. The overall neonatal morbidity was not significantly different between the groups. This suggests that both highly pathological Doppler findings are affecting the surviving neonates adversely. However, the higher rates of intrauterine and neonatal deaths in the reversed flow cases should be noticed.

The highly pathological Doppler findings (absent and reverse end-diastolic flow) of the umbilical artery and fetal aorta, which are attributable to severe impairment of placental circulation, and represent compromised fetal condition with high incidence of perinatal and neonatal mortality. In our opinion, the finding of a reverse flow spectrum of the umbilical arteries or fetal aorta should be accepted as a more abnormal Doppler finding, compared to absent end-diastolic flow. If absent or reversed end-diastolic flow is detected, a very close antenatal follow-up is advised and delivery should be considered if biophysical parameters and venous Doppler indices become abnormal.

Chromosomal abnormalities

It was shown that absent end-diastolic flow in the UA is associated with chromosomal abnormalities like trisomies, triploidies, or chromosomal deletions.[56] Setting out from the point that structural anomalies are more frequent in fetuses with chromosomal aberrations, the authors recommended a rapid acquisition of a karyotype in fetuses with congenital anomalies and an absent end-diastolic flow in the UA.[35]

Impact on perinatal consequences

Abnormal UA FVWs are associated in IUGR fetuses with one of the following outcomes: early delivery, reduced birth weight, oligohydramnios, NICU admission, and prolonged hospital stay.[27,57] In a meta-analysis it was shown that the use of UA Doppler sonography in pregnancies complicated by IUGR reduces perinatal mortality up to 38% and improves perinatal outcome.[17] A review consisting of 7000 high-risk pregnancies[58] found that Doppler ultrasound was associated with a trend toward reduction in perinatal death especially in pregnancies complicated with pre-eclampsia or IUGR. The Doppler ultrasound use was also associated with fewer inductions of labor and fewer hospital admissions, without reports of adverse perinatal effects. The reviewers concluded that the use of Doppler ultrasound in high-risk pregnancies is likely to reduce perinatal mortality.

Neonatal intraventricular hemorrhage

Fetal status as well as neonatal complications of prematurity in IUGR both contribute to adverse perinatal outcome and increase the risk for the development of intraventricular hemorrhage (IVH). Data suggest that absent and reversed end-diastolic flow in the UA early in gestation carries a high risk of subsequent neonatal IVH.[59] However, this observation is not independent of other perinatal variables: prematurity and difficult births remain the most important determinants of this complication.

Neuromotor outcome

Valcomonico *et al.*[57] evaluated the association of UA Doppler velocimetry with long-term neuromotor outcome in IUGR fetuses with normal ($n=17$), reduced ($n=23$), and absent or reversed ($n=31$) UA end-diastolic flow. The infants who survived the neonatal period were observed for a mean of 18 months. Their postural, sensorial, and cognitive functions were evaluated at 3, 6, 9, 12, and 18 months of age. Although, due to a small number of cases the results did not reach statistical significance, the incidence of permanent neurological sequelae increased as the UA end-diastolic flow decreased (35% with absent or reversed flow, 12% with reduced flow, and 0% with normal flow). Recently, in another study[60] 23 IUGR fetuses with absent or reversed UA end-diastolic flow were matched with fetuses with appropriate growth. All children were followed for 6 years, and intellectual development, neuromotoric development was significantly diminished in fetuses with abnormal FVWs. Only social development was not impaired in fetuses with abnormal UA FVWs. Similar results were previously published by our working group too.[38,61]

Intrapartum studies

A review of intrapartum UA Doppler velocimetry for adverse perinatal outcome gave disappointing results.[62] Out of 2700 pregnancies, which were evaluated for the intrapartum use of Doppler velocimetry, the technique proved to be a poor predictor for outcome

measures like low Apgar scores, intrapartum fetal heart rate abnormalities, umbilical arterial acidosis, and cesarean section for fetal distress.

Umbilical artery Doppler ultrasound in unselected patients

Theoretically, the use of routine UA Doppler ultrasound in unselected or low-risk pregnancies would be to detect those pregnancies in which there has been failure to establish or maintain the normal low-resistance umbilical and uterine circulations (a pathological process leading to placental dysfunction and associated with intrauterine growth retardation and preeclampsia), before there is clinical evidence of fetal compromise. In practice, observational and longitudinal studies of Doppler ultrasound in unselected or low-risk pregnancies have raised doubts about its application as a routine screening test, and authors have cautioned against its introduction into obstetric practice without supportive evidence from randomized trials.[63–65] The relatively low incidence of significant, poor perinatal outcomes in low-risk and unselected populations presents a challenge in evaluating the clinical effectiveness of routine UA Doppler ultrasound, as large numbers are required to test the hypothesis.

Multiple gestation

The S/D ratio of twins at the UA is in agreement with singleton pregnancies in the third trimester.[66] Twins with an abnormal UA FVW tend to be born earlier, have a higher perinatal mortality and morbidity, and have more frequent structural anomalies than fetuses without abnormal Doppler results.[67]

In cases of twin–twin transfusion syndrome, a poor placental implantation site, or chromosomal anomalies discordant growth between the twins may occur. This is a very high-risk situation, with high perinatal mortality and morbidity. The diagnosis is made mainly by ultrasound biometry. The best predictor for diagnosis of discordant twins appears to be the presence of either a difference in the UA S/D ratio greater than 15% or a different estimated fetal weight greater than 15%.[68] Recently, it has been reported that abnormal UA velocimetry can be observed in small twins more often in monochorionic than dichorionic twins.[69] Doppler ultrasound abnormalities of the UA in either twin are associated with poor perinatal outcome in twin–twin transfusion syndrome.

The biophysical profile and multivessel Doppler ultrasound in IUGR

Biophysical profile scoring (BPS) and Doppler surveillance are the primary methods for fetal assessment in IUGR. As placental insufficiency worsens, the fetus adapts by progressive compensation. Previously it has been suggested that the sequential changes in arterial and venous flow occur before some biophysical parameters (fetal tonus, movement, breathing, amniotic fluid volume, and nonstress test) decline.[70,71] Baschat *et al.*[36] evaluated whether multivessel Doppler parameters (UA, UV, MCA, DV, and inferior vena cava) precede biophysical fetal parameters in fetuses with severe IUGR. They found that combining multivessel Doppler and composite BPS will provide significant early warning and a definitive indication for action in the management of severe IUGR, and suggested that delivery timing may be based on this new gold standard.

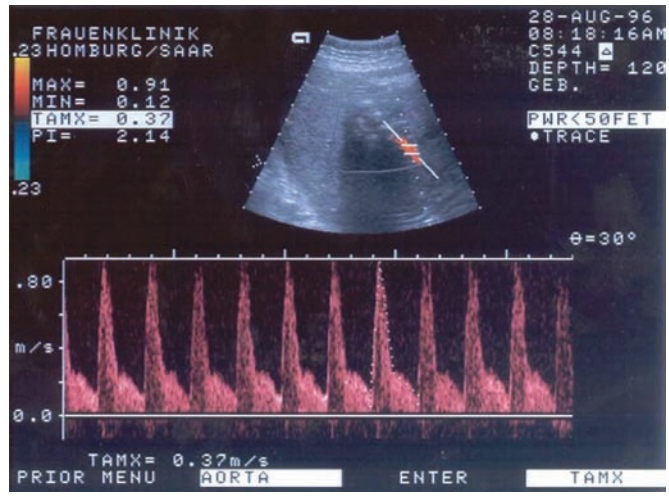

Figure 50.6 Normal flow velocity waveforms of the fetal descending aorta in the third trimester.

Fetal descending aorta

Besides the UA, routine Doppler sonographic examination at the descending fetal aorta is possible. FVWs of the FDA are usually recorded at the level of the diaphragm. In fact, FVWs at the level of the diaphragm and distally to the origin of the renal arteries are different.[72] Normal blood FVWs in the FDA is highly pulsatile, with a minimal diastolic component (Figure 50.6). The descending part of the aorta provides perfusion to the fetal abdominal organs, umbilical–placental circulation, and lower extremities. The flow velocity waveform of the FDA shows a continuous forward stream during the whole heart cycle, but when compared to the FVW of the UA, the end-diastolic flow is less than the systolic component. Due to this reason the S/D ratio in the fetal aorta goes further than the S/D ratio in the UA. As pregnancy advances, the fetal aortic diameter gets wider, which decreases peripheral resistance and increases diastolic flow component. Nevertheless, this does not cause a significant S/D ratio decrease in the FDA.[73] Resistance and pulsatility indices (RI and PI, respectively) in the last trimester are also not affected significantly, and show a similar course as in the UA.

Increased placental impedance combined with redistribution of blood flow from nonvital to vital organs may result in changes in the aortic FVWs. An elevated S/D ratio, RI and PI (Figure 50.7) is associated with both IUGR and adverse perinatal outcomes, such as severe growth restriction, necrotizing enterocolitis, fetal distress, and perinatal mortality.[74–81] Absent end-diastolic flow at the FDA is also a predictor of fetal heart rate abnormalities (Figure 50.8). It was shown that absent flow in the FDA was detected 8 days prior to the onset of decelerations at fetal heart rate monitoring.[78] The sensitivity and specificity of absent end-diastolic flow in the FDA for prediction of IUGR with fetal heart rate abnormalities are 85% and 80%, respectively.[80,81]

Abnormal FVWs of the FDA were also evaluated for intellectual function and minor neurological dysfunction.[38,61,82,83] At 7 years of age, verbal and global performances as well as neurological examination were significantly better in the fetuses with normal aortic FVWs.

Albeit most of the studies showed Doppler velocimetry abnormalities of the FDA is a predictive test for the onset of decompensation due to placental insufficiency in the IUGR fetuses (Figures 50.8 and 50.9), it cannot be recommended as a screening or diagnostic test for IUGR in an unselected obstetric population.[84]

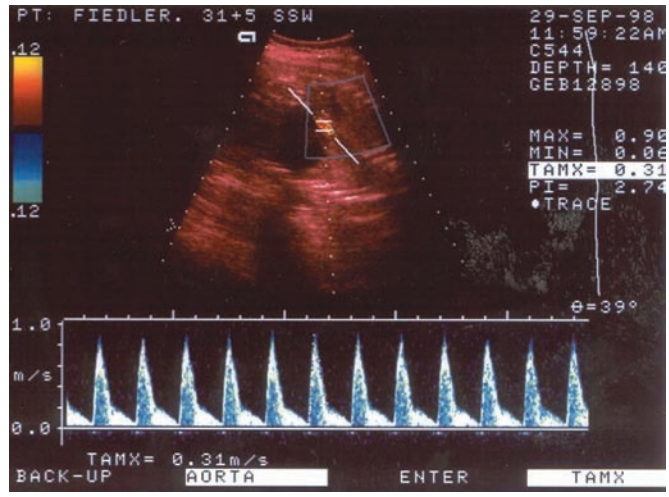

Figure 50.7 Abnormal flow velocity waveforms of the fetal descending aorta in the third trimester (high resistance index).

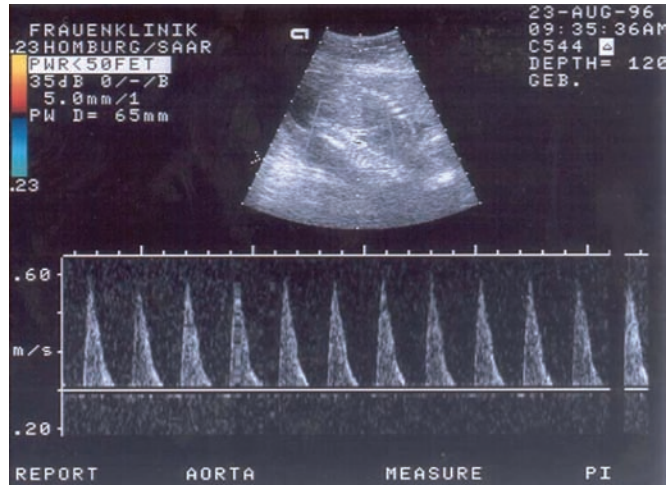

Figure 50.8 Absent end-diastolic flow (AEDF) of the fetal descending aorta (FDA) in the third trimester.

Middle cerebral artery

The circle of Willis is composed anteriorly of the anterior cerebral arteries (branches of the internal carotid artery that are interconnected by the anterior communicating artery) and posteriorly of the two posterior cerebral arteries (branches of the basilar artery that are interconnected on either side with internal carotid artery by the posterior communicating artery).[85] These two trunks and the MCA, another branch of the internal carotid artery, supply the hemispheres on each side (Figure 50.10). All of the defined arteries have different FVWs, therefore, it is important to know which artery is being examined during clinical practice.[86]

The most favorably positioned vessel for Doppler sonographic examination of fetal brain perfusion is the MCA. As the pregnancy advances, the vascular resistance in the MCA decreases (Figure 50.11),[87] and the Doppler indices change. During the early stages of pregnancy, end-diastolic flow velocities in cerebral vessels are small or absent, but velocities increase towards the end of gestation. In the normal developing fetus, the brain is an area of low vascular impedance and receives continuous forward flow throughout the cardiac cycle. IUGR due to placental insufficiency is likely to be caused by redistribution of fetal blood flow in favor of the fetal brain and 'stress organs', at the expense of less essential organs such as subcutaneous tissue, kidneys, and liver. Finally, the already

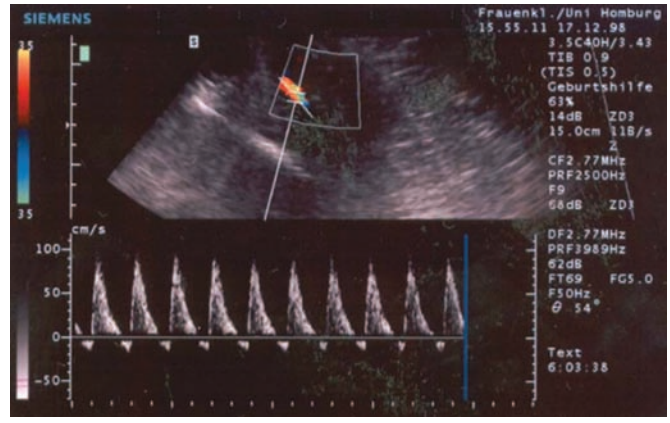

Figure 50.9 Reverse flow (RF) in the fetal descending aorta.

Figure 50.10 Circle of Willis and middle cerebral artery visualized with color Doppler.

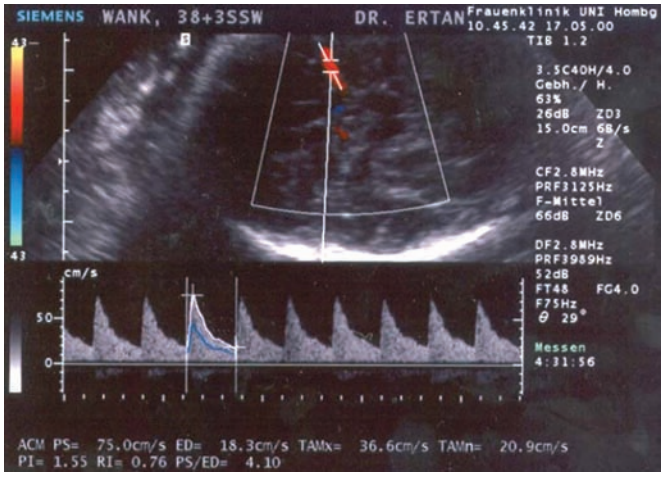

Figure 50.11 Normal flow velocity waveforms of the middle cerebral artery in the third trimester.

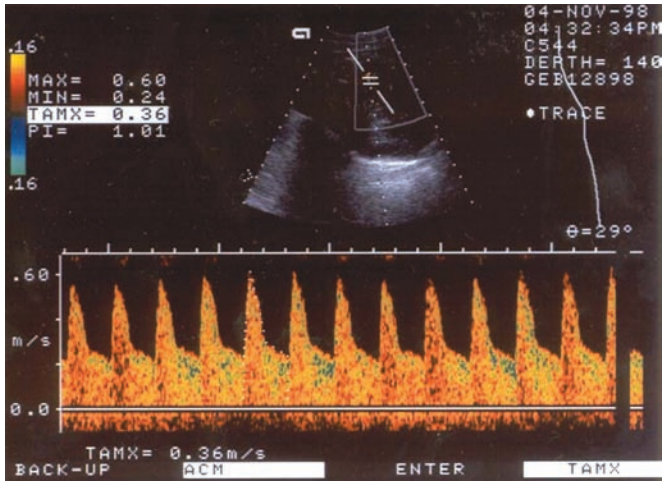

Figure 50.12 Abnormal flow velocity waveforms of the middle cerebral artery in the third trimester ('brain sparing effect').

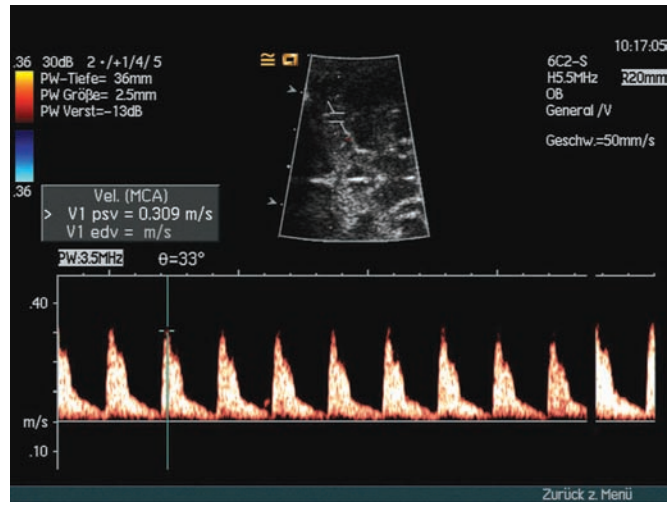

Figure 50.13 Low end-diastolic flow ('normal PI') after the brain sparing effect ('decentralization') this presumably reflects the preterminal stage due to development of brain edema.

low resistance to blood flow in the brain drops further to enhance brain circulation (Figure 50.12). This results in increased end-diastolic velocities, and a decrease in the S/D ratio of the MCA ('brain sparing effect').[88]

Abnormalities of the UA flow correlated with fetal compromise better than intracerebral artery blood flow impairment. This suggests that high placental impedance precedes the onset of the 'brain sparing effect'. In a study, in which 576 high-risk pregnancies were evaluated for the UA and MCA velocimetry, neither test was able to predict adverse perinatal outcome in the normal growing fetus.[89] Results showed that simultaneous assessment of UA and MCA velocimetry in IUGR fetuses did not improve the perinatal outcome. When the UA velocimetry was normal, the MCA velocimetry did not improve the prediction of IUGR or adverse perinatal outcome. However, when the velocimetric values of both arteries were abnormal, the risk of being growth restricted and having an adverse perinatal outcome was doubled.

It has been reported that the MCA PI is below the normal range when pO_2 is reduced.[90] Maximum reduction in PI is reached when the fetal pO_2 is 2–4 standard deviations below normal for gestation. When the oxygen deficit becomes greater, there is a tendency for the MCA PI to rise; this presumably reflects the prefinal stage due to development of brain edema (Figure 50.13).

Hyperactivity of the fetus, increase of intrauterine pressure (e.g., polyhydramnios), and external pressure to the fetal head (e.g., by the probe) might erroneously increase end-diastolic flow velocities in the MCA.[91] Different investigators have undertaken

studies – utilizing data obtained from the UA and MCA – to develop indices for evaluation of intrauterine risk.[85]

Prediction of fetal hemoglobin in red cell alloimmunization

Fetal anemia caused by red cell alloimmunization can be detected noninvasively by Doppler ultrasound on the basis of an increase in the peak systolic velocity in the MCA.[92,93] Although there is no strong correlation between these two parameters when the fetus is nonanemic, the correlation becomes stronger as the hemoglobin levels decrease.[93] Prospective evaluation of the MCA peak systolic velocity to detect fetuses at risk for anemia in red cell alloimmunization showed that 90 of the 125 anticipated invasive procedures could be avoided.[94]

In anemic fetuses, change in hematocrit leads to a corresponding alteration in blood viscosity and to an impaired release of oxygen to the tissues. Increased cardiac output and vasodilatation are the main mechanisms by which the fetus attempts to maintain the oxygen and metabolic equilibrium in various organs. It is likely that when the fetus is nonanemic or mildly anemic, there are only minor or insignificant hemodynamic changes. Therefore, the blood velocity does not change. When the fetus becomes more anemic, various mechanisms compensate to maintain the oxygen and metabolic equilibrium in the various organs. The MCA peak systolic velocity changes proportionally to the hemoglobin deficiency.

Doppler measurements appear to be valuable for estimating hemoglobin concentration in fetuses at risk for anemia. Doppler sonography of the MCA has the potential to decrease the need for invasive testing (amniocentesis, cordocentesis) and its potential risks.[95]

Fetal venous circulation

In recent years research on the fetomaternal circulation has focused more on the venous side of the fetal circulation. Physiologically, blood flow velocities in the umbilical vein (UV) and the portal circulation are steady and nonpulsatile. However, it has been shown that both fetal body and breathing movements can interrupt the FVWs. In a recent review, it was concluded that several pathologic conditions such as non-immune hydrops, severe IUGR, and cardiac arrhythmias also result in an abnormal, pulsatile venous blood flow.[96] However, the relationship between fetal venous blood flow patterns and imminent fetal asphyxia or fetal death is still unknown. Recently, studies on venous circulation in the fetal brain[97] and pulmonary venous circulation in the diagnosis of pulmonary hypoplasia were performed.[98] Venous Doppler also has applications in several other disorders (Table 50.4).

Table 50.4 Indications for fetal venous Doppler sonography

Fetal arrhythmias
Suspected twin-twin transfusion syndrome
Nonimmune hydrops fetalis (NIHF)
Suspected stenosis in the cardiac outflow tract
Congenital heart disease
Severe centralization of the fetal circulation (brain sparing)
Suspicious fetal heart rate tracings

An understanding of the fetal venous circulation provides a platform for the clinical management of perinatal problems, especially timing of delivery in high-risk pregnancies, a subject that is dealt with later in this section.

Summary

Doppler ultrasound is a noninvasive technique that is commonly used in high-risk pregnancies. Examination of fetomaternal vessels using Doppler sonography has been subject of intensive investigation in recent years. However, to date, randomized controlled trials were able to establish only limited clinical value of Doppler velocimetry to improve perinatal outcome in high-risk situations. Umbilical artery, fetal descending aorta and middle cerebral artery Doppler velocimetric studies are acceptable tools in the diagnosis and management of intrauterine growth restricted fetuses, and in the reduction of perinatal mortality in high-risk pregnancies. The majority of severely compromised fetuses also show pathological venous velocimetry, which might give valuable clinical information for surveillance in high-risk pregnancies and their optimal perinatal management. In addition, Doppler sonography might have a role in predicting long-term neuromotor outcome. Large-scale randomized controlled trials are needed to establish the clinical utility of Doppler ultrasound in obstetrics.

Acknowledgments

51 Effect of exercise on fetoplacental Doppler flow

H. A. Tanriverdi, A. K. Ertan and W. Schmidt

The effects of maternal exercise on placental bed blood flow

Sustained bouts of maternal exercise have both acute and chronic effects on placental bed blood flow. During exercise, blood flow is diverted away from the viscera to the exercising muscle and skin.[1] The magnitude of the reduction in flow is directly proportional to the exercise intensity and the muscle mass used (which varies with the type of exercise), and with common types of exercise performed at usual exercise intensities, the reduction usually exceeds 50%. This exercise-induced decrease in visceral flow persists throughout pregnancy but, in late pregnancy, the magnitude of the decrease is blunted in women who continue to exercise regularly.[2–4] Once the exercise ceases, flow rapidly returns to normal. Thus, during a routine exercise session both glucose and oxygen delivery to the placental site are acutely reduced and the magnitude of the decrease varies with exercise type and intensity, maternal fitness and the time point in pregnancy when the exercise is carried out.[4,5]

However, women who perform weight-bearing exercise regularly during pregnancy augment the pregnancy-associated increases in plasma volume, intervillous space blood volume, placental volume and cardiac output.[5,6] The fact that regular weight-bearing exercise augments the changes in these parameters by between 10% and 50% also suggests that it increases the rate of placental bed blood flow at rest. If this inference is correct, then exercise training during pregnancy should actually increase the glucose and oxygen delivery to the placental site throughout mid- and late pregnancy.

The main concern about exercise in pregnancy is that reduced uterine blood flow may cause hypoxia in the fetus.[7] Recent studies using Doppler ultrasonography found an increase in the systolic/diastolic (S/D) ratio of uterine circulation, indicating an increase in resistance of the main vessels that supply the uterus.[8,9]

Although uteroplacental blood flow may decrease with exercise, compensatory mechanisms may exist to ensure adequate fetal oxygenation. In studying ewes, Chandler reported an increase in uterine extraction of oxygen that occurred with the decreased uterine blood flow after maternal exercise.[10] Curet *et al.* reported altered distribution of uterine blood flow in favor of the placenta in ewes.[11]

Complicated pregnancies and exercise

Two worrisome antenatal complications of pregnancy are intrauterine growth restriction (IUGR) and preterm labor. Strenuous exercise in pregnancy has been assessed and is not harmful to the mother or the fetus in healthy women if it is of limited duration. Heavy work or exercise also does not appear to increase the risk of a preterm delivery or IUGR in women at low risk for an adverse pregnancy outcome.[12]

The influence of exercise during pregnancy and its effect on birth weight and pregnancy outcome remains uncertain. The most recent technical bulletin from the American College of Obstetricians and Gynecologists (ACOG)[13] suggests that lower birth weights are observed among vigorously exercising women, but there is no information linking exercise with an adverse outcome of the fetus. The effect of maternal exercise on prenatal complications is also unknown. A recent review from the Cochrane database was unable to demonstrate important benefits or risks to the mother or fetus with exercise in pregnancy.[12]

Small patient numbers or failure to take into consideration the confounding variables in larger samples hampers the studies assessing exercise with birth weight and pregnancy outcome. Because the labor force is composed of more working women, many who exercise at conception and continue during pregnancy, the impact of exercise on pregnancy outcome in working women is very important. Influences of exercise, stress and occupation on pregnancy outcome are difficult to examine because of confounding variables not taken into account in large

investigations and the lack of an adequate sample size in smaller studies.

As physical stress is relatively easy to standardize, several groups have studied changes in pregnant women as a result of sporting exertion, particularly the measurable physiological changes in the organisms of the mother and child. Although using different types of exercise – produced by ergometer, treadmill and running tests – all authors came to the conclusion that light and medium physical exercise has no significant adverse effect on the mother or the fetus.[14–16]

Doppler flow measurements of the fetoplacental unit after physical exercise of the mother have been performed with varying results by several investigators.[16–30] Only one study compared Doppler flow in uncomplicated and complicated pregnancies after physical exercise of the mother.[31] In this study Hackett *et al.* studied 34 women (12 uncomplicated and the other 22 complicated by hypertension, IUGR fetus or both) in the third trimester of singleton pregnancies. The patients underwent a bicycle exercise test during which pulsed Doppler sonographic assessment of the uteroplacental circulation was performed. Exercise appeared to increase the pulsatility of the uteroplacental Doppler waveform in all cases. The changes in the waveforms were more exaggerated in the complicated pregnancies, particularly when the resting waveform had been abnormal. These changes indicate an increase in uteroplacental vascular resistance with exercise, suggesting a deleterious effect of physical exertion in the third trimester, particularly in the presence of hypertension or IUGR fetus.

The effect of physical exertion on the fetoplacental unit in pregnancies complicated by IUGR or hypertensive disorders is of special clinical interest, because these fetuses are known to be at risk for long-term neurological morbidity.

Doppler sonographic examination during exercise in complicated pregnancies: Own results

We conducted a study including measurements of the fetal aorta, fetal middle cerebral artery, umbilical artery and uteroplacental vessels in appropriate-for-gestational-age (AGA) and IUGR fetuses to investigate changes of the fetoplacental unit after defined maternal exercise in the third trimester of pregnancy.

Materials and methods: A total of 33 pregnant women with AGA fetuses and 10 patients with IUGR fetuses in the third trimester were examined. Multiple pregnancies, cases with maternal renal disease, maternal diabetes, maternal cardiovascular pathology other than hypertension and fetuses with chromosomal or structural anomalies were excluded from the evaluation. IUGR was defined as a fetal abdominal circumference < 5th percentile for the gestational age of our reference ranges.[33]

The exercise period began with an acclimatization period of 3 min (30 W), followed by 10 min of moderate exertion (1.25 W/kg body weight for each woman). A bicycle ergometer from Mijnhardt (Mijnhardt-Jäger b.v., Bunnik, The Netherlands) was used.

Immediately after the exercise period, Doppler flow measurements were performed. The test period was 35 min. In the IUGR group fetal heart rate (FHR) monitoring was performed for an additional 15 min before and after the exercise.

Doppler flow recordings of the umbilical arteries, fetal aorta, middle cerebral and uterine arteries were performed. During all Doppler examinations the patients were positioned semirecumbent to avoid 'vena cava syndrome'.

Doppler flow velocity waveforms were obtained from a free-floating central part of the umbilical artery in the absence of body movements, fetal breathing or cardiac arrhythmia with the sample volume covering the whole vessel. Care was taken to keep the insonation angle in the umbilical artery at a minimum. The fetal aorta was localized in its abdominal part at the origin of the renal arteries. The angle between ultrasound beam and fetal aorta was kept below 55°. The middle cerebral artery was visualized at about 1 cm of its origin in the circle of Willis in an axial view. The insonation angle in the middle cerebral artery was always below 15°. Care was taken to minimize fetal head compression, because this is known to influence the flow velocity waveforms of the middle cerebral arteries.

For uterine artery Doppler, the transducer was placed in the right or left lower part of the abdomen. Color Doppler imaging was used to localize the main uterine artery cranial to the crossing of the external iliac artery. The examination was repeated on the opposite side. The insonation angle was kept below 55° at the uterine arteries.

Abnormal umbilical, uterine and fetal aorta Doppler results were those > 2 standard deviations (SD) above the mean for gestational age of our local reference ranges.[34] Fetal brain sparing was supposed when the RI was < 2 SD below the mean of our local reference ranges for the middle cerebral artery.[34]

Glucose and lactate levels were measured in capillary blood samples taken from the finger pad before and after exercise ('Monotest-Lactat in Halbmicro-Technik', Boehringer Mannheim). The pulse and blood pressure of the mother were automatically registered at 3-min intervals during the test (Dinamap, Critikon, Tampa, FL, USA).

Results

Normal pregnancies

The mean performance on the bicycle ergometer was 79 W (±11 W). Gestational age at delivery was 40.0 weeks (±8 days). The mean birth weight was 3270 g (0383 g).

Mode of delivery: Twenty-four (73%) women delivered vaginal spontaneously, one (3%) vaginal operative and eight (24%) by cesarean section.

Table 51.1 Changes of RI during exercise in AGA pregnancies ($n=33$)

	RI (mean ± SD)			
	Before exertion (baseline)	After exertion		
		1–6 min	7–12 min	13–18 min
Fetal aorta	0.8 ± 0.21	0.82 ± 0.29	0.81 ± 0.22	0.82 ± 0.26
P value		< 0.01	ns	< 0.05
Middle cerebral artery	0.82 ± 0.48	0.77 ± 0.32	0.84 ± 0.54	0.83 ± 0.41
P value		< 0.01	ns	ns
Umbilical artery	0.62 ± 0.12	0.6 ± 0.12	0.62 ± 0.12	0.62 ± 0.1
P value		ns	ns	ns

P value		ns	ns	ns

RI, resistance index; ns, difference not significant; SD, standard deviation

Doppler flow results of normal pregnancies ($n=33$) (Table 51.1)

Umbilical artery: The observed RI was within the normal range before and after exertion. However, in four (12%) fetuses the measurements reached the threshold range after exercise.

Fetal aorta: The mean RI before exercise was 4.9 (±1.3). In eight (24%) fetuses the RI was at the threshold range (between 0.83 and 0.86) and in one (3%) fetus at the pathological range (> 0.86). A significant increase in the RI was determined following exertion ($P < 0.01$). However, the mean value did not reach the pathological level. An increase in the RI of the aorta shortly after exertion was observed in 21 (63%) fetuses [in 5 (24%) within the threshold range, in 16 (76%) in the pathological range].

Middle cerebral artery: Before exercise, RI was in the normal range in all cases. A significant reduction in the RI was determined shortly after the exertion phase ($P < 0.01$). Twenty minutes after exertion, the results were almost the same as the baseline records.

Uterine artery: The observed RI was within the normal range before and after exertion.

Fetal heart rate: The FHR remained nearly unchanged before and after exertion (Figure 51.1). In one case fetal bradycardia (lasting approximately 2 min at the end of the exertion phase) was observed. This patient developed pre-eclampsia in the last 2 weeks of pregnancy.

Maternal parameters: The maternal blood pressure and the maternal heart rate increased during the exertion phase but returned to the initial values at the end of the test.

The maternal glucose levels decreased by 21% ($P < 0.001$) after exercise, while the lactate values increased almost twofold from 14.6 to 27.6 mg% ($P < 0.001$).

IUGR pregnancies

The mean performance on the bicycle ergometer was 68 W (±10 W). Gestational age at delivery was 37.6 weeks (±19 days). The mean birth weight was 2065 g (±526 g).

Mode of delivery: Five (50%) women delivered vaginal spontaneously and five (50%) by cesarean section.

Doppler flow results of IUGR pregnancies ($n=10$) (Table 51.2)

Umbilical artery: In three (30%) fetuses the baseline value was in the threshold and in another three (30%) fetuses it was pathological. After exercise the RI was in the threshold range in one (10%) fetus and pathological in four (40%) fetuses.

The RI in the umbilical artery was pathologic in three fetuses already before exercise. This had a marked influence on the mean RI value, because of the very small sample size. Thus, the calculated mean values of all measurements were in the pathological range from the beginning. After exclusion of these three cases, the RI became normal and no significant changes in the RI of umbilical arteries occurred during the test.

Fetal aorta: RI before exercise was within the pathological range in three (30%) fetuses and in two (20%) fetuses within the threshold range. The RI following exertion increased significantly ($P < 0.05$).

Doppler values of four (40%), five (50%) and six (60%) fetuses were within the pathological range, respectively, for measurements after exertion between 1 and 6 min, 7 and 12 min and 13 and 18 min.

The mean values of fetal aortic RI values in IUGR fetuses were higher than in AGA fetuses ($P < 0.05$). In contrast to the AGA group, in the IUGR group all

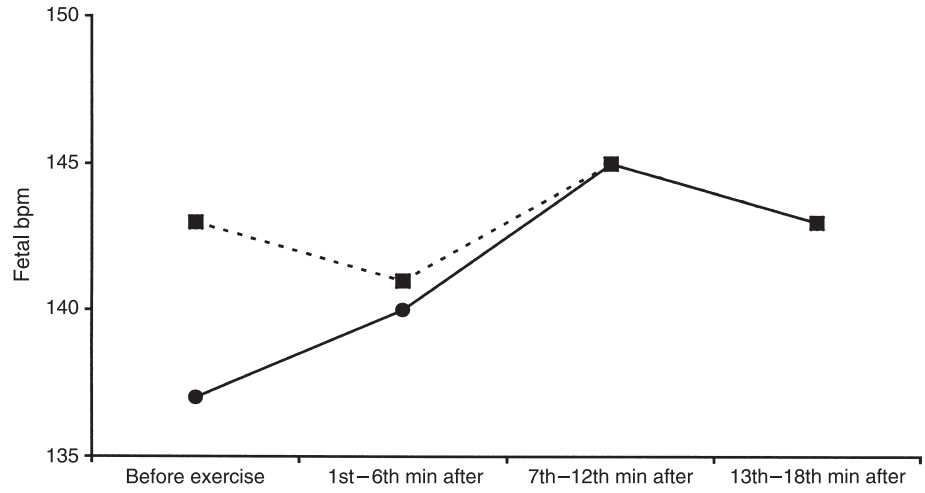

Figure 51.1 Fetal heart rate during the test period (mean ± SD) in AGA (squares) and in IUGR (circles) pregnancies.

Table 51.2 Changes of RI during exercise in IUGR pregnancies ($n=10$)

	RI (mean ± SD)			
		After exertion		
	Before exertion (baseline)	1–6 min	7–12 min	13–18 min
Fetal aorta	0.85±0.37	0.87±0.42	0.89±0.51	0.89±0.51
P value		<0.05	<0.05	<0.05
Middle cerebral artery	0.8±0.38	0.77±0.29	0.74±0.11	0.76±0.33
P value		<0.05	<0.05	<0.05
Umbilical artery	0.82±0.82	0.83±0.81	0.84±0.72	0.77±0.39
P value		ns	ns	ns
Umbilical artery (without extremes)	0.64±0.11	0.66±0.18	0.64±0.09	0.69±0.17
P value		ns	ns	ns
Uterine artery	0.41±0.19	0.52±0.2	0.47±0.12	0.47±0.07
P value		ns	ns	ns

RI, Resistance index; ns, difference not significant; SD, standard deviation

RI values after exercise were within the threshold or the pathologic range and did not return to normal values after exercise.

Middle cerebral artery: The RI revealed a stepwise reduction until 7–12 min after exertion ($P < 0.05$) and made a 'plateau' until 13–18 min after exertion. In six (60%) fetuses, the RI following exertion was lower than the baseline values.

In growth-retarded fetuses, the RI returned to normal levels more slowly than in AGA fetuses. In contrast to AGA fetuses, at the end, RI in IUGR fetuses remained well below the values registered at baseline ($P < 0.05$).

Uterine artery: There were no significant changes in RI of the uterine vessels during the test.

Fetal heart rate: The FHRs before and after exercise remained unchanged (Figure 51.1).

Maternal parameters: Maternal blood pressure and heart rate increased during exercise but regained normal values rapidly after exercise. The maternal glucose levels decreased about 24% ($P < 0.001$), while the lactate concentrations doubled from 11.6 to 24.2 mg% ($P < 0.001$).

Discussion

This study reports Doppler flow measurements of the placental vascular bed, the fetal aorta, umbilical artery together with the fetal cerebral arteries in the

human AGA and IUGR fetus after physical exercise of the mother.

There are conflicting data regarding the question of uteroplacental supply during and after physical exercise by the mother in uneventful pregnancies and pregnancies at risk. The main hypothesis for guiding this study was that maternal exercise has both acute and chronic effects on placental bed blood flow. During the exercise, maternal blood flow is diverted away from the viscera to the exercising muscle and skin (fetoplacental blood steal effect). The magnitude of the reduction in flow is directly proportional to the exercise intensity and the muscle mass used (which varies with the type of exercise), and with common types of exercise performed at the usual exercise intensities, the reduction usually exceeds 50%. This exercise-induced decrease in visceral flow persists throughout pregnancy.[35]

The present Doppler flow results of the fetal aorta and fetal middle cerebral arteries in normal pregnancies showed significant differences before and after exertion. The RI in the aorta increased following exertion and remained higher for a considerable time (approximately 20 min), although the findings did not become pathological. In IUGR fetuses, the increase of the RI in the fetal aorta was more important with resistance indices being in the pathological range during the time period of the test.

The RI in the cerebral artery reduced significantly following exercise and returned very quickly approximately to its initial value in AGA fetuses. In IUGR cases, reduction of the RI could be observed until the end of the test without return to pretest values, thus indicating an initially decreased fetal cerebral circulation in IUGR cases after maternal exercise. RI of the placental vascular bed and the umbilical arteries remained unchanged throughout the test period. In three cases of IUGR, we found elevated RI values in the umbilical artery prior to maternal exercise. After exclusion of those cases, RI values in the umbilical artery were in the physiological range during the test in AGA and IUGR fetuses. These findings are in good accordance with the results reported in the literature.[30,36–41] Furthermore, FHR remained unchanged after maternal exercise in AGA and IUGR fetuses. This is partly in accordance with previous studies.[30,42–47] Differences in study protocols might account for these differences.

The presented results support evidence of fetal cerebral vasodilatation leading to redistribution of fetal blood volume to the cerebrum as a physiologic answer after moderate maternal exercise during the third trimester of pregnancy. In IUGR fetuses, cerebral vasodilatation (brain sparing phenomenon) lasted longer than in AGA fetuses and did not return to initial levels during the test period, pointing toward an altered fetal oxygenation under these circumstances. Furthermore, our results suggest that maternal exercise does not significantly alter uterine and umbilical perfusion in AGA and IUGR pregnancies suggesting absence of change in the uterine vascular bed resistance.

Other studies concerned with Doppler sonography during exercise in pregnant women

In 1956, Morris *et al.*[48] already studied changes in uterine circulation following physical exertion by the mothers. The authors found a statistically significant lengthening of the uterine clearance half-time of NaCl and hence a reduction in circulation during exertion.[48] At rest, in contrast, the clearance half-time was shorter and uterine circulation improved. The main point critical to the results of this study was that during the examination procedure the patient rested in a supine position, thus inducing possible vena cava occlusion syndrome.

Several investigators reported unchanged uteroplacental blood flow and umbilical perfusion after bicycle stress test in the third trimester.[30,49–52] Morrow *et al.* found higher resistance indices in the uterine arteries and elevated fetal heart rates after exercise by the mother in the third trimester. The RI in the umbilical artery, however, was unaltered.[53] Erkkola *et al.* demonstrated in a series of uncomplicated pregnancies an increase in RI of the uterine arteries and the maternal blood pressure after exercise, whereas no change in the RI occurred in the umbilical artery. Of note, the FHR increased significantly after exercise.[54]

The predictive value of maternal aerobic exercise for pregnancy-induced hypertension was studied by Hume *et al.* in a small series.[55] Pre-eclampsia developed in four patients with RI values being elevated in the umbilical artery after recovery in these four patients. It was concluded that aerobic exercise of the mother might be a valuable tool in predicting hypertensive pregnancy complications.[55] On the other hand, decreased umbilical artery RI values were reported after maternal exercise in the third trimester, thus indicating an improved placental circulation following exercise in healthy women.[28]

Hackett *et al.*[56] performed a bicycle exercise test in 34 women in the third trimester. Twelve pregnancies were uncomplicated, whereas 22 of the cases were complicated by small-for-gestational-age fetuses or maternal hypertension. Increase in pulsatility indices was more prominent in complicated pregnancies than in uncomplicated gestations, thus indicating an important reduction of uteroplacental blood flow by maternal exercise in complicated pregnancies.[56] In a more recent study, a fetal cerebral vasodilatation with decrease in umbilical resistance induced by submaximal maternal dynamic exercise was reported. FHR remained unchanged in this study.[18]

Conclusions

(1) *In healthy pregnant women* without obstetric or medical complications, the benefits of exercise seem to outweigh the risks. Therefore, pregnant women should continue to exercise, provided careful guidelines are followed. However, pregnant women may have to modify their exercise regimens because of the physiologic changes associated with pregnancy. Although lower birth weights are noted among offspring of women who exercise during pregnancy, these birth weights are still within normal ranges. Currently, there are no data to confirm that exercise during pregnancy has deleterious effects on the fetus.

(2) Maternal exercise does not significantly alter uterine and umbilical perfusion in AGA and IUGR pregnancies suggesting absence of change in the uterine vascular bed resistance. However, submaximal maternal exercise was followed by a fetal cerebral vasodilatation and an increase of resistance in the fetal aorta, which was more evident in IUGR fetuses. This might be due to a slight fetal hemoglobin desaturation in those cases. These findings underline the need of close antenatal surveillance of IUGR fetuses by Doppler flow measurements in order to detect circulatory deterioration in those fetuses and to reduce long-term morbidity. This is an important and relevant task of modern perinatal medicine.

Appendix

Guidelines for exercise during pregnancy

The ACOG has published a set of guidelines for exercise during pregnancy and the postpartum period. The most recent ACOG guidelines are listed in Table 51.3. These recommendations are made for women who do not have any additional risk factors for adverse maternal or perinatal outcome.[13]

Contraindications to exercise

According to ACOG[13] conditions that should be considered, contraindications to exercise during pregnancy include the following:

Absolute contraindications to aerobic exercise during pregnancy

- Hemodynamically significant heart disease
- Restrictive lung disease
- Incompetent cervix/cerclage
- Multiple gestation at risk for premature labor
- Persistent second- or third-trimester bleeding
- Placenta previa after 26 weeks of gestation
- Premature labor during the current pregnancy
- Ruptured membranes
- Pre-eclampsia/pregnancy-induced hypertension

Relative contraindications to aerobic exercise during pregnancy

- Severe anemia
- Unevaluated maternal cardiac arrhythmia
- Chronic bronchitis
- Poorly controlled type 1 diabetes
- Extreme morbid obesity
- Extreme underweight (body mass index < 12)
- History of extremely sedentary lifestyle
- IUGR in current pregnancy
- Poorly controlled hypertension
- Orthopedic limitations
- Poorly controlled seizure disorder
- Poorly controlled hyperthyroidism
- Heavy smoker

Warning signs to terminate exercise while pregnant

- Vaginal bleeding
- Dyspnea prior to exertion
- Dizziness
- Headache
- Chest pain
- Muscle weakness
- Calf pain or swelling (need to rule out thrombophlebitis)

Table 51.3 American College of Obstetricians and Gynecologists' guidelines for exercise during pregnancy and postpartum

1. Regular exercise (at least three times per week) is preferable to intermittent activity
2. Avoid exercise in the supine position after the first trimester. This position is associated with decreased cardiac output in most pregnant women, causing a decreased distribution of blood to splanchnic beds including the uterus
3. Pregnant women should stop exercising when fatigued and not exercise to exhaustion
4. Non-weight-bearing exercises such as cycling or swimming will minimize the risk of injury and facilitate the continuation of exercise during pregnancy
5. Adequate diet should be ensured
6. Avoid types of exercise in which loss of balance could be detrimental to maternal or fetal well-being, especially in the third trimester. Further, any type of exercise involving the potential for even mild abdominal trauma should be avoided
7. Adequate hydration, appropriate clothing and optimal environmental surroundings during exercise should be ensured
8. The physiologic and morphologic changes of pregnancy persist 4–6 weeks postpartum. Thus, prepregnancy exercise routines should be resumed gradually based on a woman's physical capability

- Preterm labor
- Decreased fetal movement
- Amniotic fluid leakage

Conclusions and recommendations of ACOG for exercise during pregnancy[13]

- Recreational and competitive athletes with uncomplicated pregnancies can remain active during pregnancy and should modify their usual exercise routines as medically indicated. The information on strenuous exercise is scarce; however, women who engage in such activities require close medical supervision.
- Previously inactive women and those with medical or obstetric complications should be evaluated before recommendations for physical activity during pregnancy are made. Exercise during pregnancy may provide additional health benefits to women with gestational diabetes.
- A physically active woman with a history of or risk for preterm labor or fetal growth restriction should be advised to reduce her activity in the second and third trimesters.

52 Doppler velocimetry in intrauterine growth restriction: a practical clinical approach

G. P. Mandruzzato, Y. J. Meir and G. Maso

Introduction

Intrauterine growth restriction (IUGR) according to the current definition is that of a fetus that fails to reach its potential growth. The term IUGR should only be used with regard to the fetus, while small for gestational age (SGA) should be used only with regard to the newborn.[1] This distinction must be kept in mind very clearly. It is true that perinatal mortality and morbidity are significantly increased in cases presenting a birth weight less than the 10th percentile for gestational age (therefore defined as SGA) and also less than the 15th percentile.[2] However, it has been shown that symptoms of hypoxemia are observable in cases presenting a birth weight greater than the 50th percentile, but showing a restriction of growth by ultrasound biometry during fetal life, with the same frequency as in SGA newborns.[3] IUGR can be associated to many conditions (malformations, karyotype aberrations, infections, maternal diseases), but the most frequent and most dangerous complications are represented by chronic fetal hypoxemia. This is the consequence of obliterative placental vasculopathy, which reduces the maternal–fetal supply first of nutrients and later on of oxygen. This ominous condition is encountered in about 30% of IUGR fetuses and is the cause of poor perinatal outcome (intrauterine death or damage, acute hypoxemia in labor, neonatal death and morbidity early and late as well). Moreover, it has been postulated that IUGR can also be responsible for diseases occurring in adult life.

Chronic fetal hypoxemia induces changes in many fetal vital functions (hemodynamics, heart activity, fetal movements and behavior, amniotic fluid turnover) and one of the first to be observed is blood flow redistribution. As Doppler technology enables us to study these changes in a non-invasive way, it has become a fundamental tool for assessing the fetal oxygenation and the fetal response to hypoxemia, thus becoming a useful guide in the clinical management of IUGR fetuses.

Characteristics of Doppler velocity waveform

The Doppler velocity waveform (DVWF) reflects the velocities of blood during a cardiac cycle. The so-called 'angle-independent parameters' are commonly used for studying the characteristics of the DVWF. The velocities of the systolic phase are compared to that of the diastolic one according to different formulas. The simplest is the systolic/diastolic (S/D) ratio obtained by dividing the two. The resistance index (RI) is obtained by dividing the systolic velocity for the systolic minus the diastolic. Probably, the most comprehensive parameter is the pulsatility index (PI) because it takes into consideration not only systolic and diastolic velocities but also the mean of the velocities. However, the characteristics of the DVWF, and hence the different parameters, are mainly influenced by the diastolic phase, reflecting the peripheral resistance downstream the explored segment of the vessels, especially in the case of investigations performed on arteries. When the peripheral resistance is markedly increased, the forward blood flow may be absent or also reverted. These particular patterns of the DVWF are called absent/reverse end diastolic (ARED) flow. After the introduction of the color flow mapping (CFM) technique, it is possible to identify very tiny vessels and vascular structures also, which can be sampled by the Doppler technique. Hence, it is possible to build a map of fetal hemodynamic patterns in normally evolving pregnancies and in those affected by hypoxemia as well.

Fetal and umbilical hemodynamics in normal pregnancies

In case of normally evolving pregnancy, Doppler investigation on somatic and cerebral fetal arteries (FA) shows a fairly constant pattern of the DVWF, indicating an almost stable peripheral resistance or a small progressive reduction. Using the same technology on the umbilical arteries (UA), a significant progressive reduction of peripheral resistance can be observed possibly related to the increasing need of nutrients and oxygen by the growing fetus.

The main objects of investigation are UA and fetal thoracic descending aorta. With the progress of ultrasound imaging technology and the use of CFM, allowing identification and sampling of even tiny vessels, many other arteries like cerebral (internal carotid and middle and anterior cerebral), renal, mesenteric, adrenal, splenic, iliac aortic arch and coronary have been studied.

As a consequence, a very comprehensive overview of the fetal physiologic hemodynamics has been obtained, which is the fundamental basis for studying and understanding the possible changes occurring in pathologic pregnancies.

Arterial Doppler changes in hypoxemic IUGR

As already mentioned, the most frequent and severe complication of IUGR is represented by the chronic fetal hypoxemia, which is a consequence of the placental obliterative vasculopathy. With Doppler technology, it is possible to study the hemodynamic changes occurring in this condition in UA and those occurring in FA.

The first step of the fetal adaptation to hypoxemia is represented by blood flow redistribution inducing vasoconstriction in the somatic arteries and vasodilatation in the cerebral arteries. This phenomenon is called 'brain sparing effect' and is finalized to preserve sufficient oxygenation to the central nervous system. It has been postulated that such a 'sparing effect' occurs also at the level of the adrenal and coronary arteries. Therefore, peripheral resistance is increased in the somatic and splanchnic arteries and reduced in the cerebral arteries.

When placental obliterative vasculopathy occurs, the peripheral resistance is also increased in UA. It has been shown that PI elevation is proportional to the obliteration of the placental vascular bed.[4]

From the clinical point of view, it is possible to assess both the cause (UA) and the effect (FA) of hypoxemia using Doppler investigation.

Doppler patterns of IUGR

Doppler study on UA and fetal thoracic descending aorta has been performed in 653 IUGR fetuses. In all the cases, gestational age has been established on the basis of ultrasonic biometry carried out in early pregnancy [by measuring the crown–rump length (CRL)] and not later than 20 weeks of gestation (by measuring the biparietal diameter). IUGR has been diagnosed if the fetal biometry (abdominal circumference) showed a deviation of more than 2 weeks in the expected curve of growth that has been established in our institute. Cases presenting fetal abnormalities (anatomical and/or chromosomal) have been excluded from this study. After IUGR recognition, Doppler investigation is done at weekly or minor intervals, depending on the severity of the growth restriction and the maternal clinical conditions by measuring the PI values. Cases presenting PI values greater than the second standard deviation are considered abnormal. Fetal biometry has been performed weekly if severe restriction was observed and/or abnormal PI was present, and at 14-day intervals in cases presenting normal Doppler values. Computer-assisted cardiotochography (CTG) according to the Oxford System 8002 has been performed for monitoring fetal conditions.

The IUGR cases have been divided into four groups according to the characteristics of the Doppler patterns. In the first group, 71 cases presenting ARED flow have been included (10.8%). In the second group, the cases ($n=64$, 9.8%) presenting abnormal PI (over the second SD) in both vascular districts are collected. In the third group are the cases ($n=85$, 13%) presenting abnormal PI only in the aorta while still depicting normal values in the UA. The fourth group is represented by cases showing normal PI values in both aorta and UA ($n=433$, 66.3%).

The prevalence of fetal distress (FD) has been calculated for each group. FD has been diagnosed on the basis of short-term variation (ST) below 3 ms in pregnancy and on the basis of the presence of late decelerations or bradycardia and/or fetal acidemia on the fetal blood sample during labor, requiring cesarean delivery. Overall, the prevalence of FD was 31% but with a statistically significant difference in the four groups.

FD has been observed in 100% of the cases in the first group. This prevalence is reduced to 74% in the second group and even more, 33%, in the third. In the fourth group this figure is 12%.

Sensitivity and specificity of Doppler for predicting FD has been calculated separately for FA and UA. The sensitivity is 62.69 for FA and 35.18 for UA. The specificity is 81.56 for FA and 96.71 for UA. The reason for the difference depends on the pathophysiological background of the hemodynamic changes of the two vascular districts. Fetal vessel changes, as in the aorta, represent the adaptation to hypoxemia while UA changes are the consequence of increased peripheral resistance provoked by placental obliterative vasculopathy.

Practically, by studying hemodynamics in UA we can assess the cause of chronic fetal hypoxemia, whereas by studying the fetal vessels we can assess

the phenomenon of fetal adaptation to the reduced oxygen supply.

As already discussed, it has been shown that PI values are proportional to the obliteration of the placental vascular bed, but evidence has also shown that DVWF becomes altered only when at least 60% of the placental vascular bed is obliterated[5] and oxygen supply to the fetus is strongly reduced. Hence, the specificity of PI in UA is much higher than that observed in FA.

Therefore, according to the Doppler patterns, the first group (ARED) represents a condition of restriction of oxygen supply to the fetus inducing a severe hypoxemia. Unfavorable perinatal outcome (death or handicaps in survivors) has been observed only in this group. The second and third groups represent a condition of reduced oxygen supply and fetal adaptation and possible FD. The fourth group represents IUGR fetuses not affected by chronic hypoxemia.

The clinical consequences can be indicated as follows:

Group 1: Timing of prompt delivery should be taken into consideration.

Groups 2 and 3: Close surveillance and timing of the delivery according to fetal monitoring and maternal corticosteroids administration if gestational age is lower than 34 weeks. Vaginal delivery after spontaneous onset of labor is possible in about 50% of the cases.

Group 4: Clinical and instrumental control at weekly or 14-day intervals. In the majority of cases, vaginal delivery after spontaneous onset of labor occurs.

Particular attention should be paid to IUGR cases when ARED flow is observed. This hemodynamic condition is encountered in about 10% of IUGR fetuses, and is usually associated with a low gestational age, with a mean of 30 weeks.

As the outcome is largely different in the case of end-diastolic flow absent (EDFA) as compared to reverse flow (RF), being better in the first condition, the characteristics of the management should be different. In fact, it has been shown that perinatal mortality and handicap rates are significantly higher in the case of RF.[6]

Conclusions

IUGR can be associated with many fetal adverse conditions (malformations, chromosomal aberrations, infections) but the most important cause of both restriction of growth and poor perinatal outcome is represented by chronic fetal hypoxemia (CFH). This condition is the consequence of placental obliterative vasculopathy, which affects the maternal–fetal supply of nutrients first and later on of oxygen. As a consequence, hemodynamic changes occur in UA and FA as well. These modifications are easily observable with Doppler technology by analyzing the characteristics of the DVWF.

As CFH occurs in about 30% of IUGR, therefore requiring close control and possibly active management, the crucial point, after IUGR recognition, is represented by the identification or the exclusion of CFH. By studying DVWF on UA and FA, it is possible to assess the characteristics of the blood flow from the mother to the fetus and to monitor the aspects of the fetal adaptation if CFH is present. Fetal thoracic descending aorta is easy to identify and sample by using pulsed Doppler.

According to the DVWF patterns and PI values, it is possible to distinguish the IUGR fetuses affected by CFH from those that are not. As a consequence, the characteristics of the control can be differentiated.

Moreover, if CFH is present, it is possible to monitor its evolution by obtaining information about clinical practical validity, in order to optimize the management and the timing of the delivery if necessary.

53 Doppler evaluation of the fetal venous system

G. Maso, G. Conoscenti and G. P. Mandruzzato

Introduction

Fetal blood flow measurements have become an important tool in the surveillance of high-risk pregnancies. There is a vast amount of literature on umbilical arteries and the fetal arterial system, but fetal venous circulation has only recently been evaluated.

The introduction of high-resolution ultrasonography, combined with color Doppler imaging (CDI), offered a breakthrough in the study of the fetal venous system, considerably enhancing our understanding in normal physiologic conditions, as well as in abnormal circumstances.

This review will focus on the embryologic, anatomic and physiologic characteristics of fetal venous circulation. The knowledge of the development and physiology represents the basis to understand the structural anomalies and the hemodynamic changes that occur in the venous district in pathological conditions.

Embryology of the fetal venous system

In a 4-week embryo, three pairs of veins are found. The vitelline veins run from the yolk sac to the sinus venosus via liver sinusoid, and are connected to each other via anastomoses around the duodenum. The umbilical veins (UVs) transport oxygenated blood from the chorion to the sinus venous, bypassing the liver. They merge with the cardinal veins, the third pair of embryonic veins, which originate from the body of the embryo and open into the right and left horns of the sinus venosus of the primitive heart.

The fetal liver and its development in the septum transversus play an important role in modifying the primitive vitelline and UVs into their final morphology. With the rapid growth of the liver, the UVs connect with the liver sinusoids. The asymmetric development of the heart and the rotation of the intestinal tract cause a major change in the venosus circulation by forming a single venous blood stream from the left to the right.

In the 6-mm embryo, the complete right UV, the cranial part of the left UV, the left vitelline vein and part of the anastomoses obliterate and a new vessel, the ductus venosus (DV), develops. This is a shunt vessel between the left UV and the right hepatocardinal channel, which will become the upper inferior vena cava (IVC). At this stage, all the placental blood enters the right atrium through the left distal UV, the DV and the proximal right vitelline vein, which bypass the liver sinusoids. The upper two anastomoses of the distal vitelline veins fuse to form the portal vein, whereas the distal anastomoses form the superior mesenteric and splenic veins and the proximal parts become the hepatic veins (Figure 53.1).

IVC and superior vena cava (SVC) originate from the cardinal veins, which form the main drainage system of the embryo's body (Figure 53.2). The anterior and posterior cardinal veins drain the cranial and caudal parts of the body of the embryo, respectively. The left brachiocephalic vein is formed during the eighth week from the right anterior and the right common cardinal veins, through left to right anastomoses, whereas the left anterior cardinal vein disappears. Azygos and hemiazygos veins originate from the upper portion of the division of the supracardinal veins, whereas the caudal part becomes the caudal part of the IVC.[1–4]

Anatomy of the fetal venous system

Two venous systems can be identified within the fetal liver: an afferent system, or umbilical–portal system, taking blood from the placenta and the gut to the liver, and an efferent system, provided by the hepatic veins, taking blood from the liver to the heart (Figure 53.3). The DV shunts oxygenated blood from the umbilical–portal system directly to the heart.

In the afferent venous system, the UV enters the abdomen within the falciform ligament, ascending steeply toward the liver and runs along its surface in

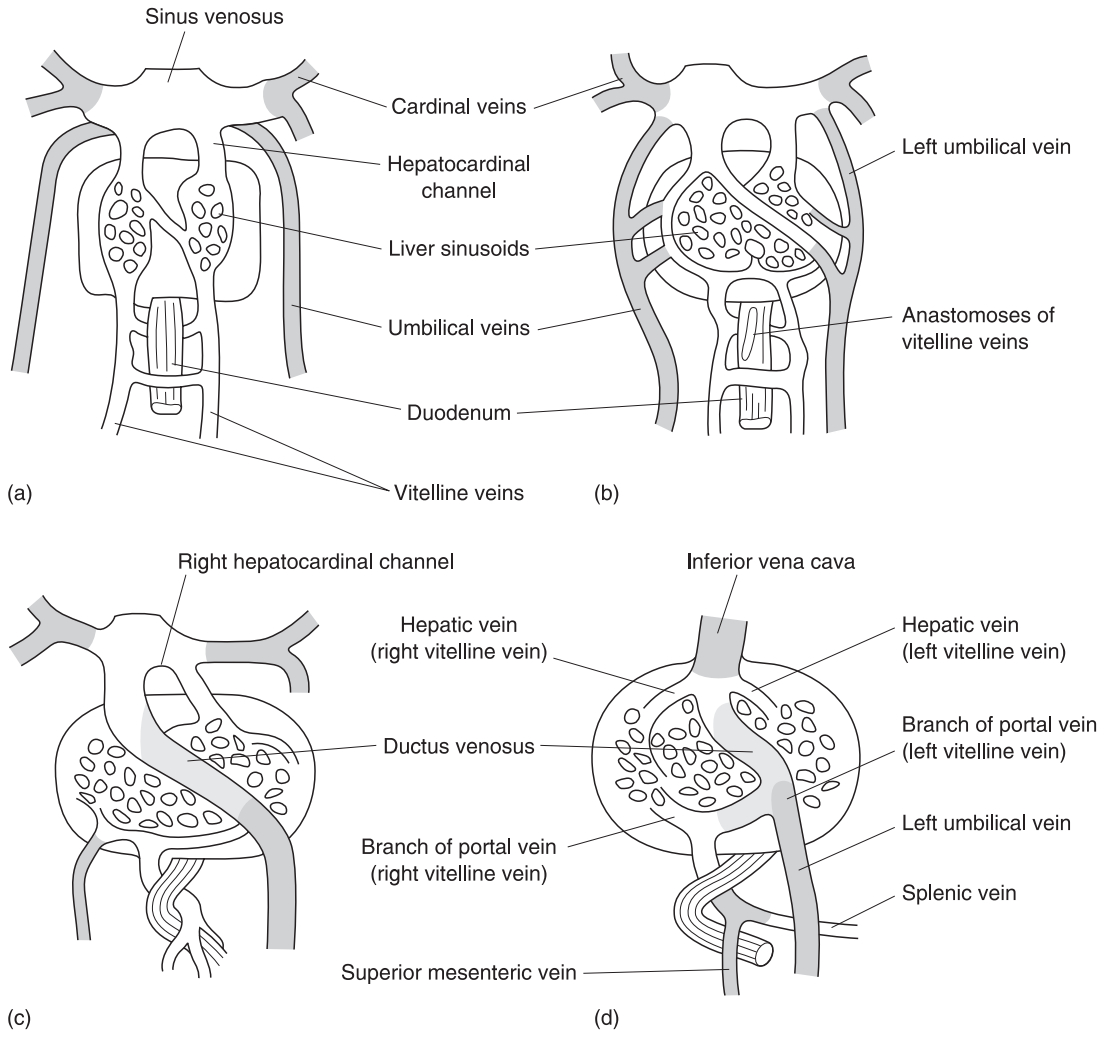

Figure 53.1 Embryology of umbilical, portal and hepatic venous systems. Reprinted from Hoffstetter *et al.*[2] with permission.

the cephalad direction. It then joins a confluence of vessels termed the portal sinus. This is a wide L-shaped vessel at the distal part of the UV, connecting the right and left intrahepatic portal veins. These perfuse the right and left hepatic lobes, respectively. There are two main left intrahepatic portal veins (superior and inferior). The right intrahepatic portal vein shows a more abundant branching pattern. The vein originating from the confluence of the splenic and superior mesenteric veins outside the liver represents the extrahepatic portal vein.

The DV originates from the portal sinus as the latter turns at an almost right angle into the right lobe of the liver. The diameter of the DV is approximately one-third that of the UV. This is a branchless, hourglass-shaped vessel ascending in the direction of the diaphragm, which joins distally with the hepatic left vein and the IVC, just proximal to the entrance into the right atrium (Figure 53.4). The existence of a 'sphincter' that regulates the blood flow through the DV to the heart has been postulated, and it has been assumed that the control of this anatomic structure is dependent on the concentration of oxygen.

The efferent system is represented by a number of vessels arising from the right and left hepatic lobes (right, middle and left hepatic veins), which drains into the subdiaphragmatic vestibulum. The hepatic veins, DV and IVC open into the subdiaphragmatic vestibulum, an inverted funnel-shaped vascular space just below the diaphragm, ending at the right atrium.[3–5]

Physiology of the fetal venous system

The anatomical relationship in the hepatic afferent venous system supports the well-established concept that oxygenated blood flow from the placenta is distributed through the UV to the portal sinus, which supplies the left and right intrahepatic portal veins and the DV. Deoxygenated blood from the extrahepatic portal veins is diverted almost exclusively to the right hepatic lobe. The alignment of UV and DV,

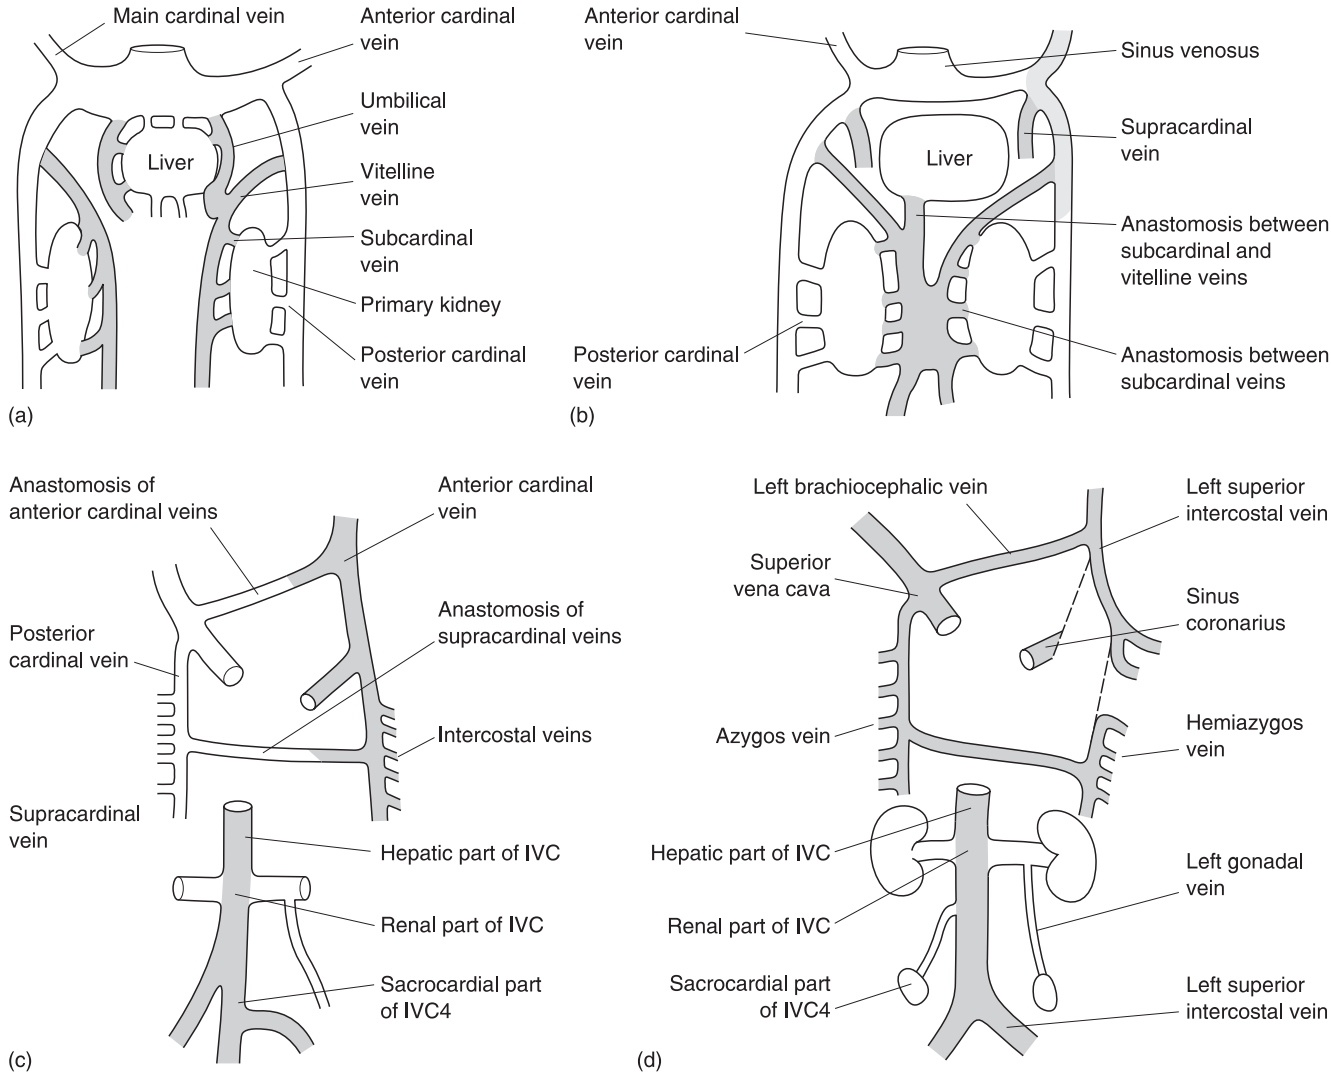

Figure 53.2 Embryology of inferior and superior vena cavae. Reprinted from Hoffstetter *et al.*[2] with permission.

although not in anatomical continuity for the interposed portal sinus, favors the preferential streaming of oxygenated blood to the DV and consequently to the heart (Figures 53.3 and 53.4). Approximately 50% of the UV blood flow enters the DV and accounts for 98% of the blood flow through the DV. The portal blood is mainly directed to the right lobe of the liver.

As far as the vessels of the efferent venous system are concerned, it is possible to observe that the right hepatic vein runs parallel to the IVC, whereas the left and middle hepatic veins run parallel to the DV. It has been postulated that this spatial rearrangement is the consequence of distribution of more oxygenated blood flow. The left hepatic lobe, in fact, is primarily supplied with the blood flow from the UV via the left portal vein.

Moreover, it has been shown that there is streamlining of blood flow within the thoracic IVC: blood from the DV and the left hepatic vein flows in the dorsal and leftward part, whereas blood from the right lobe, the distal IVC and the right hepatic lobe flows in the ventral and rightward stream part of IVC. The ventral and rightward stream, together with blood from SVC, is directed to the right atrium and through the tricuspid valve into the right ventricle, ejected into the main pulmonary artery and shunted, via ductus arteriosus, into the descending aorta. The dorsal and leftward stream is directed toward the foramen ovale, thereby delivering well-oxygenated blood flow directly to the left heart and, via ascending aorta, to the myocardium and the brain.[3,6,7]

Normal Doppler findings

The application of high-resolution and color Doppler ultrasonography has allowed the structural and functional evaluation of the fetal venous system.

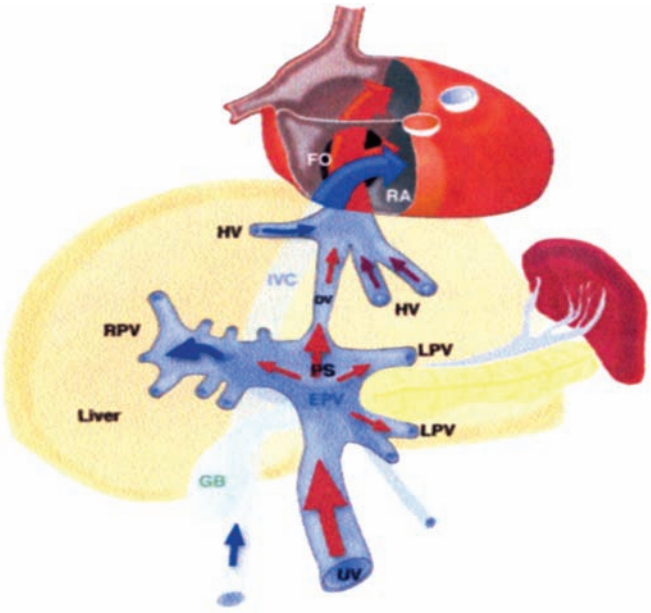

Figure 53.3 Representation of fetal umbilical and hepatic venous system. The arrows indicate the direction of flow. The colors show the degree of oxygenation (red, high; purple, medium; blue, low). FO, foramen ovale; RA, right atrium; DV, ductus venous; UV, umbilical vein; HV, hepatic veins; IVC, inferior vena cava; PS, portal sinus; LPV, left portal vein; RPV, right portal vein; EPV, extrahepatic portal vein; GB, gallbladder. Reprinted from Mavrides *et al.*[5] with permission.

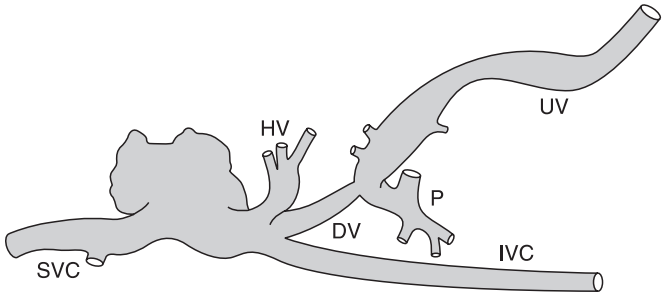

Figure 53.4 Sagittal view of the fetal venous system. RA, right atrium; DV, ductus venous; UV, umbilical vein; HV, hepatic veins; IVC, inferior vena cava; P, portal system; SVC, superior vena cava.

During sonography, the UV can be detected in a sagittal or transverse section of the abdomen. In the transverse section, it curves toward the right-hand side of the upper abdomen (Figure 53.5).

The DV can be visualized in its full length in a midsagittal longitudinal section of the trunk or in an oblique transverse section through the upper abdomen. Its origin from the UV can be found where CDI indicates higher velocities compared with the flow in UV, and sometimes this produces an aliasing effect. The blood flow velocities accelerate due to the narrow lumen of the DV, the maximum inner width of the narrowest portion being 2 mm (Figures 53.6 and 53.7).

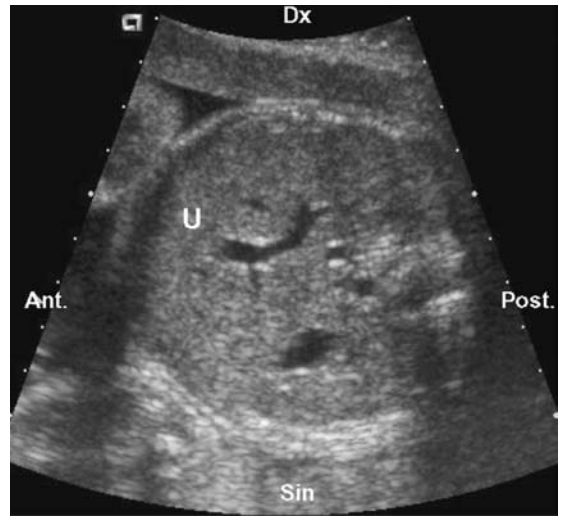

Figure 53.5 Transverse view of the fetal abdomen. The UV curves toward the right-hand side.

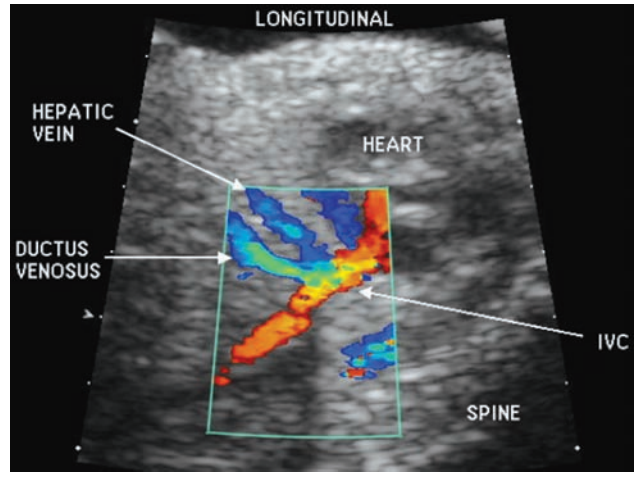

Figure 53.6 Midsagittal view of the fetal upper abdomen. DV and hepatic vein merge into the IVC forming the subdiaphragamatic infundibulum, a funnel-shaped vascular space just below the diaphragm, ending into the right atrium.

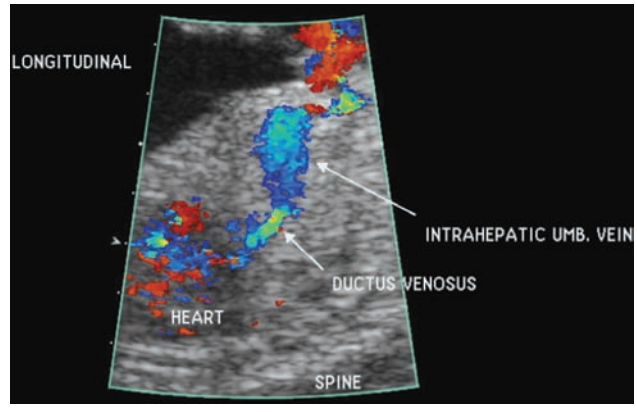

Figure 53.7 Midsagittal section of the fetal trunk: DV is visualized in its full length arising from the UV. The CDI indicates higher velocities compared with the flow in the UV: aliasing effect is present.

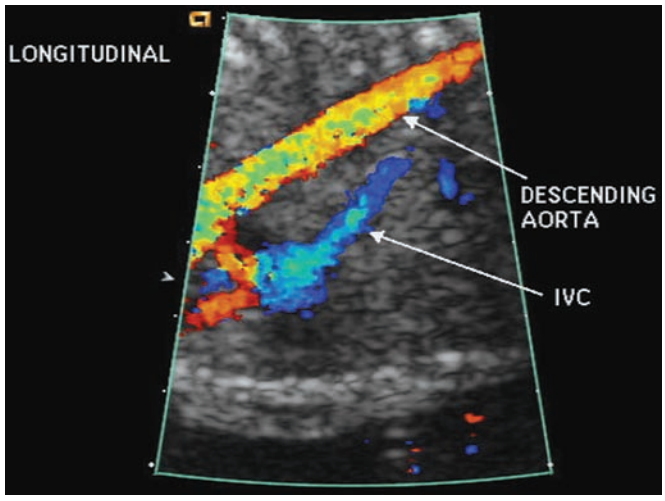

Figure 53.8 Coronal plane of the upper abdomen: the IVC runs anterior, to the right of and nearly parallel to the descending aorta.

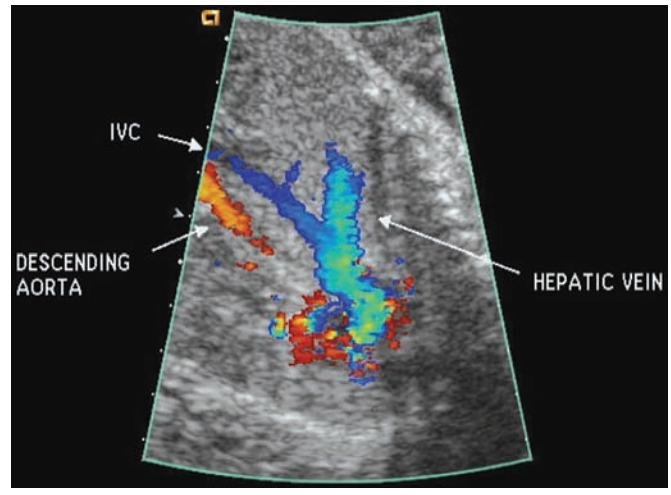

Figure 53.9 Coronal section through the right hepatic lobe. The right hepatic vein and IVC merge into the subdiaphragmatic infundibulum.

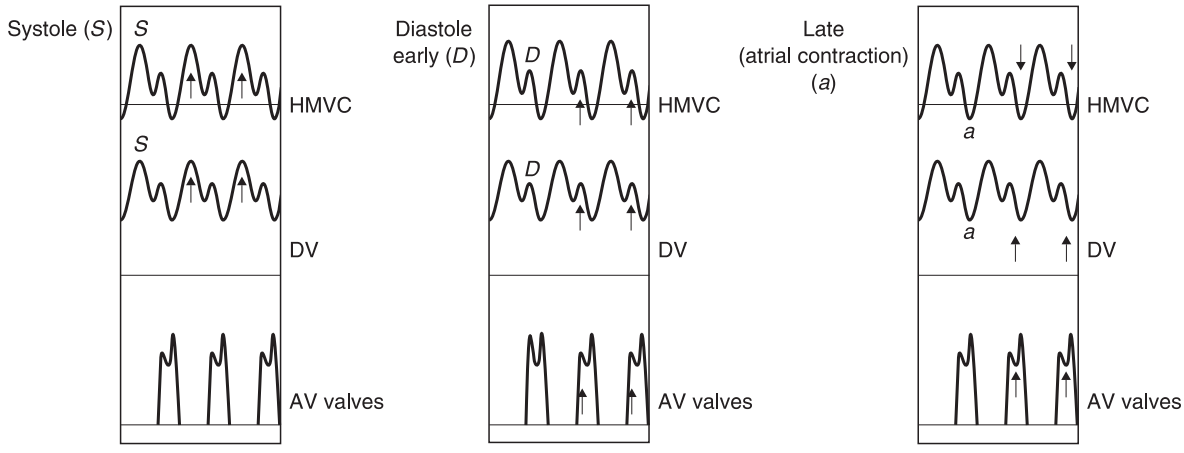

Figure 53.10 Doppler waveform patterns in the DV, HV and IVC, and their relationship with the cardiac cycle (AV, atrioventricular valves; S, systole; D, early diastole). A physiologic reverse flow is evident in IVC/HV during atrial contraction (a). With permission from Hecher K. The fetal venous circulation. In Harrington K, Campbell S, eds. *A Colour Atlas of Doppler Ultrasonography in Obstetrics*, 71–9.

The IVC could be well evaluated either in the longitudinal or coronal section; it runs anterior, to the right of and nearly parallel to the descending aorta (Figure 53.8).

The hepatic veins can be visualized either in a transverse scan section through the upper abdomen or in a sagittal–coronal section through the hepatic lobes (Figure 53.9).

The typical waveform for blood flow in the venous vessels, excluding the UV and portal veins, consists of three phases related to the cardiac cycle (Figure 53.10). The highest pressure gradient between the venous vessel and the right atrium occurs during ventricular systole (S), resulting in the fastest blood flow velocities forward from the fetal heart. Early diastole (peak D) with opening of the atrio-ventricular valves and passive early filling of the ventricles (peak E of the biphasic atrio-ventricular flow waveform) is associated with a second forward peak flow. The lowest velocities (a) in fetal venous vessels can be observed during the atrial contraction of the late diastole (peak A of the biphasic atrio-ventricular flow waveform).

The DV flow pattern is characterized by a triphasic forward flow (Figure 53.11): it is directed toward the heart through the whole cardiac cycle. Even in early pregnancy, there is no retrograde flow during atrial contraction.

In the IVC and hepatic veins (Figures 53.12 and 53.13), a physiological reverse flow during atrial contraction is observed. The percentage of reverse flow in the IVC decreases with advancing gestational age.

As for the site of sampling, it is of vital importance in the evaluation of the fetal venous system.

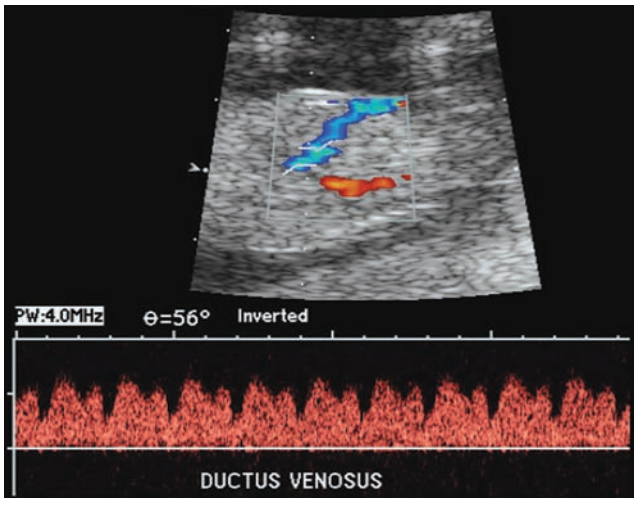

Figure 53.11 Triphasic forward Doppler flow waveform in the DV. It is directed toward the heart through the whole cardiac cycle. A nadir of forward flow is observed during atrial contraction.

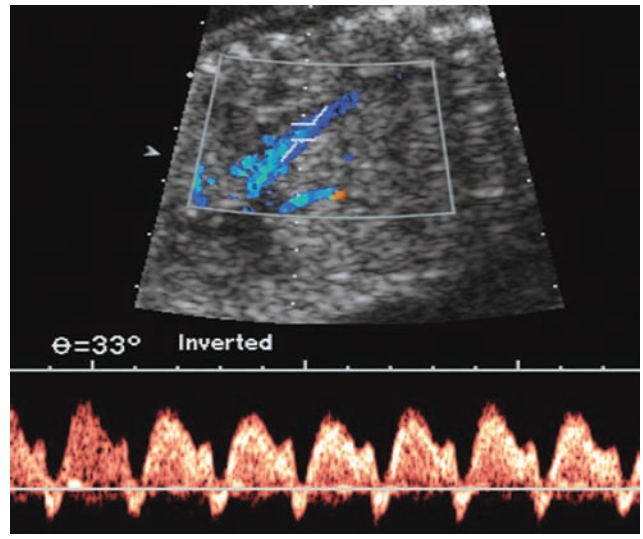

Figure 53.13 Doppler flow waveforms in the IVC: a physiological slight reversal flow is recorded during atrial contraction (a).

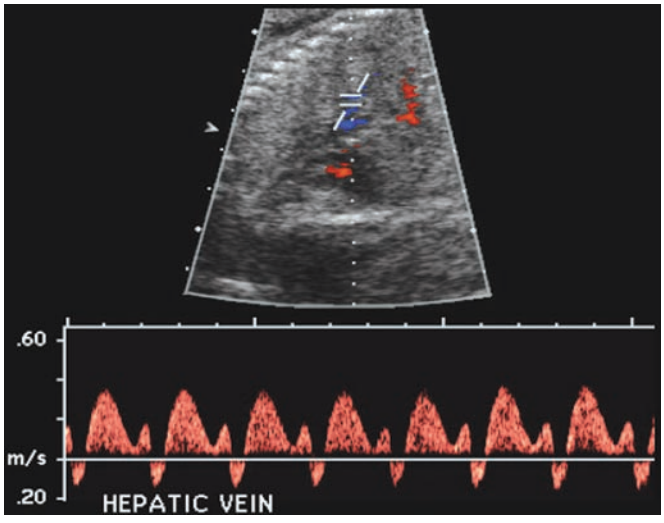

Figure 53.12 Doppler flow waveforms in the HV: a physiological slight reversal flow is recorded during atrial contraction (a).

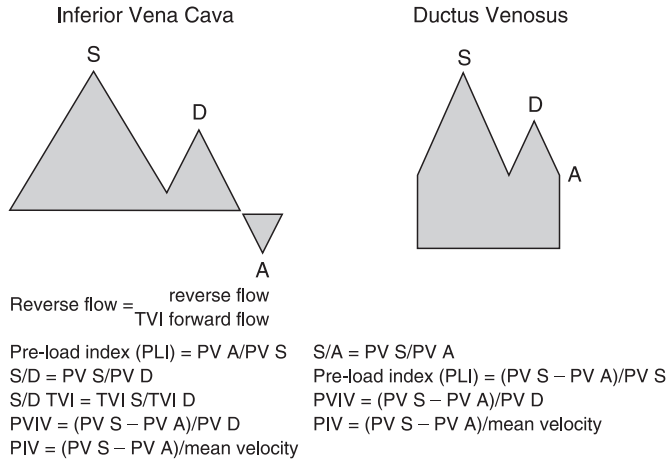

Figure 53.14 Angle-independent indices reported in the literature for the IVC and the DV. S, systole; D, diastole; A, atrial contraction; TVI, time velocity integral; PV, peak velocity; PLI, preload index; PVIV, peak velocity index for vein; PIV, pulsatility index for vein.

It has been shown that the highest velocities of the DV are at the inlet, immediately above the UV, relative to the outlet into the IVC. It has been established that the inlet part of the DV should be evaluated for Doppler waveform analysis.

As for the IVC, large standard deviations for various Doppler waveform variables and a mixture of overlapping signals from different bloodstreams have been shown at the subdiaphragmatic venous infundibulum. It has been established that the site of sampling is between the renal vein and the DV: this is the place of the highest reproducibility.[6–9]

More than 10 different angle-independent indices of the IVC and the DV have been proposed and reference ranges have been compiled (Figure 53.14). 'Pulsatility index for veins' and 'Peak velocity index for vein' are now commonly used for the highest correlation with adverse outcome variables, such as fetal acidemia and perinatal mortality.[9–11] Even if flow volume and absolute velocity measurements can be evaluated, it has been demonstrated to have higher inaccuracy and intraobserver variation compared to qualitative ratios. This is mainly due to vulnerable errors of the evaluation of vessel diameter measurements and unreliable or high angle of insonation.

The mean and peak velocities increase significantly in venous vessels with advancing gestational age. The highest and lowest velocities are found in the DV and the right hepatic vein, respectively. Conversely, the angle-independent indices decrease

during gestation and this is consistent with a reduction in cardiac afterload because of the decrease in placental resistance. It may also reflect increased ventricular compliance. The reduction in cardiac afterload causes a decrease in end-diastolic ventricular pressure and therefore an increase in venous blood flow velocity toward the heart during atrial contraction.[10,11]

As shown for arterial Doppler evaluation, from a methodological point of view, it is essential to avoid measurements during fetal breathing movements. Changes in intrathoracic pressure during breathing movements have significant effects on Doppler waveforms. Inward movement of the abdominal wall during inspiration is accompanied by an increase of blood flow velocities, whereas a decrease in velocities is evident during expiration. As the shape of Doppler waveforms shows changes during the breathing movements, indices or velocity ratios should be evaluated during fetal apnea (Figures 53.15 and 53.16).[6,7,12]

The easiest vessel to investigate is the UV. Reference ranges for quantitative UV blood flow has been also compiled, according to the following formulae: UV volume flow (ml/min) = time averaged velocity (mm/s) × cross-sectional vessel area (mm^2); UV absolute flow (ml/min) = vessel cross-sectional area (mm^2) × mean velocity × 60. However, methodological differences in blood flow study have limited the quantitative evaluation of the UV in clinical practice. Qualitative analysis of the UV waveform in normal conditions shows a continuous forward flow without pulsations after the first trimester (Figure 53.17). Mild sinusoidal pulsations synchronous with the fetal heart rate (FHR) have been described in some normal fetuses between 34 and 38 weeks and during fetal breathing movements (20% of the cases in the free-loop portion). These have to be distinguished from the pathological pulsations in cases of severe fetal compromise and nonimmune hydrops[6,13–15] (Figure 53.18).

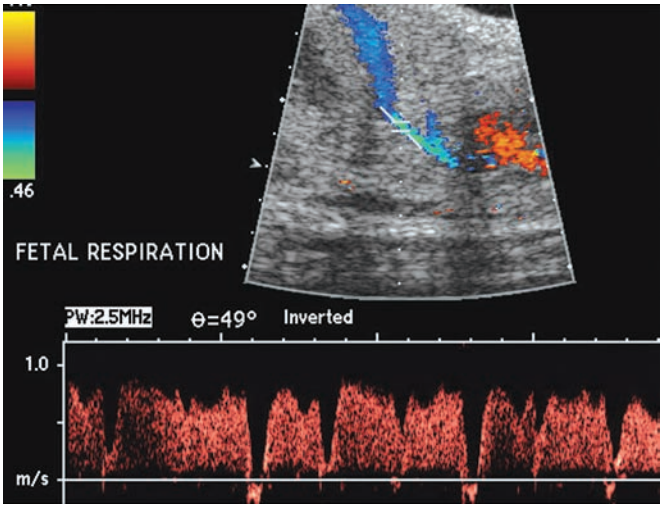

Figure 53.15 Doppler flow waveforms during breathing movements in the DV.

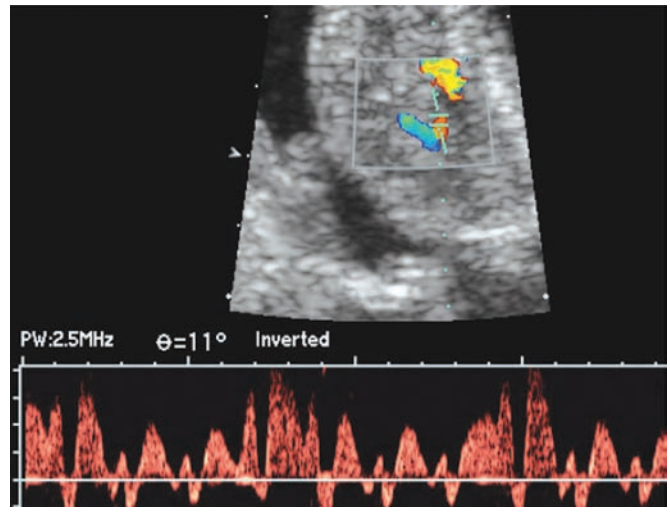

Figure 53.16 Doppler flow waveforms during breathing movements in the IVC.

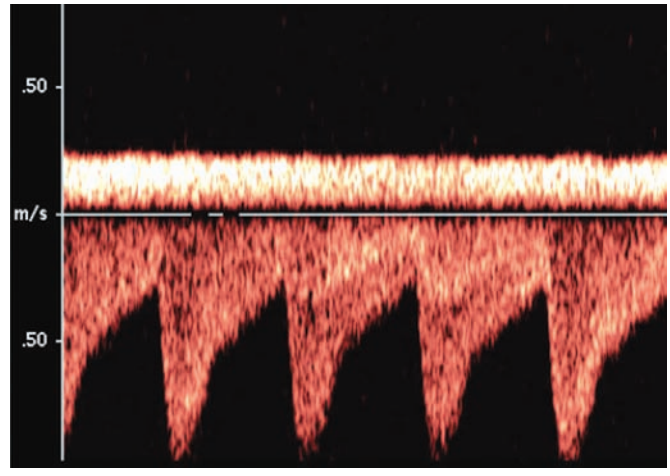

Figure 53.17 Qualitative analysis of the UV waveform: a physiologic continuous forward flow without pulsations is observed after the first trimester.

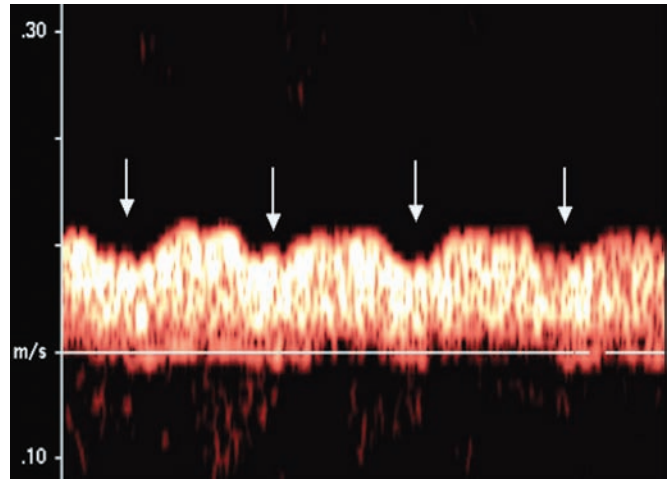

Figure 53.18 Umbilical vein pulsations with notches synchronous with atrial contractions. Diphasic pulsations due to the increased central venous pressure and/or opening of the DV may be secondary to congestive heart failure or imminent fetal hypoxemia/acidemia.

Table 53.1 Classification of the fetal venous system anomalies (from Fasouliotis *et al.*[3])

A. Cardinal veins
   a. Complex malformations, heterotaxic syndrome
   b. Isolated malformation

B. Umbilical veins
   a. Primary failure to create critical anastomoses
      – Complete: abnormal connection of UV (venosus shunts) into iliac vein, IVC, SVC and right atrium
      – Partial: persistence of right umbilical vein (PRUV) with or without DV
   b. Secondary occlusion

C. Vitelline veins
   a. Primary failure to create critical anastomoses
      – Complete agenesis of portal system
      – Partial agenesis of right or left portal branch (portosystemic shunt)

D. Anomalous pulmonary venous connection (total or partial)

Structural anomalies of the fetal venous system

A brief review of the embryologic landmarks was given in order to understand the fetal venous system structural anomalies (see section 'Embryology of the fetal venous system'.

The abnormal development of fetal venous vessels may be related to either of two different pathogenesis: the primary failure to transform or to form the critical anastomoses and the secondary occlusion of an already transformed system.

Four major groups of anomalies can be identified on the basis of the etiology (primary or secondary), the vessel involved and the embryologic precursor (Table 53.1): (A) abnormal connection of the cardinal veins; (B) abnormalities of the UV; (C) abnormalities of the vitelline veins; and (D) anomalous pulmonary venous connection (not discussed in this chapter).

Anomalies of the fetal venous system may be also classified simply considering either (1) the abnormalities of the caval venous system or (2) the anomalies of umbilical, portal and hepatic veins. The abnormal connections of the cardinal veins are part of the heterotaxy syndromes.

An interrupted or absent IVC with azygos vein continuation or the persistence of the left SVC are the result of primary failure to create the anastomoses in embryologic period and may be a sign of cardiosplenic syndromes.

The anatomical correlations of aorta to the IVC and the spine, and the venous connections to the atria are very helpful to diagnose left and right atrial isomerisms. In situs solitus, the aorta is located to the left of the spine, whereas in situs inversus the location is reversed. In right isomerism, the aorta and the IVC are on the same side of the spine, either right or left. Aplasia of the spleen should be a sign of right isomerism. In left isomerism, the aorta runs medial to the spine, the IVC is not identified and the azygos vein runs dorsal and lateral to the aorta, either on the right-hand side or on the left-hand side. In this subtype of heterotaxy syndrome, multiple spleens are usually present. A situs ambiguus is a common finding in both types of isomerism: the stomach can be in a left, right or medial position. Also, the position of the liver can be variable.[2–4,6,16,17]

Abnormalities of the IVC and the SVC are often associated with major impairments of the development of the heart, intestinal tract and body symmetry, influencing significantly the prognosis.[2–4,6] The anomalies of the umbilical veins represent the major and most common group of structural anomalies of the fetal venous system.

Primary failure to form the critical anastomoses results in an aberrant vessel that shunts the blood flow from the placenta to the systemic veins. This spectrum of anomalies may involve the iliac vein, the IVC or the SVC, or the direct connection with the right atrium. Agenesis of the DV is a common feature of these groups of anomalies. Two forms may be identified. The first one is represented by the direct connection of the UV with the systemic venous circulation, bypassing the liver. This is often associated with Noonan syndrome, pleural effusion and hydrops. The second form includes cases in which the UV is adequately connected with the portal vein, but fails to establish a communication with the persistent proximal part of the right vitelline vein. The result is a prolonged hypoperfusion of the liver that may lead to portal hypertension.[2–4,17–19]

Partial failure to form critical anastomoses in left and right veins is quite common. Persistence of the right umbilical vein (PRUV) is the most common anomaly observed. Three types may be identified: (1) the intrahepatic form (the UV is connected with the right portal vein instead of the left portal vein); (2) the RUV is connected directly to the iliac vein, the IVC or the right atrium; (3) both the UVs persist.[16,17]

The first type is commonly identified as an isolated finding, and is considered a benign variant,

whereas the other two are often associated with complex structural anomalies, especially cardiac malformations, or signs of congestive heart failure.

The pathophysiologic mechanisms of PRUV, primary or secondary, seem to be related to occlusion by thromboembolic events arising from the placenta. Teratogenic agents have been advocated as inducing primary failure of the critical anastomoses.

The anomalies of the vitelline veins are extremely rare and only a few cases have been reported in prenatal literature. Primary failure to form the critical anastomoses may lead to complete agenesis of the portal system or to partial agenesis of the right or left portal vein. In the complete form, enterohepatic circulation is shunted systemically.

Partial forms of absence of the portal system might represent a more benign form of vitelline veins' abnormalities.[2–4]

Venous system Doppler and fetal diseases

UV pulsations with moderate to severe notches synchronous with atrial contraction have been described as an ominous sign. They are associated with various fetal pathological conditions such as nonimmune hydrops (NIH), fetal arrhythmia, fetal congestive heart failure, placental anomalies, fetal growth restriction (FGR), absent/reverse end-diastolic flow (ARED) in the umbilical artery (UA) and abnormal FHR patterns.

Different pathophysiological mechanisms may lead to UV pulsations. Single pulsation, caused by changes in forward flow from the placenta, might be related to ARED flow in the UA during diastole or bradicardia, umbilical cord occlusion and true knot on the cord during systole. Diphasic pulsations, because of increased central venous pressure and/or opening of the DV, can be secondary to congestive heart failure or imminent fetal hypoxemia/acidemia (Figure 53.18).[20]

NIHF is a severe clinical condition of varying etiologies with poor prognosis. Differentiating between NIHF caused by congestive heart failure and other noncardiac causes is essential to formulate a prognosis.

In the presence of NIHF and umbilical pulsations, the right ventricular shortening fraction is significantly decreased, and abnormal venous return to the heart is consistent with decreased cardiac output, leading to congestive heart failure and poor fetal outcome.

Structural heart diseases involving ventricular outflow, with or without hydrops, are frequently associated with abnormal venous blood flow. Altered pump function with increased workload causes a decrease or even reversal of blood flow during atrial contraction. In cases with tricuspid regurgitation, increased reversed phase in the IVC is frequently associated to fetal hydrops. Increased central venous pressure due to regurgitant flow into the atrium can cause hydrops, which implies poor prognosis.

The diagnosis of the different types of fetal arrhythmias is possible by simultaneous waveform recordings from abdominal aorta and IVC. High-velocity reverse flow due to increased right pressure is found either in atrial contraction against a closed tricuspid valve, or in tricuspid regurgitation. The first occurs during premature atrial contraction with complete atrioventricular block, and the second during premature ventricular contraction.

Premature beats of supraventricular or ventricular origin can be differentiated depending on the characteristic differences in blood flow velocity waveforms of the venous vessels (IVC) during atrial contraction. During premature beats of atrial origin an exaggerated reverse flow is recorded earlier than expected during the heart cycle. In cases of premature beats of ventricular origin, the reverse flow is evident at the moment of end diastole, with a typical lag pattern in blood flow velocity after ventricular premature beat.[6–20]

Venous Doppler analysis is also essential to manage supraventricular tachycardia. From the observation of venous flow patterns (IVC, DV), it is possible to delay antiarrhythmic treatment if the heart rate is below 210 beats/min. Above this critical heart rate frequency, an abnormal monophasic forward flow is observed in the DV and the IVC. This pattern is related to direct impediment of diastolic filling, causing elevation of atrial and venous pressures. Due to the presence of a parallel fetal flow circuitry, the increase of the left atrial pressure leads to right side congestive heart failure and ventricular dysfunction.[6,21,22]

Fetuses with intrauterine growth restriction (IUGR) are usually delivered on the basis of abnormal results of nonstress tests such as FHR monitoring, biophysical profile or the presence of maternal pathological conditions. Although the introduction of arterial Doppler ultrasound evaluation has resulted in a significant decrease in perinatal mortality and morbidity, the transition between adaptation and decompensation because of fetal hypoxemia/acidemia is difficult to identify accurately.

The decision regarding the optimal timing of delivery, to avoid iatrogenic delivery of a mild affected premature neonate before irreversible asphyxia-related damage, is still a dilemma. The arterial multivessel evaluation (umbilical artery, descending aorta, middle cerebral artery) is commonly used in clinical practice to assess fetal well-being in high-risk pregnancy. However, this assessment has a limited value in determining the time of delivery.[6,23–28]

Although maximal decrease in vascular cerebral resistance has been found to precede the onset of late decelerations by an average of 2 weeks, it has been unsuitable to monitor IUGR fetuses closely during the last 2 weeks preceding the occurrence of acute distress or intrauterine death.

The Doppler study of the fetal venous blood flow in the IVC and the DV and other venous vessels (sinus trasversus, right hepatic vein) have raised new

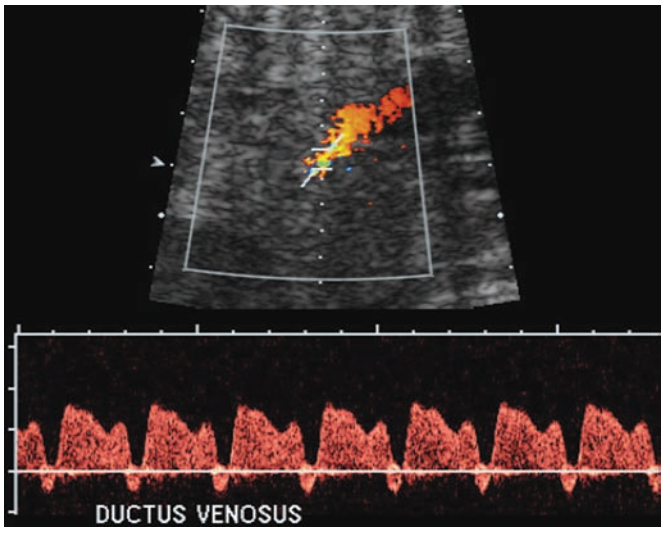

Figure 53.19 Abnormal DV waveform: reversal flow during atrial contraction is the consequence of increased end-diastolic pressure.

expectations by investigating fetal hemodynamic changes more accurately.

Two mechanisms can be considered for the onset of abnormal venous Doppler waveform: the increase of right ventricular afterload and myocardial failure. As long as the fetus is able to compensate for reduced placental supply by redistribution, preferential myocardial oxygenation delays the development of right heart failure, despite an increasing afterload. Progressive changes in fetal venous circulation may indicate failure of the compensatory mechanism and herald the development of right heart failure due to myocardial hypoxemia.[6,9,10]

It has been shown that the evaluation of Doppler venous waveforms are correlated to computerized analysis of FHR monitoring: reverse flow in DV is significantly correlated with values of short-term variation below 3.5 ms, ominous sign of hypoxemia/acidemia[29,30] (Figure 53.19).

Recent studies are focusing on the role of fetal venous Doppler evaluation, combined or integrated with other methods of fetal surveillance, such as biophysical profile and computerized cardiotocography, in the timing of delivery and the physiopathological sequence of the deterioration. Besides promising results, it has not been yet assessed as to what is the best method for timing the delivery of preterm severe IUGR fetuses.[30–32]

The widely held view that, in any case, venous Doppler abnormalities would precede deterioration of biophysical parameters has not been observed.

Ferrazzi *et al.*[30] reported that more than 50% of the fetuses delivered because of an abnormal FHR pattern did not have venous Doppler abnormalities.

Hecher *et al.*[31] observed that among fetuses born before 32 weeks of gestation, persistent abnormalities in FHR tracings preceded the occurrence of an abnormal DV pulsatility index in about 53% of the cases; simultaneous anomalies were detected in 5% of the cases.

Muller *et al.*[27] found that absent/reverse flow in the DV in a group of cases with umbilical artery ARED flow was significantly predictive of poor outcome. Delivery was indicated by non-reassuring status defined as either cardiotocographic (CTG) pathological pattern or when suspicious FHR traces were associated with absence or reversal in DV flow during atrial contraction. However, it is not indicated as to how many cases of normal DV Doppler flow waveforms were delivered for an abnormal CTG pattern.

Baschat *et al.*[32] reported that the deterioration of arterial/venous parameters occurred before an abnormal biophysical profile within 24 h in the majority of the cases.

These data show that hemodynamic changes of blood flow and decompensation, as detected by an abnormal FHR trace, biophysical profile or venous Doppler, are widely variable among fetuses and do not follow a predictable physiopathological cascade. It has been postulated that many variables have to be considered in the clinical practice. It has been shown that gestational age has a significant impact on the predictive value of venous Doppler for the timing of delivery. Moreover, in managing cases of severe preterm IUGR, the high risks involved in the sequelae of prematurity have to be considered.[33]

Probably, the combination of Doppler evaluation of the fetal circulation, to assess cardiac function, and biophysical parameters/computerized CTG, to assess central nervous system involvement, should allow more precise information about the pathophysiology and assessment of fetal growth restriction. A multicenter randomized clinical trial should be addressed to assess what is the best method of monitoring and timing the delivery of severe premature growth restricted fetuses; two ongoing trials, GRIT (Growth Restriction Intervention Trial) and TRUFFLE (Trial of Umbilical and Fetal Flow in Europe) studies, might clarify this issue.[33–35]

Conclusions

In recent years, high-resolution sonography, combined with CDI, has advanced our ability to investigate the fetal venous system. These noninvasive techniques have enhanced our understanding of the fetal venous circulation in physiologic conditions and provide us the possibility to evaluate circulatory changes in abnormal circumstances.

From the literature, it can be speculated that fetal venous Doppler may be a helpful diagnostic tool and may influence the management of fetal diseases such as cardiovascular pathologies, hydrops and fetal growth restriction.

As for the latter condition, the longitudinal Doppler analysis of fetal arterial and venous districts provides us essential information about the progressive deterioration that occurs in chronic hypoxemia. Even though abnormal venous Doppler has a high likelihood of perinatal mortality/morbidity, further studies are needed to clarify the role of fetal venous Doppler in the timing of delivery. The understanding of the variables that affect the physiopathological changes in severely compromised fetuses should provide us this crucial information.

54 Molecular background of parturition: lessons from knockout models

T. Kimura, K. Ogita, T. Tsutsui, K. Shimoya, M. Koyama and Y. Murata

Introduction

Parturition, which is the last step of new life inside the mother's body, is considered to be the result of multiple biochemical and physiological steps. For example, during the first 9 months of human gestation, the uterus is in a quiescent state, and unresponsive to contractile stimuli (phase 0). After this prelude to parturition, the uterus should prepare for labor (phase 1). During labor, the uterus contracts to dilate the cervix and to force the fetus through the birth canal (phase 2). After the final process of labor, the uterus involutes to normal size (phase 3).[1] The beginning of parturition can be considered as a transition from phase 0 and phase 1, which is undetectable clinically. The initiation of labor is the transition from phase 1 to phase 2, which is determined clinically by the onset of regular and painful uterine contractions leading to cervical dilatation and descent of the fetal presenting part.

During phase 0 and phase 1, various endocrine and immunological factors should control uterine function for it to maintain quiescence and to prepare for labor. During phases 2 and 3, stimulating molecules for uterine smooth muscle contraction and molecules related to uterine contractile systems must play a crucial role (Figure 54.1). Several papers have appeared that describe up- and down-regulation of these molecules, although few of them told us how critical these functions were for maintenance of pregnancy, as well as initiation and progress of parturition *in vivo*. The biggest advantage in using the knockout mouse model is to elucidate the actual function of these molecules *in vivo* by disrupting the specific gene responsible for the phenotype. In some cases, natural human disease caused by the gene deletion/mutation would also give us a clue for elucidating the function of the genes and substrates in parturition. This chapter will focus on the reproductive phenotypes of gene-targeted mice or human genetic diseases in which genes that were deleted are suspected of having functions for reproduction.

Endocrine system

A drastic change in the endocrine milieu occurs during pregnancy. For example, plasma estrogen concentrations at term of pregnancy are over 1000-fold of those in the non-pregnant period. Steroid hormones play a crucial role in the development of reproductive organs. Most of the knockout mouse models related to steroidgenesis showed underdeveloped sexual organs and infertility, which were inadequate for analysis of parturition. Some peptide hormones are mainly secreted from the brain, and they modulate the functions of the peripheral organs. The peptide hormone oxytocin, which directly activates uterine contractilities, will be discussed later.

Steroid hormones

Estrogen and its receptors

In the endocrine system, steroid hormones (estrogens, progestagens, glucocorticoids and androgens) and their receptors have been considered to be involved in the regulation of parturition. Near term of pregnancy, the concentrations of circulating estrogens are drastically elevated. In humans at near term of pregnancy, there is more than a 100-fold increase of plasma estrogen concentrations. High concentrations of estrogens are believed to enhance uterine sensitivity and to induce labor-stimulating molecules. As most of the estrogens are synthesized by aromatase (P450arom, *cyp19*) in the placenta of near term in human and

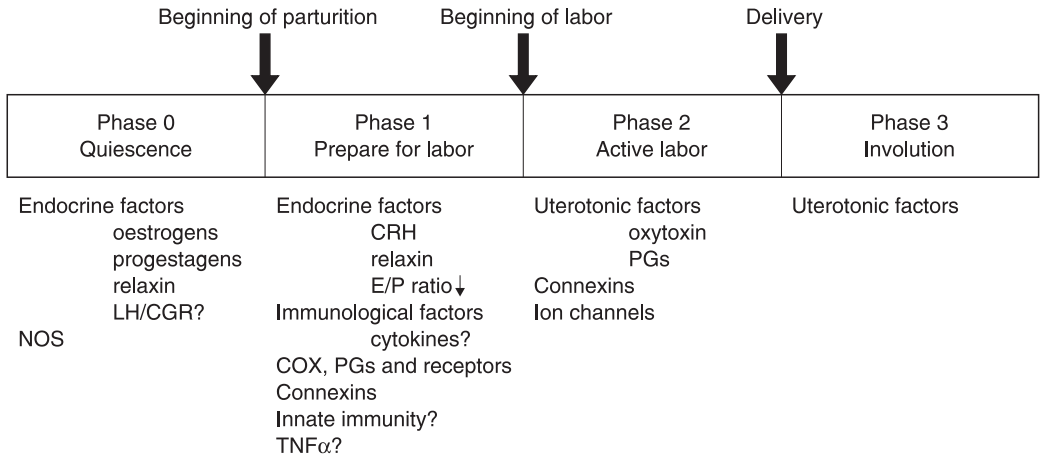

Figure 54.1 Various molecules have been reported to regulate four phases during pregnancy and postpartum. In phase 0, uterine smooth muscle should maintain quiescence even under severe distention and stretching by the conceptus. Transition from phase 0 to phase 1 is clinically undetectable, albeit this is the true initiation of parturition. Once phase 1 begins, the process to delivery is irreversible. Transition from phase 1 to phase 2 can be recognized as the onset of labor; however the attempt to stop labor at this point could already be impossible, as discussed in a lot of papers on tocolysis. Modified from Cunningham *et al.*[1]

higher primates, the antenatal histories of the aromatase-deficient patients are of great interest. Among the 16 cases reported, all appeared to be born at term with labor.[2–7] The gestational courses of two cases were precisely described. In one case, the mother suffered from progressive virilization during pregnancy[7] and in the other case the mother was administered tocolytic reagent for several weeks.[2] In both cases, labor occurred spontaneously at term and the mothers delivered their babies vaginally. Maternal estradiol and estriol concentrations near term were $< 3\%$ and $< 1\%$, respectively. These results from a natural 'knockout' human model indicated that extremely high amounts of estrogens during the third trimester are not necessary for the process of human parturition. Aromatase knockout (ArKO) female mice were completely infertile because of a hypoplastic uterus and ovary.[8] Adult male and female ArKO mice had higher concentrations of testosterone and androstendione, the precursors of estrogens. Concentrations of these androgens during the fetal and neonatal periods were not evaluated.

The estrogen effect is mediated by two distinct nuclear receptors, namely estrogen receptor (ER) α and ERβ. Female ERα knockout mice showed a hypoplastic uterus and were completely infertile.[9] Although they were infertile and implantation did not occur, decidualization could be induced with mechanical stimulation by progesterone dependent manner.[10] On the other hand, female ERβ knockout mice possessed a hormonally responsive uterus and grossly normal ovaries, and they were subfertile in terms of the frequency and size of the litters. Their parturition was not disturbed. The nature of this subfertility was caused by ovarian dysfunction.[11] ERα is necessary for the development and function of the uterus and ovary; however, ERβ appears to play a role that is more limiting on the ovary.

Progesterone and its receptors

In rodents, progesterone withdrawal is the most important trigger for parturition. As progesterone is the fundamental precursor of all other steroidgenesis, it is impossible to down-regulate progesterone synthesis without disturbing other steroidgenesis by specific gene disruption. There are two progesterone receptor (PR) isoforms, PR-A and PR-B. It is hypothesized that PR-B acts in a competitive manner to PR-A function. PR-A knockout female mice revealed extensive abnormalities, including anovulation, defective sexual behavior, a hypertrophic uterus and underdeveloped mammary glands, which led to infertility.[12] PR-B knockout female mice were fertile and sustained normal parturition at term.[13]

Glucocorticoid and its receptor

In sheep, up-regulation of fetal glucocorticoid triggers their parturition.[14] In mice, glucocorticoid receptor (GR) knockout caused severe respiratory failure after birth, and more than 80% of GR$-/-$pups died. The impaired feedback loop of the hypothalamo–pituitary–adrenal axis led to higher plasma corticosterone concentrations (approximately 2.5-fold) in GR$-/-$and GR$+/-$neonates. After mating GR$+/-$male and GR$+/-$female, 75% of pups are expected to have higher glucocorticoid concentrations *in utero*. However, there were no observations of preterm birth or other parturition failure in these cases, as well as in GR$+/-$or GR$-/-$pregnant females.[15] These observations reveal that knockout mouse models involving estrogen, progestagen and glucocorticoid systems are unsuitable for the study of parturition. The natural human model (fetuses suffering from aromatase deficiency) suggests that extremely high concentrations of estrogens in the third trimester are not necessary for maintenance of pregnancy and initiation of labor. To elucidate the

function of estrogens, progesterone and glucocorticoid in parturition using the gene-targeting mice model, development of a novel tissue- and phase-specific gene-targeting strategy such as the Cre-loxP plus Tet-Off system should be mandatory.

Androgens

Androgens may also play an important role in parturition. Infusion of androstendione into pregnant rhesus monkeys increased uterine contractility, maternal plasma estradiol and oxytocin concentrations, as well as fibronectin in the amniotic fluid, and then induced preterm birth.[16] In humans, there were two reports of mothers with P450 aromatase deficiency and a mother with congenital adrenal hyperplasia caused by mutant P450 oxidoreductase. In both studies, the mothers suffered from virilization with hyperandrogenism in their antenatal periods.[7,17] However, these mothers did not experience preterm birth. Therefore, excess of circulating androgens, the high levels of which caused virilization in adult women, might have no effect on human parturition. The most potent form of androgens is dehydrotestosterone, which is converted from testosterone by steroid 5α-reductases. There are two isoforms of the enzyme, type 1 and type 2. Steroid 5α-reductase type 2 mutation in humans and mice causes male pseudohermaphroditism, characterized by normal internal genitalia but with external genitalia resembling those of the female. Steroid 5α-reductase type 1 knockout (5αR1-null) mice showed normal reproductive behavior in both male and female, and the female became pregnant normally. However, approximately 70% of pregnant 5αR1-null mice failed to undergo delivery at term.[18] These mutant mice showed normal luteal regression, withdrawal of circulating progesterone and normal uterine contractility to oxytocin and prostaglandin (PG) $F_{2\alpha}$. Administration of antiprogestin RU 486 or ovariectomy recovered parturition in 5αR1-null mice. Steroid 5α-reductase type 1 localized in the endometrial epithelium and cervical epithelium. Progesterone and 20α-hydoxyprogesterone concentrations in uterine tissue were higher in 5αR1-null mice at term of pregnancy. The cervix of 5αR1-null mice failed to ripen at term and relaxin administration prevented their parturition defect by enhancing cervical ripening.[19] These observations suggest that parturition defect in 5αR1-null mice was caused by local aberrant progesterone metabolism, rather than systemic androgen metabolism.

Peptide hormones

Corticotrpin-releasing hormone (CRH)

In primate and human pregnancy, the placenta produces a large amount of CRH. McLean *et al.*[20] reported that CRH may act as a 'placental clock', i.e. serum concentration of CRH could predict preterm birth or timing of labor in humans. CRH was shown to potentiate both oxytocin- and $PGF_{2\alpha}$-induced myometrial activity;[21,22] however, the actual function of CRH in the pregnant uterus is still unclear. In rodents, the placenta does not produce CRH. The CRH-deficient mouse might not be a good model for testing placental CRH function; however, it could still help to understand the function of the fetal hypothalamo–pituitary–adrenal axis at parturition, as Liggins suggested.[14] CRH−/− mice born from CRH+/− female mated with CRH+/− male grew normally and were fertile without glucocorticoid replacement. CRH−/− female mated with CRH−/− male delivered their pups between 19 and 20 days of gestation, although the authors did not compare the date with that of wild-type mothers. The CRH−/− pups born from CRH−/− dams died because of severe lung dysplasia, and maternal glucocorticoid substitution rescued the pups.[23] These observations indicated that both fetal and maternal hypothalamo–pituitary–adrenal axes do not play a crucial role in mouse parturition. However, maternal glucocorticoid administration helps fetal lung maturation similar to humans' clinical settings for the preterm baby.

Relaxin and its receptor

Relaxin is a polypeptide hormone composed of two amino-acid chains as a member of the insulin family. Relaxin has been believed to promote maturation of the uterine cervix at parturition. Recent meta-analysis of recombinant or porcine relaxin administration to pregnant women indicated that there was a reduction in the risk of the cervix remaining unfavorable or unchanged with induction, with relaxin administration. However, the cesarean rate was similar.[24] Relaxin-null mutant mice have been developed, and they were fully fertile. Some of the relaxin-null pregnant females had protracted labor, although the mean gestational period was similar to that of the wild type. Relaxin-null dams exhibited normal nursing behavior, and the pups could not suckle milk from the breast because of underdevelopment of the nipples.[25] In pregnant relaxin-null mice, decrease of collagen content was not observed in the nipples and vagina. Increase of water content in pubic symphysis was smaller than that observed in wild-type mice, suggesting that the female reproductive tract and nipples were harder than in the wild-type mice.[26] In relaxin-null mice, myometrial oxytocin receptor and ERa expressions in late pregnancy (day 18.5) were attenuated.[27] LGR7, which was at first cloned as an orphan receptor with structural homology to gonadotrophin and thyrotrophin receptors, was proved as a receptor for relaxin.[28] LGR7 knockout female mice exhibited normal fertility, but some of the pups (approximately 15%) died at parturition. Protracted delivery was also observed in LGR7-null mice. Length of the gestation period was similar to that of wild-type mice. Underdevelopment of the nipple was also observed.[29] On the whole, relaxin plays a role in the preparation for parturition, although it is not a critical factor for completion of birth.

Growth hormone receptor (GHR)

The GH/insulin-like growth factor 1 system exerts direct and indirect effects on gonadal function and the reproductive system. However, the phenotypes on parturition for GH-deficient patients are not well documented. In mice, female reproduction of GHR/GH binding protein-deficient (GHR-KO) mice was precisely investigated. GHR-KO mice had fewer numbers of ovulatory follicles and corpola lutea. When they became pregnant, GHR-KO mice conceived fewer pups, and the pups were smaller. On the other hand, their placentas were larger than those of wild-type mice. The date of parturition was delayed by 1 day; however, the mechanism of this delay was not characterized.[30,31]

Gonadotrophin receptors

There are two dominant gonadotrophin receptors, namely follicle-stimulating hormone receptor (FSHR) and luteinizing hormone/chorionic gonadotrophin receptor (LH/CGR). FSHR-null mice showed infertility due to hypoestrogenism. FSHR+/−mice revealed age-dependent reproductive deficits and developed unilateral uterine masses.[32] LH/CGR-null female mice showed a hypoplastic uterus and ovary. Follicular growth beyond the antral stage was arrested. Replacement therapy with estradiol and progesterone rescued the hypoplastic uterus completely, although female mice were infertile.[33] In humans, activation and inactivation mutants of FSHR and LHR were reported. Similar phenotypes to knockout mice were reported in both patients having inactivating FSHR and LH/CGR mutations.[34] It has been shown that LH/CGR is expressed in the human uterus. A very preliminary experiment suggests that administration of human CG to the patients of preterm labor might decrease the incidence of birth.[35] If the patients with LH/CGR inactivation mutation are conceived by oocyte donation–*in vitro* fertilization–embryo transfer program, the clinical course of their pregnancy could reveal the importance of uterine LH/CGR functions on maintenance of pregnancy and parturition.

Immunological system

There is an idea that parturition resembles 'rejection of conceptus as a semiallograft' from the mother. However, if maternal immune recognition were crucial for parturition, neither strained mice nor severe combined immunodeficiency mice would deliver their pups. Classical T-cell-mediated adapted immunity does not seem to play a significant role in preterm labor and term parturition in humans and mice, because the duration of gestation does not decrease in proportion to the number of previous deliveries. There are various reports suggesting the relation between physiological or pathological parturition and cytokines, chemokines, growth factors and their receptors. We suspect these phenomena reflect that the reproductive system may employ inflammation reaction for maternal adaptation or modulation to maintain pregnancy and/or parturition.

Interleukins (ILs)

IL-1 and its receptor

IL-1 is one of the central modulators of immune reaction/inflammation. Systemic administration of IL-1 can induce preterm birth in mice,[36] and pretreatment of IL-1 receptor antagonist prevents this IL-1-induced preterm labor.[37] Knockout model mice disrupting the IL-1 system (IL-1β-null mice,[38] IL-1β converting enzyme-null mice,[39] IL-1 type 1 receptor-null mice[40]) were fully fertile. In IL-1β type 1 receptor-null mice, litter size was significantly smaller than in wild-type mice.[41] Intracervical or intrauterine challenge of lipopolysaccharides or heat-killed *Ecshericia coli* is considered as a model for intrauterine infection. Preterm delivery could be induced in both IL-1β-null[42] and IL-1 type 1 receptor-null pregnant mice[43] by the intrauterine infection model. The challenge to delivery periods was similar to that observed in wild-type mice. Up-regulation of IL-1-induced cytokine/growth factors [IL-6, tumor necrosis factor (TNF) a, interferon (IFN) γ] and constitutive nuclear factor κB p65 protein expression were attenuated in IL-1β-null mice.[44] These data suggest that the intrauterine infection-induced preterm birth in the murine model does not require the maternal IL-1 signaling system.

Interleukin 6

IL-6 has numerous biologic activities, including induction of acute-phase proteins, regulation of hematopoiesis and terminal differentiation of B-cells. Various reports indicated the induction of IL-6 in chorioamnionitis/intrauterine infection, which causes preterm labor.[45,46] IL-6-null mice were fully fertile and there was no disturbance in parturition.[47] Signal transduction of IL-6 is mediated by the gp130 protein, a subunit signal transducer molecule of the dimeric IL-6 receptor and also a subunit of the receptors for leukemia inhibitory factor, oncostatin M, IL-11, ciliary neurotrophic factor and cardiotrophin 1. gp-130-null mice were lethal *in utero*, due to hypoplastic myocardium and impaired hematopoiesis.[48] Administration of exogenous IL-6 to wild-type pregnant mice did not lead to preterm birth. Intrauterine bacterial inoculation into IL-6-null pregnant mice induced preterm birth, at a rate similar to that in wild-type mice.[49] These observations revealed that IL-6 is neither necessary nor sufficient for the murine intrauterine infection preterm birth model.

Other interleukins and their receptors

IL-8 is considered to play an important role in cervical ripening before and during labor in the human

uterus (reviewed by Kelly[50]). However, mice lacking IL-8 receptor homolog revealed a normal phenotype on their reproduction.[51] IL-2 receptor γ chain is shared for multiple cytokine receptors for IL-2, IL-4, IL-7, IL-9 and IL-15. Mice lacking the IL-2 receptor γ chain gene had an irregular estrous cycle; however, they were fertile. Interestingly, IL-2 receptor γ chain-null mice lacked uterine natural killer cells (uNK cells) on day 13 of gestation, but their parturition, litter size and body weight of offspring were similar to those of wild-type mice.[52] IL-15-null mice, which lack natural killer differentiation in lymphoid tissue, also had no uNK cells.[53] Their course of pregnancy and parturition was not disturbed. uNK cells are a major cellular component of decidua, and have been considered to play an important role in limiting normal trophoblast invasion and in immunological modulation of the fetal–maternal interface (e.g. reviewed by Croy *et al.*[54]). The course of pregnancy observed in uNK cells-deficient mice raised a big question about the functional significance of these cells.

IL-10 inhibits proliferation and cytokine synthesis in type 1 T-cells and can induce immunological non-responsiveness or anergy, acting preferably for Th1/Th2 balance hypothesis during pregnancy. However, IL-10-null mice conceived with larger numbers of implantation sites, heavier weight of pups and similar duration of gestation. There was no tendency to increase resorption of the fetus during pregnancy and preterm birth.[55]

TNF-α was implicated in the etiology of preterm birth. Amniotic fluid levels of TNF-α were elevated in patients with preterm labor or intrauterine infection. Recently, a relation between polymorphism in the promoter region of the TNF-α gene and preterm rupture of membrane[56] or bacterial vaginosis[57] has been reported. TNF-α-null mice were fully fertile.[58] There are two types of TNF receptors, and TNF receptor type 1-null mice showed early senescence and poor fertility, due to ovarian dysfunction.[59] However, these experimental models showed normal parturition process, although the number of pups was apparently smaller in TNF receptor type 1-null mice.[59]

Innate immune system

The innate immune system, which recognizes non-specific pathogen-derived molecules by toll-like receptors (TLRs), causes an inflammatory response including production of various cytokines and metalloproteinases. A unique target molecule for each TLR has been determined. For example, TLR-2 recognizes di- and tripalmitoylated peptides, TLR-3 recognizes double-strand RNAs, and TLR-4 recognizes the lipid-A component of lipopolysaccharides. Myeloid differentiation factor 88 (MyD88), the downstream adapter molecule, plays a crucial role in signal transduction from TLRs to inflammation reaction. These molecules are expressed in the placenta,[60] and one genetic polymorphism for TLR-4 (Asp 299 Gly) resulting in decreased receptor function may associate with a predisposition to preterm birth in humans.[61] Various knockout mice had already established for TLRs and MyD88, and all of them were healthy and fertile (reviewed by Kaisho and Akira[62]). Knockout mice of the molecules related to the innate immune system might provide useful models with which to analyze susceptibility to preterm birth resulting from infection.

Molecules stimulate/modulate uterine contractility

Oxytocin and its receptor

Oxytocin is one of the most potent uterotonic agents identified and is widely used in routine clinical settings for augmentation and induction of labor. Oxytocin has also been considered essential for milk let-down during lactation. Oxytocin is synthesized not only in the hypothalamic paraventricular and supraoptic nuclei, but also in the pregnant uterine endometrium[63] and fetal membrane.[64] As the oxytocin receptor up-regulation is observed in term myometrium[65] as well as in term deciduas,[66] oxytocin may act by both endocrine and paracrine manner to promote labor. Oxytocin-null mice were produced[67,68] and they were fully fertile and able to deliver litters at term. Their milk ejection reflex was severely disturbed, leading to the death of the pups by starvation. If the pups had been nursing, they would have survived. It was speculated that endogenous Arg^8-vasopressin compensated the oxytocin action, because the dissociation constants of Arg^8-vasopressin and oxytocin to oxytocin receptor are similar. However, the physiological responsiveness of oxytocin receptor to Arg^8-vasopressin was 1/10–1/100 of the oxytocin responses,[69,70] meaning that a pharmacological dose of vasopressin is required to induce physiological uterine contraction. Therefore, this hypothesis is unlikely. Oxytocin-null male mice showed social amnesia (less developed social memory) and aggression,[71,72] although their sexual behavior appeared to be normal.

In mice, initiation of labor is primarily determined by luteolysis, and corpus luteum expresses the oxytocin receptor. Continuous infusion of oxytocin to wild-type or oxytocin-null mice revealed that oxytocin can either delay labor at low doses or initiate preterm labor at high doses. A low dose of oxytocin prevented luteolysis and retarded progesterone withdrawal. The dose required to prevent luteolysis was lower in oxytocin-null mice than in wild-type mice, probably due to up-regulation of the oxytocin receptor in corpus luteum of oxytocin-null mice.[73] In wild-type and oxytocin-null mice, contrary to the up-regulation of the oxytocin receptor in term myometriun, the receptor in corpus luteum was

down-regulated at term of pregnancy, which led to luteolysis and initiation of labor. The substances that compensate contractile activity of oxytocin should be further elucidated.

There was a report that the oxytocin receptor knockout mice were lethal (personal communication).[74] However, Nishimori's group successfully developed oxytocin receptor-null mice, and their phenotype on parturition appeared to be similar to that of oxytocin-null mice (Takayanagi *et al.*,[74a] in preparation). Further investigations of their phenotype with regard to reproduction, parturition and behavior are ongoing.

PGs and their receptors

PGs are synthesized from arachidonic acid, which is mainly released from cell membrane phospholipids by the activity of cytosolic phosholipase A_2. The arachidonic acid is then converted to PGH_2, which is the precursor for other PGs, prostacyclin (PGI_2) and thromboxane (TX) A_2, via the action of cyclooxygenase (COX) 1 or COX-2. Then, specific PG isomerases/synthetases convert PGH_2 to the specific forms. PGs are widely synthesized and distributed in the body. Particularly around parturition, they are synthesized and secreted from the placenta, fetal membrane and uterine myometrium. Numerous reports have indicated an up-regulation of PGE_2 and $PGF_{2\alpha}$ (or other PGs) and modulation of their receptors around parturition (reviewed by Olson *et al.*[74]).

Cytosolic phospholipase A_2-α (cPLA$_2$-α)

cPLA$_2$-α preferentially hydrolyses fatty acids and lysophosholipids to provide precursors for PGs and platelet activating factor. cPLA$_2$-α-null females could not deliver between day 18.5 and day 20.5; instead, they delivered a smaller number of live pups at days 21.5–22.5, and the offspring did not survive.[75,76] Cesarian section at term was able to yield viable neonates. Administration of a progesterone antagonist RU486 was able to rescue parturition defect of cPLA$_2$-α-null mice and restore the pups' viability. These observations suggest that the parturition defect of cPLA$_2$-α-null mice was caused mainly by the defect of luteal regression, rather than by the shortage of PGs as uterine-stimulating substrates.

Cyclooxygenases

COX-1 carries out 'house keeping' functions such as cytoprotection of stomach mucosa, platelet aggregation and regulation of blood flow. COX-1 is expressed in many cell types and, in general, it shows constitutive activity. COX-1-null female mice showed normal fertility, but their parturition was delayed, leading to neonatal death. Bolus administration of $PGF_{2\alpha}$ at day 19.5 resulted in labor within 24 h and restored the pups' viability.[77] In wild-type mice, they showed up-regulation of COX-1 and oxytocin receptor in the uterus near term of pregnancy, and induction of both molecules was diminished in COX-1-null mice. Double knockout of COX-1 and oxytocin restored their parturition at term.[77] This observation supported the idea that oxytocin acts as a luteosupportive factor to corpus luteum in pregnant mice.[73] Uterine $PGF_{2\alpha}$ production at term was impaired in both COX-1-null and COX-1/oxytocin-null mice, and uterine $PGF_{2\alpha}$ concentrations were very low in both types of mice. It is very interesting to know which molecule compensates the uterotonic function after luteolysis, with a smaller amount of $PGF_{2\alpha}$ and without oxytocin in COX-1/oxytocin-null mice.

COX-2-null mice showed severe renal pathology (dysplasia) and female infertility.[78,79] The uterus of COX-2-null mice could not decidualize after typical pseudopregnant stimuli, and showed implantation failure when wild-type fertilized eggs were transferred.[80] Pharmacological inhibition of COX-2 by selective COX-2 inhibitor (celecoxib) in COX-1-null mice induced complete implantation failure, suggesting that COX-2 is necessary for preparation of uterine receptivity.[81] The actual function of COX-2 in murine parturition cannot be analyzed by gene-targeting models. Administration of lipopolysaccharides induced preterm birth in COX-1-null mice, with induction of COX-2 messenger RNA (mRNA) and $PGF_{2\alpha}$ in the uterus. Selective COX-2 inhibitor was more potent to inhibit lipopolysaccharide-induced preterm birth than selective COX-1 inhibitor. These pharmacological studies using COX-1-null mice suggested that COX-2 plays a pivotal role when preterm birth is induced by infection.[82]

Membrane prostaglandin receptors

After the first molecular cloning of the receptor for TXA_2, the receptors for prostaglandin prostanoids have been cloned by homology screening. They are classified as the G-protein-linked rhodopsin receptor family with seven transmembrane domains (reviewed by Nasumiya *et al.*[83]). Specific receptors for PGD_2, TXA_2, PGI_2, PGE_2 and $PGF_{2\alpha}$ have been cloned and are referred to as DP, TP, IP, EP and FP, respectively. There are four subtypes for EP (EP1–EP4). Several isoforms of EP1, EP3, FP and TP have also been reported. $PGF_{2\alpha}$ action is mediated by FP, which is coupled with G-protein, leading to the increase of intracellular calcium $[Ca^{2+}]_i$ concentration and stimulation of myometrial contraction. The action of PGE_2 is more complex. Activation of EP1, EP3A and EP3D leads to elevation of $[Ca^{2+}]_I$, whereas EP2 and EP4 activate adenylate cyclase, which leads to myometrial relaxation. In the myometrium, it has been reported that there is up-regulation of EP2 and suppression of FP during pregnancy[84] and increase of FP, EP3 and suppression of EP2[85] at the onset of labor. As cyclic adenosine monophosphate induces uterine muscle relaxation and elevation of $[Ca^{2+}]_i$ activates the uterus, these observations are reasonable for maintenance of uterine quiescence and stimulation of parturition during the course of pregnancy.

Mice lacking EP1, EP2 and EP3 genes are healthy and fertile. In EP3-null mice, febrile response induced by IL-1β was attenuated.[86] Most of the EP4-null mice died due to a persistent ductus arteriosus. Less than 5% of the EP4-null mice survived and they were fertile.[87,88] No authors have mentioned precisely the course of parturition of EP-deficient mice.

In contrast, mice lacking FP gene were fertile, but females could not deliver pups at term. This prolonged pregnancy caused degeneration of the placenta and intrauterine fetal death. By cesarian section, the fetus could be rescued; however, administration of $PGF_{2\alpha}$ or oxytocin at term was not effective to induce labor. Up-regulation of the oxytocin receptor in the uterus at term was abolished. Oophorectomy on day 19 recovered the parturition process of FP-null mice, and they delivered pups normally. Oophorectomy also restored the oxytocin receptor up-regulation in the pregnant uterus at term.[89] In FP-null nice, induction of COX-2 in the uterus on day 20 was totally abolished. On the other hand, COX-1 in the uterus was up-regulated on day 17 and decreased at the time of parturition in wild-type mice; however, this decline of COX-1 level was also disturbed in FP-null mice. Induction of uterine connexin (Cx) 43 mRNA was abolished in FP-null mice. After oophorectomy on day 19, COX-2 up-regulation, COX-1 down-regulation and Cx43 up-regulation at the time of spontaneous labor normalized to the wild-type level. Administration of exogenous progesterone after oophrectomy in FP-null mice inhibited parturition. Treatment of FP-null mice with COX-non-selective or COX-2 selective inhibitors after oophrectomy also prolonged the time from oophrectomy to delivery.[90,91] These findings suggest that progesterone withdrawal is the critical factor to determine the onset of mouse parturition, and COX-2-derived prostaglandins compensate the uterine stimulative activity, although there is no FP in the myometrium.

Nuclear prostaglandin receptors

Recently, the existence of specific prostaglandin transporters, which mediate influx of PGs into the cells, has been demonstrated. Moreover, trafficking of COX-2 to nuclear envelope was also determined. These data suggest the existence of specific nuclear receptors for PGs (reviewed by Helliwell *et al.*[92]). Peroxisome proliferator activated receptors (PPARs) are putative targets for the nuclear action of PGs and other eicosanoids.

It has been shown that PPARγ preferentially binds to 15d-PGJ_2, the final metabolites of PGD2. As human gestational tissues contain PGD synthases and PGD_2 in amniotic fluid,[93] the function of PPARγ in the pregnant uterus is of great interest. PPARγ is also considered as a target molecule of thiazolidinedione drugs, which are widely used as insulin sensitizers. PPARγ-null mice were lethal *in utero*, due to defects in placental vascularization.[94] Using Cre-loxP recombination system, conditional PPARγ knockout mice were obtained. Female mice, in which the PPARγ gene was conditionally deleted in epithelial cells, T- and B-cells and ovary cells, showed impaired fertility with smaller litter size. In this mouse strain, uterine PPARγ was intact and parturition was not disturbed.[95]

PPARδ-null mice also showed high (approximately 90%) embryonic lethality. The connections between placenta and decidua were abnormally loose. The labyrinth was smaller; however, the vascular structure was fully developed, different from the placentas observed in PPARγ-null mice.[96] PGI_2 was considered as a mediator for embryo implantation,[97] and PGI_2 is revealed as one of the natural ligands for PPARδ.[98] In contrast to these observations, surviving PPARδ-null mice were generally healthy and fertile, albeit they displayed more than a 60% reduction in adipose mass. PPARα-null mice showed normal fertility.[99] Taken together, PPARs (especially PPARγ and PPARδ) play an important role during placentation. Their function in parturition has not been determined from knockout mice models, although several of their natural ligands (various eicosanoids and unsaturated fatty acids) were detected in gestational tissues during pregnancy.

Connexins

Cxs are the protein subunits of intracellular gap junction channels. In mammals, there are at least 15 Cx family genes. Among them, Cx43 is up-regulated in pregnant myometrium at term and this induction is considered to ensure the coordinate contraction of uterine smooth muscle during labor to produce expulsive force effectively. Mice lacking Cx43 died postnatally because of congenital obstruction of the right ventricular outflow.[100] Another subtype of Cxs, Cx32 or Cx40 genes, were 'knocked in' into the Cx43-null mice to elucidate the functional specificity of Cxs. Both Cx43-null heterozygous Cx32 and heterozygous Cx40 knock-in mice (−/Cx32 and −/Cx40, respectively) could deliver their pups, suggesting that these molecules are possibly compatible in uterine function at parturition. Cx43-null heterozygous Cx32 knock-in dams failed to nurse their pups, due to impairment of milk ejection.[101] These model mice could not indicate the necessity of gap junction in term myometrium for regulation of uterine contraction.

Ion channels

Ion channels are necessary for proper electrophysiological responses of the excitatory organs (nerves, muscles, etc.); however, few reports are available about their gene-targeting model and reproduction. SK channels are potassium selective, voltage independent and activated by increases of $[Ca^{2+}]_i$, which occur during an action potential and induce repolarization of membrane potential. There are three subtypes of SK channels. A tetracyclin-based genetic switch sequence was introduced into the 5′-flanking of mouse SK3 gene. Administration of doxycyclin to the mouse

abolished the SK3 gene transcription effectively. On the other hand, homozygous mutant shows overexpression of SK3 gene and protein (approximately threefold). The phenotype after down-regulation by doxycyclin was almost negligible. On the other hand, the homozygous female showed protracted labor and the majority (7/10) of the pups died during parturition *in utero*. In adult mice, the respiratory response during hypoxic attack was abnormal; they could not increase their respiratory rate and apnea occurred. Doxycyclin administration, which abolished the SK3 expression, rescued these phenotypes.[102] Overexpression of Ca^{2+}-activated K^+ channel affected the uterine contractility most severely at parturition.

Nitric oxide synthases (NOS)

Nitric oxide may play an important role in the regulation of myometrial relaxation and cervical ripening. Three major isoforms of NOS, viz. neuronal NOS (nNOS), endothelial NOS (eNOS) and inducible NOS (iNOS), are expressed in the non-pregnant and the pregnant uterus. Knockout mice of these three NOSs were reported to be fertile and there were no abnormalities on their parturition.[103–105] Calcitonin gene-related peptide (CGRP) inhibits the contractile activities of smooth muscles. CGRP-induced vascular smooth muscle relaxation was mediated by nitric oxide. CGRP also inhibited KCl-induced contraction in uterine myometrium. However, this inhibition was observed in all nNOS-null, eNOS-null and iNOS-null mice models equivalently to the wild-type mouse.[106] These observations suggest that the nitric oxide–NOS system may not be necessary to ensure myometrial relaxation during pregnancy, although there is a possibility that the another type of NOS could compensate the function of the targeted NOS.

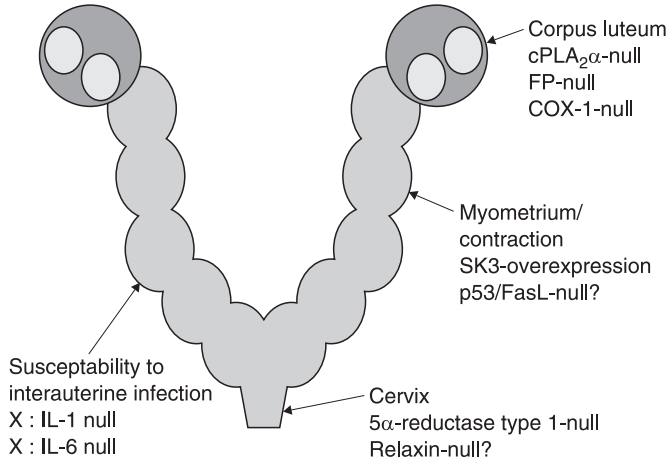

Figure 54.2 Summary of gene-targeted mice whose phenotype is affected on parturition. Note that most of the target points of knockout mice were corpus luteum: the failure of luteolysis. The relationship between deficiency of the immunological system and susceptibility to infection-induced preterm birth is of great interest; however, only negative data are available.

Conclusion

Since our first review of the knockout mouse model and parturition,[107] various gene-targeting model mice have been produced. Especially after finishing the human genome project in 2002 and the near completion of the mouse genome project, knockout mice are the ultimate strategy to investigate genes of unknown functions. All of the observations listed here and in other reviews[108,109] indicate that a few deficient genes, which are conventionally considered as a very important factor to regulate parturition, successfully disturbed their parturition. Moreover, in most of the knockout mice whose parturition was intruded, the process of luteolysis rather than the uterotrophic or uterotonic action was actually impaired (Figure 54.2). Gene targeting of the endocrine system often resulted in infertility, because of the hypoplastic reproductive system. Most of the gene-targeting mice related to the immune system and the substrates related to uterine contraction could successfully deliver their pups. Conventional uterotonic pathways such as oxytocin and the prostaglandin system could be preserved by redundant manner except for the function of the targeted molecule concerned with luteolysis. Some interesting knowledge could be obtained from human diseases from gene mutations, such as fetal aromatase deficiency. We clinicians should observe precisely the course of pregnancy and parturition in patients who are suffering from genetic disorders, even when they showed normal sequence.

For the future, an unexpected phenotype can be obtained from double- or triple-gene knockout mice. A good example was reported by Embree-Ku and Boekelheide,[110] indicating that absence both of p53 and FasL genes in female mice led to dystocia. Further analysis should be done to determine the unexpected pathway from these apoptosis-related genes to uterine contraction at parturition. Using the available resources of knockout model mice, we could further analyze the mechanism of parturition with some physiological and/or pharmacological manipulation. We also expect to find novel strategies against preterm birth through these experimental models, which is still a leading cause of mortality and morbidity of the infant.

Acknowledgments

We thank Ms. Naoko Hagino for excellent secretarial help. This work was supported in part by grants-in-aid for scientific research (Nos. 14571557, 15390505, 15591746 and 16390476) from the Ministry of Education, Science and Culture of Japan (Tokyo, Japan).

55 Mechanism of human uterine contraction

T. Kawarabayashi and Y. Inoue

Introduction

The uterus is one of the smooth muscle organs that carry out their physiological roles through contractile activities that are tonic and/or phasic contractions, which vary according to the function of each organ. The contractile activities are characterized by three elements (amplitude, duration and frequency), and their combinations determine the type of motility. On the other hand, the arrangement of the smooth muscle bundles, which are composed of smooth muscle cells, determines the direction of the force. The contractile properties of smooth muscle organs are generally correlated with the electrical activity of the plasma membrane; however, the influence of electrical activity varies from organ to organ. Some muscles do not generate action potentials, while others produce active responses. As for the relationship between action potential and contraction, it can be said that the pattern, duration and frequency of action potentials determine the pattern of contractions including each duration and frequency. Moreover, differences in electrical properties might be expected to correlate with the different mechanisms by which bioactive substances and drugs affect the activity of each smooth muscle organ. Therefore, various types of smooth muscles can be classified according to their excitability. For example, stomach and trachea are classified as poorly excitable muscles, and vas deferens and ureter as quiescent, but highly excitable muscles. As for the myometrium, it is placed in the group of spontaneously active and readily excitable muscles like the tenia of cecum, intestine and portal vein. The contractility of this muscle group is greatly influenced by changes in electrical activity. However, one of the most important roles of the uterus is to retain a fetus by suppressing contractility until such time as adequate fetal growth can be achieved, and then to expel the fetus by rhythmic contraction. Long-term and short-term control mechanisms are essential to achieve this dual role. The activity of the myometrium is highly influenced by hormonal conditions to keep the fetus *in utero*, and a variety of stimulants (oxytocin, prostaglandins, catecholamines, etc.) that promote expulsion of the fetus. The course of pregnancy and parturition vary between different species, and myometrial functions would be expected to show similar variation. In the human, a periodicity consisting of 1 min of contraction and a few minutes of relaxation is essential for both mother and fetus. The mother can perform pushing efforts during the contraction phase, and the fetus can recover from the hypoxic state during the relaxation phase. This periodicity probably determines the fundamental characteristics of human uterine contractility.

Electrical activity in the human myometrium

Few studies have recorded the intracellular electrical activity of the human myometrium, though there have been many studies on the electrophysiological properties of animal myometrium. In 1971, Nakajima reported intracellular action potential of human isthmic myometrium using a microelectrode. His description was limited to the mean resting potential (−46.4 mV), and the configuration of the action potential (plateau type). In 1982, therefore, we initiated electrophysiological experiments in human myometrium using the single sucrose-gap method. The specimens consisted of small strips of pregnant human isthmic myometrium dissected from the lower uterine segment at the time of term cesarean section with patients under epidural anesthesia under informed consent, prior to the administration of oxytosis. This material can be easily and consistently obtained from the human uterus without complications. We used the single sucrose-gap method to make a simultaneous record of spontaneous electrical and mechanical activity; this is the most stable method for recording long-term activities.

Passive electrical properties

Resting membrane potential

The resting membrane potential of a spontaneously active smooth muscle, such as intestine and myometrium, is lower than that of a non-spontaneously active smooth muscle. In these muscles, the resting potential is defined as the maximum polarization between action potentials recorded by the microelectrode method. If the tissue shows bursts of spontaneous activity, the value obtained during the quiescent period is taken as the membrane potential. In pregnant human myometrium, it is easier to measure the resting membrane potential because of the long-lasting quiescent period, since the frequency of the action potential is very low in comparison with that of the rat. However, it is obvious that many factors, such as faulty impalement, deficiencies in the microelectrodes, tip potentials of the microelectrodes, stretching of the tissue, bathing temperature and so on affect the membrane potential. Therefore, it is difficult to compare the date reported by different investigators even for the same tissue. The actual value of the resting membrane potential in term-pregnant human myometrium is about -46 to -50 mV,[1,2] and this is compatible with the values in term-pregnant rat myometrium.[3,4] Even in isolated pregnant human myometrial cells dissected from the incisional edge of the lower uterine segment at the time of cesarean delivery, the mean resting membrane potential is -49.4 mV, the same as in intact tissue.[5]

The resting membrane potential of the myometrium is highly influenced by external potassium and sodium in animals. In the rat, when potassium is increased from the normal concentration (5.9 mM in Krebs solution), the membrane gradually depolarizes.[6] On the other hand, when sodium is decreased, the membrane depolarizes and contracture develops in pregnant mouse[7] and rat[6] myometrium. It is considered that the contracture produced by sodium removal is largely calcium dependent, and that an increase in calcium conductance, secondary to membrane depolarization and sodium–calcium exchange, is involved in the calcium-dependent contracture.[8] In myometrium of pregnant woman, the resting membrane potential is primarily influenced by the permeability for potassium ion, but sodium permeability also has an important role.[2]

Length constant

We can obtain the electrical response of pregnant human myometrium evoked by various intensities of stimulation recorded at three different distances from the stimulating partition. The amplitudes of the electrotonic potentials show outward rectification. Linear relations between the applied inward current intensities and the amplitudes of the electrotonic potential were seen at more than three places. There was a long–linear relationship between spatial decay of the electrotonic potential produced at a given current intensity and the distances from the partition. This indicates an exponential decay of the electrotonic potential along the tissue. The length constant describes the efficiency with which a current will spread through the tissue. This content is significant in determining the propagation of action potentials through the tissue. The mean value of the length constant was 1.0 ± 0.1 mm, which was the distance at which the electronic potential decayed to $1/e$. This value is shorter than that measured in the longitudinal muscle of term-pregnant rat myometrium (2.9 mm),[3] but is similar to that observed in the circular muscle of midpregnant rat myometrium (1.02 mm).[9]

Membrane time constant

The membrane time constant is calculated from the relationship between the time to reach the half amplitude of the electrotonic potential at a steady sate and the distance between the recording electrode and the stimulating electrode. The slope of the line represents the relationship of $\tau m/2\lambda$, where τm and λ are the time constant of the membrane and the length constant of the tissue, respectively. The time constant is used as an indicator of membrane resistance. An increase in membrane permeability can therefore be measured as a decrease in τm. The time constant of pregnant human myometrium is 396 ± 46 ms[2]; this value is larger than that of the pregnant rats (180–228 ms).[3,10]

Effect of the reproductive state on passive electrical properties

The cells of the myometrium are spindle-shaped, ranging in size from 2 to 10 μm in diameter, and from 200 to 600 μm in length, depending on the species and hormonal state of the individual. The muscle cells are largest during the later stages of pregnancy, primarily because of the stimulatory influence of the sex steroids and the muscle distention caused by fetal growth.[11] Measurements of longitudinal muscle cells isolated from the uteri of 21-day pregnant rats (delivering day), showed an average size of $232 \pm 74 \times 16.2 \pm 7.0\,\mu$m.[12] Hormones, especially estrogen, and muscle distention also affect the electrical properties of the myometrium.[13] In rat, the resting membrane potential gradually depolarizes (from -43 to -36 mV in circular, -45 to -41 mV in longitudinal muscle), and there is a progressive increase in the length constant (from 2.5 to 2.9 mm in longitudinal muscle) and time constant (from 180 to 228 ms in longitudinal muscle) throughout pregnancy and delivery.[3,4] Thus, a spontaneous action potential is more easily generated and propagated through the myometrium as pregnancy progresses. The overall excitability of the myometrium in late pregnancy culminates in the initiation and progress of labor. The same may occur in human myometrium, though this has not been verified because of the difficulty in obtaining early and midpregnancy myometrium.

Active electrical properties

Action potentials

In a small animal with a bicornuate uterus, such as the rat or mouse, the myometrium consists of a well-defined outer longitudinal layer and an inner circular layer separated by an extensive vascular plexus; the electrophysiological characteristics of each muscle are different. The predominant types of action potentials in rat uteri at midpregnancy are spike in the longitudinal muscle and plateau in the circular muscle.[14] In human myometrium, it is difficult to dissect the longitudinal and circular muscle and therefore difficult to distinguish the action potentials characteristic of these two layers. However, spike- and plateau-type action potentials can be distinguished from the pattern of traces using the microelectrode method[2] and single sucrose-gap method.[15] Plateau potentials are more frequently observed, but these do not allow the prediction of whether the pattern of action potentials will be spike or plateau type before the onset of spontaneous activity. However, all contractions are well synchronized with the action potential, and even a single spike effectively triggers a small contraction; the tension does not revert to the resting level but is summated to a fused tetanus if the intervals between spikes are short enough. The amplitude of the contraction depends on the frequency of the spike potentials. In the plateau-type, the initial spike triggers the contraction, and the duration of the contraction is considerably prolonged in proportion to the plateau duration, though the amplitude is not greatly increased.[15]

The configuration of spontaneous action potentials in human myometrium is very similar to the pattern observed in rats; however, the time courses are remarkably different (about 10 s in rat vs. 60 s in human). The duration of both plateau-type and spike-type action potentials gradually decreases and finally disappears in excess calcium (7 mM) and calcium-free solutions, as well as with application of the calcium antagonist, diltiazem.[16] Moreover, superfusion with sodium-deficient (15.5 mM) and calcium-free solution increases the amplitude of the electrotonic potential and inhibits any active response, in comparison with the responses in the calcium-free solution.[2] Calcium ions can therefore be considered to play an essential role in constituting the action potential, and sodium ions influence the generation of the action potential.[9]

Pacemaker potentials

Myometrium is a spontaneously active and highly excitable muscle. Most of the uterine muscles show spontaneous rhythmic action potentials, which arise in pacemaker cells, and are transmitted over the organ as a whole. As in other visceral smooth muscles and the heart, uterine pacemaker activity is characterized by a slow depolarization of the muscle cell membrane culminating in generation of the action potential. As the pacemaker cells are not localized to a specific area of the myometrium, these cells can only be recognized by the pattern of electrical activity. It is said that all uterine muscle cells are capable of becoming pacemakers.[17] The frequency of pacemaker activity determines the rate of contraction. In pregnant rat myometrium, the slow depolarization is associated with a gradual increase in membrane resistance, presumably due to a reduction in potassium conductance, as judged from the increase in amplitude of the electrotonic potential recorded from a single cell.[3] It is also possible that the slow depolarization results from an increase in sodium permeability, since the pacemaker potential is dependent on the presence of sodium in the external environment and is unaffected by the removal of calcium.[18] Recently, we found hyperpolarization (below -60 mV) -activated inward currents (I_h) in circular but not in longitudinal muscle in pregnant rat uterus under voltage–clamp conditions. Since I_h is activated at the resting membrane potential, it is likely that this current contributes spontaneous activity in circular muscle cells of rats in late pregnancy.[19]

The pacemaker potential is also observed in pregnant human myometrium. The membrane potential gradually depolarizes and the action potential is ultimately evoked. Though steady current pulses are applied, evoked potentials are not regular and the pattern gradually changes in accordance with the periodicity of the membrane. The pacemaker potential is greatly influenced by temperature; the frequency of spontaneous contractions increased markedly, but their duration decreased when temperature of the bathing fluid was increased from 26°C to 39°C. External magnesium ion suppresses the gradient of the pacemaker potential and the duration of each action potential.[20–22]

Ion channels in the human myometrium

Calcium channels. It is well known that contractions of the myometrium are related to an increase in the concentration of intracellular free calcium ion, and it is also known that a large difference in calcium concentrations exists between the extracellular fluid ($\sim 10^{-3}$ M) and intracellular cytosol ($\sim 10^{-7}$ M). Therefore, calcium influx from the extracellular space into the cytosol is very important in regulating myometrial contractility. Two types of channels for calcium influx have been suggested.[23] One is a potential-sensitive calcium channel that opens when the membrane depolarizes and is normally responsible for the action potential. The other type is a receptor-operated channel, which is controlled or operated by a receptor for a stimulant substance. Nowadays, it is well known that voltage-dependent calcium channels (VDCC) represent the major machinery for intracellular calcium mobilization and two types of VDCC, L (long-lasting)-type (dihydropyridine-sensitive) and T (transient)-type, are identified. Therefore, we evaluated the

difference in the expression of mRNA of two types of calcium channels between the longitudinal and circular muscle layers of rat myometrium during pregnancy. Changes in the expression of mRNA encoding L-type (α1C) and T-type (α1G, α1H and α1I) calcium channels in longitudinal and circular muscle cells of the rat myometrium were examined using a comparative kinetic RT/PCR method. During the course of pregnancy, α1C mRNA expression showed an N-shaped change in longitudinal muscle, but simply increased after midpregnancy in circular muscles. The mRNAs for α1G and α1H, but not that for α1I, were expressed in both longitudinal and circular muscles. In longitudinal muscle, the change in α1H mRNA was similar to that in α1C mRNA during gestation, but the expression of α1G mRNA changed significantly only at term (day 22). In circular muscle, a1H mRNA expression was stable at any stage during pregnancy, but α1G mRNA significantly increased on day 15 and at term. No relationship was observed between VDCC mRNA expressions and either proliferation or hypertrophy of circular muscle during pregnancy. These results suggest that the expression levels of L-type channels change dynamically and may contribute directly to the regulation of cell excitability and that the T-subtype that increases during pregnancy differs between longitudinal and circular muscle cells.[24]

In pregnant human myometrium, two different types of VDCC have been observed at the single-channel level using the patch clamp technique,[2] and the inward calcium current was characterized by activation and inactivation properties.[25] One of these had a single-channel conductance of 12 pS, and was only activated by depolarizing pulses from a holding potential of -100 mV; this channel was inactivated at a holding potential of 60 mV. The second type had a single-channel conductance of 29 pS activated by depolarizing pulses from a holding potential of -60 mV. Summate currents also showed different time courses for current relaxation, i.e. the 12 pS calcium channel (transient type: T-type) was rapidly inactivated, whereas the 29 pS calcium channel (long-lasting type: L-type) was slowly inactivated. The majority of the 12 pS calcium channels are likely to be inactivated at a normal resting potential of about -50 mV, as indicated by the experiments that used the whole-cell voltage–clamp technique.[2] The physiological importance of the L-type current must be related to the formation of plateau potential, judging from its higher threshold potential and slower inactivation. Activation of the T-type calcium channel may be responsible for the spike component, and it may trigger activation of the long-lasting-type calcium channel. Recently, three types of T-type channel a1 subunits, α1G ($Ca_v3.1$), α1H ($Ca_v3.2$) and α1I ($Ca_v3.3$), have been cloned and we examined the electrophysiological characteristics of three cloned human α1H isoforms of the T-type calcium channel $Ca_v3.2$ expressed in pregnant human uterus. Then, our results suggested that molecular-structure variation within the III-IV linker influenced the voltage dependence of activation and inactivation, and kinetics. Although the role of T-type calcium channels in uterus remains unknown, changes in the uterine expression of these α1H isoforms may influence the physiological function during pregnancy.[24]

Sodium channels. Sodium ions may play an important role in generating the pacemaker potential and the action potential in uterine muscle. In the longitudinal muscle layer of pregnant rat myometrium, a fast sodium channel current (tetrodotoxin sensitive) was recorded from freshly isolated single cells using whole-cell voltage–clamp technique, and it was suggested that the fast sodium channel current might play a role in cell-to-cell conduction and possibly in regulation of spontaneous electrical activity.[26]

In cultured cells obtained from pregnant human myometrium, a large voltage-activated inward current was identified as sodium channel conductance by the following criteria: (1) removal of sodium from the bath eliminated the current; (2) the current was blocked by the sodium-channel-blocking agent, tetrodotoxin and (3) the current was observed in the absence of calcium.[27] The sodium current was large (maximal inward current 7.2 $\mu A/cm^2$) and of short duration (decayed within 10 ms); the onset of activation was -40 mV, with a peak inward current at -10 mV. Steady-state voltage inactivation of this channel showed half-maximal inactivation at -67 mV, indicating that this channel is largely inactivated at normal resting potentials. The sodium currents do not appear to contribute to the rising phase of the action potential in human myocytes.[27] Further study is required to clarify the physiological role of sodium channels.

Potassium channels. The potassium channels are involved in terminating action potentials and in returning the membrane potential to its resting level. Furthermore, the resting potential is primarily set by the permeability to potassium ion, and changes in the membrane potential can affect the initiation of the action potential and, hence, contraction. In the myometrium of pregnant women, it is believed that the changes in potassium permeability primarily affect the resting potential,[2] and that this might be involved in the action of catecholamine β_2-agonist and the effect of high calcium on the duration of action potentials.[16,20] Though a single-channel potassium current has not yet been recorded from the human myometrium, several studies of potassium current obtained from the myometrial cells of experimental animals by the patch–clamp technique have been reported.[28–30] It has been suggested that calcium-activated potassium channels, which are controlled by intracellular calcium, are not activated by calmodulin, but rather that calcium binds directly

to the gating site for channel activation.[29] Furthermore, three potassium currents (fast, intermediate and slow) are found in rat myometrium; the fast current is predominant in cells from estrus rats, whereas intermediate current is more frequent in cells from diestrus rats. In addition, norepinephrine potentiates the fast current and reduces the intermediate current.[30] Using rat or pig myometrial potassium channels incorporated into lipid bilayers, it has been shown that myometrial β–adrenergic receptors may be coupled to a guanosine tri phosphate (GTP)-dependent protein that can directly gate calcium-activated potassium channels.[31] Current research is directed at understanding the mechanisms of potassium channels through the molecular biological technique. One of the most conspicuous channels is the high (big)-conductance potassium channel, BK channel. It has a large single-channel conductance of around 250 pS and is a calcium-activated channel (K_{Ca}). A major role for BK_{Ca} channels is likely to be the restoration of resting conditions following an action potential. Thus, the calcium influx and depolarization occurring during the action potential in smooth muscle would both contribute to an increase in the probability of opening of BK_{Ca} channels resulting in repolarization of the membrane. This would decrease the probability of opening of the VDCC and in this way reduce excitability and facilitate relaxation.[32] As for human myometrium, it is reported that the mRNA for BK_{Ca} channels is abundant in human myometrium.[33] As the other potassium channels, delayed rectifier potassium channel,[34,35] transient A-type potassium channel[2] and ATP-sensitive potassium channel (K_{ATP})[36] are reported.

Effect of the reproductive state on active electrical properties

Near the end of pregnancy the circular muscle activities of the rat uterus exhibit characteristic changes that are a prerequisite for normal delivery. These changes consist of a progressive alteration in the configuration of action potentials from a single, plateau type in early and midpregnancy to a repetitive train discharge at term.[4,37] The action potentials cause brief, irregular contractions during early and midpregnancy and regular contractions of longer duration at term. Furthermore, uterine volume (muscle stretching) and circulating estrogens may be more important than the fetoplacental unit in the evolution of circular muscle activity in the pregnant rat.[13] The protein synthesis inhibitor, cycloheximide, can suppress the evolution of activity and delay parturition.[38] The action potential of longitudinal muscle exhibits a burst discharge of spikes and the pattern does not change throughout pregnancy. However, estradiol hyperpolarizes the membrane and a burst of spikes is generated from sustained depolarization. Progesterone, by contrast, slightly hyperpolarizes the membrane and typical burst discharges occur without sustained depolarization. Simultaneous treatment with progesterone and estradiol produces a plateau potential.[3] Although sex steroids affect membrane properties, the changes that occur during pregnancy cannot be explained by the action of such hormones. There is only one report that describes the electrical activity of human myometrium in early pregnancy.[15] The action potential is composed of long plateau potential or abortive spikes superimposed on the long plateau. The duration tends to be longer than in-term pregnancy.

Relationship between electrical activity and contraction

Contraction of the myometrium is related to the concentration of intracellular free calcium ion; the increase in intracellular calcium might arise from an influx of calcium from the extracellular space, the translocation of calcium ions in or near the cell membrane and/or the release of calcium from internal stores. Myometrium of pregnant women usually generates spontaneous action potentials and extracellular calcium might enter the cell through the calcium channels during these action potentials. In our sucrose-gap experiments, contractions were always synchronized with the corresponding action potentials. Therefore, the amount of calcium that enters during the action potential is sufficient to activate the contractile mechanism and to release additional calcium from internal stores, thereby amplifying the transmembrane signals.[39] On the other hand, the periodicity of 1-min contraction and a few minutes of relaxation is essential for the mother and fetus during the stress of parturition. A long and hypertonic contraction decreases uteroplacental blood flow, causes fetal hypoxia, and small contractions cannot expel the fetus further. The myometrium has a spontaneous periodicity and thereby generates action potentials and contractions of appropriate duration. Under physiological conditions, the contractility of the uterus is regulated by changing the electrical activity. It might be very easy to regulate the frequency, duration and probably amplitude of spontaneous contractions evoked by each action potential by changing the resting membrane potential.

In obstetric practice both periodic contractions and sufficient periods of relaxation are the most important factors for the well-being of the fetus and the progress of delivery. Considering these fundamental characteristics of the human uterine contraction, relaxation mechanisms are essential for the fetus and the mother, and should be better understood along with the stimulation of the contractions. A reduction in intracellular calcium is essential for relaxation. Currently, two pathways are speculated for the myometrium to lower the intracellular calcium ions to produce relaxation. One is a calcium pump in the plasma membrane or the membrane of the sarcoplasmic reticulum, and the

other is a sodium–calcium exchange mechanism that is an antiporter present in the plasma membrane carrying sodium in one direction and calcium in the other. In the myometrium of pregnant women, we suggested the presence of the sodium–calcium exchange mechanism and the specific inhibitory effect of magnesium ion. This mechanism might prevent the long tonic contractions, to protect the fetus from hypoxia during pregnancy and parturition.[40]

Propagation of excitation

In the human uterus, the resting tonus maintains uterine shape and fetal position. Resting tonus is maintained by random activation of the myometrium by action potentials. However, well-coordinated contraction is essential for the successful expulsion of the fetus after the onset of labor. In order to achieve this coordination, many myometrial cells have to contract at the same time, and local contractions obtained by the coordination of the cells have to be synchronized over the whole of the uterus as parturition progresses. Since small muscle strips of myometrium of pregnant women exhibit spontaneous periodicity with 1-min contraction and a few minutes relaxation, this periodicity may facilitate coordinated contraction. In our clinical study, the qualitative characteristics of uterine contractions in labor were evaluated by a double-guard-ring tocodynamometer attached to the fundus and the caudal part of the uterus. The synchronizing ratio of two contraction waves was significantly higher in the active phase than in the latent phase of labor, and nearly regular upward or downward observed in each case.[41] Furthermore, the percentages of both concurrent and synchronous contractions were higher than those of Braxton Hichs contractions, and both values increased significantly between 5 and 6 cm of cervical dilation.[42] On the other hand, small contraction waves (30 s or less duration of each wave) recorded by a guard-ring tocodynamometer were observed in 7.5% of the cardiotocographs examined, and the rate of small-wave appearance in each gestational week tended to decrease gradually as the pregnancy progressed. This was not observed after 41 weeks of gestation and was frequently observed in cases of effective β_2-stimulant intravenous infusion for the treatment of preterm labor.[43] The synchronizing ratio of peaks of small contraction waves was almost the same as the ratio in the active phase of labor.[41] Thus, synchronization of local contractions results in the effective contractions of human parturition. However, the uterus does not have any specific conduction pathways for excitation. Instead, the action potential spreads into the surrounding cells in three dimensions in accordance with their cable-like properties. The length constant of the membrane gradually increases throughout pregnancy in the rat, as described earlier, and the conduction velocity of the action potential in longitudinal preparations of pregnant rat myometrium increases from 9.2 cm/s at late pregnancy to 10.5 cm/s during delivery.[44] Gap junctions, which are assumed to be the structure involved in electrical and chemical communication between cells, increase during parturition and disappear after delivery in experimental animals.[45] This structure is observed in human myometrium from women in preterm labor.[46] These changes may contribute to the propagation of excitation during parturition.

Effects of ions and drugs on electrical activity and contraction

Calcium

Extracellular calcium has been shown to play an important role in the activation of smooth muscle and the amplitude of the tension can be related to the external calcium concentration and, consequently, to the calcium influx in pregnant rat myometrium.[47,48] Moreover, the inward calcium current may affect potassium conductance during the plateau potential in the circular muscle of pregnant rat myometrium, and the potassium conductance provides the plateau duration, and consequently the duration of the contraction.[49] In myometrium of pregnant women, spontaneous contraction is strongly affected by external calcium; 2.5 mM calcium in Krebs solution is the most efficient concentration in terms of frequency, amplitude and duration of whole contractions. Both excess calcium and low calcium suppresses the generation of spontaneous contraction; however, the mechanism of these two types of suppression may differ. Calcium ions may play dual roles in the electrical activity of the myometrium: an excitatory role in action potential and an inhibitory role accomplished by membrane stabilization and calcium-mediated potassium activation. Therefore, the effects of excess calcium on spontaneous contractions may depend on the balance of excitatory and inhibitory effects. If the increase of calcium influx during the action potential is predominant, the amplitude of the contraction will increase; however, the contraction will be diminished if the generation of action potentials is suppressed by membrane stabilization and activation of the outward potassium current. In contrast, low calcium may decrease the influx of calcium and consequently suppress the contraction, since both the amplitude and the duration of contraction are generally decreased in low-calcium solution.[16,22]

Magnesium

Magnesium sulfate has been used as a tocolytic agent to prevent preterm labor. The effect of magnesium on the spontaneous electrical and mechanical activities of the circular muscle of term pregnant rat uterus

suggests that the effect is largely due to suppression of the plateau potential.[50] According to the whole-cell voltage–clamp method on freshly isolated single pregnant rat myometrial cells, magnesium inhibits the calcium current, affecting mainly the transient component.[51] In myometrium of pregnant women, frequency, amplitude and duration of spontaneous contractions all decrease with increases in external magnesium; the frequency change is the most significant.[22] Magnesium ion suppresses the gradient of pacemaker potential, and consequently the frequency of contraction.[20]

Oxytocin

The initiation of either term or preterm labor is considered to be a final common phenomenon induced by augmented uterine contractions, regardless of the incipient cause. And it is well known that oxytocin plays an important role in the initiation of labor in both term and preterm parturients. However, a satisfactory direct comparison of the functional roles of oxytocin in term and preterm labor had not been elucidated. We had demonstrated that the inhibitory effects of both peptidyl and non-peptidyl oxytocin antagonists on spontaneous uterine contractions of pregnant rats became greater as the pregnancy progressed. This change was accompanied by a significant increase in myometrial oxytocin receptor density.[52] Then, we made a direct comparison of the functional roles of oxytocin in term and preterm labor in rats. First, we determined the myometrial oxytocin receptor density and maternal plasma concentrations of oxytocin and progesterone on gestational days 18, 20 and 22 (morning) and at the onset of delivery (day 22 afternoon) in rats with labor at term and at the onset of delivery (day 20 afternoon) in rats in preterm labor induced by the combined use of bilateral ovariectomy and estradiol injection. We also evaluated the effects of a non-peptidyl oxytocin antagonist on the initiation of both term and preterm labor. Consequently, the number of tritiated oxytocin-binding sites in myometrial membranes rapidly increased on gestational day 22 (morning). Plasma progesterone level decreased in an inverse fashion. A rapid increase in circulating oxytocin concentration was observed at the onset of delivery, and both the plasma oxytocin concentration and the receptor density had the same values in rats with preterm labor as in rats with term labor. The oxytocin antagonist delayed the initiation of labor in rats with term and preterm labor in a dose-dependent manner.[53]

On the other hand, the direct effect of oxytocin on spontaneous electrical and mechanical activities in myometrium of pregnant women has been investigated using the single sucrose-gap method.[54] Oxytocin potentiates spontaneous contractions by enhancing the plateau part of action potentials; the spike-type configuration becomes plateau. This potentiation depends on the external calcium concentration, and the effects on frequency and amplitude of contractions may vary. In our microelectrode experiments, two types of spontaneous action potentials were seen in the myometrium of pregnant women; a long plateau and a spike-like action potential. With no change in the resting membrane potential, low concentrations of oxytocin evoked an action potential with plateau phase, increased the amplitude and duration of the plateau potential or increased the frequency of generation of action potentials. Oxytocin also lowered the threshold for evoking an action potential. Higher concentrations depolarized the membrane with an associated reduction in membrane resistance.[55] Oxytocin evokes action potentials and contractions in high frequency; the duration of the action potential is short and the contraction is small in the presence of diltiazem (calcium antagonist). The results of the potassium contracture experiment also suggest that oxytocin evokes a contracture in the absence of an action potential by releasing calcium from intracellular storage sites.

This possibility is supported by another study measuring intracellular calcium using Fura-2 in isolated cells of pregnant rat myometrium.[12] Then, we examined the changes in responsiveness of freshly isolated longitudinal muscle cells from rat uterus to oxytocin during gestation by measuring contractility as well as intracellular free calcium concentration. We have demonstrated the pregnant stage-dependent contraction of freshly isolated myometrial cells in response to an extracellular hormone, oxytocin, in Ca^{2+}-containing medium. The oxytocin effect appeared to be through oxytocin receptor since the effect could be blocked by a specific oxytocin antagonist. The magnitude of the contraction of the isolated cells in response to extracellular oxytocin was in the order of 21-day $\gg$ 18-day $>$ 15-day pregnant rat longitudinal muscle cells. In a concentration-dependent manner, oxytocin elicited a rapid increase in intracellular calcium ion of longitudinal muscle cells isolated from different stages of the pregnant rat uterus, especially at the term of pregnancy. The time (4–5 s) required to reach a maximum increase in intracellular calcium ion of the isolated longitudinal muscle cells in response to oxytocin was the shortest among all previously reported studies. The results also indicated that the freshly prepared longitudinal muscle cells maintained their functional calcium signaling system. The order of the responsiveness of the isolated longitudinal muscle cells to oxytocin was 21-day $\gg$ 18-day $>$ 15-day pregnant rats in terms of rate, affinity and magnitude. Oxytocin appears to transmit its signal mainly through stimulating a voltage-dependent and/or receptor-operated non-selective calcium channel. However, the possibility that a part of the oxytocin action occurs through stimulating the release of calcium from intracellular store sites of longitudinal muscle still remains.[56]

The excitatory effect of oxytocin is modified by external magnesium ion in the myometrium of

pregnant women. Relatively high magnesium (2.4 mM) suppresses the spontaneous activities; however, oxytocin enhances the contractions and the plateau part of action potentials to a greater extent than does the magnesium-free solution. In the potassium contracture experiment, the oxytocin-induced contracture during the tonic phase is potentiated by magnesium. Magnesium may potentiate the excitatory effect of oxytocin at superficial sites of the plasma membrane, allowing the possibility of intracellular action.[57] The interaction between calcium and magnesium is probably very significant in the regulation of the action of oxytocin on uterine contractility.

It is obvious that oxytocin is involved in the initiation and progress of labor in many species and also plays an important role in lactation. From another point of view about the initiation of labor and lactation, we clarified the possibility that oxytocin might modulate oxytocin neurons in the paraventricular nuclei of female rats throughout pregnancy and parturition. Our results show that the firing rates of paraventricular neurons in virgin and pregnant rats decreased in activity; however, the neurons of delivering and lactating rats exhibited excitatory responses. This excitation reversed to inhibition again after the lactating period ended. It is suggested that negative feedback by oxytocin in virgin and pregnant rats might reverse to positive feedback in delivering and lactating animals as a result of changes in hormonal conditions. This reverse might be closely related to the initiation of delivery.[58]

Catecholamines

The effects of catecholamines on the myometrium differ among animal species, and even in the same animal, depending on the hormonal status of the individual and each muscle layer. For example, in a rat at midpregnancy longitudinal muscle possesses mainly β-adrenoceptors, while circular muscle has a-adrenoceptors.[14] However, in late gestation, activation of the a-adrenoceptors occurs in the longitudinal muscle, while the circular muscle switches from α- to β-adrenoceptor dominance.[59]

In the myometrium of pregnant women, noradrenaline always exhibits α-excitatory action at 10^{12}–10^{6} g/ml; however, β-inhibition of β_2-stimulant is also observed.[20] It is suggested on the basis of animal studies that activation of a-receptors in the longitudinal muscle is mainly mediated by slow depolarization of the membrane (due to an increase in chloride conductance), which leads to an increase in spike frequency; in the circular muscle, it is mediated by prolongation of the plateau of action potentials (due to an increase in calcium conductance). β-Action of the myometrium also includes membrane hyperpolarization due to an increase in potassium conductance and an increase in cyclic adenosine monophosphate (cAMP) production underlies the suppression of spontaneous contraction.[60] Catecholamine action may fundamentally affect uterine contractility during pregnancy and parturition.

In obstetric practice, adrenergic β_2-stimulants have been widely used as tocolytic agents to prevent preterm delivery. However, commercially available tocolytic agents often have severe adverse effects (such as tachycardia, tremor of the hands and lung edema) because they simultaneously exert weak a and β_1 effects on the cardiovascular system. Another concern about β_2-stimulants as tocolytic agents is that their tocolytic effect is inconsistent among patients and the so-called myometrial desensitization phenomenon in which the recurrence of contractions might be related to a decrease in cAMP production.[61] Recently, we produced a new β_2-stimulant (KUR-1246) with a higher selectivity for uterine β_2-receptors (and thus weaker side effects).[62] Then, we performed the experiment to evaluate the usefulness of this new β_2-adrenergic stimulant as a tocolytic agent and to clarify the mechanisms that underlay the diverse inhibitory effects of β_2-stimulants that were seen in human myometria *in vitro*. Consequently, KUR-1246 was approximately 80 times and 7 times more selective for β_2-receptors than isoproterenol and ritodrine, respectively. The inhibitory effect of KUR-1246 was as strong as the inhibitory effect of the conventional β_2-adrenergic stimulants. A wide range of inhibitory effects was observed, even when high concentrations of isoproterenol or KUR-1246 were applied. There was a correlation between the degree to which isoproterenol suppressed contractions and the number of [^{3}H]dihydroaloprenolol-binding sites on the membrane in each muscle strip. These results suggest that KUR-1246 should be a very useful β_2-adrenergic stimulant for use as a tocolytic agent because of its high selectivity for the β_2-receptor and its potent inhibitory effect. The diversity of the inhibitory effects that are induced by β_2-stimulants is at least partly due to the differences in β_2-receptor density among term-pregnant human myometria (Sakakibara *et al.*, 2002).

Other drugs

There are a few studies on the electrophysiological action of other drugs on the human myometrium. Prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and methylergometrine maleate (methergin) potentiate the plateau part of the action potential and contraction of the myometrium of pregnant women.[63,64] The action of methergin is not inhibited by phentolamine (an α-blocker). Plateau enhancement may be the main effect. Both oxytocin and $PGF_{2\alpha}$ potentiated the spontaneous contractions by affecting the plateau part of action potentials; spike-type configurations became plateaus. However, high dosages of both the drugs were required to obtain consistent excitatory effects *in vitro*. In obstetric practice, on the other hand, uterine contractions can be induced by low doses of these drugs. The

pharmacological application of oxytocin or $PGF_{2\alpha}$ might only play a triggering role in uterine contractions at induction or augmentation of labor, and complex interactions might be involved in the initiation and potentiation of contractions *in vivo*.[63]

Conclusion

The myometrium has spontaneously active and highly excitable membrane with many voltage-dependent ion channels. Contractility of the myometrium is regulated by the electrical activity of this membrane. The main external controlling factors are sex steroid hormones. The balance of estrogen and progesterone, and the changes during the course of the menstrual cycle, pregnancy and parturition, changes the resting membrane potential, the pattern of action potentials and the effects of drugs, such as catecholamines and oxytocin. Hormones also affect the conduction of excitation and produce morphological changes of cell size. All of these changes lead to synchronized contractions that are effective in expulsion of the fetus. It is particularly important for the fetus that the periodicity of the phasic contractions is strictly maintained.

56 Animal studies of fetal maturation

N. Shinozuka

Introduction

In the field of perinatal research, we investigate a continuously growing organism that is adjusting and developing its vital functions from womb to extrauterine life.[1] In clinical terms 'the matured fetus' is a fetus that has reached a certain stage of functional growth and development, where it obtains an ability to live outside the womb alone. In a fetal physiological study, unlike in others, we must emphasize this special feature of the fetus. The following must be taken into account in fetal studies: fetal status continuously changes as pregnancy progresses. The gestational age is an important factor in development. The environment of the fetus is affected by both maternal and fetal factors. The fetus responds to the insults from outside with a variety of reactions. Glucocorticoids play an important role in development and maturation throughout the fetal life.[2–5] Thus, when we study a fetal physiological response at a certain gestational age, the result means the degree of the developmental or maturational stage of the fetus.

The respiratory, cardiovascular and neurological functions are the major functions that support life. The development of lung function was described in another section. The following issues related to studies in fetal cardiovascular and neurological maturation are outlined:

1. Animal studies in fetal physiology. Methodology using chronic animal model.
2. Animal studies in normal developmental and maturational course of cardiovascular function.
3. Chronic fetal stressed model to study fetal reaction for investigating maturation.

Animal studies in fetal physiology. Methodology using chronic animal model

For a clinician in perinatal medicine, the major concern in animal studies could be the interpretation of the results to human fetal physiology. Dynamic changes in fetal developmental course, namely maturation, have been the targets for our research.

The chronic fetal study, which is a more complicated and invasive method compared with acute model, is an essential procedure for animal experiments for investigating 'maturation'. A lot of basic research has been carried out to establish a chronic state animal model of the fetus. At the beginning of fetal physiological research, an acute fetal preparation procedure had been used.[6–8] From the 1960s, a sheep fetal preparation procedure has been applied for the chronic study model. In the 1970s and the 1980s, this methodology of fetal chronic preparation, namely 'unanesthetized fetus *in utero*',[9–12] was established as the standard procedure for investigating fetal physiology.[13–17] No objection could be raised that an ideal animal model for perinatal research purposes should be a non-human primate model, such as a baboon or a rhesus monkey. However, a non-human primate fetal study requires a lot of complicated systems such as a special cage, a tether system to connect cables and catheters for maintaining preparation, special animal care and so on, and, above all, a great deal of expense. In contrast, when we consider the availability of pregnant ewes, the total cost, ease of animal care, surgical preparation and management, the advantage of the sheep chronic experiment is clear even if the physiological difference between species is taken into account. Thus, fetal preparation using pregnant ewes has been a widely approved basic procedure for investigating fetal physiology.

The chronic preparation of the sheep fetus

The term of the fetal sheep is around 145–150 days of gestation (dGA). Birth weight at term is around 4.0–4.5 kg in the Rambouillet–Columbia sheep. Depending on the study protocol, the fetal preparation is usually done at around 100–125 dGA. The size of sheep fetus is appropriate for surgical preparation (approximately 2.0 kg at around 110 dGA).

The techniques have been described in detail elsewhere, and only a brief outline of the procedure is given in this section.[18–22]

Usually, ewes mated on only a single occasion and carrying a fetus of known gestational age are used for experiments. The gestational age is counted from the mating period and confirmed by ultrasound later. Prior to the surgery, the ewe is housed in a metabolic stall in a room with controlled light/dark cycles. Surgery is performed under halothane general anesthesia.

The uterus is exposed through a midline abdominal incision. Hysterotomy is performed and fetuses are fixed with several catheters and electrodes. The polyvinyl vascular catheters are placed via the carotid artery and jugular vein and/or femoral artery and vein. An amniotic cavity catheter is also placed. For recording fetal biophysical and neurological activities, several electrodes are attached. For recording an electrocardiogram, usually the steel electrodes are placed at the chest wall. For exploring fetal neurological activity the electorocorticogram (ECoG) electrodes using stainless wires terminating in metal pins or screws are placed bilaterally through the fetal cranial frontal bone to touch the dura mater. The ECoG signals are characteristically low voltage, low frequency and noisy bioelectric signals. To obtain high-quality ECoG signals, some techniques such as application of sealed cables (e.g., coaxial cables), placement of an indifferent and a ground electrode are required. For recording myometrial activities (uterine contraction) several wire electrodes are sewn to the myometrium. Following surgical preparation of the ewe and fetus, all fetal catheters and leads are grouped to exit the lateral abdominal wall of the ewe at a single point. Surgical closure is accomplished in layers. During and the days following surgery, antibiotics are given to the ewe and the fetus.

Maintenance

A heparin solution (10 units/ml of physiological saline) was continuously infused at a rate around 0.5 ml/h into each vascular catheter to ensure that it remained open. Fetal condition, i.e., its well-being, is usually checked by using fetal arterial blood gas data. Other fetal biophysical data such as ECoG or fetal heart rate (FHR) are also the parameters for assessing fetal well-being.

Data acquisition

The biological signals have been recorded using analog recording charts. In recent years, all data are usually recorded by means of computer-assisted data acquisition systems (DAS) that are equipped with biological amps, frequency filters, analog to top digital converters and so on. Fetal blood pressure is measured using the pressure transducer and the actual fetal pressure values are calibrated by amniotic cavity pressure. All data are stored digitally for further analysis. Sheep experiments are shown in Figures 56.1 and 56.2.

Studies in normal developmental and maturational course of cardiovascular function

The conceptual schema of fetal maturation with gestational age is shown in Figure 56.3. The degree of functional maturation must be represented as an exponential growth curve as reported for the variation in cortisol level with gestational age[4,23] (Figure 56.4). Basic research on sheep experiments suggests that the

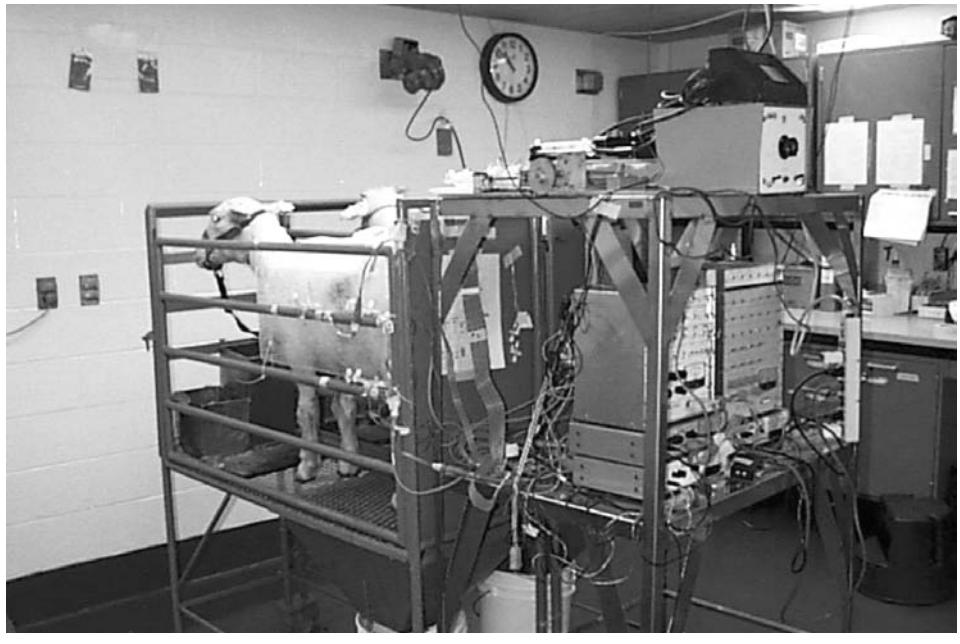

Figure 56.1 The sheep experiments. Several catheters and electrodes are fixed to the fetus.

Figure 56.2 Example of a data acquisition system. The biological signals from the fetus are recorded digitally to the computer aided system for further analysis.

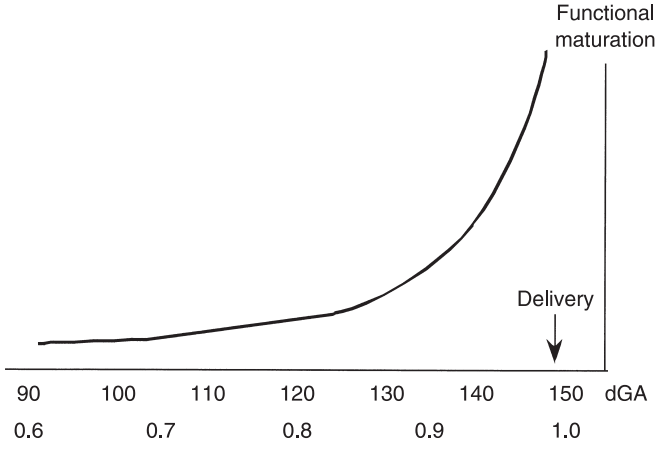

Figure 56.3 The conceptual schema of fetal maturation with gestational age. Example of sheep (term at around 145–150 dGA).

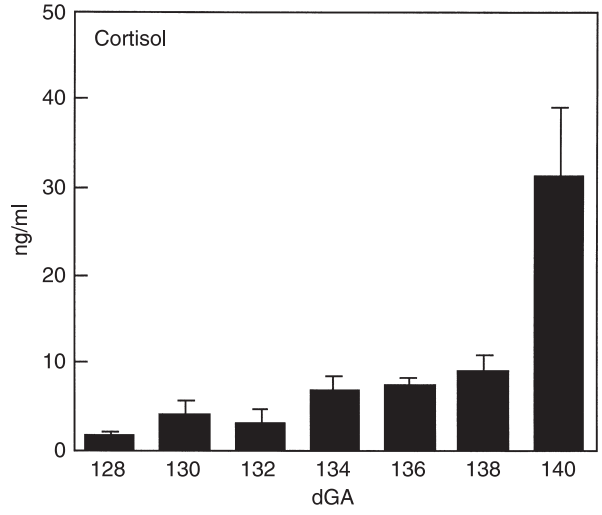

Figure 56.4 The cortisol level at fetal sheep plasma.

fetal organic maturation is accelerated around 120 dGA.[24–30] Although the developmental stage of 120 dGA, which means 80% development, does not simply translate to that of 32 weeks for the human fetus, the process of functional development and maturation should be similar.

Cardiovascular maturation

In the sheep fetus during late gestation, arterial blood pressure (BP) increases steadily and fetal heart rate (FHR) deceases steadily.[26,27,30–32] Typical changes in fetal blood pressure and heart rate with gestational age in sheep are shown in Figure 56.5. It has been assumed that the BP increase during the end of gestation is a result of both an increase in cardiac output and a rise in peripheral vascular resistance; whereas the decrease in FHR has been attributed to the baroreflex function as a result of increased BP. The baroreflex is induced by increased parasympathetic function via the vagus on basal FHR.

It has been shown that influences of sympathetic and parasympathetic activity on baseline FHR in the sheep fetus. The hormones that have stimulatory effects on the fetal cardiovascular system increase with gestational age.[26,27,30–32] The roles of the fetal endocrine, autonomic nerve system and baroreflex control on the fetal cardiovascular system have not

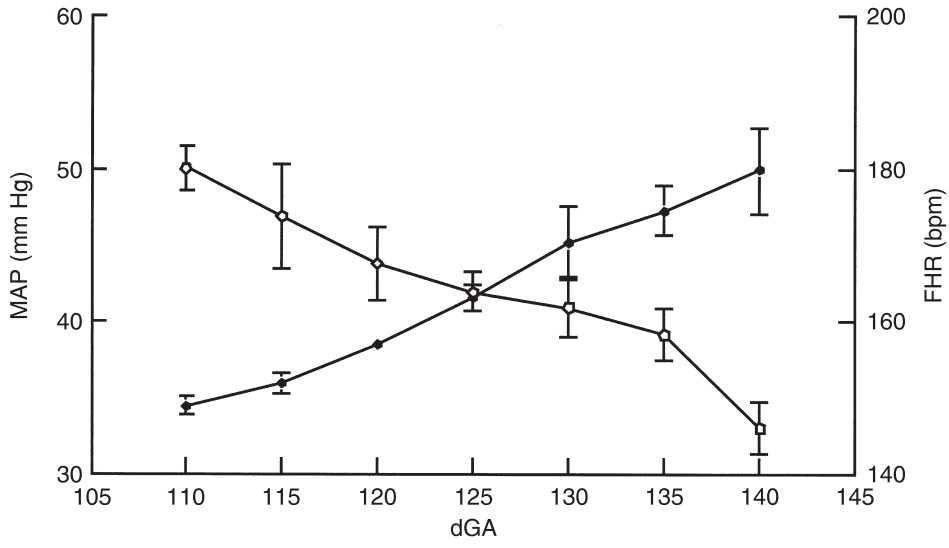

Figure 56.5 Mean fetal arterial blood pressure (MAP) and fetal heart rate (FHR). MAP increased from 110 to 140 days gestation (dGA), whereas FHR decreased steadily from 110 to 140 dGA. bpm: beats/min).

yet been characterized. In clinical medicine, FHR monitoring is an important procedure for fetal management. However, to understand the physiological meaning of FHR, we must consider the biophysical background factors, i.e., the degree of development, gestational age, intrauterine environment and so on.

Previous animal studies have reported the specification of fetal cardiovascular developments as follows: (1) Cardiac output increased in proportion to fetal gestational age and fetal weight.[33–35] (2) The cardiac output in the fetus is controlled almost solely by alteration of the heart rate.[34,36] (3) The fetal heart operates near the upper limit of the Frank–Starling curve.[37,38] (4) The fetal heart has a limited ability to change stroke volume (inotropic action).[33–35] (5) Baroreflex has been shown to operate in late gestation and plays an important role in regulating variability of arterial pressure and heart rate.[26,39] For these reasons, the ontogenic changes in baroreflex function in fetal cardiovascular maturation must be characterized. In this section, study related to the ontogenic changes in baroreflex function in fetal sheep is introduced.

Study design

1. Ontogenic changes on baroreflex function: Twenty fetal sheep were fitted with instruments and the following baroreflex protocol was carried from 110 to 140m dGA with 5-day interval.
2. Cardiovascular changes on steroid administration to the fetus: Starting at 133 ± 1 dGA, saline (control group, CNTL) or betamethasone (Beta) was administered to the fetal jugular vein at a rate of 10 μg/h over the next 48 h. Betamethasone infusion was started at 18:00 hours. Baroreflex protocol was carried out after 40 h of Beta infusion.

Baroreflex study protocol[40,41]

Since baroreflex has been shown to play an important role during late gestation in sheep, many studies have been reported on the control of the fetal circulation. Several methods have been used for evoking the baroreflex response of the fetus. The sensitivity of the baroreflex response elicited depends on the method used. We used sodium nitroprusside (SNP) for inducing hypotension and phenylephrine (PE) for inducing hypertension. SNP is known to act as a vasodilator of both arterial and venous vessels, resulting in reduced peripheral vascular resistance and venous return.[42] PE acts as an alpha agonist that increases the force of contraction and vascular smooth muscle contraction, increases peripheral resistance and reduces heart rate by vagal reflex.[43] The baroreflex function was analyzed by adding both hypotension and hypertension trial data with the mathematical model of logistic procedure.[44] The detailed procedure is as follows:

1. Hypotension: After 1 h basal recording, SNP (10 μg/ml) was infused intravenously to the fetus at 0.1–6.4 ml/min with 2 min interval at each increment. Infusion was stopped when fetal blood pressure (FBP) had decreased by 30% or FHR fell below 100 bpm or arrhythmia appeared. Fetal arterial blood samples were taken at –5 min, end of infusion and +10 min.
2. Hypertension: After at least 1 h of recovery period from the above hypotension experiment, fetuses received PE (25 μg/ml) intravenously at 0.1–1.6 ml/min with 2 min interval at each increment, until FBP increased 30% or FHR fell below 100 bpm or arrhythmia appeared. Fetal arterial blood samples were taken at – 5 min, end of infusion and +10 min.

FBP and electrocardiogram (EKG) data were recorded with DAS at 250 Hz sampling rate. Mean

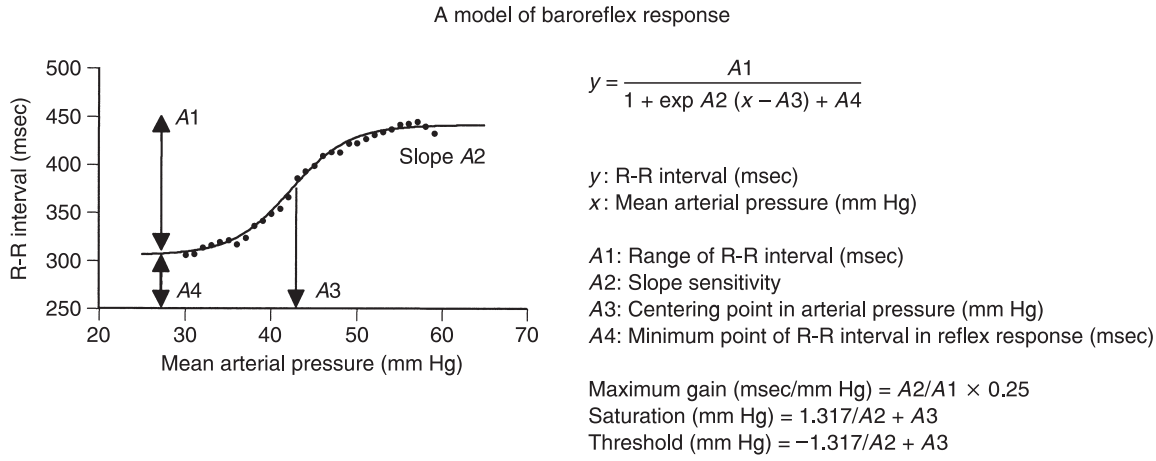

Figure 56.6 Mathematical model in analyzing baroreflex response. Using a logistic model, maximum gain, saturation and threshold are assessed as indices of baroreflex function.

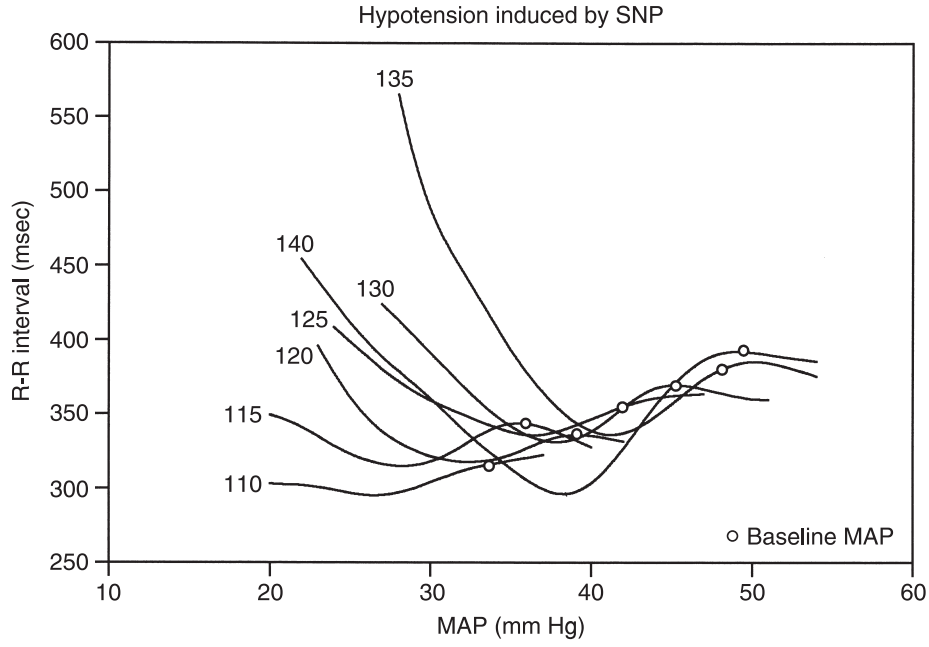

Figure 56.7 Hypotension by SNP. Open circle shows baseline (starting point). Initial reaction of SNP infusion is increase in FHR (shortening of R–R interval) against FBP fall. Compensatory tachycardia was reversed as SNP dosage increased. Then, the breakdown bradycardia caused by decreased volume in venous return and vagal activity appeared. This phenomenon of breakdown bradycardia appeared after 120 dGA and is most ominous at 135 dGA.

arterial pressure (MAP) and R–R interval from EKG signals were used for later analysis. The baroreflex function was analyzed using the logistic model shown in Figure 56.6.[44]

Ontogenic changes in baroreflex function

Hypotension induced by SNP

An initial baroreflex action during hypotension induced by SNP was to increase FHR (shortening of R–R interval) against dropping FBP due to vasodilatation. Increase in FHR by FBP fall is a sympathetic activity.

Compensatory tachycardia was reversed as SNP dosage increased. This phenomenon is not clear until 115 dGA, is distinguished at 120 dGA and is most ominous at 135 dGA. This breakdown bradycardia is assumed to be caused by decreased volume in venous return and vagal activity. The difference in response to SNP infusion at each gestational age suggests a developmental degree and a balance between sympathetic and parasympathetic control of cardiac function. However, since cardiac output is defined by stroke volume and heart rate, the factor of inotropic function, even if it is limited, must be taken into consideration. The significant difference in response between 135 and 145 dGA must be caused by the inotropic function. Moreover, this result suggests that 135 dGA is the most critical period of baroreflex development. The vagal reflex is most sensitive and the breakdown bradycardia is easily induced (Figure 56.7).

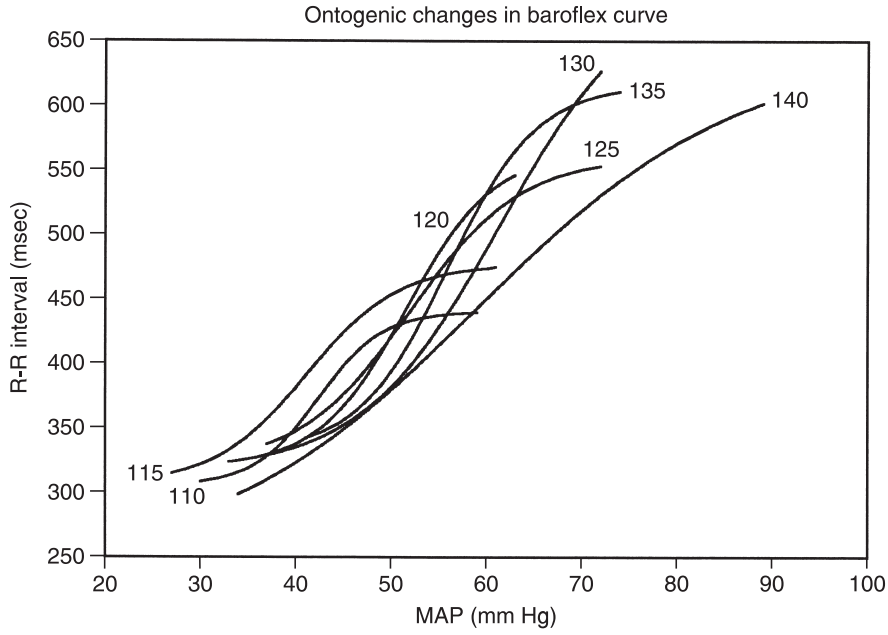

Figure 56.8 Ontogenic changes in baroreflex curve. The apparent difference in range and slope of baroreflex curves at each gestational age is found.

Hypertension induced by PE

During PE-induced hypertension trial, R–R interval increased linearly according to FBP rise. PE acts mainly as an alpha agonist, and heart rate fall is induced by vagal reflex. The difference in baroreflex slope might be a result of the activity and sensitivity in pressure of the vagal function. Significantly higher FBP achieved against similar FHR at slope saturation during late gestation suggests the development of cardiac contractility function and this must also be considered.

Analysis of baroreflex function (ontogenic study)

The baroreflex curve was studied using the data obtained from SNP-induced hypotension and PE-induced hypertension (Figure 56.8). When we look at the speculation in range and slope of baroreflex curves at each gestational age, the character of maturational course is clear. A summary of the developmental changes in baroreflex function are shown in Figure 56.9. Two critical points at 115–120 and 135–140 dGA were distinguished in baroreflex development. Significant changes in maximum gain were observed at 135–140 dGA, in saturation at both 115–120 and 135–140 dGA, and in thresholds at 115–120 dGA. As stated above, these critical points at maturational course might be caused by the degree of developmental activity, sensitivity, and balance between sympathetic and parasympathetic nerves, peripheral vessel activity, as well as the inotropic action (contractility of the heart).

Effect of gulcocorticoids on cardiovascular function

Previous studies showed that glucocorticoid administration to the sheep fetus increases both FBP and femoral vascular resistance. However, precise effects of cardiovascular baroreflex response to glucocorticoids have not yet been clarified. An example of studies on betamethasone effect on the fetal baroreflex function at 135 dGA is shown.

FBP and FHR changes on betamethasone infusion

FBP showed a constant increase after betamethasone (Beta) infusion to the fetuses. In the Beta group, FBP was statistically higher after 7 h of infusion compared with the baseline FBP of the past 24 h before infusion. FBP was also statistically higher in the Beta group after 8 h of infusion compared with the control (CNTL) group. In contrast to the fetuses in CNTL, which showed nominal 24 h variation in FHR, Beta fetuses showed significant decrease in FHR after betemethasone infusion. FHR fall in Beta fetuses from 5 to 9 h after infusion was significant compared to the baseline FHR of the past 24 h before infusion. FHR from 5 to 12 h after infusion in Beta fetuses was significantly lower compared with CNTL fetuses (Figure 56.10). After 12 h of infusion, FHR in Beta fetuses gradually recovered to the baseline FHR level. No statistical difference was found after 24 h of infusion between Beta and CNTL fetuses.

Baroreflex function at 40 h after Beta administration

Beta fetuses showed a much wider range of FBP change with relatively narrower range of FHR change. Namely, the baroreflex curve shifted to the right and the handling range was expanded. All parameters of baroreflex function were significantly altered by betamethasone (Figure 56.11).

Recent studies have reported an elevation of FBP after infusion of glucocorticoids directly to the

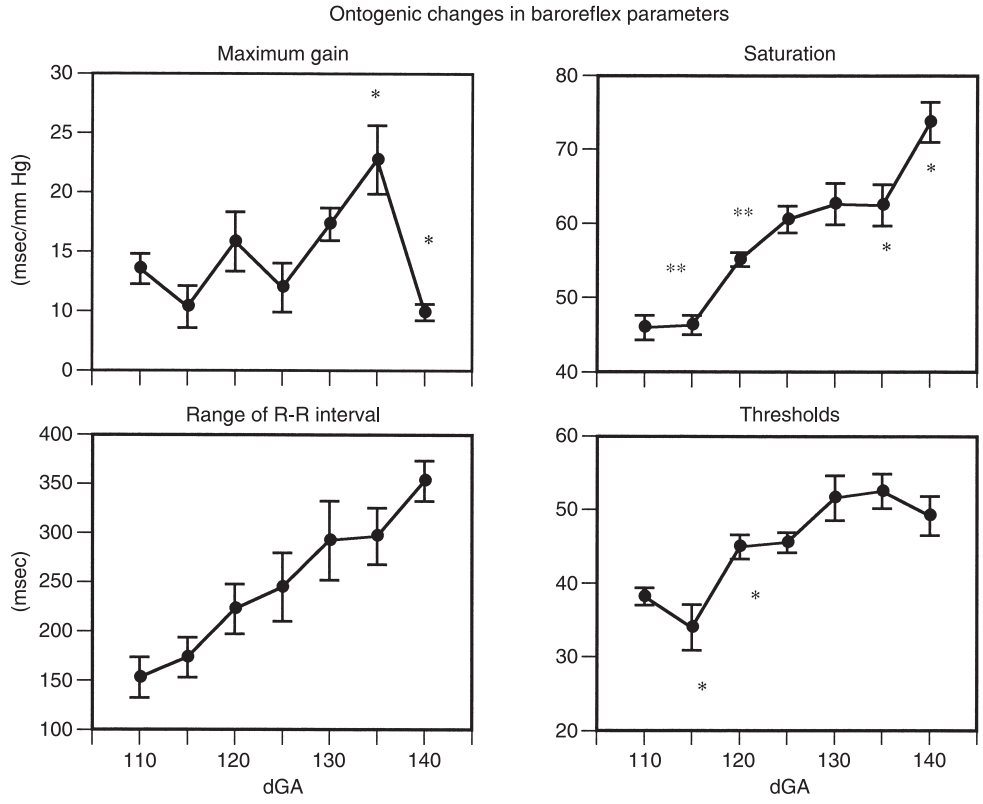

Figure 56.9 Summary of ontogenic changes in baroreflex function. Two critical points of 115–120 and 135–140 dGA were found in baroreflex development. Significant changes in max gain at 135–140 dGA, in saturation at both 115–120 and 135–140 dGA, and thresholds at 115–120 dGA. ** Difference at saturation figure. *$p < 0.05$.

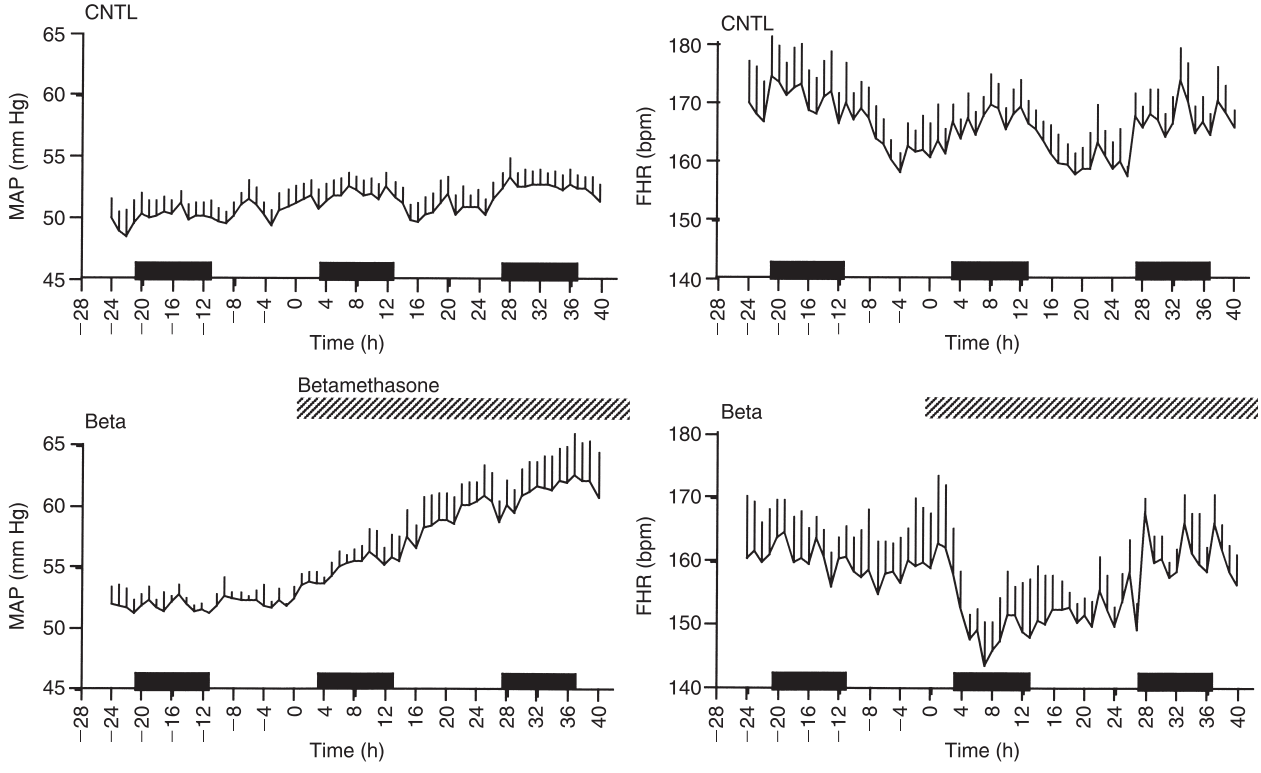

Figure 56.10 Changes in MAP and FBP by betamethasone administration on fetus. Starting at 133 ± 1 dGA, saline (control group: CNTL) or betamethasone (Beta,) was administered to the fetal vein at a rate of 10 μg/h over the next 48 h. Hourly fetal blood pressure (FBP), fetal heat rate (FHR) in the control group (CNTL) and betamethasone-treated (Beta) fetuses. Values shown are means ± SEM for every hour. Time 0 was settled at the beginning of vehicle or betamethasone infusion. Filled bar represents hours of darkness (21:00–07:00 hours). Shadowed bar represents the infusion periods.

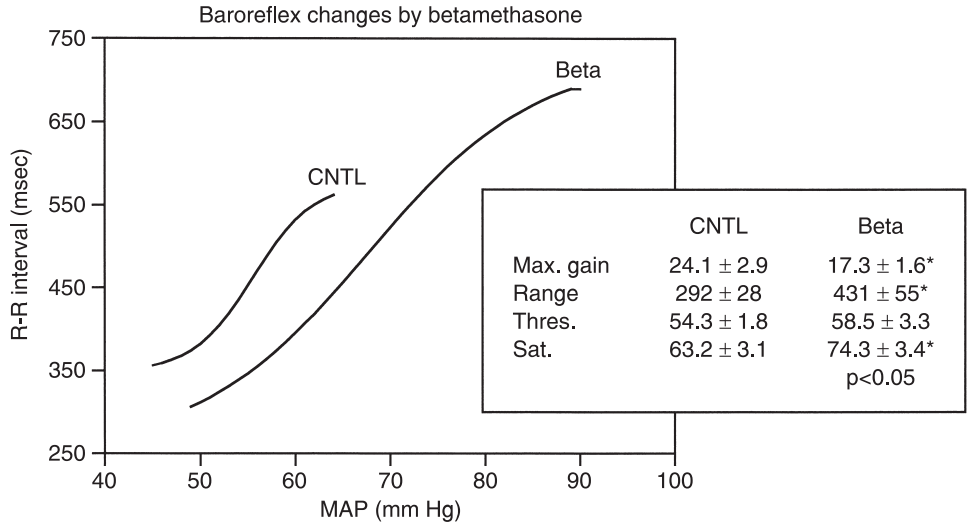

Figure 56.11 Baroreflex changes by betamethasone. Significant changes in each parameters of baroreflex function are found. The curve shifted to the right and expanded the range of handling.

fetus.[45–49] The mechanisms producing an increase in FBP during betamethasone infusion have been discussed in terms of mediation of an increase in fetal total peripheral vascular resistance and/or fetal cardiac output.[45–49]

Betamethasone may accelerate fetal cardiovascular maturation. Chronological FHR changes in Beta fetuses suggest that there are at least two steps of process ware involved in cardiovascular alterations induced by betamethasone. Initial cardiovascular response to increased FBP and significant decrease in FHR in the first 12 h of betamethasone infusion might be caused by basic baroreflex response to the rise in FBP. The second step of FHR recovery against FBP rise may be mainly caused by resetting of the baroreflex response including sympathetic and parasympathetic autonomic nervous activity. In addition, at this stage, changes in cardiac output by betamethasone must be taken into account. The newborn lamb's heart has the ability to alter the inotropic state. Thus, near-term fetus must have the ability to use inotropic action of the heart, even if it is limited, and the magnitude of the inotropic ability would indicate the degree of maturation of the fetal heart function. Another study using betamethasone-treated fetuses showed that fetal femoral blood flow and femoral vascular resistance tend to recover at the end of 48 h after betamethasone infusion.[46–49] Therefore, the second step cardiovascular alteration is also mediated by betamethasone administration to the fetuses.

The above results suggest that there are several important periods of gestational age in the course of cardiovascular maturation and that the process of maturation is mediated and modified by glucocorticoids. One of the major current concepts of programming cardiovascular system states that the precise timing and sequence of maturational events during fetal life are fundamental to normal development.

Chronic fetal stressed model to study fetal reaction for investigating maturation

From a clinical viewpoint, the major interest in fetal physiology has been fetal hypoxia. A lot of studies have been carried out to clarify the variety of reactions of the fetus to acute hypoxia insult *in utero*. Much knowledge related to biophysical background in perinatal medicine such as deceleration in heart rate monitoring, behavioral state alterations and so on have been obtained from animal experiments. Recent epidemiological studies, as Baker stated,[68–70] indicate that an adverse intrauterine environment affects fetal physiological development and may be the origin of later disease. Hence much attention has been focused on the fetal environment in the womb. Do the chronic changes in environment, in other words, the chronic stress to the fetus really alter the fetal maturational course and beyond? Restricted maternal nutrition has been shown to have an apparent effect on fetal cardiovascular function. Animal studies in rats and sheep have demonstrated hypertensive offspring induced by maternal nutrient restriction and differences in fetal growth were associated with changes in cardiovascular control.

Several chronic stressed fetal models have been reported. As an altered fetal environment model, prolonged hypoxia in chronic sheep studies[50–55] has demonstrated long- and short-term effects on fetal cardiovascular function. A long-term fetal placental embolization model[56–58] has demonstrated that umbilical blood flow and heart rate pattern alterations cause hypertension and myocardial hypertrophy. A repeated cord occlusion model[59,60] has reported the response alteration in hormonal and cardiovascular

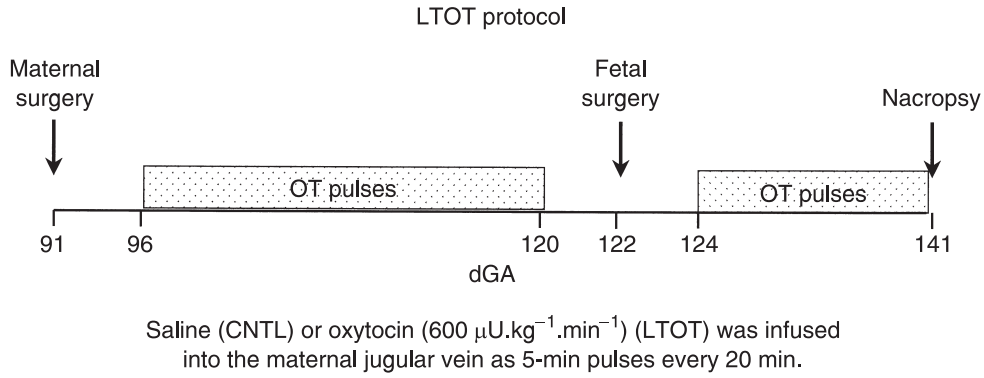

Figure 56.12 LTOT protocol. Ewes received ether saline (control group: CNTL) or oxytocin (600 μU/kg/min; long-term oxytocin group: LTOT) infusions into maternal jugular vein at 0.033 ml/min as 5-min pulses starting at 96 dGA. Oxytocin pulse infusion was stopped 1 day before fetal surgery and recommenced 2 days after fetal surgery.

responses. However, a few studies have been reported related to the experimental model of long-term environmental alteration/stress to the fetus.

In this section we introduce a long-term light stressed fetal model by means of increased uterine activity of oxytocin (LTOT model).

LTOT model[41,61–63]

Myometrial contractures are characterized by long-lasting low amplitude myometrial contractility occurring throughout pregnancy in sheep. Contractures induce a fall in fetal arterial oxygen pressure (PO_2), a decrease in uterine blood flow, and also produce mechanical stress to the fetus by compression. A previous study has shown that oxytocin (OT) induced contractures in late gestation sheep altered fetal pituitary-adrenal[61,62] functions and might accelerate neurological development as revealed by the ECoG voltage amplitude.[64,65] Since fetal hypothalamic-pituitary-adrenal axis plays an important role in ovine parturition, this kind of neuroendocrine alteration by increased myometrial contractures should be associated with alteration of physiologic function. We hypothesized that long-term increased myometrial contracture frequency, namely long-term frequent light stress to the fetus, would alter fetal physiological development and fetal responses to acute stress episodes. We therefore exposed pregnant sheep with repeated pulses of oxytocin from 96 to 131 dGA. OT dose did not cross the ovine placenta, therefore no direct effects of OT on the fetus are responsible for any fetal changes.[66]

The LTOT protocol is shown in Figure 56.12. Ewes received ether saline (control group: CNTL), or oxytocin (600 μU/kg/min; long-term oxytocin group: LTOT) infusions into the maternal jugular vein at 0.033 ml/min as 5 min pulses starting at 96 dGA. Oxytocin pulse infusion was stopped 1 day before fetal surgery and recommenced 2 days after fetal surgery. By this procedure of oxytocin pulses, myometrial contracture frequency increased by slightly over 100% ewes in LTOT compared with CNTL ewes (Table 56.1).

Table 56.1 Effect of oxytocin pulses (LTOT) or vehicle control (CNTL) on the number of contractures per hour

	CNTL	LTOT
126–130 dGA	1.35 ± 0.13*	3.34 ± 0.06*
131–135 dGA	1.45 ± 0.09*	3.21 ± 0.07*
136–140 dGA	1.52 ± 0.13*	3.13 ± 0.06*

Contracture frequency was counted every day and averaged in each animal to obtain representative values for each period.

Mean ± SEM, * $p < 0.01$.

Using the LTOT model, the following issues were studied:

1. Hormonal environment (cortisol and ACTH)
2. Blood and arterial blood gas environment
3. Response to acute fetal hypoxemia (1 h) induced by administering nitrogen to the ewe through 131 ± 1 dGA
4. Ontogenic cardiovascular changes and baroreflex alteration
5. Behavioral alterations

Hormonal environment

Basal fetal plasma ACTH and cortisol values obtained during the study period are presented in Figure 56.13. There were no significant differences in ACTH and cortisol values between CNTL and LTOT. However, cortisol/ACTH ratios (ng/pg) were significantly lower in LTOT at 128–132 dGA (CNTL, 0.13 ± 0.02, 0.24 ± 0.09, 0.21 ± 0.08; LTOT, 0.06 ± 0.03, 0.08 ± 0.04, 0.08 ± 0.04). Cortisol is higher at 140 dGA in both CNTL and LTOT groups.

Blood and arterial blood gas environment

Fetal arterial blood gas values are summarized in Table 56.2. PO_2 was lower in LTOT at 126–135 dGA and O_2 content was higher in LTOT at 131–140 dGA.

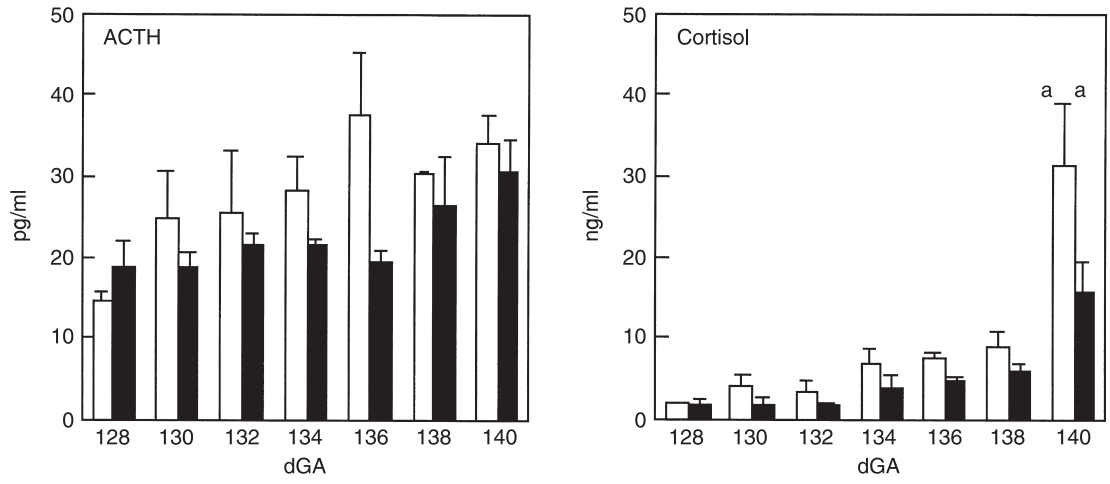

Figure 56.13 Fetal plasma ACTH and cortisol concentrations in CNTL (□) and LTOT (■). Mean ± SEM, a: $p < 0.05$ compared with 128–138 dGA.

Table 56.2 Arterial blood gas values of CNTL and LTOT during study period

		CNTL	LTOT

Blood samples were taken at 9:00–10:00 every day. Data were averaged in each animal to obtain representative values for each period.

Mean ± SEM, *$p < 0.05$ CNTL vs. LTOT.

Response to acute fetal hypoxemia

Acute fetal hypoxemia insult was induced at 131 ± 1 dGA by administering nitrogen to the ewe through a tracheal tube for 1 h, beginning at the start of oxytocin or saline pulse. Maternal and fetal arterial blood samples (0.5 ml) were taken at −60, −15, −5, 5, 10, 20, 30, 40, 60 and 120 min. Blood samples were measured using a blood gas analyzer. Oxygen saturation (%) and hemoglobin (μg/dl) were measured with a hemoximeter. O_2 content (ml/dl) was calculated from the hemoglobin (Hb), O_2 saturation and PO_2 values.

Fetal PO_2 was significantly lower and O_2 content was significantly higher in LTOT at baseline. No difference was found in maternal blood gas and pH values at baseline (Table 56.3). At the end of 60 min hypoxemia, fetal pH, O_2 saturation, O_2 content were significantly higher in LTOT, although PO_2 did not differ between the two groups (Table 56.4). At 120 min (60 min after acute hypoxemia insult), blood gas values in both groups returned to normal value and no difference was found between the two groups (Table 56.5).

Relationship between maternal and fetal PO_2 and O_2 content showed lower PO_2 but higher O_2 content at the same maternal oxygen delivery in LTOT. Linear model analysis showed statistically significant LTOT effect ($p < 0.001$; Figure 56.14).

O_2 content at PO_2 was significantly higher in LTOT and O_2 saturation at PO_2, which expressed an O_2 dissociation curve, was obviously shifted to the left in LTOT (Figure 56.15). Linear model analysis proved that the model of the same slope with different intercepts – whether or not of LTOT – was the best fitting model and the effect of LTOT was statistically significant ($p < 0.001$).

During hypoxemia and recovery period, fetal pH tended to shift higher and its variability was less in LTOT compared with CNTL (pH variability expressed as coefficient of variation (CV): CNTL, 0.33 ± 0.15; LTOT, 0.12 ± 0.06, mean ± SD, $p < 0.05$) (Figure 56.16).

Ontogenic cadiovascular changes and baroreflex alteration

FBP was significantly higher from 126 to 128 dGA in the fetuses of LTOT ewes compared with the fetuses of CNTL. FHR was significantly lower in the fetuses of LTOT from 126 to 131 dGA (Figure 56.17). The slope of daily FBP changes (CNTL, 0.76 ± 0.21; LTOT, 0.27 ±

(b) $Y = 0.45 \times X - 0.034 \times X \times Z - 1.16$ (CNTL $Z = +1$: dashed line; LTOT $Z = -1$: straight line; $p < 0.001$).

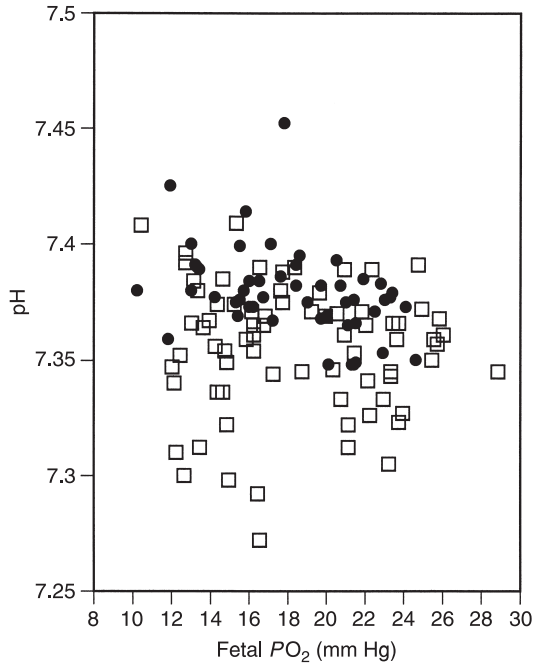

Figure 56.16 Fetal pH values before and during acute hypoxemia. □ CNTL; ● LTOT.

0.06 mmHg/dGA) and FHR (CNTL, −1.91 ± 0.20; LTOT, −0.70 ± 0.41 bpm/dGA) was significantly lower in LTOT (Figure 56.18).

There was no difference in the fall in FBP at the end of SNP infusion. FBP dropped by 31–37%. However, total SNP dosage (adjusted by fetal weight) required to produce this fall in FBP was significantly higher in LTOT (CNTL, 21.1 ± 3.7; LTOT, 34.7 ± 4.6 μg/kg). Initially, the fetus tries to compensate for the fall in FBP by increasing the FHR. In contrast, CNTL fetuses tend to show early breakdown of compensatory reaction and fall into bradycadia. The breakdown point to fall into bradycardia was significantly different between CNTL and LTOT (CNTL, 41.6 ± 0.6bpm, 328 ± 10 ms; LTOT, 38.7 ± 1.4 bpm, 328 ± 16 msec) (Figure 56.18). PO_2 and O_2 saturation values were significantly lower at the end of SNP infusion in CNTL. No difference was found in blood gas during the experiment in LTOT fetuses (Table 56.6). ACTH and cortisol responses to hypotension showed attenuated response (Figure 56.19). However, no differences were found in cortisol/ACTH ratios (ng/pg) between CNTL and LTOT groups.

The baroreflex curve was shifted to the right and showed a mature pattern in LTOT fetuses. Maximum gain (ms/mmHg) was significantly different between CNTL and LTOT (CNTL, 24.4 ± 2.7; LTOT, 16.6 ± 2.3) (Figure 56.20).

Behavioral alterations

ECoG has been used for analyzing fetal neurological activity. Examples of analog ECoG recording are shown in Figure 56.21. ECoG activity represents basic

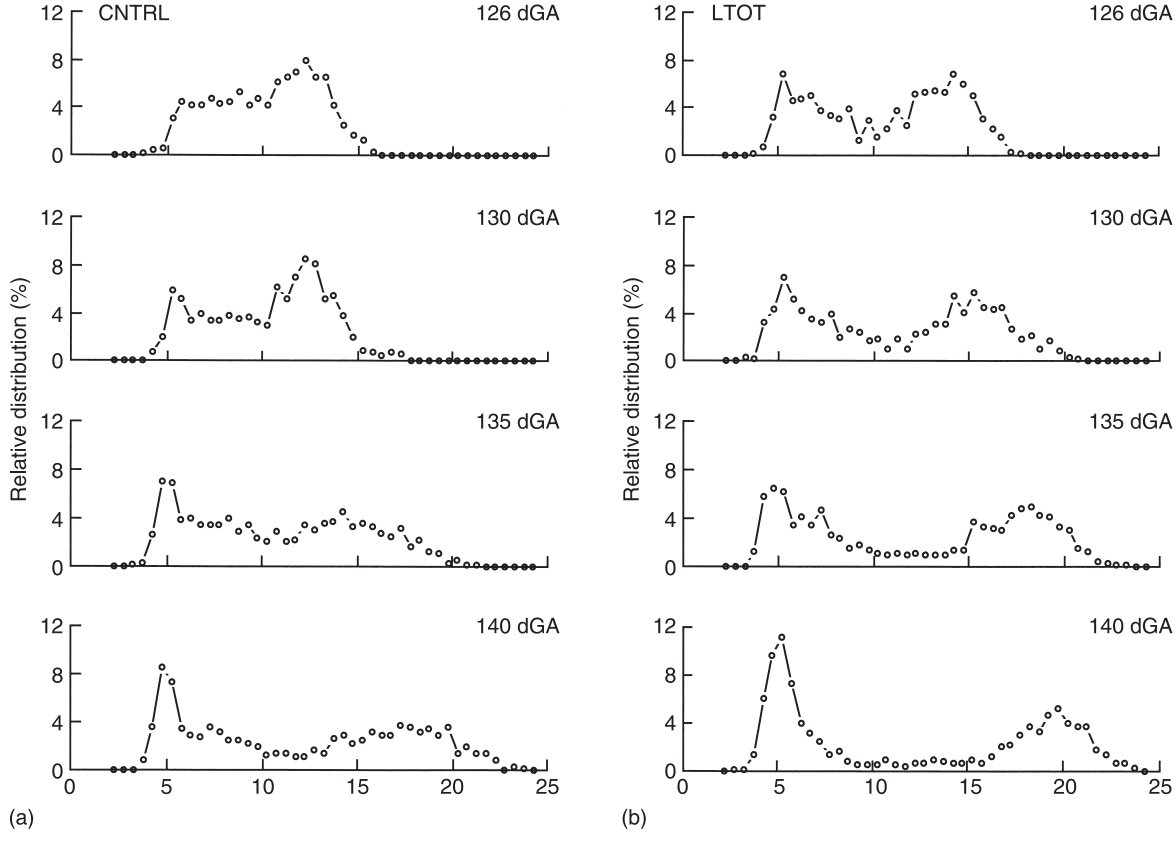

Figure 56.22 ECoG spectral edge frequency at each gestational age. ECoG power spectra analysis by calculation spectral edge frequency distribution showed apparent distinction between low- and high-frequency peaks in LTOT (Figure 56.2). In LTOT, high spectral edge frequency was statistically higher in LTOT at 126–140 dGA and low frequency was statistically lower at 126 and 130 dGA. Difference of the HV and LV peaks.

behavioral rhythm; little is known about diurnal variation of ECoG pattern. Characteristic ECoG patterns have been discussed with alternation between low-voltage fast-activity (LV) state and high-voltage slow-activity (HV) state. As pregnancy progresses the amplitude increases and the difference between the HV and LV states becomes clear.

The ECoG characteristic changes were analyzed by means of ECoG power spectral distribution analysis. Three-hour raw ECoG data sampled at 250 Hz were

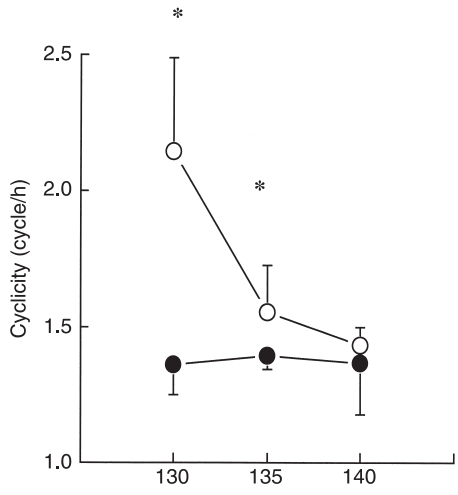

Figure 56.23 Peak HV–LV cycle frequency (cycle/hr) at 130, 135, 140 dGA CNTL ○ and LTOT ● Mean ± SEM *$p < 0.05$.

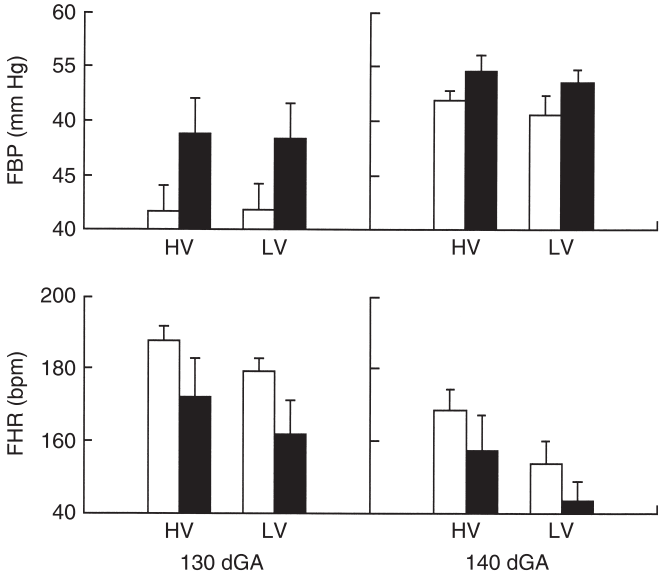

Figure 56.24 FBP and FHR in HV and LV states at 130 and 140 dGA.

analyzed using conventional fast Fourier transform (frequency resolution at 0.04 Hz, range 0–41.6 Hz). Spectral edge frequency (90%) was calculated. Three-hour data (recorded at 10:00–14:00) at 126, 130, 135, 140 dGA were studied (Figure 56.22). ECoG power spectra analysis by calculation spectral edge frequency distribution[73,74] showed apparent distinction between low- and high-frequency peaks in LTOT (Figure 56.22). In LTOT, high spectral edge frequency was statistically higher in LTOT at 126–140 dGA and low frequency was statistically lower at 126 and 130 dGA. The mature pattern in ECoG spectra was found in LTOT fetus.

In addition, HV–LV ECoG cyclicity analysis[21] was done using the following procedures: (1) denoising by wavelet transform filtering; (2) HV–LV ECoG cyclicity

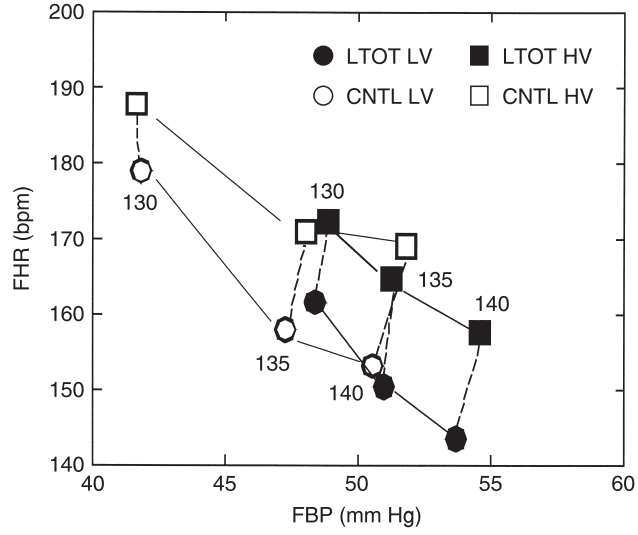

Figure 56.25 LV and HV state difference in FBP and FHR in CNTL and LTOT. The pattern of cardiovascular changes in behavioral state is shifted to the right in LTOT fetus suggesting acceleration of maturation in LTOT.

by periodogram analysis. Hourly peak cycle and cycle were calculated by using period gram. Daily data at 130, 135 and 140 dGA were studied (Figure 56.23). Peak HV–LV cycle frequency in CNTL was changed to lower values by gestational age whereas that in LTOT was already low at 130 dGA and no difference was found by gestational age. Peak HV–LV cycle frequency was statistically lower in LTOT at 130 and 135 dGA.

FBP and FHR in each HV and LV state at 130 and 140 dGA are shown in Figure 56.24. Mean FBP was significantly higher and FHR was significantly lower in both HV and LV states in LTOT compared with CNTL.

FHR was increased in HV state from 130 dGA. Both FBP and FHR were increased in HV state at 140 dGA. The difference in state characteristics becomes apparent by plotting on one chart. The difference between LV and HV states with respect to FBP and FHR in CNTL and LTOT is summarized in Figure 56.25. The pattern of cardiovascular changes in behavioral state is shifted to the right in LTOT fetus suggests acceleration of maturation in LTOT.

In the LTOT studies, no difference was found at necropsy in body weight, organ weight and placenta between CNTL and LTOT.

What happens on long-term light stress to the fetus?

A single contracture produced in response to a single pulse of OT administered to the pregnant ewe in late gestation stimulates the release of fetal ACTH. A longer period of fetal exposure to contractures at an earlier stage of maturation altered the sensitivity of the fetal adrenal to ACTH both under basal and following exposure to hypoxemia, hypotension and

hypertension. In the LTOT study, fetal PO_2 was lower and O_2 content higher in LTOT fetuses than in CNTL fetuses. This finding indicates that LTOT fetuses were not hypoxemic. They adapted to repeated mild stress and developed compensatory mechanisms by altering oxygenation accompanied by a shift of the oxygen dissociation curve to the left.

We also found an alteration in cardiovascular ontogenic change and baroreceptor response in LTOT fetuses. The baroreflex curve in LTOT showed a right shift and mature pattern as indicated in previous ontogenic studies. From the results obtained, we speculate that LTOT fetuses have more ability of isotropic function than CNTL fetuses. Fetal cardiovascular maturation during the final month of pregnancy is characterized by a rise in FBP and a fall in FHR. Higher FBP and lower FHR in LTOT fetuses compared with gestation matched controls suggest an acceleration of fetal cardiovascular maturation.

ECoG is one of the main indices of fetal neurological function. Biological variation is dependent upon behavioral states in late gestation. Difference in FBP and FHR in each HV–LV state indicates the degree of state maturation. The alteration of ontogenic changes in the relationship of FBP and FHR to fetal ECoG states (HV/LV states) following LTOT suggests an acceleration of fetal neurological maturation.[67,68]

Considering all results, we speculate that the altered intrauterine environment induced by increased uterine contracture activity accelerates endocrinological, neurological and functional maturation either by altered fetal oxygenation, glucocorticoid activity and/or physical stimulation of the fetus.

Fetal maturation, adaptation or adjustment by various stresses to the fetus

From the above-mentioned animal studies, a hypothesis arises that any stress to the fetus, environmental or congenital, could induce an acceleration of functional maturation. Initial compensatory response of the fetus to the environmental stress would be the acceleration of the maturation process.

An adequate stress such as uterine contracture must be a necessary factor for fetal stimulation. For the clinician, not only the gestational age but the maturational age also must be a desirable index to assess fetal well-being. Further basic research is required to answer these questions.

There is currently much interest in the effects of the quality of the intrauterine environment. Recent epidemiological studies indicate that an adverse intrauterine environment affects fetal physiological development and may be at the origin of later adult disease.[18,69–72] Restricted maternal nutrition has been shown to have an apparent effect on fetal cardiovascular function. Animal studies have demonstrated that hypertensive offspring is induced by maternal nutrient restriction and differences in fetal growth were associated with changes in cardiovascular control. Barker's hypothesis,[69,70] shows that fetal origins of adult disease is an important keyword in perinatal biomedical science. This concept has been called fetal programming, which means that an early environmental stimulation changes the developmental course and induces later physiological alteration. The environmental interactions in early development lead to changes in the physiological and physical phenotype of the developing embryo or fetus in expectation of future advantage in a particular predicted adult environment. The word 'programming' sounds as if the biological process is commanded and coded. Gluckman and Hanson use the term 'predictive adaptive responses' (PARs) to describe environmental responses.[71]

In the period before birth, environmental factors play an important role in the biological process of fetal maturation and some aspects of future life is possibly defined. By studying fetal maturation and its alteration by environmental stimulation, we can learn about the future process in development and health.[18,71,72] For these reasons, much attention should be paid to the investigation of fetal physiology and biomedical sciences.

57 Basic background of congenital anomalies: NTD

K. Fujimori and A. Sato

Introduction

Neural tube defects (NTDs) are the second most common class of congenital anomalies after cardiac defects. A worldwide incidence of isolated (i.e. non-syndromic) NTDs is 1.4–2.0 per 1000 live births.[1] They can also occur as part of a genetic syndrome or constellation of abnormalities. They are a major cause of stillbirth, neonatal and infant death, and lifelong severe handicap. Anencephaly accounts for one half of all cases of NTDs and is incompatible with life. With treatment, 80–90% of infants with isolated spina bifida survive with varying degrees of handicap. Factors that influence eventual neurological function include the size and location of the defect, trauma to exposed neural tissue, timing of surgical closure, degree of associated ventriculomegaly, and occurrence of complication such as infection. It is well known that NTDs are among the few preventable birth defects. Preconceptional counseling and folic acid supplementation are very important.

Embryology and types of NTDs

The neural folds in the brain and spinal cord regions fuse in the midline, converting the neural tube by days 26–28 of embryonic life (Figure 57.1).[2] Recent data indicate that closure occurs in separate regions that then fuse.[3] Clinical data suggest five possible closure sites. NTDs likely result from either failure of closure in one or more sites, or failure of two sites to meet. Neural tube closure is normally complete by the end of the fourth week after conception (6 weeks after the last menstrual period), a time when many women do not yet realize they are pregnant.

The most common types of NTDs are listed in Table 57.1.[4] Anencephaly is the most severe defect, in which the forebrain, meninges, vault of the skull, and scalp all fail to form. It is lethal, resulting in stillbirth or early neonatal demise. Spina bifida involves failure of fusion of the caudal portion of the neural tube, usually of three to five contiguous vertebrae and

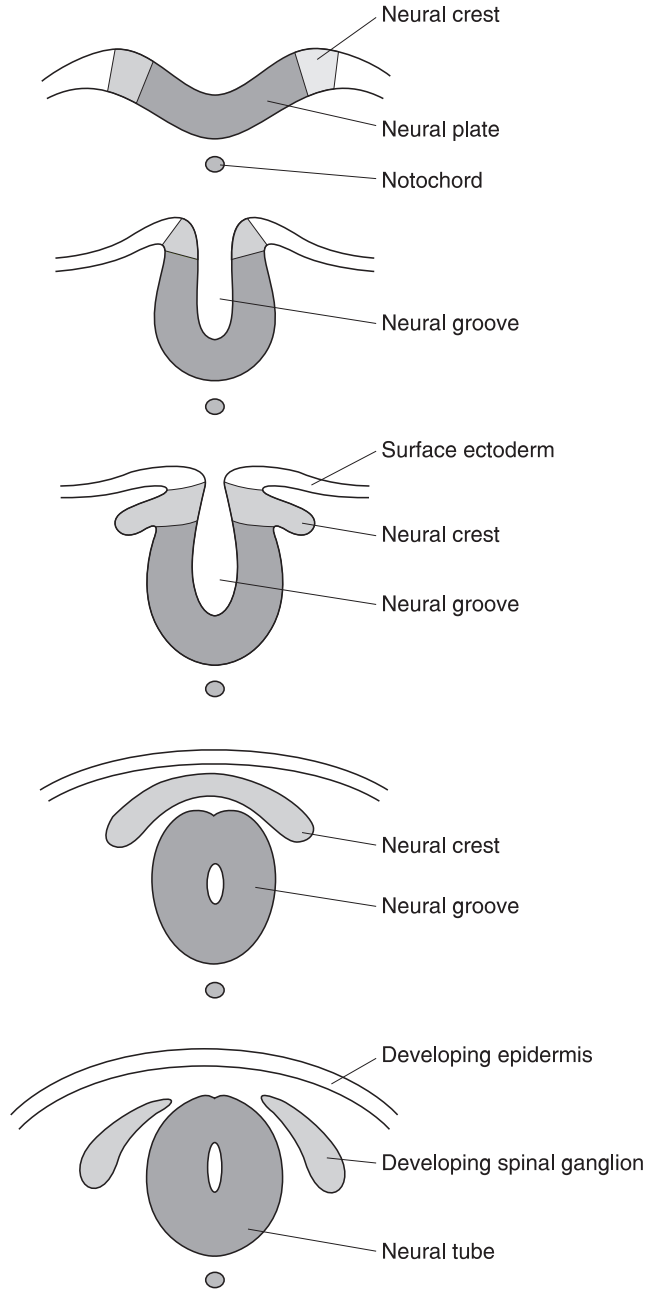

Figure 57.1

Table 57.1 Neural tube defect pathophysiology

Neural Tube Defect	Malformation
Cranial	
Anencephaly	Failure of fusion of cephalic portion of neural folds; absence of all or part of brain, neurocranium, and skin
Exencephaly	Failure of scalp and skull formation; exteriorization of abnormally formed brain
Encephalocele	Failure of skull formation; extrusion of brain tissue into membranous sac
Iniencephaly	Defect of cervical and upper thoracic vertebrae; abnormally formed brain tissue and extreme retroflexion of upper spine
Spinal	
Spina bifida	Failure of fusion of caudal portion of neural tube, usually of 3–5 contiguous vertebrae; spinal cord or meninges or both exposed to amniotic fluid
Meningocele	Failure of fusion of caudal portion of neural tube; meninges exposed
Meningomyelocele	Failure of fusion of caudal portion of neural tube; meninges and neural tissue exposed
Myeloschisis	Failure of fusion of caudal portion of neural tube; flattened mass of neural tissue exposed
Holorachischisis	Failure of fusion of vertebral arches; entire spinal cord exposed
Craniorachischisis	Co-existing anencephaly and rachischisis

spinal cord or meninges or both exposed to amniotic fluid. Meningocele is the protrusion of the meninges and cerebrospinal fluid into a sac covered by epithelium. Myleomeningocele is most common and involves serious defects that include the spinal cord, nerve roots, meninges, and cerebrospinal fluid. It occurs mostly in the lumbar area. As meninges or neural tissue plus meninges are exposed to the amniotic fluid and eventually to the environment, neural tissue is damaged, causing the structures supplied by the damaged nerves to be dysfunctional. Lesions in the lumbosacral area can lead to paraplegia and lack of bowel or bladder control. The level of the lesion is usually reflected in the severity of the clinical deficit, with higher lesions having more pronounced deficits.

Open defects are often associated with ventriculomegaly or hydrocephaly as a result of a block to cerebrospinal fluid circulation. The increased intracranial pressure may cause pressure atrophy of the developing brain, although neurological dysfunction cannot be reliably estimated from the thickness of the compressed cortical mantle. Rachischisis describes the situation in which none of the vertebral arches fuse, and the entire spine is open. This condition is generally incompatible with life.

Etiology

Many risk factors of NTDs are known, including family history, exposure to certain environmental agents, genetic syndromes, and racial or ethnic groups. Main and Mennuti presented the recognized causes of neural tube defects, as listed in Table 57.2.[5]

Family history is the most important risk factor for NTDs. Because they are multifactorial in inheritance, the risk to a first-degree relative is approximately 2–3%. While this is lower than the risk of autosomal dominant or recessive disorder, it is 20–30 times higher than the risk of NTDs in the general population. The level of risk is directly related to the number of affected relatives and their degree of relatedness of the fetus.[6,7] However, only 5% of NTDs occur in families with a positive family history.[8] More than 90% occur in families with no prior history.[9]

Exposure to certain environmental agents has been implicated in NTD formation. Exposure must occur during the first 28 days of gestation when the neural tube is developing. Hyperglycemia from insulin-dependent diabetes increases the risk of NTD.[9] Although this may inhibit fetal glycolysis, functional deficiency of arachidonic acid or myoinositol in the developing embryo, or alterations in the yolk sac,[10] the exact mechanism is unknown. Hyperthermia (high maternal body temperature) during neural tube formation has also been implicated in causing defects. Maternal fever and sauna baths have both been reported to increase the relative risk up to sixfold.[11]

Anticonvulsants, most notably valproic acid and carbamazepine, induce NTDs. Especially, fetuses exposed to valproic acid in the first trimester have a 1–2% risk of spina bifida.[12] This is because valproic acid acts as an antagonist and impairs folate absorption. Aminopterin and isotretinoin also have been associated with anencephaly or encephalocele.

Some inherited syndromes known to include NTDs are Meckel–Gruber, Roberts SC phocomelia, Jarco–Levin, and Harde syndrome, as well as trisomy 13, trisomy 18, and triploidy. These autosomal recessive diseases have 25% recurrence risk, and trisomies 13 and 18 and triploidy have a 1% recurrence risk.[13] Cloacal extrophy and sacrococcygeal teratoma may be associated with spina bifida, and amniotic bands may cause spina bifida or anencephaly.[13]

Some geographic regions and racial or ethnic groups are associated with NTDs. The UK has the highest frequency of NTDs, with an incidence of almost 1% compared with 0.2% in the USA.[14]

Table 57.2 Recognized causes of neural tube defects

Multifactorial inheritance—anencephaly, meningomyelocele, meningocele, and encephalocele
Single mutant genes
Meckel syndrome—autosomal recessive (phenotype includes occipital encephalocele and rarely anencephaly)
Median-cleft face syndrome—possible autosomal dominant (phenotype includes anterior encephalocele)
Robert syndrome—autosomal recessive (phenotype includes anterior encephalocele)
Syndrome of anterior sacral meningomyelocele and anal stenosis—dominant, either autosomal or X-linked
Jarco-Levin syndrome—autosomal recessive (phenotype includes meningomyelocele)
HARDE syndrome—autosomal recessive (phenotype includes encephalocele)
Chromosome abnormalities
13 trisomy
18 trisomy
Triploidy
Other abnormalities, such as unbalanced translocation and ring chromosome
Probably hereditary, but mode of transmission not established
Syndrome of occipital encephalocele, myopia, and retinal dysplasia
Anterior encephalocele among Bantus and Thais
Teratogens
Valproic acid (phenotype includes spina bifida)
Aminopterin/amethopterin (phenotype includes anencephaly and encephalocele)
Thalidomide (phenotype includes, rarely, anencephaly and meningomyelocele)
Maternal predisposing factors
Diabetes mellitus (anencephaly more frequent than spina bifida)
Specific phenotypes, but without known cause
Syndrome of craniofacial and limb defects secondary to aberrant tissue bands (phenotype includes multiple encephaloceles)
Cloacal exstrophy (phenotype includes myelocystocele)
Sacrococcygeal teratoma (phenotype includes meningomyelocele)

China, Egypt, and India also have a very high incidence of NTDs. The reasons for these high incidences are considered to be related to both the ethnic (genetic) background of the inhabitants and the environmental influences, such as diet. For example, Sikhs living in India have more than twice the incidence of NTDs as Sikhs living in Canada.[7]

Certain ethnic and racial groups also appear to be at high risk. For example, a study using population-based data from California found that incidence of NTDs of Hispanic women was higher than Caucasian women (1.12 vs. 0.96 per 1000). African-American and Asian women were at low risk (0.75 and 0.75 per 1000).[15]

Several investigators reported that obese women had a two- to threefold risk for NTDs as well as other anomalies.[16–18] Subsequently, Shaw *et al.* found a significant twofold increased incidence of NTDs in women whose body mass index (BMI) was 30 or higher.[19,20]

Although there is no firm evidence that influenza virus causes congenital malformation,[21] Lynberg *et al.* reported in a case–control study that children born to women with influenza early in pregnancy had a threefold risk of NTDs. This may be related to be associated with hyperthermia.[22]

The most important environmental influence in NTDs formation appears to be related to the dietary intake of folic acid, because pregnancies complicated by a fetal NTD have lower maternal plasma levels of folate than pregnancies that are unaffected. Recently, a specific gene defect associated with folic acid metabolism has been implicated. A thermolabile variant of 5,10-methylenetetrahydrofolate reductase (MTHFR) has the mutation 677CT, which results in a substitution of valine for alanine. This variant enzyme has reduced activity leading to altered homocysteine metabolism. Hyperhomocystinemia increases the risk for fetal NTDs, atherosclerosis, thromboembolism, and recurrent miscarriage.[23] Several studies have shown that parents who have had a pregnancy complicated by an NTD and their affected offspring are more likely to carry a mutation in the gene encoding the enzyme MTHFR than the unaffected population. For example, in The Netherlands, 14–16% of mothers, 10–15% of fathers, and 13–18% of children with spina bifida are homozygous for the MTHFR mutation compared with 5% of the general population.[24–26] Other mutations in this enzyme with similar effects also have been reported.[26] Therefore, it seems possible that folic acid supplementation helps to overcome the effects of this enzyme mutation, resulting in more normal levels of homocysteine and adequate production of methionine. The Medical Research Council Vitamin Study Research Group published the results of a large, prospective, randomized, double-blind study of folic acid supplementation conducted at 33 centers in seven countries.[27] The results showed that folic acid supplementation reduced NTD recurrences by 70%.[27] Czeizel and Dudas subsequently showed that periconceptional

folic acid supplementation decreased the risk of first occurrence of an NTD.[28] But, folic acid supplementation does not prevent all cases, other unknown genes or factors are presumed to cause some cases. Recently, Rothenberg *et al.* showed that autoantibodies against folate receptors were present in sera from women whose pregnancies are complicated by an NTD. They hypothesized that autoantibodies against folate receptors in women could be associated with pregnancy complicated by an NTD.[29]

Diagnosis

Alpha-fetoprotein

Prior to the late 1970s, there was no way to identify NTDs during pregnancy, but then it was discovered that amniotic fluid and maternal serum alpha-fetoprotein (MSAFP) was a marker for pregnancy of NTDs. AFP is a fetal-specific globulin similar to albumin in molecular weight and is synthesized early in gestation by the yolk sac and subsequently by the gastrointestinal tract and fetal liver. The kidney and placenta also produce trace amounts of AFP. The level of fetal plasma AFP peaks between 10 and 13 weeks of gestation and declines exponentially from 14 to 32 weeks and then more sharply until term. AFP enters the fetal urine and is excreted into the amniotic fluid. Peak levels of amniotic fluid AFP (AFAFP) are reached between 12 and 14 weeks of gestation, decline between 10% and 15% per week during the second trimester, and are almost non-detectable at term.[30] AFP passes into the maternal circulation by diffusion across the placental membranes and may also be transported via the placental circulation.[31] AFP levels in maternal plasma or serum rise above non-pregnant levels as early as the seventh week of gestation. Although maternal serum levels are significantly lower than amniotic fluid levels, these increase during gestation.[32] When there is a fetal abnormality such as an opening uncovered by epithelium in the body or a number of other problems, then the maternal AFP serum levels are increased. Brock and Sutcliffe showed that amniotic fluid AFP levels were much higher in pregnancies complicated by fetal anencephaly.[33] Subsequently, Brock *et al.* demonstrated that maternal serum AFP levels were also elevated in affected pregnancies.[34] The first large prospective trial for maternal serum AFP screening was the UK Collaborate Study on Alpha-fetoprotein in Relation to Neural Tube Defects.[35] Subsequently, other investigators confirmed the effect of screening for NTDs.[36–38]

Maternal serum AFP (MSAFP) screening for NTDs is ideally performed between 16 and 18 weeks of gestation. MSAFP is measured in nanograms per liter and reported as a multiple of median (MoM) of the unaffected population. MoM is used because AFP levels do not follow a Gaussian distribution, and because it aids in comparison of results from different laboratories and populations. Cutoffs between 2.0 and 2.5 MoM (for most laboratories) as upper limits indicate an increased risk for a fetal NTD of other structural anomaly (and warrants further evaluation). It is considered that the detection rates are almost 100% for anencephaly and 85–92% for open spina bifida, with a false-positive rate between 2% and 5%.[39] A number of factors can influence the interpretation of an MSAFP value. The most important factor for efficient MSAFP screening is the accuracy of the gestational age determination. Consequently, a first-trimester ultrasound (especially measurement of crown–rump length, CRL) is the preferable means of documenting gestational age, and femur length and biparietal diameter should be measured to confirm gestational age for AFP screening. Maternal weight affects the MSAFP concentration. The heavier the women, the lower the MSAFP value as a result of dilution in the larger blood volume. Maternal ethnicity may also alter the interpretation of an MSAFP level, because black women have a 10–15% higher MSAFP than non-blacks.[40] This is important because the incidence of NTDs in blacks is lower. Pregnant women with insulin-dependent diabetes mellitus have MSAFP values that are significantly lower than the non-diabetic women in the second trimester, which require adjustments in the interpretation.[41,42] This is critical because there is up to a 10-fold higher frequency of NTDs in the offspring of these patients. MSAFP must also be altered in multiple gestations. Because the maternal serum AFP level is approximately doubled in normal twin pregnancy, different cutoffs are needed to interpret this test in multiple gestations. When a 2.5 MoM cutoff in twin pregnancy is used, 99% of cases of anencephaly and 89% of open NTDs are detected but generate a 30% false-positive rate.[43] Raising the twin cutoff to 5.0 MoM decreases the false-positive rate to 3% but also decreases the detection of anencephaly to 83% and of open NTDs to 39%. Wapner *et al.* reported a detection rate of 50–85% and a false-positive rate of 5% using a cutoff of 4.5 MoM.[44] Because serum screening for fetal abnormalities in multiple gestation will always be limited by the inability to confirm which fetus is affected, many centers do not offer serum screening in multiple gestation even for NTDs.

Women with MSAFP levels higher than the cutoff level of 2–2.5 MoM should be referred for genetic counseling and consideration of a diagnostic test. The diagnostic test offered to women with a positive MSAFP test result is genetic amniocentesis. If the AFAFP level is elevated, an assay is performed to determine the presence or absence of acetylcholine-esterase. Acetylcholine-esterase is predominantly neuronally derived, giving it additional specificity for nervous system lesions. Therefore, elevated AFAFP levels together with the presence of acetylcholine-esterase are considered diagnostic for a fetal NTD. A combined use AFP and acetylcholine-esterase identified 100% of cases of

anencephaly, 100% of cases of open spina bifida, and 20% of ventral wall defects, with a false-positive rate of 2.2 per 1000 amniocentesis.[45] One advantage of amniocentesis is that amniotic fluid can also be obtained for determination of the fetal karyotype. In pregnancies complicated by an elevated MSAFP level, the incidence of fetal aneuploidy is 0.61% in ultrasonographically determined normal fetuses and 16% in abnormal fetuses.[46,47]

Women already known to be at high risk of having a fetus with an NTD because of a previously affected pregnancy, a positive family history, medication exposure, diabetes, or other risk factors can be offered a diagnostic test directly. Performing a genetic amniocentesis in all these women would result in a 98% detection rate for NTDs and a 100% detection rate for aneuploidy. However, all high-risk women for NTDs would undergo amniocentesis unnecessarily. Although second-trimester amniocentesis is a relatively safe procedure, it is associated with a post procedure pregnancy loss rate of approximately 1 in 200.[48]

Ultrasound

The ultrasound diagnosis of NTDs is based on soft tissue and bone findings with the recognition of associated abnormalities in the skull and brain. The soft tissue findings include absence of skin covering the defect and presence of a round sac (Figure 57.2) that may correspond to a meningocele or myelomeningocele. The bone findings are derived from the vertebral abnormalities associated with spina bifida.

Spina bifida is associated with a variety of typical intracranial abnormalities, including ventriculomegaly (Figure 57.3) and hypoplasia of the posterior fossa structures. The associated abnormalities include frontal bone scalloping (lemon sign; Figure 57.4)[49] and obliteration of the cisterna magna with either an absent cerebellum or abnormal anterior curvature of the cerebellar hemispheres (banana sign; Figure 57.5).[49] The fruit signs are very helpful for early diagnosis of the open spina bifida.

There are three main scanning sections used in the evaluation of the spine: sagittal, transverse, and coronal (see Romero *et al.*,[50] pp. 36–43). In the sagittal section, the normal spine appears as two parallel lines converging in the sacrum. Sagittal scans are also useful for evaluating the spinal curvatures of which exaggeration may be an indirect sign of spina bifida. In the coronal section, the normal spine appears as either two or three parallel lines. Spina bifida is typically characterized by a widening of the two external lines due to a divergent separation of the lateral processes of the vertebrae (Figure 57.6). Sagittal and coronal views are most useful in this evaluation. In the transverse section, the neural canal appears as a closed circle. In the presence of a defect, the posterior laminae are typically absent, and the lateral processes are set apart (Figure 57.7).[51] The presence of a sac is

Figure 57.3 Severe ventriculomegaly in the 30th week of gestation is present on the transverse view of the head with meningomyelocele

certainly helpful in the diagnosis of the spinal defect whereas the absence of a sac can make detection difficult. This myelomeningocele sac should not be confused for a skin-covered defect. It is a common belief that indirect signs of spina bifida, such as paralysis of the lower extremities and bladder distention, can be useful in the diagnosis of the lesion.

The accuracy in the diagnosis of spina bifida depends on the experience of the sonographer, the quality of the equipment, and the amount of time dedicated to the scan. It is believed that the accuracy of referral centers should be close to 100%, in large part due to recognition of associated cranial findings.

Figure 57.4 Axial ultrasound in the fetal head demonstrated bifrontal deformity of the calvaria (arrows) (lemon sign)

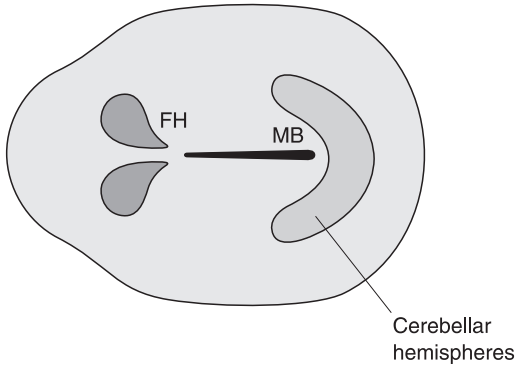

Figure 57.5 Obliteration of the cisterna magna with either absent cerebellum or abnormal anterior curvature of the cerebellar hemispheres (banana sign)

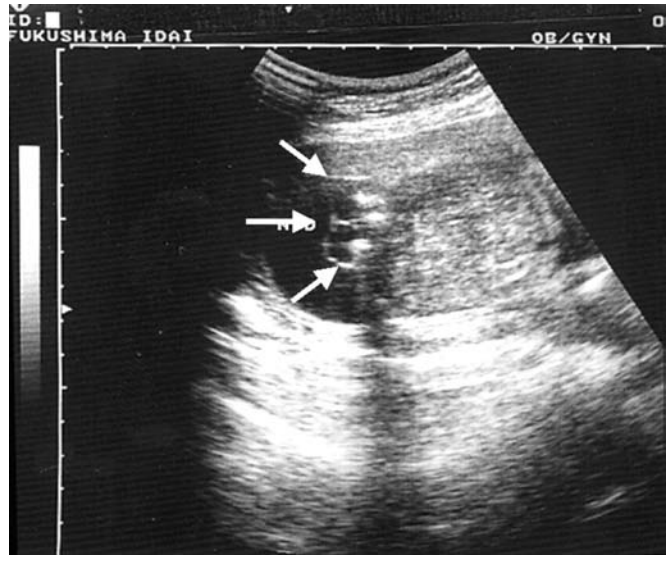

Figure 57.7 Transverse scan of the body of a fetus affected by a large spinal defect (arrows). The cystic and irregular echoes arising posteriorly from the defect suggested the presence of meningomyelocele.

The accuracy of routine non-targeted examinations is uncertain. In the RADIUS (routine antenatal diagnostic imaging with ultrasound) trial, in which routine ultrasound was performed in conjunction with maternal AFP screening, the sensitivity was 80%.[52] In a survey of European centers, Boyd *et al.* reported overall sensitivity of 75%, but a large variation between centers from 33% to 100%.[53] In one retrospective study conducted in Great Britain, the estimated sensitivity was marginally higher for serum AFP screening, 84–92%, than for ultrasound screening, 70–84%.[54] In all these studies, it is unclear whether the cranial signs of fetal spina bifida were systematically researched. In a more recent retrospective multicentric study using the cranial signs, the sensitivity of ultrasound was 85%.[55] Careful scanning of the rest of the fetus should be performed to exclude associated abnormalities.

Several authors have reported on the accuracy of the prenatal diagnosis of spina bifida by ultrasound. Table 57.3 shows the results of the three largest series available for study (see Romero *et al.*,[50] pp. 36–43).

Regarding the diagnosis of other NTDs using ultrasound, anencephaly was the first congenital anomaly identified *in utero*.[56] The diagnosis relies on the failure to demonstrate the cranial vault. The anencephalic fetus has a typical frog-like appearance and usually has a short neck (Figure 57.8). The diagnosis can probably be made within 10 weeks of gestation by transvaginal ultrasound.

Cephalocele is also to be diagnosed by transvaginal ultrasound within 10 weeks of gestation. Specific

Table 57.3 Accuracy of ultrasound in the prenatal diagnosis of spina bifida[50]

	n	Prevalence (%)	Sensitivity (%)	Specificity (%)	PPV	NPV
Allen et al.	374	2.1	87	99	87	99
Persson et al.	10,147	0.1	40	100	100	99
Roberts et al.	1261	1.4	30	96	92	99
Roberts et al.	1991	1.7	80	99	80	99

PPV, positive predictive value; NPV, negative predictive value.

Figure 57.8 Acrania/anencephaly. Transvaginal scan in coronal plane shows protruding brain (arrows) with absent calvaria. This has a 'Mickey mouse' shape on coronal scans.

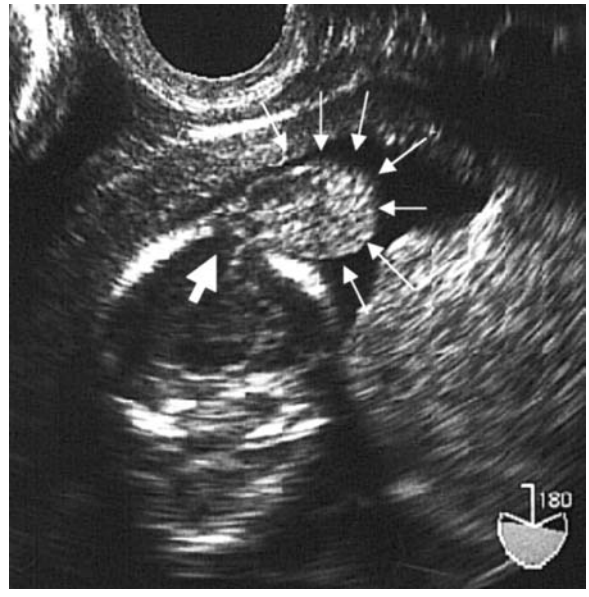

Figure 57.9 Encephalocele. Transvaginal scan of cranium shows large amount of brain protruding posteriorly (thin arrows) and a bony defect (big arrow).

findings in diagnosis of the cephalocele are to identify the soft tissue masses from scalp and the skull defect (Figure 57.9). The helpful findings for differential diagnosis are: (1) cephaloceles are often associated with hydrocephaly, (2) brain tissue can be seen in some cephaloceles, (3) cystic hygromas with multiple septa are often associated with other signs of hydrops and have a paracervical origin, and (4) severe scalp edema can be confused with a cephalocele, but usually a sagittal scan can identify an intact skull and the diffuse nature of the condition (see Romero *et al.*,[50] pp. 36–43).

Route of delivery

NTDs remain controversial as to whether the route of delivery influences outcome. Theoretically, a vaginal delivery may be further damaged by the mechanical forces of labor and by amniotic fluid contamination of the cerebrospinal fluid because of exposed neural tissue during labor. In the early 1980s, Chervenak *et al.* reported that infants with NTDs delivered by elective cesarean section (CS) have a better outcome in a small series of infants.[57] However, in a retrospective study of children with spina bifida, significant differences in any of several neurologic functions were not noted regardless of the route of delivery. In the early 1990s, two papers published conflicting results from large populations of affected infants. A prospective series in 1991 by Luthy *et al.* compared infants with spina bifida delivered by CS before labor, CS after labor, and vaginal delivery.[58] The level of motor deficit was assessed for each child as their motor level in relation to their radiologically determined anatomic level with degree of deficit and then evaluated across delivery categories. A significantly greater degree of motor loss, regardless of the anatomic level of the lesion, was noted in children delivered after labor, either by CS or vaginally. The greatest preservation of motor skills was noted in children delivered by CS before the onset of labor. In contrast, another review of outcomes in a similar, relatively large series of infants with NTDs did not reveal significant differences among routes of delivery.[59] As endpoints, this study assessed neurologic level and method of community locomotion. Infants were broadly grouped into functional neurologic

levels of L2, L3–4, and below L5 levels. Although vaginal delivery initially seemed to be more neurologically deleterious to breech infants, even this significance was lost on follow-up of these infants. However, as breech presentation, resulting from neurologic dysfunction of hydrocephalus with an enlarged head, is common in pregnancies complicated by fetal spina bifida, cesarean delivery is standard for the breech fetus with an NTD.[59] The best delivery route for the vertex fetus remains controversial. No prospective randomized trial of vaginal delivery vs. cesarean delivery for vertex fetuses with spina bifida has been performed. All studies of vaginal vs. cesarean delivery are retrospective and all suffer from various biases.[58,60,61] Theoretically, cesarean delivery possibly avoids mechanical trauma and infection of the fetal spine.

As it is still not clear whether or how the method of delivery significantly affects neurologic outcome in these infants, the American College of Obstetricians and Gynecologists recommends that decisions about the timing and route of delivery should be made individually in consultation with personal experience and knowledge of such complications, which may include maternal–fetal medicine specialists, neonatologists, and pediatric neurosurgeons.[4]

Generally, delivery at term is optimal. However, rapidly increasing ventriculomegaly may prompt delivery before term so that a shunting procedure can be performed.

The fetus with spina bifida should be delivered at a hospital with neonatal intensive care facilities and personnel capable of managing the spine defect and any immediate complications.[62] Because individuals with an NTD are at risk of developing a severe, potentially life-threatening allergy to latex, clinicians handling the infant should wear latex-free gloves.[63]

Fetal surgery (*in utero* repair)

Isolated open spina bifida often results in permanent neurological damage. Observations are consistent with a two-hit hypothesis in these fetuses. The first 'hit' is the defect itself, and the second comes from continued exposure to amniotic fluid.[64] An experimental evidence from both animal and human studies suggests that early gestational repair of open spina bifida may help preserve neurological function that might be lost due to *in utero* mechanical and chemical trauma. Animal studies involving primates, rats, and pigs have demonstrated that, compared to an untreated group, surgical closure successfully preserved neurologic function.[65–67]

Moreover, several investigators theorized that antenatal closure or coverage of the spine defect might prevent some of the neurological damage. Recently, both open surgical closure and laparoscopic techniques are being evaluated. Harrison's group, by using the fetal sheep model, has shown that repair of induced fetal spine defects prevent tissue damage and improve neurological function.[68] Bruner *et al.* described four human fetuses whose open lower spine defects were covered endoscopically with a maternal skin graft at 22–24 weeks.[69] It was hoped that this would prevent herniation of the hindbrain into the foramen magnum with obstruction and ventriculomegaly, the Arnold–Chiari malformation. They also compared 10 fetuses that underwent open surgical repair at 26–30 weeks with 20 fetuses without antenatal repair.[70] The surgically treated fetuses had a significantly decreased need for ventriculoperitoneal shunt placement after delivery. Johnson *et al.* at the Children's Hospital of Philadelphia (CHOP) also suggests that a reversal of the hindbrain herniation and a decreased incidence of neonatal ventriculoperitoneal shunting for hydrocephaly can be achieved.[71]

Open maternal–fetal surgery for NTD was initially undertaken at four centers in the USA as an investigative procedure under the guidance of institutional review boards. Many centers believe the procedure to be an innovative therapy that should not be ethically withheld. However, a survey of almost 1000 members of the Society for Maternal–Fetal Medicine indicated that 56% felt the procedure has still not been validated.[72]

Fetal surgical repair of open spina bifida exposes the mother to the risks of anesthesia, hemorrhage, chorioamnionitis and sepsis, thrombosis, tocolytic induced pulmonary edema, and uterine rupture. Additionally, preterm labor, preterm premature rupture of membranes, and oligohydramnios may occur in up to 50% of the patients.[73] Because of concerns about the safety and unproven benefits, fetal surgery for the correction of open spina bifida should be considered investigational. This surgery should only be conducted in a collaborative research setting in highly specialized centers.[74] The randomized trial has begun in the face of strong physician and patient belief that maternal–fetal surgery for NTD is a proved and beneficial technique. If clinical outcomes are not improved by the intervention, future open surgical procedures for this condition should be abandoned.[75] It also remains controversial because spina bifida is not a lethal defect.

Management

Although recent reports indicate that NTDs *in utero* repair may improve neurologic function and reduce morbidity from hydrocephalus and the Arnold–Chiari malformation by reversal of the hindbrain herniation component, the treatment of NTDs has been performed by postnatal surgical management. Postnatal surgery is aimed at covering the exposed spinal cord, preventing infection, and treating hydrocephaly with a ventricular shunt. Steinbok *et al.* reported a 91% shunt rate in 101 children after minimum follow-up period of 8.6 years.[76] The CHOP published shunt rates among 189 children

treated for spina bifida between 1983 and 2000.[77] One hundred percent (35/35) of children with thoracic level lesions received shunts, compared with 88% (100/114) of children with lumbar lesion and only 68% (27/40) of children with lesions confined to the sacrum. In recently treated patients, the upper level of the spina bifida lesion appears to be a major determinant of the need for shunt placement. Fewer neurosurgeons are automatically placing shunts at the same time as the spinal lesion is closed.

Prevention

The risk of having an NTD pregnancy can be reduced by raising folic acid consumption around the time of conception.[78–80] But how much folic acid supplementation is enough to prevent NTDs is still controversial. Women in Western countries typically have a baseline folate level of 5 ng/ml (normal range, 6–20 ng/ml).[81] The Food and Drug Administration in the USA established standard fortifying cereal and grain products such as cereal, bread, rice, and pasta with folic acid. By putting 140 μg of folic acid into each 100 g of grain products, it was established that the folic acid intake would increase 100 g per day.[82] Although women of reproductive age should be advised to ingest a diet that includes folate-rich foods, several studies have shown that diet alone is not effective in increasing serum folate levels. Therefore, folic acid supplementation should be encouraged.

The ingestion of supplement 0.2 mg of folic acid each day would reduce the incidence of NTDs by only 20%.[81] These calculations are supported by data from the US Public Health Service that confirm that since the grain fortification began the incidence of NTDs in the USA has decreased by only 19%.[83] It is recommended that women of reproductive age take 0.4 mg of folic acid supplement each day. This would reduce the incidence of NTDs by 36%. Intake of a 4 mg supplemental dose is recommended for women with high risk for an offspring with NTDs. For example, if previous pregnancy has been complicated by an NTD, the mother's intake of folic acid supplement should be 4 mg per day in the next pregnancy, starting at least 4 weeks before conception and continuing through the first 3 months of pregnancy.[84] This would reduce the incidence of NTDs by 82%. A 5-mg/day supplement dose is predicted to reduce the incidence of NTDs by 85%.[81] Although folic acid is considered non-toxic even at very high doses and is rapidly excreted in the urine, there seems to be minimal risk associated with a high supplementation of 5 mg of folic acid per day. Supplementation of folic acid could mask the symptoms of pernicious anemia. However, folic acid cannot mask the neuropathy typical of this diagnosis. Currently, 12% of patients with pernicious anemia present with neuropathy alone.[85] With folic acid supplementation, this proportion may be increased, but there is no evidence that initiating treatment after the development of a neuropathy results in irreversible damage.[86]

The March of Dimes contracted the Gallop Organization to conduct a random-digit-detailed telephone survey of a national sample of 2001 women aged 15–45 years to assess knowledge about folic acid use.[87] Less than one-third of women of childbearing age consume a daily supplement containing folic acid. Only 13% of women knew that folic acid helps prevent birth defects, and only 7% knew that folic acid should be taken before pregnancy.

Without folic acid supplementation, the empirical recurrence risk after one affected child is 3–4%, and after two affected children it is 10%. With supplementation, the risk after one affected child is less than 1%.[14]

In humans, the only source of folic acid is the diet, and absorption occurs primarily in the proximal jejunum. Before folic acid can be absorbed, it must be reduced to the monoglutamate form.[88] Pancreatic conjugates within the intestine are responsible for this process. The activity of conjugate is decreased by anticonvulsants, oral contraceptives, alcohol, and sulfa drugs. So, women taking antiepileptic agents have decreased absorption of folic acid resulting in folic acid deficiency.[89–91]

Folic acid supplementation may not decrease the risk of NTDs in women with high first-trimester blood glucose levels, or high first-trimester maternal temperature, or in women who take valproic acid. In women with high glucose levels and high maternal temperature, the exact mechanism is unknown. First-trimester valproic acid use results in a 1–2% risk of having a fetus with spina bifida, but the mechanism may be different from that of other antiepileptic agents.[92] Fetuses with aneuploidy or genetic syndromes may have NTDs as a result of their specific generic abnormality. These NTDs are not prevented by folic acid.

Prognosis and outcome

About 23% of the estimated NTD pregnancy is aborted.[93,94] Despite aggressive intervention, nearly 14% of all spina bifida neonates do not survive past 5 years of age, with the mortality rate rising to 35% in those with symptoms of brainstem dysfunction secondary to the Arnold–Chiari malformation.[95] Mothers who choose to continue the pregnancy must be prepared for a child who needs significant care and may incur high medical expenses. Unfortunately, many healthcare professionals have considered that the fetus with spina bifida would be mentally retarded, never walk, and suffer bladder and bowel incontinence. Recently, Mirzai *et al.* commented that the majority of children with myelomeningocele could have a normal IQ and a socially acceptable degree of continence, and be able to walk.[96] The greatest concern is whether the child with spina bifida will ever walk. In a 25-year

follow-up of 71 patients treated at birth in an aggressive, non-selective manner, Bowman *et al.* observed that 46% of young adults (33/71) ambulated the majority of the time (75–100%).[62] An additional 13% (9/71) ambulated 25–50% of the time. Forty-one percent (29/71) ambulated only with the aid of a wheelchair. When stratified by lesion level, patients with lower defects were more likely to ambulate the majority of the time. The next problem of the fetus with spina bifida is intelligence. Bowman *et al.* reported that 85% of the 71 young adults followed by their group were attending or had graduated from high school and/or college, and 63% attended regular classes.[62] Forty-five percent were actively employed, and almost 10% worked as volunteers. Most of the 71 patients lived with their parents, although 11 lived independently and two were married. Mirzai *et al.* noted that 60% of their young adults had normal IQ and development.[96] However, a normal IQ was seen in 76% without hydrocephaly. McLaurin *et al.* reported that 70% of myelomeningocele had a normal IQ.[97] Steinbok *et al.* observed that 58% of their cohort attended public school, and were in the appropriate grade for their age.[76] So, most children with spina bifida are not mentally retarded. Regarding bladder and bowel incontinence, Bowman *et al.* noted that 85% of their young adults (60/71) used clean intermitted catheterization (CIC), and 90% of them (54/60) performed their own catheterization. For those patients on CIC, 15% always had urinary continence, 68% were dry the majority of the time (75–100%), and 7% were dry 50% of the time. Fifty-two percent of the young adults reported bowel control the majority of the time, and 52% reported 100% social bowel continence.[62] Steinbok *et al.* reported 75% social continence of urine, defined as the ability to remain dry and odor-free without the use of a diaper, and 86% social continence of bowel.[76]

It should be obvious from these reports that most affected children will grow into young adults with normal intelligence, walking, and with social continence of both bladder and bowel. Bruner and Tulipan emphasized that, although a small number of affected children would experience devastating sequelae, equal number would be apparently normal, and prenatal imaging is becoming increasingly sophisticated in identifying the extent of disease and likely long-term outcomes.[98]

Table 57.4 Estimated incidence of neural tube defects based on specific risk factors in the United States[53]

Population	Incidence per 1000 Live births
Mother as reference	
General incidence	1.4–1.6
Women undergoing amniocentesis for advanced maternal age	1.5–3.0
Women with diabetes mellitus	20
Women on valproic acid in first trimester	10–20
Fetus as reference	
1 sibling with NTD	15–30
2 siblings with NTD*	57
Parent with NTD	11
Half sibling with NTD	8
First cousin (mother's sister's child)	10
Other first cousins	3
Sibling with severe scoliosis secondary to multiple vertebral defects	15–30
Sibling with occult spina dysraphism	15–30
Sibling with sacrococcygeal teratoma or hamartoma	≤15–30

NTD = neural tube defect.
*Risk is higher in British studies. Risk increases further for three or more siblings or combinations of other close relatives.

Recurrence risk

Several types of NTDs appear to have a unique recurrence risk. Hall *et al.* reported 7.8% recurrence risk with high spina bifida, 0.7% with low spina bifida, 2.2% with anencephaly, and no increase risk for craniorachischisis, encephalocele, or multiple defects.[99] Main and Mennuti reported the estimated incidence of NTDs based on specific factors in the USA (Table 57.4).[5] The common risk factor, family history, varies with the underling population risk. The recurrence risk was more than 10 times greater than the rate in the general population.

58 Basic background of congenital anomalies: congenital heart diseases and lung diseases

T. Kanzaki

Epidemiology

Congenital heart disease (CHD) is the most common severe congenital abnormality with an incidence of about 8.8 in 1000 live births. Epidemiologic studies that have excluded patent ductus arteriosus in premature infants have suggested an overall lower incidence of CHD (3.7 in 1000 live births).

Table 58.1 Comparison of disease seen in infant and fetal series

Diagnosis	Brompton (%)	NERICP (%)	Fetal (%)
Ventricular septal defect	15.4	15.7	5
Complete transposition	10.4	9.9	2
Tetralogy of Fallot	9.9	8.9	3
Coarctation	10.5	7.5	3
HLHS	3.7	7.4	11
Mitral atresia	0	0	5
Critical aortic stenosis	1.1	1.9	4
AVSD	3.9	5.0	17.5
Pulmonary stenosis/atresia	4.9	6.4	5
Atrial septal defect	0.5	2.9	0
TAPVC	3.6	2.6	< 1
Cardiomyopathy	2.7	2.6	4
Tricuspid atresia	4.7	2.6	4
Double-inlet ventricle	4.3	2.4	2
Double-outlet ventricle	3.0	1.5	3
Trunk	2.1	1.4	1.5
Ebstein's malformation	0	0	7
Tumor	0	0	1
Corrected transposition	0.8	0.9	< 1
Miscellaneous	11.3	10.4	< 1

AVSD, atrioventricular septal defect; Brompton, Royal Brompton Hospital, London; HLHS, hypoplastic left heart syndrome; NERICP, New England Infant Cardiac Care Program; TAPVC, totally anomalous pulmonary venous connection

Table 58.2 Risk factors for CHD

Fetal
Chromosomal abnormalities
Extracardiac anatomic abnormalities
Non-immune hydrops fetalis
Fetal cardiac arrhythmia
Maternal
Family history of CHD
Maternal metabolic disorders
Maternal teratogen exposure

A clear difference in the proportion of individual anomalies between the fetus and the infant can be seen in Table 58.1.[1] This is because these are all lesions readily detectable during the screening four-chamber scan. In contrast, the rate of detection of ventricular septal defects, complete transposion and teratology of Fallot is lower than in infancy because these lesions are not readily detectable on routine scan. Nevertheless, CHD remains the most common severe abnormality in the newborn. Its prenatal diagnosis allows for better pregnancy counseling and improved neonatal outcome.

CHD and chromosomal abnormalities

Traditionally, the etiology of most congenital heart defects has been considered multifactorial, with interaction between genetic and environmental factors. Only about 10–15% of all congenital heart defects have been attributed to known chromosomal abnormalities, genetic syndromes, and teratogenic embryopathies. The risk factors for CHD can be grouped into two main categories, fetal and maternal (Table 58.2).

The frequency of chromosomal abnormalities in infants with CHD has been estimated as 5–10% from postnatal data. Some studies have suggested that up to 39% of fetuses with congenital heart defects diagnosed by fetal echocardiogram at 18–20 weeks' gestation have a chromosomal anomaly, although chromosomal anomalies account for only 5% of congenital heart defects in liveborns. This discrepancy is attributed to *in utero* losses of aneuploid fetuses.

Cardiac defects tend to be specific common chromosomal abnormalities and their associated congenital cardiac defects (Table 58.3).[2] In general, malformations of the right side of the heart are rarely associated with karyotypic abnormalities. The diagnosis of transposition of the great vessels and tricuspid atresia is not usually associated with chromosomal abnormalities. On the other hand, atrio-ventricular septal defect, perimembranous ventricular defect, tetralogy of Fallot, double-outlet right ventricle, and hypoplasitic left heart syndrome are associated with chromosomal abnormalities.

Table 58.4 is a list of the most common chromosomal abnormalities and their associated congenital cardiac defects.[2] Data obtained from postnatal studies suggest that the incidence of cardiac defects is 40–50% in trisomy 21, 25–45% in Turner's syndrome, and more than 90% in trisomies 13 and 18.

Single-gene disorders associated with CHD

Although the etiology of many syndromes remains unknown, approximately 3% of congenital heart defects are attributed to single-gene defects. Table 58.5 is a list of the more common genetic syndromes of unknown etiology and their associated cardiac and extracardiac features.[3]

Table 58.3 Congenital heart disease and associated chromosomal abnormalities

Cardiac defect	Fetuses, total	Aneuploid fetuses	Infants, total	Aneuploid infants
Atrioventricular septal defect	193	75	186	133
Ventricular septal defect	70	34	542	47
Hypoplastic left heart syndrome	168	10	108	3
Pulmonary atresia/stenosis	61	3	201	1
Transposition of the great arteries	22	0	119	0
Aortic atresia/stenosis	42	2	73	3
Tricuspid atresia	46	2	19	0
Truncus arteriosus	15	2	68	1
Coarctation of aorta	114	33	132	11
Tetralogy of Fallot/ Double-outlet right ventricle	86	19	159	20

Table 58.4 Incidence and type of congenital heart disease in chromosomal aneuploidy

Chromosomal abnormality	Incidence at live birth	Associated cardiac abnormality (%)	Common cardiac abnormalities
Trisomy 21	1:800	40–50	Atrioventricular septal defect, ventricular septal defect
Trisomy 18	1:8,000	> 90	Ventricular septal defect, double-outlet right ventricle
Trisomy 13	1:20,000	> 80	Ventricular septal defect, atrial septal defect
45,X	1:10,000	25–45	Coarctation of aorta, bicuspid aortic valve

Table 58.5 Single-gene disorders associated with congenital heart defects

Syndrome	Associated cardiac defects	Other anomalies detected prenatally	Inheritance
Holt–Oram	Septal defect, coarctation of the aorta, HLHS	Absent thumb, upper-extremity phocomelia, syndactyly	AD, sporadic
Noonan	Septal defect, pulmonary stenosis, patent ductus arteriosus	Cystic hygroma, micrognathia	AD
CATCH-22	Conotruncal heart defect	Cleft lip, cleft palate, microcephaly	AD
Ellis–van Creveld	Atrial septal defect, single atrium	Cleft lip, postaxial polydactyly, Dandy–Walker malformation	AR
Treacher–Collins	Septal defects, patent ductus arteriosus	Micrognathia	AD
Kartagener	Dextrocardia	Situs inversus, communicating hydrocephalus	AR
Kippel–Feil	Ventricular septal defect	Sacral agenesis	AD, sporadic
Williams	Aortic stenosis, septal defects	Unilateral renal agenesis, IUGR	AD, sporadic

AD, autosomal dominant; AR, autosomal recessive; HLHS, hypoplastic left heart syndrome; IUGR, intrauterine growth retardation

Table 58.6 Empiric estimation of recurrence risk for congenital heart defects

	Individual(s) affected			
Defect	One sibling	Two siblings	Mother	Father
Ventricular septal defect	3	10	6–10	2
Patent ductus arteriosus	3	10	4	2.5
Atrial septal defect	2.5–3.2	8	4–4.5	1.5
Tetralogy of Fallot	2.5	8	2.5	1
Pulmonary stenosis	2	6	4–6.5	1.5
Coarctation of the aorta	2–8	6	2	2
Aortic stenosis	2	6	13–18	3
Transposition of the great vessels	1.5	5		
Endocardial cushion defects	3	10		
Hypoplastic left heart	2	6		
Ebstain anomaly	1	3		
Pulmonary atresia	1	3		

Recurrence risk

In general, recurrence risk of 1–5% is estimated for the majority of congenital cardiac abnormalities. For the majority of cases the exact cause of the congenital heart defect is unknown, making it difficult to precisely predict whether the anomaly will occur again in a future pregnancy. Large population studies of isolated defects provide the most practical recurrence risks, though they may not always be applicable and their limitation should be outlined to the patients. In general, recurrence risks are higher in the child of the affected rather than the siblings, and increase significantly with each additional affected relative. Affected mothers are also at a higher risk of having affected offspring than affected fathers. These data are summarized in Table 58.6.[4]

59 Clinical and genetical approach to skeletal dysplasia

K. Ozono, N. Namba, Y. Miyoshi, K. Wada and T. Michigami

Introduction

Skeletal dysplasias comprise more than 200 diseases and are not infrequent as a whole. However, each of the skeletal dysplasias is rather rare and many pediatricians are unfamiliar with the recent advances in understanding of the pathogenesis and the medical management of these diseases. Skeletal dysplasias are clinically important, especially for the neonatologist since the respiratory complications sometimes result in neonatal death. Recent advances in the research on bone and cartilage metabolism have shed light on the molecular mechanisms of skeletal diseases and made a great contribution to the management of patients with skeletal dysplasia.[1–3] The identified genes responsible for skeletal dysplastic diseases are increasing in number (Table 59.1).[4–8] Importantly, several new techniques have been developed for diagnosis and treatment of patients with skeletal dysplasias.

Bone formation or skeletogenesis consists of two different pathways, membranous bone formation and enchondral bone formation. The former process is direct bone formation from mesenchymal cells without a cartilage mold. The skull is the representative bone formed via membranous bone formation. In contrast, most bones including long bones and vertebrae are formed by enchondral bone formation. Several important factors have been identified as being involved in this process and some of them are reviewed in this chapter.[1–7] Moreover, the defects of these factors lead to skeletal dysplastic diseases.

The manifestations of skeletal dysplasia are numerous. *In utero*, polyhydroamnios and growth retardation of fetus is often associated with skeletal dysplasias. After birth, respiratory difficulty is the primary issue to be solved in patients with severe skeletal dysplasias. Characteristic faces and disproportionate short stature are often the hallmarks of skeletal dysplasias in childhood. Extraskeletal features including hypoplastic hair, skin legions and immunological abnormality imply specific skeletal dysplasia.

The wide variation in phenotypic severity is one of the features of skeletal dysplasia. Sometimes the names of diseases are distinct to describe the difference in phenotype even when the same gene is responsible for the diseases. Such diseases are allelic and have similar features, although the severity and the survival rate are quite different. For example, mutations of the FGF receptor 3 (FGFR 3) gene are associated not only with achondroplasia, the most common chondrodysplasia, but also with thanatophoric dysplasia and hypochondroplasia.[9] Another example is the case of the defects in the type II collagen gene including hypochondrogenesis, spondyloepiphyseal dysplasia, Kniest and Stickler diseases.[10]

In general, phenotype is severe in patients with skeletal dysplasias found in the perinatal period, and long survival is not achieved in many of them mainly due to respiratory problems. Elucidation of the relationship between the skeletogenesis and lung development may lead to better treatments for severe forms of skeletal dysplasias. In contrast, the treatments for childhood cases of skeletal dysplasias have been improved such as growth hormone for achondroplasia, bisphosphonate for osteogenesis imperfecta and bone marrow transplantation for malignant osteopetrosis. Thus, the opportunity has increased for pediatricians to treat patients with skeletal dysplasia.

In this manuscript, we take an overview of some of the key players in the enchondral bone formation and their implication in skeletal diseases. We aim to help clinicians to manage patients with skeletal dysplasia with better understanding of the diseases. At first, molecular mechanisms of the proliferation and differentiation of chondrocytes in growth plate are reviewed. Then, recent advances in genetics and clinical aspects are described in several representative skeletal dysplastic diseases. Clinical approach to skeletal dysplasia is mentioned in the last part of the manuscript.

Table 59.1 Skeletal dysplasia and its responsible gene

1. *FGF receptor or FGF*	
Achondroplasia	FGFR3 (G1138A,C)
Hypochondroplasia	FGFR3 (C1659A,G; C1620A)
Thanatophoric dysplasia	FGFR3 (I, C742T; II, A1948G)
Pfeiffer syndrome	FGFR1 (C755G); FGFR2 (T1036C; G1037A)
Crouzon syndrome	FGFR2 (G1037A; T1036C,A; C1073G, etc.)
Jackson–Weiss syndrome	FGFR2
Apert syndrome	FGFR2 (C934G; C937G)
Beare–Stevenson cutis gyrata syndrome	FGFR2
Muenke craniosynostosis	FGFR3 (C749G)
Hypophosphatemic rickets, AD	FGF23
2. *Collagen*	
Osteogenesis imperfecta	COL1A1; COL1A2
Achondrogenesis type II	COL2A1
Hypochondrogenesis	COL2A1
Spondyloepiphyseal dysplasia	COL2A1
Kniest dysplasia	COL2A1
Stickler dysplasia	COL2A1; COL11A2
Stickler dysplasia type 2	COL11A1
Spondyloepimetaphyseal dysplasia (Strudwick type)	COL2A1
Multiple epiphyseal dysplasia type 2	COL9A2
Metaphyseal dysplasia (Schmid)	COL10A1
3. *Matrix protein*	
Pseudoachondroplasia	COMP
Multiple epiphyseal dysplasia	COMP
Shprintzen–Goldberg syndrome	FBN1
Keutel syndrome	MGP
Multiple epiphyseal dysplasia	MATN3
4. *Hormone, hormone receptor, signal transducer*	
Metaphyseal dysplasia (Jansen)	PTH/PTHrP receptor (gain)
Blomstrand chondrodysplasia	PTH/PTHrP receptor (loss)
Albright osteodystrophy	Gsα
McCune–Albright syndrome	Gsα
Vitamin D dependency type I	1-α-hydroxylase

Table 59.1 Continued

Vitamin D dependency type II	Vitamin D receptor
Osteoporosis-pseudoglioma	LRP5 (loss)
High bone mass	LRP5 (gain)
Familial expansile osteolysis	TNFRSF11A
Juvenile Paget's disease	OPG
5. *Enzyme*	
Hypophosphatasia	TNS alkaline phosphatase
Osteopetrosis	Carbonic anhydrase II, TCIGR1, CLCN7, GL
Pycnodysostosis	Cathepsin K
Smith–Lemli–Opitz syndrome	δ^7-sterol reductase
Mucopolysaccharidoses	Lysosome enzyme (Hurler, Morquio)
X-linked recessive chondrodydplasia punctata	Arylsulfatase E
Rhizomelic chondrodysplasia punctata	PEX7
Coffin–Lowry syndrome	RSK-2
Noonan syndrome	PTPN11
SEMD Pakistani type	PAPSS2
Osteolysis Torg type	MMP2
Wolcott–Rallison syndrome	EIF2AK3
OLEDAID	NEMO
6. *Transcription factors*	
Boston-type craniosynostosis	MSX2
Campomelic dysplasia	SOX9
Cleidocranial dysplasia	CBFA1
Saethre–Chotzen syndrome	TWIST
Polysyndactyly type II	HOXD-13
Greig syndrome	GLI3
Polydactyly type A	GLI3
Ulnar-mammary syndrome	TBX3
Holt–Oram syndrome	TBX5
Townes–Brocks syndrome	SALL1
Nail–patella syndrome	LMX1B
Tricho-rhino-phalangeal dysplasia type 1	TRPS1
Ellis–van Creveld	EVC
EEC syndrome	p63
Trichodentooseeous syndrome	DLX3
Leri–Weill dyschondrostosis	SHOX
7. *Others*	
Diastrophic dysplasia	Sulfate transporter (DTDST)
Achondrogenesis type IB	Sulfate transporter (DTDST)

Table 59.1 Continued

Atelosteogenesis type 2	Sulfate transporter (DTDST)
Craniometaphseal dysplasia	Pyrophosphate transporter (ANK)
Chondrodysplasia	Growth/differentiation factor-5
(Hunter–Thompson, Grebe)	(CDMP-1)
Osteosclerosis	SOST
Brachydactyly type C	CDMP-1
Camurati–Engelmann	TGFB1
SED tarda	SEDL (ER-Golgi transport)
Cartilage–hair hypoplasia	RMRP
Kenny–Caffey syndrome	TBCE (chaperone protein)
Multiple synostosis syndrome	Noggin
Spondylocostal dysostosis	DLL3
Brachydacyly A1	IHH
Progressive pseudorheumatoid dysplasia	WISP3
Brachydacyly B2	ROR2
Dyggve–Melchior–Clausen dysplasia	FLJ90130
Shwachman–Diamond	SBDS

Common mutations are described in parentheses.

Development of cartilage and bone

Enchondral bone formation is a multistep process where chondrocytes proliferate and differentiate step by step, resulting in layered structure, namely resting, proliferating, hypertrophic and calcifying zones (Figure 59.1).[3] After the extracellular matrix is calcified, bone tissue (primary spongiosa) replaces cartilage. During the chondrocytic differentiation, the main components of the matrix are changed from collagen type II to collagen type I via collagen type X. Recently, many molecules including SOX9, FGF receptor 3 (FGFR3) and parathyroid hormone-related peptide (PTHrP) have been found to play important roles in the process.[1–3] These integrated networks of such bioactive factors tightly control enchondral bone development in the limb. Moreover, the genes encoding these molecules are responsible for several types of skeletal dysplasias. The process of chondrocytic differentiation is terminated by the death of hypertrophic chondrocytes, followed by blood vessel invasion, which promotes replacement of the cartilaginous matrix by the primary spongiosa.

The first step of chondrocytic differentiation or chondrogenesis is the mesenchymal cell condensation of undifferentiated progenitor cells. The differentiation of mesenchymal precursor cells into chondrocytes requires a transcription factor, Sox9.[11,12] Sox9 is a member of the Sox family of transcription factors that contain high mobility group (HMG)-box DNA-binding domain. Sox9 upregulates the expression of characteristic cartilaginous matrix genes such as collagens type II, IX, and XI, and aggrecan. In humans, haploinsufficiency of the Sox9 gene causes campomelic dysplasia (MIM 114290), which is characterized by deformities of long bones.[13] Most affected neonates die from respiratory failure due to hypoplastic tracheal and rib cartilage. Interestingly, some XY patients with campomelic dysplasia exhibit male-to-female sex reversal because Sox9 is involved not only in chondrogenesis but also in mammalian sex determination as a downstream regulator of the transcription factor, SRY.

FGFR3, as the other FGFRs, is a membrane bound protein, consisting of three immunoglobulin-like domains in the extracellular portions, a transmembrane domain and two tyrosine kinase domains in the intracellular portion.[14] FGFR3 is expressed in the proliferating chondrocytes. Its ligands, most importantly FGF18, bind to the FGFR3 and activate the receptor by its autophosphorylation and the phosphorylation of other substrate proteins.[15] The major signaling pathways of FGFR3 are thought to be the mitogen activating protein kinase (MAPK) pathway and the STAT-1 pathway. These signals mediate the inhibitory effects of FGFs on the proliferation and differentiation of chondrocytes.

The importance of FGF signaling in skeletal development was first revealed with the discovery that a point mutation in the transmembrane domain of FGFR3 causes achondroplasia (MIM 100800).[14] The abnormality of the FGFR3 gene is also associated with hypochondroplasia (MIM 146000), thanotophoric dysplasia (MIM 187600), and severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN) syndrome.[16]

PTHrP was initially discovered as a causal factor of humoral hypercalcemia of malignancy.[17] However, gene-targeting experiments have revealed that PTHrP plays an important role in chondrogenesis via a local action.[18] PTHrP-null mice, for example, exhibit a severe disorder of enchondral bone formation, characterized by shortened bones and premature maturation and ossification of the cartilaginous tissues.[19] Mice lacking the parathyroid hormone (PTH)/PTHrP receptor exhibit similar phenotypes. PTHrP and PTH, the latter of which is one of the main regulators of calcium and bone metabolism share the PTH/PTHrP receptor. Therefore, the PTH/PTHrP receptor mediates both the endocrine actions of PTH and the auto/paracrine actions of PTHrP. The PTH/PTHrP receptor is mainly expressed in the transitional zone between proliferating and hypertrophic cells (i.e., the prehypertrophic zone) in growth plate. PTHrP regulates the transition from proliferation to differentiation in chondrocytes.

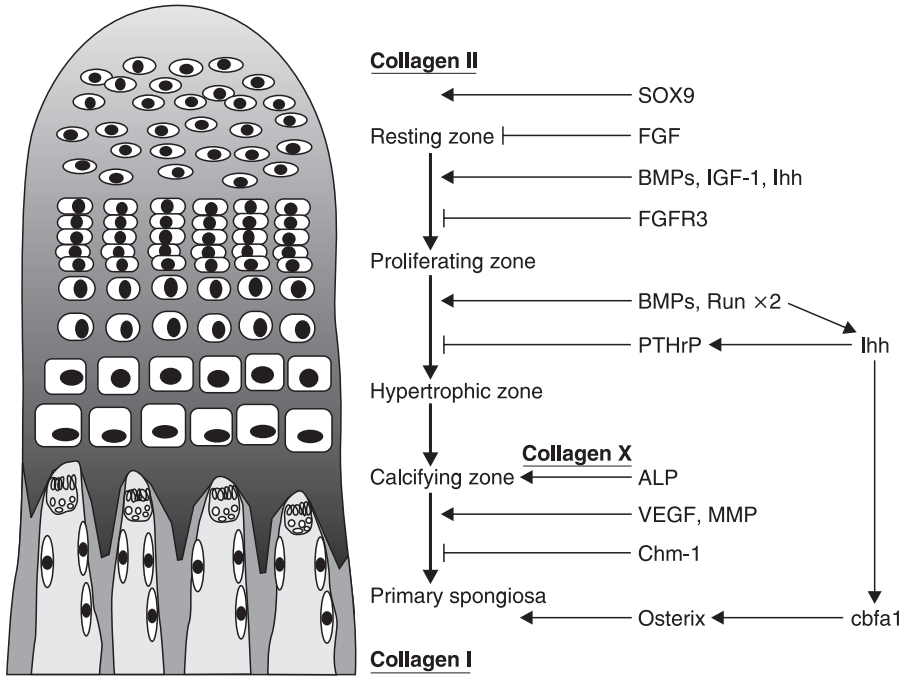

Figure 59.1 Enchondral bone formation. Chondrocytes form the layer structure according to the stage of differentiation in growth plate and eventually cartilage is replaced by bone matrix, primary spongiosa. In the process of the enchondral bone formation, chondrocytes proliferate and differentiate into hypertrophic chondrocytes, then matrix is calcified. The main matrix proteins which are underlined are changed from collagen type II to collagen type I via collagen type X. Many molecules including SOX9, PTHrP, and FGFR3 have been found to play an important role in the process as shown in the figure. FGF, fibroblast growth factor; BMP, bone morphogenic protein; IGF-1, insulin-like growth factor; Ihh, Indian hedgehog; FGFR3, FGF receptor 3; PTHrP, PTH-related peptide; ALP, alkaline phosphatase; VEGF, vascular endothelial growth factor; MMP, matrix metaroproteinase; Chm-1, chondromodulin-1.

Indian hedgehog (Ihh), a member of a family of proteins that are important for embryonic patterning, is highly expressed in the prehypertrophic zone and in the upper hypertrophic chondrocytes.[20,21] Actually, Ihh is secreted by prehypertrophic and early hypertrophic chondrocytes. The mice Ihh–/– show abnormal chondrocytic differentiation and a failure to specify appendicular perichondrial cells to the osteoblast lineage.[22] Ihh induces the expression of PTHrP and inhibits differentiation of hypertrophic chondrocytes followed by the delay of the mineralization of cartilage matrix. This effect of Ihh on chondrocytic differentiation is mediated by increasing PTHrP production in the growth plate. Because PTHrP keeps chondrocytes in the proliferative pool and suppresses Ihh production, PTHrP and Ihh establish a negative-feedback loop that maintains a balance of chondrocyte proliferation and differentiation.[22] Ihh is also a potent stimulator of chondrocyte proliferation, and conversely an inhibitor of chondrocyte maturation.[23] In this sense, Ihh has the positive effect on normal chondrocyte proliferation in a PTHrP-independent manner. Heterozygous missense mutations in the Ihh gene have been recently identified as a cause of autosomal dominant form of brachydactyly type A1 (MIM 112500).[24] This type of brachydactyly is characterized by the shortening or the absence of middle phalanges.

Runx2, also called cbfa1, belongs to the Runt transcription factor family.[25–27] Runx2 was initially discovered as an essential molecule for osteoblast differentiation.[25–27] It has been shown that inactivating mutations of one allele of the human Runx2 gene cause cleidocranial dysplasia (MIM 119600).[25] However, further experiments revealed that Runx2 is also expressed in chondrocytes, and severe delay of chondrocyte maturation is found in genetically manipulated mice lacking this factor.[28]

Hypertrophic chondrocytes are the most characteristic in shape and produce the specific matrix protein, collagen type X. Then, the matrix is calcified and replaced by bone tissue. In other words, an avascular cartilage template is reconstructed into highly vascularized bone tissue. In contrast to immature chondrocytes which secrete angiogenic inhibitors, hypertrophic chondrocytes produce angiogenic stimulators such as vascular endothelial growth factor (VEGF) and FGF, and become a target for capillary invasion.[29] The invasion of blood vessels is critical in the last stage of chondrocyte maturation. The mammalian growth plate is highly hypoxic and expresses the transcription factor hypoxia-inducible factor 1 (HIF-1), which belongs to the PAS subfamily of bHLH (basic helix–loop–helix) transcription factors and is known to induce the VEGF expression in many tissues and cells.[30] HIF-1 is not

sufficient to induce VEGF expression in cartilage or other factor(s) block the inducible activity of HIF-1 before the maturation of chondrocytes becomes complete.

The degradation of calcified cartilage matrix is another important event for enchondral bone formation. During hypertrophic change, chondrocytes synthesize type X collagen, which is associated with denaturation and loss of type II collagen resulting from increased collagenase activity. The transcription factor Cbfa1 has been shown to regulate expression of matrix metalloproteinase (MMP) 13 (collagenase-3).[31] MMP-9 is also an important enzyme for matrix degradation.[32] Remarkably, inactivation of matrix metalloproteinase-9 (MMP-9) resulted in bone phenotype similar to that found in VEGF-knockout mouse, suggesting the involvement of proteinases as well as VEGF in the processes of vascular invasion in growth plate and endochondral ossification. Indian hedgehog plays an important role in skeletal angiogenesis and calcification of cartilage.[33]

As described in this section, enchondral bone formation is elaborately regulated by many factors such as transcription factors, growth factors, enzymes and matrix proteins. Moreover, the defect in the regulation leads to dysplastic bone and cartilage formation both in humans and mice.

Clinical and genetical aspects of skeletal dysplasias

Skeletal dysplasias associated with FGFR abnormality

The abnormality of FGFR3 gene is associated with achondroplasia, hypochondroplasia, thanatophoric dysplasia and the most rare form, SADDAN.[14–16] Its cognate ligand remains unclear, but FGF18, 17 and 8 are likely to elicit its signal via binding to the FGFR3.[15] These ligands are produced in the perichondrium. The FGF family of proteins consists of at least 23 structurally related polypeptides that play a critical role in a variety of biological processes. The FGFRs represent a family of four tyrosine kinase receptors (FGFR1–4) that bind FGFs with variable affinity.

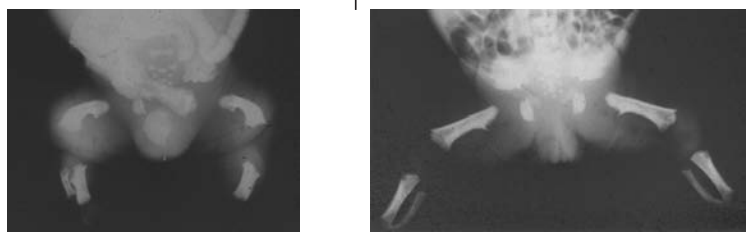
Achondroplasia is the most common form of rhizomeric dwarfism with a rate of 1 per 15,000–30,000 births. The disease is inherited in an autosomal dominant manner, but more than 90% of the cases are sporadic. Advanced paternal age is reported in sporadic cases. Its clinical features are short stature caused by rhizomelic shortening of the limbs, characteristic faces with frontal bossing and mid-face hypoplasia, exaggerated lumbar lordosis, and trident hand. As typical radiologic features, caudal narrowing of the interpediculate distance, rather than the normal caudal widening, and a notch-like sacroiliac groove are found in children with achondroplasia. Interestingly, the same mutation of the FGFR3 gene is the cause of achondroplasia in almost all patients (G to A transition at nucleotide 1138).[34,35] This mutation causes the substitution of amino acid 380 (Gly380Arg), and can be recognized by polymerase chain reaction (PCR) followed by digestion with restriction enzyme SfcI. The same mutation of FGFR3 was also found in Japanese patients with achondroplasia. The detection of this mutation is especially helpful in the diagnosis of neonatal patients with this disease. Other minor mutations are also reported (G to C at nucleotide 1138 and G to T at nucleotide 1123).

In our experience, some patients with achondroplasia are not recognized prenatally even when routine examination with ultrasonography is undertaken. This is partly because the disproportion develops more prominently after birth. In our study in which the relationship between age and clinical data (height, arm span and measurements of skeletal radiographs) were statistically analyzed in 27 achondroplasia patients with the G380R genotype, the height standard deviation score decreased with age. In making a clinical diagnosis of achondroplasia in early infancy, it should be noted that short stature and squared pelvis deformity are not prominent in some cases.[36]

To treat the short stature of patients with achondroplasia, recombinant human growth hormone (GH) has been administered. First-year response is typically a 2–3 cm increase in growth velocity in prepubertal children.[37] However, the effect of GH treatment on the final adult height is not conclusive so far. GH treatment, at least in the prepubertal period, seems to influence the degree of disproportion. The activating mutation of FGFR3 promotes apoptosis of chondrocytes. Insulin-like growth factor (IGF)-I, which is a mediator of GH, may reduce apoptosis of chondrocytes expressing mutated FGFR3.[38] More recently, it has been reported that c-type natriuretic peptide is effective to prevent shortening of long bones in the mice model for achondroplasia.[39]

Achondroplasia can be associated with respiratory difficulty in early infancy and childhood, although the degree of the difficulty is usually not so severe. One of the respiratory difficulties is manifested as sleep apnea syndrome.[40,41] Although a large-scale study on sleep apnea syndrome in achondroplasia is lacking, but approximately 30% of patients with achondroplasia suffer from sleep apnea syndrome. In a serious situation, sleep apnea syndrome leads to hypoxia, pulmonary hypertension, heart failure and sudden death. The causes of sleep apnea syndrome in achondroplasia are both obstruction of airway and failure of central control of respiration. The obstructive sleep apnea is derived from the small oral cavity with a relatively large tongue, hypertrophy of tonsilla and adenoid as well as weakness of trachea. Neurological problems including hydrocephalus and compression of the spinal cord due to a small foramen magnum are relatively common in achondrolasia and may cause central sleep apnea syndrome. Polysomnography is used

	Telephone receiver (femur)	Cloverleaf skull
Type I	+	+ or –
Type II	–	+



Type I Type II

Figure 59.2 Two types of thanatophoric dysplasia. Thanatophoric dysplasia types 1 and 2 are characterized by telephone receiver-like bended femur and straight femur, respectively as x-ray figures are shown in the bottom. Cloverleaf skull is often associated with type 2 and sometimes with type 1.

to make a diagnosis of sleep apnea syndrome. Symptomatic patients require tonsillectomy, adenoidectomy or continuous positive airway pressure therapy.

Thanatophoric dysplasia, a lethal form of dwarfism, is also caused by mutations of the FGFR3 gene. In histological analyses, the most characteristic feature in thanatophoric dysplasia is the protrusion of perichondrium into the growth plate. The growth plate is irregular and narrow, as in other chondrodysplasias. An anomaly of the brain (abnormal fissure in the temporal lobe) is also observed. Thanatophoric dysplasia is divided into two subtypes according to the finding of the shape of the femur (I, curved femur; II, straight femur) (Figure 59.2). A cloverleaf-like deformity of the skull is often associated with type II but may also be present in type I. The most common mutations in type I and II of thanatophoric dysplasia were reported to be Arg248Cys and Lys650Glu, respectively.

Hypochondroplasia is a relatively mild disease, manifested as short stature. The head is not affected. The spinal canal narrows in its caudal portion as is true in achondroplasia. Fingers are short, although hands are not of the trident type. Asn540Leu is reported to be the most common mutation found in this disease.

The other form in this family is called SADDAN, which stands for severe achondroplasia with developmental delay and acanthosis nigricans. The patients with SADDAN survive infancy without prolonged life-support measures. The FGFR3 mutation (A1949T, Lys650Met) occurs at the nucleotide adjacent to the TD type II (TD2) mutation (A1948G: Lys650Glu) and results in a different amino acid substitution in the kinase domain activation loop.

All these disorders are autosomally dominant, mainly sporadic, and are caused by gain-of-function mutations, leading to a constitutively active FGFR3. The degree of activation of FGFR3 correlates well with the severity of the chondrodysplasia; the mutated FGFR3 found in thanatophoric dysplasia is the most activated form. This relationship provides the first evidence for negative regulation of chondrogenesis by FGFR3. Several animal models have established that FGFR3 negatively regulates chondrocyte proliferation. MAPK is a major downstream effecter of FGFR3 activity. Indeed, chondrocytes expressing a constitutively active form of MEK, the MAPK activator, present an achondroplasia phenotype similar to that observed with constitutively active FGFR3. Conversely, blockade of MAPK activation rescues achondroplasia obtained with constitutively active FGFR3. In addition, it has been shown that FGFR3 represses chondrocyte proliferation through activation of the transcription factor STAT1 by a yet unknown mechanism.

Collagenopathy

Type I collagen is the most abundant protein in bone. This type of collagen is synthesized as the heterotrimer of procollagens a1(I) and a2(I). Heterozygous mutations in the two genes for procollagen a1(I) and a2(I). (*COL1A1* and *COL1A2*) have been found in patients with osteogenesis imperfecta (MIM 166200, 166210, 166220, 166230).[42,43] These mutations cause a change either in the structure of the protein or in the number of collagen molecules made. The severe forms of osteogenesis imperfecta are reported to have a glycine substitution within the Gly-X-Y amino acid repeat. Mutated collagens interfere with the formation of collagen fibrils. In contrast, null mutations of *COL1A1* cause the mild form of osteogenesis imperfecta.[44]

Osteogenesis imperfecta is characterized by low bone mineral density (BMD) with fragility, and frequent bone fracture leads to deformity of long bones and chronic bone pain. It was classified into four forms by Sillence *et al.*[45]: a dominant form with blue sclerae, type I; a perinatally lethal OI syndrome, type II; a progressively deforming form with normal sclerae, type III; and a dominant form with normal sclerae, type IV. However, type IV is rather heterogeneous and includes patients with a moderate to severe disease who do not fit type I or III. Thus, other types of OI (V, VI, and VII) without identifiable collagen type I mutations have been recently described.[43]

There is no curative treatment for osteogenesis imperfecta. However, the therapy using pamidronate, a derivative of bisphosphonate, has recently been developed and has successfully alleviated symptoms in children with OI. In short, cyclic intravenous administration of pamidronate improved BMD and reduced the frequency of bone fracture. However, there are few studies reporting the outcome measures of bisphosphonate therapy in children with OI. Glorieux *et al.* observed that in patients with severe osteogenesis imperfecta aged 3–16 years, intravenous pamidronate (mean annual dose 6.8 mg/kg) increased lumbar vertebral BMD by an average of 42% per year.[46] The same group also demonstrated that in children with OI types III or IV less than 2 years of age, a 12-month treatment with pamidronate at a mean dose of 12.4 mg/kg increased lumbar vertebral BMD by 86% to 227%. Recently, Astrom and Soderhall reported that monthly infusions of pamidronate for 2–9 years resulted in gradual increase in total body and lumbar spine bone density in children with OI.[47]

As another novel treatment for patients with severe osteogenesis imperfecta, transplantation of bone marrow cells containing adult mesenchymal stem cells has been attempted.[48] Mesenchymal stem cells can differentiate into multiple cell types present in several tissues, including bone, fat, cartilage, and muscle, making them ideal candidates for cell-based therapies. More recently, mesenchymal cell therapy using isolated mesenchymal stem cells has been reported.[49] In the report, donor marrow-derived mesenchymal cells were administered to treat six children who had undergone standard bone marrow transplantation for severe osteogenesis imperfecta. Five of six patients showed engraftment in one or more sites, including bone, skin, and marrow stroma, and had an acceleration of growth velocity during the first 6 months postinfusion.

Adult stem cells can be used after the *ex vivo* genetic manipulation to correct genetical disorders. For osteogenesis imperfecta, one study in which adeno-associated viral vectors were used to disrupt dominant-negative mutant *COL1A1* collagen genes in mesenchymal stem cells from patients with a severe form of osteogenesis imperfecta was reported.[50] It seems that the gene was successfully targeted in adult human stem cells.

Collagen types II, IX, X and XI are expressed in the cartilaginous tissue. Collagen type II specific to cartilage matrix is synthesized as the homotrimer of collagen *a*1(II). Mutations in the single gene for type II procollagen have been found in patients with type II achondrogenesis (MIM 200610)-hypochondrogenesis, spondyloepiphyseal dysplasia (MIM 183900), Kniest dysplasia (MIM 156550) and Stickler (hereditary arthro-ophthalmopathy) syndrome (MIM 108300).[51] The platyspondylic lethal skeletal dysplasias (PLSD), Torrance type (MIM 151210) was found to be caused by *COL2A1* mutations.[52] The platyspondylic lethal skeletal dysplasias is a heterogeneous group of chondrodysplasias characterized by severe platyspondyly and shortening of limbs. Interestingly, the most common form of PLSD is thanatophoric dysplasia (TD), which is caused by mutations in the *FGFR3* as described previously.

Type X collagen is a homotrimeric, short-chain, nonfibrillar extracellular matrix component. The expression of type X collagen is restricted to hypertrophic chondrocytes. The mutation in the *COL10A1* is associated with Schmid metaphyseal chondrodysplasia (MIM 156500).[53] It is reported that Stickler syndrome type 2 with a different vitreo-retinal phenotype from that of type 1 is caused by a mutation in the *COL11A1* (MIM 604841). Multiple epiphyseal dysplasia (MIM 132400) is caused by a mutation in the *COL9A1* or the *COMP* gene.[54,55] The *COMP* gene is also responsible for pseucoachondroplasia (MIM 177170), which is one of the most frequent skeletal dysplasias and resembles achondroplasia except for head and face.[55]

Other chondrodysplasias

The chondrodysplastic disease, achondrogenesis is characterized by severely impaired chondrogenesis with extremely short limbs and narrow thorax, leading to the perinatal death of patients with this disease. Fetal hydrops and hydroamnios are also associated with achondrogenesis. Although achondrogenesis has been subtyped in several ways, the definition reported by Borochowitz *et al.*, based on detailed analyses of clinical, radiological and morphological studies, seems to have received consensus: type I (MIM 200600) A (Houston–Harris), IB (Fraccaro) and type II (Langer–Saldino, MIM 200610). A histological analysis of cartilaginous tissue is very helpful, especially to make the diagnosis of achondrogenesis type IB.[56] Achondrogenesis type IB is caused by the mutations of the diastrophic dysplasia (*DTDST*) gene.[57]

The *DTDST* gene encodes a sulfate transporter, which is required for the synthesis of sulfated proteoglycans in cartilage with other name, *SLC26A2*.[58] It is not surprising that defects of this gene result in a chondrodysplasia phenotype, although the precise mechanism whereby the impaired sulfation of proteoglycans causes abnormal enchondral ossification

remains to be elucidated. Several mutations of the *DTDST* gene were reported in patients with achondrogenesis type IB, the most severe form, atelosteogenesis type II or neonatal osseous dysplasia (MIM 256050), an intermediate form and the mildest form of the diseases, diastrophic dysplasia (MIM 222600). The recessive multiple epiphyseal dysplasia (MIM 226900) is also caused by the mutations of *DTDST*. Homozygous mutant mice for the gene were characterized by growth retardation, skeletal dysplasia and joint contractures, thereby recapitulating the essential aspects of the diastrophic dysplasia phenotype in humans. The skeletal phenotype included reduced toluidine blue staining of cartilage, chondrocytes of irregular size, delay in the formation of the secondary ossification center and osteoporosis of long bones.

The cartilage hair hypoplasia (CHH, MIM 250250) or spondylometaphseal dysplasia McKusick type is characterized by disproportionate short stature, hypoplastic hair, ligamentous laxity, defective immunity, hypoplastic anemia, and neuronal dysplasia of the intestine (Hirschsprung disease). CHH was found to be caused by mutations in the ribonuclease mitochondrial RNA processing gene (*RMRP*).[59] The untranslated *RMRP* gene encodes the RNA component of a ribonucleoprotein endoribonuclease. Normally the RNase MRP complex is involved in multiple cellular and mitochondrial functions.

The difference between the Japanese and other ethnic groups is remarkable in terms of the mutations and polymorphisms in *RMRP* gene. Four novel mutations were reported in two patients with typical and atypical CHH.[60] A patient with typical CHH had a 17-bp duplication at +3 and a *de novo* 182G > A, 218A.G. The other patient with atypical CHH had a 17-bp insertion at −20 and a 218A ? G.

The X-linked spondyloepiphyseal dysplasia tarda (SEDT; MIM 313400) has the features consisting of disproportionately short trunk, short stature, characteristic radiological findings of the spine (posterior hump, end plate sclerosis, and disk space narrowing) and the hips (short and thick femoral necks), and positive family history. The linkage analyses revealed that the *SEDL* gene on the X chromosome is responsible for the disease.[61] The *SEDL* gene product, known as sedlin is a 140 amino-acid protein with a putative role in endoplasmic reticulum-to-Golgi transport. However, function of sedlin in bone and mineral metabolism remains to be characterized.

Leri–Weill dyschondrosteosis (LWD) (OMIM 127300) is caused by the haploinsufficiency of the short stature homeobox-containing (*SHOX*) gene.[62,63] LWD is an autosomal dominant form of mesomeric dysplasia first described by Leri and Weill in 1929. Patients with this condition demonstrate short stature due to shortening of the lower legs and Madelung deformity of the forearm. The abnormality of the *SHOX* gene also causes Turner skeletal features and a certain proportion of idiopathic short stature. The *SHOX* gene was cloned from the pseudoautosomal region of the sex chromosome (Xp22 and Yp11.3) and affects the adult height. It is exclusively expressed in the first and second pharyngeal arches and in the developing distal limb bones of the human embryo. The expression of SHOX is in the hypertrophic zone and less intensely in the proliferating zone in growth plate. Although the function of SHOX in growth plate is to be elucidated, it may be involved in the fusion of growth plate and affect the growth at the pubertal stage.

Abnormality in PTH/PTHrP receptor or G protein

The family of G protein has many members, and Gsα is the representative protein which has been shown to cause bone diseases.[64] G protein is a signal effector molecule, typically forming heterotrimeric guanine nucleotide-binding proteins. Mutations in Gsα protein are divided into two groups, gain of function mutation and loss of function one. McCune–Albright syndrome and Albright osteodystrophy combined with pseudohypoparathyroidism are the diseases caused by these mutations, respectively.[65]

The PTH/PTHrP receptor is a G protein-coupled membrane-bound receptor and its best-characterized second messenger is cAMP. Although cAMP activates protein kinase A (PKA) as a downstream of PTHrP receptor, it is still not clear what molecules responsible for delay of chondrocytes maturation serve as the substrates of PKA. In the growth plate, the PTH/PTHrP receptor mRNA is expressed in prehypertrophic chondrocytes at higher levels. The critical role of the PTH/PTHrP receptor in endochondral bone development is highlighted by the discovery that two rare forms of chondrodysplasias, Blomstrand lethal chondrodysplasia (MIM 215045) and Jansen's metaphyseal chondrodysplasia (MIM 156400) are caused by mutations of this receptor. Blomstrand lethal chondrodysplasia is caused by inactivating mutations of the PTH/PTHrP receptor, while the mutated receptors found in Jansen's metaphyseal chondrodysplasia are constitutively active.[66,67] The former disease is characterized by prenatal lethality, premature and abnormal bone mineralization and ossification, and shortened limbs. Endochondral bone formation is markedly advanced in fetuses with Blomstrand chondrodysplasia, and the columnar proliferative layer in the mutant growth plate is virtually absent. The disease appears to have an autosomal recessive pattern of inheritance. Jansen's metaphyseal chondrodysplasia is an autosomal dominant disorder characterized by short-limbed dwarfism secondary to severe abnormalities of the growth plate and hypercalcemia. The laboratory findings in patients with Jansen's metaphyseal chondrodysplasia are reminiscent of primary hyperparathyroidism. According to the original report, the genomic DNA from 10 JMC patients has been examined: seven patients had the H223R heterozygous nucleotide exchange, and three patients had

distinct heterozygous mutations in the PTH/PTHrP receptor (T410P, T410R, and I458R).

When chondrocytes are forced to express either PTHrP or an activated form of its receptor, cartilage maturation is dramatically inhibited and bone formation delayed. Mice lacking either PTHrP or its receptor, in contrast, exhibit dwarfism of their long bones due to premature chondrocyte maturation. Therefore, PTHrP signaling negatively regulates the switch from a proliferative immature chondrocyte to a postproliferative mature hypertrophic chondrocyte.

More recently, a heterozygous missense mutation Arg150Cys has been identified in the PTH/PTHrP receptor gene of two patients with enchondromatosis or Ollier and Maffucci diseases (MIM 166000). Enchondromas are common benign cartilage tumors of bone that can occur as solitary lesions or, in enchondromatosis, multiple lesions. This type of mutated receptor is constitutively active *in vitro*. However, others reported that no mutations of the PTH/PTHrP receptor gene were found in patients with enchondromatosis.

Pseudohypoparathyroidism, especially type Ia, is associated with the loss of function-type mutations in the Gsa gene (*GNAS1*).[65] In patients with the disease, no response to PTH is observed in the excretion of phosphate and cAMP. In contrast to McCune–Albright syndrome, the mutations are scattered along the entire gene, including missense mutations and deletions. This disease is inherited in a dominant fashion, and the mutation is found in a single allele. Albright hereditary osteodystrophy (AHO), which consists of short stature, shortening of the fourth and fifth metacarpals, round face, obesity and ectopic calcification is associated with pseudohypoparathyroidism type Ia (MIM 103580). Since the *GNAS1* gene is an imprinted gene, the transmission of the disease to the next generation is characteristic. Maternal transmission of Gsa mutations leads to AHO associated with resistance to parathyroid hormone (pseudohypoparathyroidism type Ia), while paternal transmission leads only to the AHO phenotype (pseudopseudohypoparathyroidism). Pseudohypoparathyroidism type Ib (MIM 603233) has the resistance to PTH only in kidney, and a region responsible for the disease is also associated with the *GNAS1* locus. PHP-Ib is caused by heterozygous mutations disrupting a long-range imprinting control element. Recently, deletions that remove the differentially methylated region encompassing exon NESP55 and exons 3 and 4 of the antisense transcript, those are located near *GNAS1* region. Thus, it is confirmed that epigenetic defects in the imprinted *GNAS1* cluster are associated with pseudohypoparathyroidism type Ib.[68]

McCune–Albright syndrome is characterized by three major symptoms, café au lait pigmentation, multiple fibrous dysplasia and endocrine disorders including precocious puberty, hyperthyroidism, autonomous adrenal hyperplasia and growth hormone secreting pituitary adenoma. This syndrome is caused by the somatic mutation in the *GNAS1* gene, leading to elevated levels of cyclic AMP in cells. This gene has a hot spot of mutation at Arg of codon 201 (Arg201His or Arg201Cys).[69] Since these mutations are somatic, mosaicism for a mutation in the *GNAS1* gene is found in patients with McCune–Albright syndrome. Cells obtained from the lesions with fibrous dysplasia secreted a significant amount of interleukin (IL)-6 and exhibited an impaired response of IL-6 secretion to IL-1 in patients with McCune–Albright syndrome.[70] In response to the elevation of cAMP, IL-6 is produced perhaps through the cAMP response element of the IL-6 gene promoter. Fibrous dysplasia is a focal and benign fibrous bone lesion, which is caused by the activating mutation in the *GNAS1* gene. Hypophosphatemic rickets is sometimes observed as a complication of McCune–Albright syndrome. Two hypotheses have been put forward to explain the pathogenesis of hypophosphatemic rickets associated with McCune–Albright syndrome. One of them supposes the hypersensitivity to PTH in the renal tubules due to the mutation in the *GNAS1* gene, based on the inhibitory effect of PTH via cAMP on phosphate transport in the kidney. The other hypothesizes humoral factor(s) from the bone lesions which inhibit(s) phosphate reabsorption. In fact, Riminucci *et al.* recently reported the elevated plasma FGF-23 levels in patients with McCune–Albright syndrome.[71]

Hypophosphatasia

Hypophosphatasia (MIM 146300, 171760, 241500, 241510) is characterized by the hypomineralization of bone associated with the impaired activity of tissue-nonspecific alkaline phosphatase (TNSALP).[72] Hypophosphatasia has diverse phenotypes, and is usually classified into five subtypes based on the age of onset and clinical features; perinatal, infantile, childhood, adult type, and odontohypophosphatasia.[73] The severity of the disease is generally well correlated with the onset of the disease, except for odontohypophosphatasia, where only the teeth are affected. The patients with the perinatal type of hypophosphatasia almost always die around birth due to impaired development of the lung and the severe hypomineralization of their bones. However, the classification of these subgroups is not definite, and there is diversity in the phenotype which forms so-called spectrum. For example, we have previously reported a patient who achieved long-term survival without respiratory failure in spite of having fetal onset.[74] Since these patients survive longer despite their fetal onset, we should pay more attention to take care of them and to genetic counseling. The presence of such a case may depend on the development of a diagnosis procedure or on the specificity of the genotype. However, this benign form of hypophosphatasia found in the Japanese patients is surmised to be associated with a specific mutation, F310L, whose product retained approximately 70% of its enzymatic activity. The relatively high activity of the mutant enzyme may contribute to this relatively mild form.

On the other hand, mutations found in the severe form of the disease do not tend to be associated with restricted positions, although the three-dimensional model study showed that most of the severe missense mutations were localized in crucial domains, such as the active site.[75] Elucidation of the molecular heterogeneity underlying hypophosphatasia may contribute to our understanding of the clinical heterogeneity observed in hypophosphatasia and the improvement of treatment, especially in patients with severe forms of hypophosphatasia.

The patients with the classical perinatal form of hypophosphatasia almost always die *in utero* or during the neonatal period. Therefore, the perinatal form is a synonym for the lethal form. The second most severe form, the infantile type of the disease, is still associated with high mortality because of the impairment of respiratory function and hypercalcemia.[76] The patients with other types of hypophosphatasia usually do not suffer from life-threatening complications.

To date, more than a hundred mutations have been reported in the TNSALP gene in patients with hypophosphatasia, mainly in Caucasians and Japanese.[77] However, the mutations are scattered in the whole coding region, and only a few mutations have been recognized to occur frequently in the gene. Moreover, although the relationship between the clinical features and the mutation of the corresponding gene has also been analyzed, only a few reports detected the positive correlation between the mutations and severity.[75] The mutations responsible for mild hypophosphatasia may not cause a complete loss of ALP function, suggested by several reconstruction experiments in which mutated ALP activity was examined.

Although hypophosphatasia is usually inherited in an autosomal recessive manner, autosomal dominant inheritance is also recognized in some families with the mild form of the disease. Interestingly, the mutations in these families have been reported to show the dominant negative effect on the wild-type ALP activity, as one of the remarkable results of the recent progress in molecular biology.[78]

The mechanism for which the defect of ALP activity causes hypomineralization is not fully understood. There are three main assumptions for the role of ALP in mineralization process. First, ALP increases local phosphate concentration, leading to the acceleration of mineralization. Second, ALP decreases the concentration of local pyrophosphate, a substrate of ALP and an inhibitor of mineralization. Finally, ALP controls gene expression including osteopontin through the increase in intracellular phosphate concentration and affects the mineralization.

In patients with the infantile form of hypophosphatasia, bone marrow cell transplantation was tried to avoid the expected poor prognosis.[79] The patient was given T-cell-depleted, haplo-identical marrow from her healthy sister. Chimerism in peripheral blood and bone marrow became 100% donor. The patient survived and some clinical improvement was observed. More experience with transplantation of bone marrow or mesenchymal stem cells is necessary before the cell-based therapy becomes standard as treatment of severe hypophosphatasia.

Craniometaphyseal dysplasia

Craniometaphyseal dysplasia (MIM 123000) is a genetic syndrome characterized by the sclerotic change of cranial and tubular bones that commonly present at a young age, often with facial abnormalities and otolaryngologic manifestations such as a conductive hearing loss. Craniometaphyseal dysplasia is defective in ANK, the pyrophosphate transporter.[80] Thus, this disease supports the inhibitory role of pyrophosphate in mineralization.

Diseases with high or low bone mineral density

BMD is determined by both genetic and environmental factors. The genetical approach has shown that multiple genes have effects on BMD. Recent developments in molecular genetics and genomics have dramatically increased a power to identify genes which affect BMD. The sclerosing bone dysplasias can be classified into two groups such as increased trabecular bone density (osteosclerosis) and a cortical bone thickening (hyperostosis). There are several diseases which belong to sclerosing bone dysplasias, e.g., osteopetrosis, pycnodysostosis, and osteopoikilosis.

Osteopetrosis characterized by a marked increase in bone mass is a heterogeneous disorder of the skeleton in several animal species.[81] In humans, the disease is inherited as either an autosomal dominant or autosomal recessive trait. The autosomal dominant form exhibits mild symptoms only in adults (McKusick MIM 166600). The autosomal recessive form consists of three types; a mild type (MIM 259710), a lethal type (MIM 259720) which is rare, and infantile malignant osteopetrosis (MIM 259700) characterized by severe symptoms such as diffuse osteosclerosis of all bones, extramedullary hematopoiesis associated with bone marrow failure, and sensorineurogenic impairment in infancy. It is caused by defects in bone resorption by osteoclasts, resulting in increased bone mass and narrowing of the bone marrow cavity. Impaired bone resorption, as seen in the various forms of autosomal recessive osteopetrosis (MIM 259700), can be due to mutations in a subunit of the vacuolar H^+ pump (*TCIRG1* gene) or to mutations in the chloride channel *CLCN7* gene in humans.[82,83] Another form of osteopetrosis is caused by carbonic anhydrase II deficiency, and is associated with renal tubular acidosis and cerebral calcification (MIM 259730).[84] Very recently, mutation in the *GL* gene, the gene responsible for spontaneous mouse gray-lethal whose phenotype is a coat color defect and severe autosomal recessive form of osteopetrosis, leads to severe recessive osteopetrosis in humans.[85] X-linked recessive anhidrotic ectodermal dysplasia with immunodeficiency, osteopetrosis, and lymphoedema (OL-EDA-ID, MIM300301) is caused by

hypomorphic mutations in NEMO, the regulatory subunit of the IKK (IkappaB kinase) complex encoded in the *IKBKG* gene.[86] Germline loss-of-function mutations in *IKBKG* are lethal in male fetuses.

Hematopoietic stem cell transplantation seems to be the most effective and rational therapy for malignant osteopetrosis at the moment, because it provides normal osteoclast precursors.[87] However, several kinds of treatment including high dose of active vitamin D and long-term therapy with interferon gamma (IFN-g), also have been reported to be effective.

Cathepsin K has been cloned as an osteoclast-specific cysteine protease. The abnormalities in this gene were reported in patients with pycnodysostosis (MIM 265800).[88] The characteristic features of this disease are disproportionate short stature, front-occipital prominence, high-arched palate, proptosis, a pointed nose, and sclerotic bones.

In addition to impaired bone resorption, increased bone formation can result in sclerosing bone disorders. Recently, it is reported that the increased TGF-β signaling results in Camurati–Engelmann disease (MIM 131300).[89] The increased bone formation in sclerosteosis (SOST MIM 269500)[90] and in Van Buchem disease (MIM 239100) turned out to be due to loss-of-function mutations of the *SOST* gene, most likely increasing bone morphogenetic protein signaling. In addition, osteoprotegerin and receptor activator of NF kappa B (RANK), whose gene is TNFRSF11A, are responsible for juvenile Paget's disease and familial expansile osteolysis.[91,92]

Infantile cortical hyperostosis (Caffey disease, MIM114000) is characterized by radiological evidence of cortical hyperostosis, soft tissue swellings, fever, and irritability.[93] Caffey disease was first reported in 1945 by Caffey and Silverman. Its principal features include acute inflammatory manifestations and the early onset time, usually in the first year of life. The cause of the disease remains unclear and the disease is self-limiting.

Further, it was recently shown that the gene encoding the low-density lipoprotein receptor related protein 5 (LRP5) is one of the regulators of peak bone mass in vertebrates.[94] The autosomal recessive osteoporosis pseudoglioma (OPPG) syndrome (MIM 259770), a disorder causing both skeletal and eye abnormalities, is due to inactivating mutations in the *LRP5* gene.[95] Besides the neonatal blindness, children with OPPG have a very low bone mass and are very sensitive to fractures and skeletal deformities. The disease is not caused by abnormal collagen matrix, and this differentiates it from the severe osteogenesis imperfecta, although it shares similar phenotype with osteogenesis imperfecta. Of interest, obligate carriers of OPPG mutations show an increased incidence for osteoporotic fractures, indicating a dominant effect of this gene on bone mass. Targeted disruption of the *LRP5* gene in mice also produces osteoporosis postnatally. On the other hand, in a family that includes phenotypically normal individuals with exceptionally dense bones (high bone mass MIM 601884), a gain-of-function mutation (G171V) in the *LRP5* gene has been described.[96] The same mutation was found in another kindred with other phenotypic abnormalities, such as torus palatinus and a wide, deep mandible in addition to high bone density. LRP5 acts as a coreceptor for Wnt proteins and is expressed in osteoblasts, where it is required for the osteoblast proliferation and functions in a Runx2-independent manner. These findings demonstrate that the LRP5 signaling pathway plays an important role in the regulation of bone mass in vertebrates.

LRP6 is another coreceptor of canonical Wnt pathway. Thus, it is interesting whether LRP6 is involved in bone metabolism, although a human disease caused by the abnormality of LRP6 has not been identified. Lrp6-null mice is embryonic lethal and not suitable for the analysis of bone metabolism. We found that a novel spontaneous mutation, *ringelschwanz* (*rs*) in the mouse is in the *Lrp6* gene.[97] While heterozygous rs animals appear normal, homozygous *rs* mutants show malformations in the vertebral column, digits and the neural tube as in *Lrp6*-null mutants, these phenotypes are less severe as compared to those in null mutants. The *rs* mutation is regarded as a hypomorphic allele of *Lrp6*. The Lrp6 dysfunction in *rs* leads to a delay in ossification at birth and to a low bone mass phenotype in adults. Thus, LRP6 is certainly involved in bone metabolism as well as LRP5.

Noonan syndrome

Noonan syndrome (MIM 163950) is an autosomal dominant disorder characterized by a variable phenotype comprising proportional short stature, congenital heart defects, and minor facial anomalies.[98] The main facial findings of Noonan syndrome are hypertelorism with down-slanting palpebral fissures, ptosis, and low-set posteriorly angulated ears with a thickened helix. Cardiovascular diseases including valvular pulmonary stenosis, atrial septal defect, and hypertrophic cardiomyopathy (HCM) are observed in 50–80% of patients with Noonan syndrome. Other symptoms are webbed neck, chest deformity, mild mental retardation, cryptorchidism, feeding difficulties, bleeding diathesis, and lymphatic dysplasias. The incidence of Noonan syndrome is estimated to be between 1/1000 and 1/2500 live births.

Recently, heterozygous missense mutations in the *PTPN11* gene, located on chromosome 12 (12q24), have been identified in 33–60% of affected familial or sporadic cases of Noonan syndrome.[99–102] The product of the *PTPN11* gene, SHP-2, is widely expressed in various tissues and is involved in several signal transduction pathways in cooperation with growth factors, cytokines, and hormones. Thus, mutations in the *PTPN11* gene could cause the wide range of clinical features in Noonan syndrome. SHP-2 is composed of two tandemly arranged src homology 2 domains, N-SH2

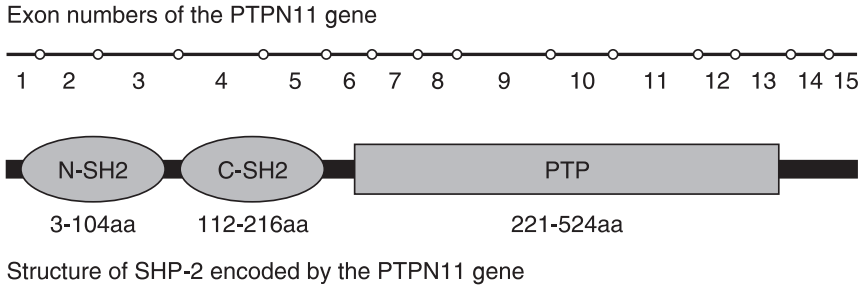


Figure 59.3 (modification of figure in Tartaglia *et al., Nature Genet* 2001) The structure of the PTPN11 gene and functional domain structure of SHP-2. The gene consists of 15 exons and the function domains of the SHP-2 protein comprise two tandemly arranged SH2 domains at the N terminus (N-SH2 and C-SH2) followed by a protein tyrosine phosphatase (PTP). The frequent mutations associated with Noonan syndrome are detected in exons 3, 8, and 13 in the gene.

and C-SH2, at the amino terminus, a single central phosphatase domain (PTP) and a carboxy-terminal tail (Figure 59.3). In the steady state, N-SH2 domain binds to PTP domain and suppresses its phosphatase activity. In contrast, the binding of both domains is loose and PTP exerts its activity in mutant SHP-2 found in Noonan syndrome. In other words, gain-of-function type mutation is found in the *PTPN11* gene in patients with Noonan syndrome. The structure of the *PTPN11* gene corresponding to the functional domain structure of SHP-2 is also depicted in the Figure 59.3. The gene consists of 15 exons. The frequent mutations are detected in exons 3, 8, and 13 in the gene.

To date, more than 70 mutations in the *PTPN11* gene have been described. Tartaglia *et al.* reported patients with *PTPN11* mutations were associated with pulmonary stenosis, while those without *PTPN11* mutations were with HCM.[103] Two other reports support the conclusion that HCM is found more frequently in patients with Noonan syndrome without *PTPN11* mutation. However, Sarkozy *et al.* showed LEOPARD syndrome (MIM 151100) with HCM was highly related to the mutations in exon 7 or 12 of the *PTPN11* gene,[102] suggesting that HCM could be associated with *PTPN11* mutations.

As mentioned above, SHP-2 is widely expressed in various tissues and cell types, and has been implicated in diverse signaling pathways including those initiated by growth factors, cytokines and hormones. SHP-2 has compound signaling functions. For instance, SHP-2 directly interacts with growth factor and cytokine receptors when its ligand induces rapidly tyrosine phosphorylation. It can also interact with a variety of signaling intermediates such as Grb2, and Gab1 and 2. As a PTP, SHP-2 is believed to function by dephosphorylation of its associated signaling molecules, thus diminishing local signals. However, the ultimate effect of SHP-2 in most signaling pathways is to enhance the signal transduction, for example, it activates the Ras-Raf-MAP kinase cascade. In most circumstances, SHP-2 plays a positive role in transducing signals relayed from tyrosine kinase-containing receptors.[103]

Perinatal period

Skeletal dysplasia, lethal type

The study in the St. John Hospital in Rome reported 14 cases of constitutional osteochondrodysplasias out of 2120 cases of newborns hospitalized (0.66%).[104] Among them, four patients (28.27%) belong to the group considered by the European Society of Pediatric Radiology as lethal. Representative lethal types of skeletal dysplasia and the corresponding causal genes are described in Table 59.2. The genes responsible for osteogenesis imperfecta, thanatophoric dysplasia, and hypophosphatasia are type I collagen gene, FGFR3 gene, and tissue non-specific ALP gene, respectively, which are essential for the development of cartilage and bone, as described in the previous section. Other important molecules in enchondral bone formation such as SOX9 and PTHrP receptor are also responsible for lethal type chondrodysplasia. Patients with campomelic dysplasia caused by SOX9 mutations often have respiratory difficulties. Other lethal forms of short limb dwarfism consist of a lethal form of arthrogryposis multiplex congenita (MIM 108110), platyspondylic lethal osteochondrodysplasia, short rib syndrome, and atelosteogenesis. Atelosteogenesis type 2 (AO2) (MIM 256050) is a neonatally lethal chondrodysplasia characterized by severe limb shortening and deficient ossification of parts of the skeleton. The disease is caused by mutations of the *DTDST* gene and its phenotypic overlap with nonlethal diastrophic dysplasia. The heterogeneous group of platyspondylic lethal skeletal dysplasias (PLSD) originally included thanatophoric dysplasias (TD1/2: MIM 187600, 187100) as the most common forms of this condition, as well as TD variants San Diego type (PLSD-SD: MIM 270230) and Torrance–Luton type (PLSD-TL: MIM 151210). The *FGFR3* gene mutations have been identified in TD1/2 and PLSD-SD, while PLSD-TL is caused by *COL2A1*. The metatropic dysplasia group includes fibrochondrogenesis, Schneckenbecken dysplasia, and various forms metatropic dysplasia.[105] The perinatally lethal metatropic group of conditions consists of lethal metatropic dysplasia (type 2) or hyperchondrogenesis, lethal

Table 59.2 Skeletal dysplasia, lethal type and responsible genes

Disease	Gene
Osteogenesis imperfecta type II	COLI
Thanatophoric dysplasia	FGFR3
Hypophosphatasia lethal type	TNSALP
Achondrogenesis	COLII
Hypochondrogenesis	COLII
Achondrogenesis IB	DTDST
Camptomelic dysplasia	SOX9
Blomstrand chondrodysplasia	PTHR1
Short rib syndrome	?

hyperplastic metatropic dysplasia (type 1) and fibrochondrogenesis. In our experience, osteogenesis imperfecta and thanatophoric dysplasia were the most frequent lethal skeletal diseases.

Amnionic fluid

Clinical analysis of patients with skeletal dysplasias, lethal type revealed several characteristic phenotypes in each disease. For example, polyhydramnios is known as one of the features in patients with congenital anomaly. However, osteogenesis imperfecta and thanatophoric dysplasia were quite different in terms of association with polyhydraminios in our patients. In 11 patients with osteogenesis imperfecta, no polyhydramnios was observed. In contrast, nine out of 11 patients with thanatophoric dysplasia were complicated with polyhydramnios.

Intrauterine growth retardation

Intrauterine growth retardation (IUGR) is often observed in fetuses with severe skeletal dysplasia. Short limb associated with skeletal dysplasia tends to underestimate the expected body weight of the fetus. In contrast, hydrops, sometimes associated with achondrogenesis and thanatophoric dysplasia, affects the weight. Patients with osteogenesis imperfecta are often skinny and show IUGR.

Bone age or calcification of bones in the fetus

In the fetus, bone age can be estimated by the number of calcified bones whose calcification occurred during the gestational period. They consisted of talus, os calcis, ishium, os pubis, sternum, vertebral bodies (coccygeal and fifth sacral), lumbar transverse processes, proximal epiphysis of tibia, and distal epiphysis of femur. We previously reported the relationship between the number of calcified bones and the gestational week. In hypophosphatasia, achondrogenesis and some forms of chondrodyplasia, calcification of bones is extremely delayed. In contrast, a mild decrease in number or normal development of calcified bones is observed in patients with osteogenesis imperfecta and thanatophoric dysplasia. These results suggest the difference in the pathogenesis of each skeletal dysplasia.

Closing comments

Due to the limitation of length, this review cannot provide readers a whole picture accounting for the recent development of investigations on skeletal dysplasia. Apparently, identification of genes responsible for skeletal dysplasia contributes to better understanding of the process in which chondrocytes, osteoblasts, and osteoclasts proliferate, differentiate, and interact with each other. Because the opportunity for the pediatrician to take care of patients with skeletal dysplasia has increased, the pediatrician should understand the biological and developmental aspects of bone and chondrocytes as well as clinical advance of treatment of patients with skeletal dysplasia.

60 Implantation

S. Saito

Introduction

Human pregnancy represents a semiallograft to the maternal host.[1] However, the semiallogeneic embryo/fetus is not rejected by the mother. When a donated embryo is transplanted to a surrogate mother, the fetus is an allograft to the mother, but the allogeneic fetus is not rejected by the mother. Pregnancy is thus a mysterious biological phenomenon. Recent studies suggest that endometrial (maternal) lymphocytes play some role in the maintenance of pregnancy via immune mediators such as cytokines.[2] It has been postulated that tolerance to paternal antigens (Ags) must be present during pregnancy. Some regulatory lymphocytes and regulatory cytokines play a very important role in preventing allograft rejection. However, these mechanisms are not so rigid. The absence of these regulatory factors is involved in multiple implantation failure, pregnancy loss and pre-eclampsia. The low rate of successful implantation in humans suggests that the expression of these cytokines and their biologic signals should be optimal, precise and synchronized. In recent years, accumulating evidence has emerged that many factors, including cytokines, growth factors and maternal lymphocytes, contribute to the success of embryo implantation and maintenance of pregnancy.

Unique human leukocyte antigen (HLA) expression on trophoblasts

The mechanism for maintenance of pregnancy has been proposed (Table 60.1). Cytotoxic T cells, which induce rejection, recognize antigeneic peptides expressed on major histocompatibility (MHC) Ag class I or class II on target cells. Interestingly, villous trophoblasts lack MHC class I and class II molecules on their surface. As a result, villous trophoblasts cannot be recognized by maternal T cells, resulting in prevention of rejection.

Natural killer (NK) cells are lymphocytes of the innate immune system that are involved in the early defenses against foreign cells.[3] NK cell activation is controlled by a dynamic balance between complementary and antagonistic pathways. NK cells express an array of activating cell surface receptors that can trigger cytolytic programs, as well as cytokine or chemokine secretion. NK cells also express cell surface inhibitory receptors that antagonize activating pathways through protein tyrosine phosphatases. The classical MHC class I molecules HLA-C and the non-classical class I molecules HLA-E and HLA-G interact with inhibitory receptors, such as killer-cell immunoglobulin-like receptors and CD94/NKG2. A wide range of MHC class I molecules such as HLA-G also bind ILT2 and ILT4, which are members of the immunoglobulin-like transcript (ILT) family. Interestingly, extravillous trophoblasts, which invade the uterus, express HLA-C, HLA-E and HLA-G.[3] Maternal NK cell-cytotoxic activity is suppressed by inhibitory receptors resulting in the fetus being protected from maternal NK cell attack. A unique characteristic of HLA-G is the generation of multiple spliced variants. Alternative splicing of the HLA-G messenger RNA yields different membrane-bound and soluble isoforms. Interestingly, soluble HLA-G, which is produced by villous trophoblasts, is an immunosuppressive molecule inducing apoptosis of activated $CD8^+$ T cells and down-modulating $CD4^+$ T cell proliferation.[4]

Table 60.1 Proposed mechanism for maintenance of pregnancy

Absence of classical MHC class I and class II molecules on trophoblasts
Expression of HLA-C, HLA-G and HLA-E on trophoblasts
Expression of complement regulatory proteins on trophoblasts (CD46, CD55 and CD59)
Fas L, Fas receptor system
Immunosuppressive factors [α2 glycoprotein, alpha-fetoprotein (AFP) and TGF-β]
uNK (CD16–CD56 bright NK cells) [granulated metrial gland (GMG) cells in mice]
Cytokines (Th2-type cytokines) and hormones
Treg cells (CD4 + CD25 + T cells, Th3, Tr1)
Regulatory NK cells (NK3, NKr1)

Therefore, soluble HLA-G probably plays a very important role in the maintenance of pregnancy at the feto–maternal interface. Soluble HLA-G may also contribute to the control of implantation. It has been reported that human implantation was strictly related to soluble HLA-G secretion by preimplantation embryos.[5] Fuzzi *et al.* reported that after *in vitro* fertilization or intracytoplasmic sperm injection, only transfer of embryos secreting HLA-G could lead to pregnancies. In contrast, no pregnancy occurred after transfer of soluble HLA-G-negative embryos. Soluble HLA-G appears to be a key molecule at the time of implantation, and in early and late placentation.

Expression of complement regulatory proteins on trophoblasts

Activation of a complement promotes cell lysis mediation by the membrane attack complex. Complements also bind and attack self tissues, especially in areas of inflammation. However, cells are protected from the deleterious effects of complement activation by complement regulatory proteins such as CD46 (MCP), CD55 (DAF), CD59 and Crry. Crry, present only in rodents, regulates the deposition of activated C3 and C4 on the surface of autologous cells. Decreased expression of complement regulatory molecules has been found in different inflammatory disorders. Complement activation is regulated by excessive expression of complement regulatory proteins on trophoblasts. However, complement deposition is recognized at the feto–maternal interface in miscarriage cases. Survival of $Crry^{-/-}$ embryos was compromised because of complement deposition and concomitant placental inflammation.[6] Interestingly, breeding with $C3^{-/-}$ mice rescued $Crry^{-/-}$ mice from lethality, suggesting that the regulation of complements is critical in fetal control of the maternal process that mediates tissue damage.[6]

In humans, antiphospholipid syndrome (APS) is characterized clinically by fetal loss and thrombosis and serologically by the presence of auto-antibodies to lipid-binding protein. Recent data suggested that complement activation, especially C5a and C5R interaction, is necessary for thrombosis of the placental vasculature.[7] APS is generally treated with anticoagulation therapy. Recent studies demonstrated that treatment with heparin prevented complement activation *in vivo* and *in vitro* and protected mice from pregnancy complications induced by antiphospholipid antibodies.[8] These data suggest that inhibition of complement activation is essential for maintenance of pregnancy.

Fas/Fas ligand (Fas L) system

The Fas/Fas L pathway plays a critical role in promoting apoptosis and regulation of immune responses. The Fas/Fas L system appears to contribute to the immune privilege of the maternal–fetal interface. The maternal decidua and fetal trophoblasts express Fas L, and expression might prevent trafficking of reactive maternal cells into the fetal circulation and vice versa. T cells specific for fetal Ags decrease in an Ag-specific manner during pregnancy, consistent with clonal deletion in the maternal immune system. Placental trophoblasts that express Fas L can induce Fas-mediated death of maternally activated T cells, and this clonal deletion is one mechanism of tolerance to the fetal allograft.[9] The Fas/Fas L system also plays an important role in implantation. Embryonic trophoblasts and maternal decidua produce conticotropin-releasing hormone (CRH) and CRH induces Fas L expression.[10] Female rats treated with a CRH receptor type 1 antagonist, antalarmin, showed a marked decrease in implantation sites and live embryos, along with diminished endometrial Fas L expression. Embryos from mothers that lacked T cells or from syngeneic matings were not rejected when the mothers were given antalarmin.[11] These data suggest that locally produced CRH promotes implantation and maintenance of early pregnancy by killing activated T cells.

Th1/Th2 balance during pregnancy

The blastocyst and maternal endometrium develop an exquisite dialog during the implantation window. Successful embryo implantation requires the synchronization of embryo development and uterine preparation. In mice, this period begins at day 3 and is completed by day 5 (Figure 60.1). Pseudopregnancy at day 2 in mice does not represent the receptive phase for implantation of embryos. Takabatake *et al.* reported that in recipient pseudopregnant mice injected intravenously with splenocytes or culture supernatant on day 2, blastocyst transfer was performed on day 2.[10] The successful implantation rate was markedly higher in the pregnancy day 4- and day 8-splenocytes-injected groups. They further clarified that a significant increase in the implantation rate was observed when pregnancy day 4-$CD4^+$ T cells were injected into the uterus. These data suggest that $CD4^+$ T cells during early pregnancy could contribute to changing the implantation window and increase the chance of implantation.

T cells can be classified into $CD4^+$ T cells and $CD8^+$ T cells by their surface markers (Figure 60.2). $CD4^+$ T cells are also classified into Th1 cells, which produce interleukin (IL) 2, interferon (IFN) γ and tumor necrosis factor β, and Th2 cells, which produce IL-4, IL-5 and IL-13. Th1 cells are involved in cellular immunity such as rejection of cytotoxic T cell responses. On the other hand, Th2 cells are involved in immunoglobulin production. Based on these findings, Wegmann *et al.* hypothesized that physiological protection from maternal rejection is due to a Th2-type response at

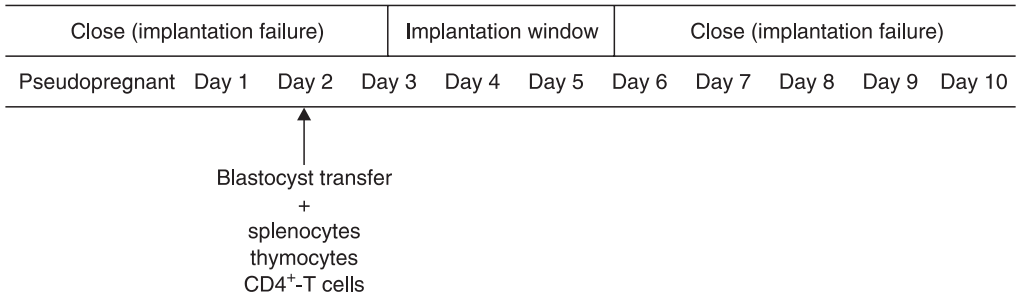

Figure 60.1 Implantation window in mice.

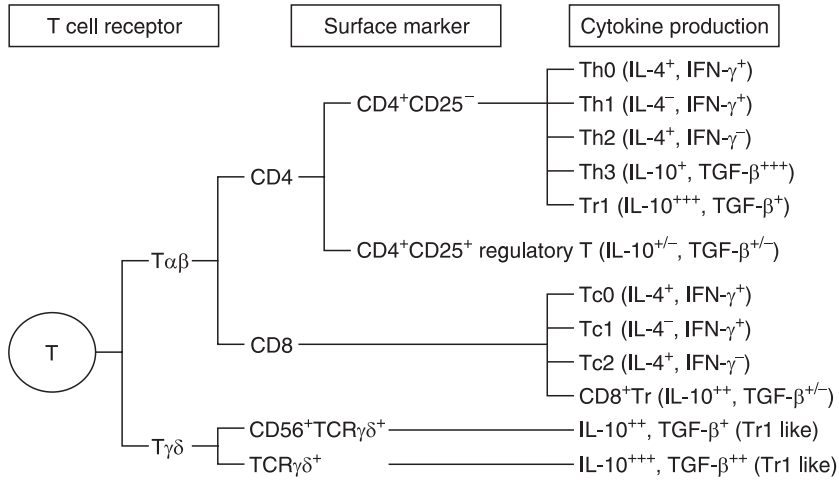

Figure 60.2 T cell subsets classified by their surface markers and cytokine profiles.

the materno–fetal interface.[12] In a mouse model, Th1 cells induced miscarriage and implantation failure. However, in humans, the peripheral blood Th1/Th2 balance in normal pregnancy is controversial, because the amplitude of this balance is very small in peripheral blood. On the other hand, the Th1/Th2 ratios in the endometrium or decidua change dramatically during the menstrual cycle and pregnancy. For example, it has been reported that the Th1/Th2 ratio was 147.5 during the proliferative phase of the endometrium, 37.4 during the secretory phase and 1.3 in early pregnancy deciduas.[13] Furthermore, the numbers and population of Th2 cells are increased at the decidua basalis compared to those at the decidua parietalis, suggesting that Th2 cells accumulate at the implantation site.[14]

Hill *et al.* first reported that Th1-type immunity is present in women with recurrent pregnancy loss, and Piccinni *et al.* first reported defective production of Th2 cytokines by decidual T cells in unexplained recurrent spontaneous abortions. Michimata *et al.* first reported decreased Th2 cells in the decidua basalis in recurrent spontaneous abortions with normal embryo, although accumulation of Th2 cells was observed in the decidua basalis in recurrent spontaneous abortions with abnormal chromosomal content.[15] These data suggested that accumulation of Th2 cells at the decidua basalis is important in maintaining pregnancy.

Regulatory T (Treg) cells in pregnancy

Recent data demonstrated that immunoregulatory activity specific for donor alloantigens is enriched in the $CD4^+CD25^+$ Treg cell population (Figure 60.2). $CD4^+CD25^+$ Treg cells play a critical role in peripheral tolerance, transplantation tolerance and maternal tolerance to the fetus. The population of $CD4^+CD25^+$ Treg cells increases in iliac lymph nodes, in inguinal lymph nodes, in the spleen, in decidua and in blood, and these cells suppress alloreactive proliferation *in vitro*.[16,17] Alubihare *et al.* injected 2×10^7 lymphocytes or an equal number of cells from a CD25-depleted cell preparation ($CD25^-$) into BALB/C nu/nu mice that lacked T cells.[16] All recipient BALB/C nu/nu female mice were mated with C57BL/6 male

mice on the day after adoptive transfer. As a result, all the fetuses were aborted in allogeneic pregnancy when $CD25^-$ cells were injected, while this treatment did not induce fetal resorption in syngeneic pregnancy. These findings suggest that $CD25^+$ cells, perhaps $CD4^+CD25^+$ T cells, mediate maternal tolerance to the fetus.

In human pregnancy, $CD4^+CD25^{bright}$ Treg cells are increased in the early pregnancy decidua, but this elevated $CD4^+CD25^{bright}$ Treg cell ratio decreases to a non-pregnancy level in miscarriage cases.[17] Therefore, $CD4^+CD25^+$ Treg cells are crucial to the maintenance of tolerance in pregnancy. Recently, Polanczyk *et al.* reported that estrogen augmented Foxp3 expression, which is an essential factor for the development of $CD4^+CD25^+$ Treg cells, and that treatment with estrogen increased the $CD4^+CD25^+$ Treg cell number in mice.[18] Estrogen might promote maternal tolerance to the fetus by increasing the number of $CD4^+CD25^+$ Treg cells.

Indoleamine 2,3-dioxygenase (IDO) expression during pregnancy

IDO is an enzyme for tryptophan catabolism and it is expressed in the blastocysts, syncytiotrophoblasts, extravillous trophoblasts, macrophages and endometrial gland cells. Pharmacologic inhibition of IDO activity resulted in dramatically decreased rates of successful allogeneic pregnancy due to maternal T cell response to fetal alloantigens.[19] IDO is a key immunosuppressive mechanism in normal pregnancies, although IDO-deficient mice can become pregnant and do not abort.

Cytotoxic T lymphocyte-associated Ag 4 (CTLA-4) plays a critical role in peripheral tolerance, and it is well known that $CD4^+CD25^+$ Treg cells express CTLA-4 on their surfaces. Interestingly, CTLA-4 induces IDO enzyme activity in dendritic cells and regulates tryptophan catabolism.[20] These findings suggest that decidual $CD4^+CD25^+$ Treg cells, which express CTLA-4 on their surface, interact with dendritic cells. As a result, these signals enhance IDO activity, resulting in maintenance of pregnancy. The cross talk between $CD4^+CD25^+$ Treg cells and the IDO enzyme may induce successful pregnancy.

Cytokine profile in decidual NK cells

The Th1/Th2 paradigm has been further developed. T cell subsets that produce the immunoregulatory cytokines IL-10 and transforming growth factor (TGF) β have been clarified. Th3 cells predominantly produce TGF-β, while Tr1 cells predominantly produce IL-10. They achieve immunoregulation via

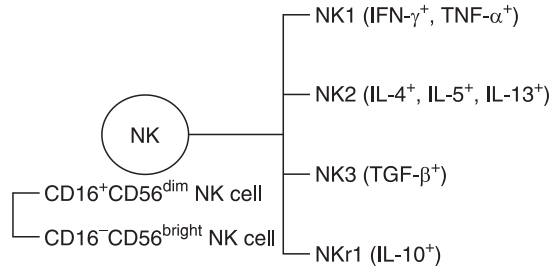

Figure 60.3 NK cell subsets by their cytokine profiles.

their cytokine production. NK cells are also classified into NK1, NK2, NK3 and NKr1 cells by their cytokine profiles (Figure 60.3).

It is well known that NK cells are the main population of lymphocytes in early pregnancy decidua. NK cells can be classified into $CD16^+CD56^{dim}$ NK cells and $CD16^-CD56^{bright}$ NK cells. The main population of peripheral blood NK cells is $CD16^+CD56^{dim}$ NK cells, whereas the main population of endometrial and decidual NK cells is $CD16^-CD56^{bright}$ NK cells. In the peripheral blood of non-pregnant subjects, IFN-γ-producing $CD16^+CD56^{dim}$ NK cells and $CD16^-CD56^{bright}$ NK cells are the main populations. After pregnancy, the populations of IL-10-producing NKr1 cells in peripheral blood $CD16^+CD56^{dim}$ NK cells and $CD16^-CD56^{bright}$ NK cells increase, although these populations decrease in miscarriage cases.[21] In the early pregnancy decidua, the main populations of $CD16^+CD56^{dim}$ NK cells and $CD16^-CD56^{bright}$ NK cells are TGF-β-producing NK3 cells, and NK3 cells in decidua are decreased in miscarriage cases.[21] Decidual $CD16^-CD56^{bright}$ NK cells produce a variety of cytokines such as granulocyte macrophage colony stimulating factor (GM-CSF), M-CSF, G-CSF, leukemia inhibitory factor (LIF) and angiotoietin. M-CSF and GM-CSF induce the DNA synthesis of trophoblasts, and LIF is an essential cytokine for implantation. Angiopoietin plays an important role in angiogenesis. These findings suggest that NK cells in the decidua play an important role in the maintenance of pregnancy by regulation of maternal immune function, placental growth and angiogenesis at the feto–maternal interface.

Conclusion

The immune environment, including the cytokine profile or lymphocyte subsets in the endometrium, clearly changes during implantation and pregnancy. These dramatic and synchronized changes are present at the local implantation site. A better understanding of these sequential events could improve clinicians' ability to treat disorders related to these processes, including infertility and early pregnancy loss.

61 Endocrinological aspects

N. Sagawa

The production of steroid and protein hormones by human trophoblasts is the largest in amount and diversity among endocrine organs in all mammalians. A unique and obligatory interrelationship is present between the hyperestrogenic state of human pregnancy and the fetal adrenal secretion of a large amount of C_{19} steroids, which serve as precursors for estrogen synthesis in the placenta. Human syncytiotrophoblast takes up maternal plasma low-density lipoprotein (LDL) cholesterol as a substrate for progesterone biosynthesis in the placenta.

The human placenta also synthesizes an enormous amount of protein and peptide hormones including human chorionic gonadotropin (hCG), human chorionic somatomammotropin (hCS), chorionic adrenocorticotropin (ACTH), and others.

Steroidogenesis in the fetoplacental unit

Steroid formation

Estrogen

The placenta is an incomplete steroid-producing organ. It must rely on precursors reaching it from the fetal and maternal circulations. The unique interdependence of fetus, placenta, and mother gave rise to the concept of an integrated fetoplacental–maternal unit.[1] The individual adult steroid-producing glands are capable of forming progestins, androgens, and estrogens, but this is not true of the placenta. There is a constant interplay of fetus, placenta, and mother to form the bulk of the sex steroids in pregnancy.[1] For estrogen formation by the placenta to occur, precursors must reach it from both the fetal and maternal compartments, whereas placental progesterone formation is accomplished in large part from circulation of maternal low-density lipoprotein cholesterol.[2] In the placenta, cholesterol is first converted to pregnenolone and then rapidly and efficiently to progesterone.[3] Production of progesterone reaches approximately 250 mg/day by the end of pregnancy, when the circulating levels are on the order of 130 ng/ml.[4] The placenta also produces estrogens by aromatization of circulating androgens. The major precursor in placental estrogen formation is dehydroepiandrosterone sulfate (DHEA-S), mainly from the fetal adrenal gland. The abundant sulfatase enzyme in the placenta converts DHEA-S to free (unconjugated) DHEA, when it reaches the placenta. DHEA is further converted to androstenedione, thereafter to testosterone, and finally to estrone and 17β-estradiol. However, the major estrogen formed in the human pregnancy is neither estrone nor estradiol but another estrogen, estriol. Estriol is not secreted by the ovary of non-pregnant women but constitutes more than 90% of the known estrogen in pregnancy urine. Concentrations increase with advancing gestation and reach 35–45 mg/24 h at term.[5] Estriol is also found in the amniotic fluid and maternal circulation.[6] The concentration of estriol in the maternal circulation is between 8 and 13 ng/ml at term.[7]

Estriol is produced by a unique biosynthetic process, which forms the interdependence of three compartments, fetus, placenta, and mother (Figure 61.1). Maternal cholesterol is transported as LDL cholesterol to the placenta. Cholesterol is converted to pregnenolone in the placenta and fetal adrenal. Fetal adrenal further metabolizes pregnenolone to dehydroepiandrosterone sulfate (DHAS), which is metabolized to 16α-hydroxy DHAS by 16α-hydroxylase in the fetal liver. DHAS and 16α-hydroxy DHAS are hydrolyzed by placental sulfatase in the placenta and the resulting DHA is further metabolized to estrone and estradiol, and 16α-hydroxy DHA to estriol by placental aromatase. The precursor of placental estrone and estradiol is derived from both maternal and fetal adrenals. In contrast, the precursor of estriol, 16α-hydroxy DHAS is predominantly originated from fetus reflecting fetal adrenal and liver function. Thus, increase in the maternal plasma estriol concentration in late pregnancy is the reflection of total functions and development of fetal adrenal, fetal liver, and the placenta.

Sulfatase deficiency occurs in male babies at an incidence of 1/15,000 pregnancies, whereby 16α-hydroxy DHAS is not hydrolyzed and is not further converted to estriol. The infant with sulfatase deficiency later develops X-linked ichthyosis.[8] Anencephalus-lacking

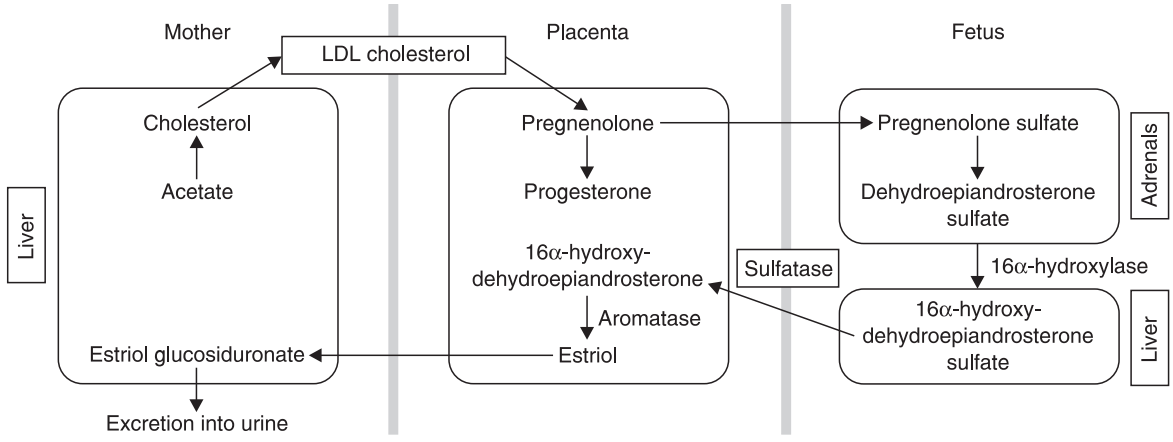

Figure 61.1 Estriol biosynthesis in fetoplacental-maternal unit.

pituitary does not secrete ACTH and estriol production is very low, approximately 10% of the normal fetus. When the fetus dies *in utero* the precursor of estriol is not provided from fetal adrenal and the estriol levels decline significantly.[1] However, changes in the maternal plasma or urinary estriol levels are too slow and do not reflect real-time fetal viability. In Down's syndrome, maternal plasma unconjugated estriol levels are low, because the production of precursor of estriol synthesis in the fetal adrenal is not adequate. Based on this fact, serum estriol levels in the late first trimester are utilized as one of the serum markers of Down's syndrome. Glucocorticoid administration suppresses placental estrogen synthesis because glucocorticoid suppresses ACTH secretion in both mother and fetus and consequently decreases DHAS secretion from both maternal and fetal adrenals.

Progesterone

The placenta is the main source of progesterone in the maternal plasma.[9] The precursor of progesterone synthesis, cholesterol, is predominantly derived from maternal plasma LDL cholesterol, since cholesterol synthesizing enzymes are not expressed in the placenta. Thus, progesterone synthesis is dependent on maternal and placental bioactivities but not on fetal viability.[10] This is the reason why the progesterone levels in maternal sera do not reflect acute fetal compromise as compared to that of estrogen. Placenta does not metabolize progesterone. A major part of placental progesterone is secreted to fetal circulation and further metabolized to glucocorticoids such as cortisol and aldosterone. The rest of the placental progesterone is secreted to maternal plasma. Plasma concentration of progesterone in the late first trimester is approximately 30–40 ng/ml and further increases to 130 ng/ml (secretion: 250 mg/day), which is approximately 10 times of corpus luteum production. Progesterone production in the syncytiotrophoblast during the early first trimester is still low and is not enough to maintain the pregnancy. Thus, corpus luteum is necessary for the maintenance of pregnancy until 6–7 weeks of gestation. Half-life of progesterone is much more shorter than that of hCG. Therefore, plasma level of progesterone decreases much earlier than that of hCG when spontaneous termination of pregnancy occurs in early pregnancy.

Corticoids

Progesterone produced in the placenta is metabolized to either cortisol or aldosterone because fetal adrenal lacks 3b-hydroxysteroid dehydrogenase (3bHSD). Cortisol is further converted to cortisone by 11b-hydroxysteroid dehydrogenase (11bHSD) in the placenta. Cortisol level in the amniotic fluid increases as fetus maturate due to cortisol excretion into fetal urine. Maternal plasma cortisol level increases secondary to the increase in cortisol binding globulin (CBG) in maternal plasma. When uteroplacental blood flow decreases in the pregnant women, complicated with pre-eclampsia, chronic hypertension or severe diabetes mellitus, blood flow in the placental intervillous space decreases resulting in the diffusion of placental steroid hormone to the fetus, increase in the steroid hormone levels in the umbilical cord. The increased cortisol might accelerate fetal lung maturation in case of fetal compromise associated with impaired uteroplacental perfusion.

Biological function of steroid

Estrogens

The functional role of placental estriol in pregnancy has caused a great deal of speculation. In many biologic systems, estriol is a weak estrogen. Its potency is approximately 0.01 times of estradiol and 0.1 times of estrone on a weight basis. However, estriol is reported to be as effective as other estrogens in one function: its ability to increase uteroplacental blood flow. Therefore, this may be a primary function of a large amount of placental estriol. Its relatively weak estrogenic function on other organ systems may be beneficial to specifically increase urteroplacental blood flow. Although acute administration of estriol is ineffective

as an estrogen and does not demonstrate extensive binding to estrogen receptors, prolonged exposure to estriol does produce estrogen effects and binding occurs. Estrogens exert their biological effect on blood flow by stimulating prostaglandin biosynthesis.[11]

Estradiol stimulates protein synthesis, cell proliferation in the endometrium, myometrium, and mammary gland. It is also involved in the regulation of vascular permeability and fluid balance. The increase in blood volume and extracellular fluid volume is mediated by estrogen. Fetus is also the target of placental estrogen and its growth and development are affected by estrogen.

Estrogens are also important for initiation of parturition at an appropriate time. Estrogen stimulates phospholipid synthesis and turnover, prostaglandin production and lysosome formation in the uterine endometrium, and modulates adrenergic mechanisms in uterine myometrium, thereby contributing to the onset of labor.[12]

Progesterone

Progesterone induces the secretory endometrium, which is required for implantation. Progesterone is also important in maintaining uterine quiescence during pregnancy by suppressing uterine smooth muscle contractility.[13] It also inhibits prostaglandin synthesis in the uterus.[14] Progesterone has also been proposed as an essential hormone of mammalian pregnancy because it inhibits T lymphocyte cell-mediated responses involved in tissue rejection.[15] In this theory, it is suggested that a high local (intrauterine) concentration of progesterone can effectively block cellular immune responses to foreign antigens. Therefore, progesterone has been aptly called the 'hormone of pregnancy' because it appears to be essential for maintenance of pregnancy in all mammals examined, and its presence has been detected in species representing all classes of vertebrates. The essential nature of progesterone for pregnancy maintenance has been demonstrated by experiments in which abortion was induced after the administration of drugs that either inhibit progesterone synthesis or compete with progesterone for receptor binding or the administration of progesterone antibodies. The specificity of the abortifacient effect was demonstrated by the concurrent administration of progesterone in some of those experiments.

Human chorionic gonadotropin

hCG is the earliest product of the cells that form the embryo, representing the first signal of the embryo even prior to implantation.[16] hCG is a glycoprotein of heterodimer with molecular weight of 36.7 kDa. It is composed of two subunits, a 92-amino acid α-subunit and a 145-amino acid β-subunit. The α-subunit is homologous to thyroid-stimulating hormone (THS), luteinizing hormone (LH), and follicle-stimulating hormone (FSH). The α-subunit gene is localized to chromosome 6. The β-subunit is similar to LH and the β-subunit gene is located on chromosome 19, fairly close to the LH-β gene. In contrast to LH, hCG contains sialic acid residues, which account for its half-life (24 h) being longer than that of LH (2 h).

Clinically, hCG can be detected in either the serum or urine 7–8 days after fertilization and is the earliest biochemical marker for pregnancy. Studies during *in vitro* fertilization cycle suggest that embryos expressed hCG mRNA as early as the eight-cell stage but that intact hCG was not present until 8 days after egg retrieval. The increase in hCG levels between days 5 and 9 after ovum collection is principally due to free β-hCG production, while by day 22 most of the circulating hCG is in the dimmer form. After implantation, hCG is produced principally by the syncytiotrophoblast layer of chorionic villi and is secreted into the intervillous space. Cytotrophoblasts also can produce hCG.

These observations are in accordance with the *in vitro* studies that suggest dimmer hCG synthesis is controlled in a two-phase manner through a supply of subunits. In contrast to LH secretion in the pituitary gland, hCG is secreted constitutively as subunits are available, and it is not stored in secretory granules as in the case of pituitary LH.[17] The immature syncytiotrophoblast produces free β-hCG subunit while the ability to produce the α-subunit by cytotrophoblast appears to lag by several days.[18] As the trophoblast matures, the ratio of α-subunit to β-subunit reaches a 1:1 ratio, and the hCG concentration reaches a peak value of 100,000 mIU/ml around 9–10 weeks of pregnancy. The placenta produces more α-subunits as gestation advances, and the ratio of α-subunit to hCG is approximately 10:1 at term.[19]

The doubling time of serum hCG levels during early gestation is approximately 30 h.[20] The hCG doubling time has been utilized as a clinical marker to differentiate normal from abnormal pregnancies such as ectopic pregnancy or spontaneous abortions. When vaginal ultrasonography cannot detect the intrauterine gestational sac even after the hCG levels reach 1100–1500 mIU/ml, an ectopic pregnancy is strongly suggested. On the other hand, higher hCG levels suggest the presence of molar pregnancy or multiple gestations.

The major biologic function of hCG during early pregnancy is to rescue the corpus luteum from its premature demise while maintaining progesterone production. Until the luteal-placental shift in progesterone synthesis occurs at the seventh week of pregnancy, hCG is required for rescue and maintenance of the corpus luteum. This is supported by the report that immunoneutralization of hCG results in early pregnancy failure.[21] In the explant experiment with first-trimester chorionic tissue, intermittent administration of gonadotropin-releasing hormone (GnRH) enhanced the pulsatile secretion of hCG from the explant tissue, implicating placental GnRH as a

paracrine regulator of hCG secretion.[22] When pregnancy is not established, the corpus luteum is preprogrammed to undergo luteolysis. hCG also stimulates the production of estradiol, 17-hydroxyprogesterone and other peptides, such as relaxin and inhibin from corpus luteum.

Ovarian progesterone is essential for maintenance of early pregnancy. When progesterone action is blocked with a competitive progesterone antagonist, such as mifepristone (RU 486), pregnancy is terminated. Removal of corpus luteum before, but not after the seventh week of gestation resulted in subsequent abortion.[23,24] Removal of corpus luteum after the ninth week of pregnancy had little or no influence on the pregnancy. Thus, progesterone supplementation is required when corpus luteum function is compromised prior to the ninth to tenth weeks of pregnancy. During later pregnancy, progesterone production in the placenta is sufficient for the maintenance of pregnancy.

hCS, human placental lactogen (hPL)

hCS was initially isolated in 1962 as hPL.[25] hCS has structural similarity to both pituitary human growth hormone (hGH) and prolactin (PRL). hCS is composed of 191 amino acids with a molecular weight of approximately 22 kDa and contains two disulfide bonds. It shares up to 96% homology with hGH and 67% homology with PRL.[26,27] hCS and hGH genes locate on the same portion of chromosome 17, which consists of five genes, two coding for hGH and three coding for hCS.[28] hCS is produced only in the syncytiotrophoblast and at a constant rate throughout gestation.[29,30] Consequently, serum hCS concentration correlates well with placental mass and viability. At term, the placenta produces hCS approximately 1–4 g/day and maternal serum hCS levels range from 5 to 15 μg/ml.

Despite the large amount of production during pregnancy, the physiological function of hCS has not been fully clarified. hCS has been suggested to have a major metabolic effect on the mother to ensure that the nutritional demands of the fetus are met, functioning as a growth hormone of pregnancy.[31] During pregnancy, maternal plasma glucose levels are decreased, plasma free fatty acids (FFAs) are increased, and insulin secretion is increased with resistance to endogenous insulin as a consequence of the GH-like and contra-insulin effects of hCS. Peripheral glucose uptake is suppressed in the mother but it crosses the placenta freely by a facilitated diffusion mechanism. Amino acids are transported across the placenta by an active transport mechanism against the concentration gradient. Transplacental passage of fatty acids is slow. Consequently, when the mother is in the unfed or starved state, glucose should be reserved largely for the fetus and free fatty acids would be used preferentially by the mother. Insulin and other protein hormones do not cross the placenta.

Regulation of placental secretion of hCS is poorly understood. Factors that regulate pituitary GH secretion are not effective in placenta. Although hCS has structural homology to hGH and PRL, it does not have growth promoting or lactogenic activity in humans.[31] There are several case reports on the healthy newborn from hCS-deficient pregnancy.[32,33] Thus, it is possible that hCS is not essential for pregnancy but may serve as an evolutionary redundancy for pituitary GH and PRL. However, it remains to be clarified whether pregnancies without hCS production would have a good outcome even in the state of nutritional deprivation.

Other placental protein hormones

Chorionic ACTH

A protein similar to pituitary ACTH has been isolated from the placenta. ACTH, lipotropin, and β-endorphin are recovered from the placental extract, presumably from the same or similar 31-kDa precursor proopiomelanocortin (POMC).[34] It is also reported that ACTH is secreted from dispersed placental cells.[35] Dexamethasone treatment does not alter the production of ACTH in the placenta.

The physiological significance of placental ACTH is unclear. ACTH plasma levels during pregnancy are lower than in non-pregnant women; nonetheless, the concentration increases as gestation advances.[36] Placenta secretes ACTH into both maternal and fetal circulations, but it does not cross the placenta. The administration of dexamethasone to pregnant women does not suppress urinary free cortisol levels as effectively as it does in men or non-pregnant women. Corticotropin-releasing hormone stimulates the synthesis and release of ACTH from chorionic tissue *in vitro*.[37]

Parathyroid hormone-related protein (PTH-rP) and other protein hormones

PTH-rP is synthesized in various tissues including the pregnant uterus, myometrium, endometrium, and placenta. The rate of PTH secretion by the adult parathyroid is modulated by plasma Ca^{2+} concentration. PTH-rP secretion from the placenta is regulated by calcium concentration.[38]

Relaxin is also expressed in the human placenta.[39] Relaxin is synthesized as a single 105-amino acid preprorelaxin which is cleaved to form two chains A and B. Relaxin is structurally similar to insulin and nerve growth factors. Relaxin acts on myometrial smooth muscle to stimulate adenylate cyclase and to promote uterine relaxation.

The placenta produces chorionic thyrotropin, but its biological significance in normal human pregnancy is yet to be clarified.

Growth hormone-variant (hGH-V) is expressed in the placenta but not in the pituitary.[40] The gene is located in the growth hormone–prolactin gene cluster. The variant of hGH, sometimes referred to as placental growth hormone, is a 191-amino acid protein that differs in 15 amino acids from hGH. hGH-V is synthesized in the placenta, presumably in the syncytiotrophoblasts. hGH-V is present in the maternal plasma by 21–26 weeks of pregnancy, increases in concentration to about 36 weeks of pregnancy, and remains relatively constant thereafter. The maternal plasma levels of hGH-V correlate well with those of insulin-like growth factor-1. Secretion of hGH-V from trophoblast is inhibited by glucose in a dose-dependent manner.[41] The biological activity of hGH-V is similar to that of hCS.

Hypothalamic-like releasing hormones

Gonadotropin-releasing hormone (GnRH)

Placenta secretes a relatively large amount of GnRH.[42] GnRH is present only in the cytotrophoblast but not in the syncytiotrophoblast. Placental GnRH is suggested to act as an hCG-releasing hormone.[43] First-trimester chorionic tissue secretes hCG in response to GnRH much more than that of term placenta.[44] The receptor for GnRH is expressed in both cytotrophoblast and syncytiotrophoblast. Trophoblast secretes inhibin and activin and regulates GnRH production in a paracrine manner. Human placenta can also synthesize thyrotropin-releasing hormone (TRH) *in vitro*.[45,46]

Corticotropin-releasing hormone (CRH)

The same CRH gene expressed in hypothalamic tissues is also expressed in the trophoblast, amnion, chorion leave, and decidua. Plasma levels of CRH in non-pregnant women are 15 pg/ml. Maternal plasma CRH levels increase to 250 pg/ml at early third trimester, and to 1000 pg/ml abruptly during the last 5–6 weeks of pregnancy.[47] After onset of labor, maternal plasma CRH levels increase further about two- to threefold.[48] The biological function of uterine CRH including placental CRH is not clear yet. Receptors for CRH are present in many tissues including fetal adrenal, placenta, and myometrium. Only a very small amount of placental CRH can enter fetal circulation, suggesting a relatively insignificant role in fetal adrenal steroidogenesis. A large amount of CRH is secreted into maternal circulation; however, there is also a large amount of CRH-binding protein in maternal plasma. The bound form of CRH is biologically inactive and targeted for degradation. The possible biological function of placental CRH is the relaxation of both uterine and vascular smooth muscles and immunosuppression. The physiological reverse of CRH function, the induction of myometrial contraction (i.e. the initiation of parturition by CRH), has been proposed.[49] CRH increases prostaglandin synthesis in placenta, amnion, chorion leave, and decidua.[50] In the hypothalamus, glucocorticoids inhibit CRH release; however, in the trophoblast, glucocorticoids do stimulate the expression of the CRH gene, two- to threefold increases in CRH mRNA, and protein expression after treatment of human trophoblast in culture.[51] Thus, in the placenta, a positive feedback loop of CRH, ACTH, and glucocorticoids is proposed.[37]

Growth hormone-releasing hormone (GHRH)

The mRNA for GHRH has been identified in the human placenta.[52] The biological function of placental GHRH is not known.

Other placental peptide hormones

Neuropeptide Y (NPY)

NPY, a 36-amino acid peptide, is originally isolated in the brain. It also is present in sympathetic neurons innervating the cardiovascular, respiratory, gastrointestinal, and genitourinary systems. NPY is also expressed in the placenta and localized in cytotrophoblasts.[48] Receptors for NPY are also present in the placenta, which secrete CRH by stimulation with NPY.

Inhibin and activin

Inhibin is a glycoprotein hormone that acts on the pituitary and inhibits FSH release. Inhibin is a heterodimer with dissimilar α- and β-subunits. The inhibin β-subunit is composed of one of two distinct peptides, βA or βB. Activin is closely related to inhibin and is formed by the combination of two β-subunits. This peptide hormone is produced by various tissues including testis, granulosa cells of the ovary, and corpus luteum. The placenta can produce inhibin α-, βA-, and βB-subunits at the maximal rate at term.[53,54] Placental inhibin, in conjunction with a large amount of sex steroid hormones produced in the placenta, may serve to inhibit FSH secretion and thereby block ovulation during pregnancy. Serum activin levels decline rapidly after delivery.[55] Receptors for activin are present in the placenta and amnion. Inhibin may act via GnRH to regulate hCG production in the placenta.[53]

Natriuretic peptides

Atrial natriuretic peptide (ANP), a 28-amino acid peptide, is predominantly produced in the atrial myocytes, but is also produced in the placental trophoblast.[56] Brain natriuretic peptide (BNP), predominantly produced in the heart, is also secreted from amnion cells.[57] These natriuretic peptides induce natriuresis, diuresis, and relaxation of smooth muscle. The receptors for natriuretic peptides are also expressed

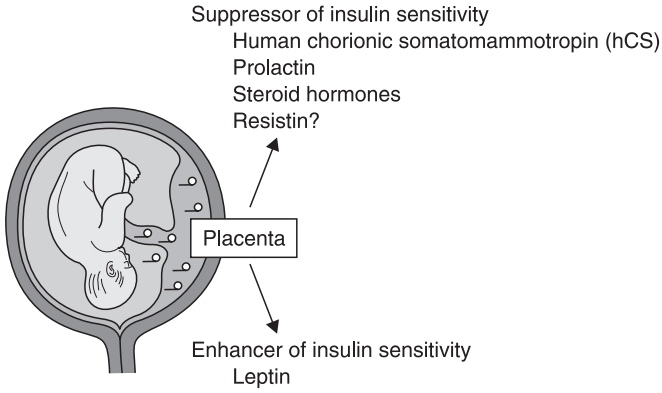

Figure 61.2 Regulation of maternal insulin sensitivity by placental hormones.

in the human placenta as well as in the myometrium, suggesting a possible role of ANP and BNP in uterine relaxation during pregnancy.[58]

Leptin

Maternal insulin sensitivity is regulated by various factors including placenta-derived hormones (Figure 62.2). Several placenta-derived hormones, such as prolactin, hCS or hPL, and steroid hormones, have been considered to decrease insulin sensitivity.[59] Placental production of these hormones is increased in accordance with the increasing size of the placenta. Recently, novel peptide hormones, leptin and resistin, originally identified as adipocytokines and regulating glucose and energy metabolism, have been reported to express in the human placenta.[60,61]

Leptin is initially identified as an adipocyte-derived hormone that decreases food intake and body weight via its receptor in the hypothalamus.[62] Subsequent animal studies revealed various physiological functions of leptin.[63,64] Leptin plays an essential role in reproduction by regulating GnRH secretion from the hypothalamus.[65,66] It also modulates glucose metabolism by increasing insulin sensitivity and activates the sympathetic nervous system.[67,68] In humans, leptin is also produced by placental trophoblasts and is secreted into both maternal and fetal circulations.[60] Leptin production in the placenta is increased in pregnancies complicated with several pathologic conditions.[69–71] Plasma leptin levels are significantly elevated in molar pregnancy.[69] Leptin gene expression in the placenta is augmented in severe pre-eclampsia, and maternal plasma leptin levels in severe pre-eclampsia are significantly higher than those in normotensive pregnant women.[70] Leptin production in the placenta is also increased in diabetic pregnancy with insulin treatment.[71] Leptin is also proposed to play a functional role in implantation by virtue of its stimulatory effect on matrix metalloproteinase expression in cytotrophoblast.[72]

Resistin

Resistin is a newly identified adipocyte-derived hormone that decreases insulin sensitivity and increases plasma glucose concentration, thus contributing to the development of type II diabetes mellitus.[73] Resistin is proposed to link obesity to insulin resistance.[74] Adipocyte secretes various substances that modulate insulin sensitivity, such as free fatty acid, TNF-α, and leptin. Resistin was recently cloned by Steppan *et al*.[73] as a substance whose expression in the adipose tissue decreases by treatment with thiazolidinedione, an antidiabetic drug. Thus, resistin is proposed to be a major factor that induces insulin resistance and hyperglycemia in obese persons.

Northern blot analysis revealed resistin mRNA expression in term placenta as well as in the amniotic membrane.[61] Resistin mRNA expression was also detected in a trophoblastic cell line (BeWo cells) and a very faint band was detected in decidua vera tissue. *In situ* hybridization and immunohistochemistry suggest the expression of resistin in placental villi, mainly in syncitiotrophoblast. Resistin protein was secreted from cultured placental tissue.[61] Resistin gene expression in term placental tissue was significantly larger than that in chorionic villous tissue in the first trimester. By contrast, the resistin gene was expressed to a lesser degree in adipose tissue than in term placental tissue. Moreover, resistin gene expression in the adipose tissue of pregnant women at term did not differ from that of non-pregnant women. As resistin is supposed to induce insulin resistance and increase the plasma glucose level,[73,74] it is possible that placental resistin may contribute to regulation of maternal glucose metabolism in concert with various placental hormones including leptin (Figure 62.2).

However, the regulatory mechanism of resistin gene expression in the human placenta is not yet elucidated. Further investigation on the effects of these hormones on the maternal glucose metabolism and insulin sensitivity may provide a better understanding of the placental role in maternal energy metabolism and fetal growth.

62 Regulation of extravillous trophoblast differentiation

K. Fukushima, K. Tsukimori and H. Nakano

During early development, cytotrophoblast (CT) differentiation contributes to the organization of the feto–maternal interface. One layer of the differentiated trophoblast, which is marked by an invasive phenotype, is called extravillous trophoblast (EVT). EVT invades decidual tissue and the maternal uterine wall. Recent evidence shows that EVT invasion has a crucial role in organizing and maintaining feto-placental circulation. In this chapter, we focus on interstitial and endovascular invasion and their regulatory mechanisms during EVT differentiation.

Differentiation of CT

During the early phase of human pregnancy, CT cells are derived from trophectodermal cells of the blastocyst and contribute to organization of the feto–maternal interface through cell proliferation and differentiation. Differentiation of CT proceeds by two pathways that result in morphologically and functionally distinct trophoblast populations (Figure 62.1). One population consists of multinucleated, non-replicating syncytiotrophoblast cells (ST), beneath which lie immature, replicating, mononuclear villous CT. After the blastocyst attaches to the endometrium, mononuclear CT cells that surround the embryonic disk fuse to ST to form a syncytial layer. This layer covers the intravillous space and transports nutrients, wastes, and gases between fetal and maternal blood.[1]

The other population is the EVT, and these cells have invasive properties. EVT cells leave the cellular column to intrude into the decidua and uterine wall, and they are observed as cytokeratin-positive cells in the decidua, the intima of the spiral arteries, and the proximal third of the myometrium. It is thought that interstitial invasion of the placental bed by EVT promotes placental anchorage. Interstitial invasion is accompanied by endovascular invasion, in which some invading EVT cells interact, resulting in replacement of endothelium and the muscular tunica of maternal vessels, including the spiral arteries. This replacement substantially decreases vascular resistance and results in increased blood flow toward the intervillous space.[2,3]

Alteration of adhesion molecules during interstitial invasion

Examination of tissue sections of human placental bed biopsies shows that EVT cells switch integrin phenotype during differentiation and invasion.[4] The CT stem cells, which are anchored to the basement membrane, express α6b4 integrin. Formation of the cell column is accompanied by $\alpha5\beta1$ up-regulation, and as EVT cells intrude into the uterine wall they express the $\alpha1\beta1$ subunit as well as the $\alpha5\beta1$ subunit. Generally, α6b4 staining is weak and discontinuous at the uterine wall.[4] During this normal trophoblast invasion, the extracellular matrix (ECM) undergoes a transition from laminin (Ln) to fibronectin (Fn) and collagen type IV (C4). Ln is abundant in the superficial areas that face the villous trophoblast. In contrast, C4 and Fn are more abundant at deeper sites.[4,5] Thus, it can be assumed that EVT cells alter their integrin expression in parallel with the variation in ECM distribution during invasion. Not only integrin adhesion receptors, but also E-cadherin expression are altered during the invasive pathway.[6] Expression of E-cadherin, the cell–cell adhesion molecule, is strong in CT stem cells and weak in differentiating and invading EVT cells.[7] These findings are summarized in Figure 62.2.[7,8]

EVT invasion is a biochemically active process because invading cells have to secrete proteases including serine protease, cathepsin, and metalloproteinases. Matrix metalloproteinases (MMPs) have 15 family members that are classified by substrates and structured into four subgroups. The MMPs are inactivated by tissue inhibitor of metalloproteinases (TIMP). The TIMP family consists of four members: TIMP-1, -2, -3, and -4. Among all of these enzymes,

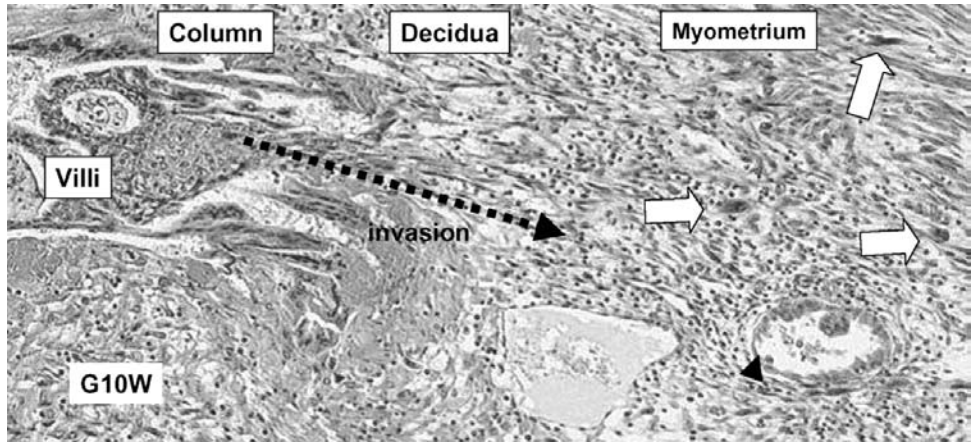

Figure 62.1 Microscopic appearance of extravillous trophoblast in placenta in early gestation during invasion. H&E stained placental tissue from patients with cervical cancer who underwent radical hysterectomy at 10 weeks of gestation. Arrow, invaded extravillous trophoblast; arrow head, maternal vessel replaced by trophoblast.

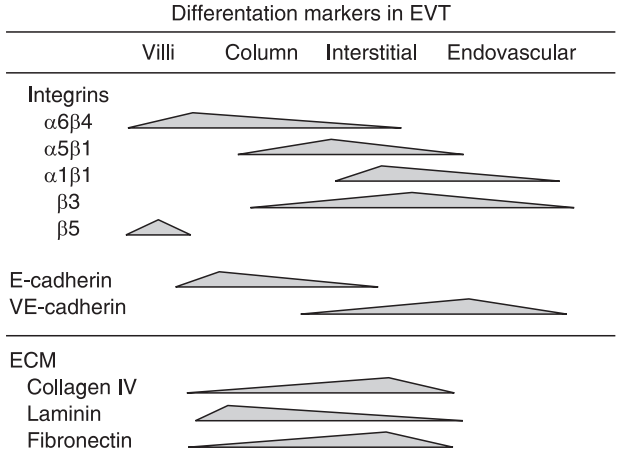

Figure 62.2 Alteration of adhesion molecules expressed in EVT during invasion. Scheme of the alteration of integrin and cadherin expression and distribution of extracellular matrix at each placental site during invasion. Modified from Zhou *et al.*[8,16]

MMP-2 and MMP-9 are considered to be the most important for EVT invasion.[9,10] Several pieces of evidence have shown that ECM and integrin can affect the activity of MMPs and behavior of EVT cells.[11,12] MMP-9 is up-regulated at deeper sites as in the case of integrin $\alpha 1\beta 1$.[13] Damsky *et al.*[5] investigated the effect of integrin–ECM interaction on EVT invasive properties using antibody inhibition to matrigel invasion assay. Antibodies against Ln and C4 blocked EVT invasion. The anti-$\alpha 6$ antibody did not inhibit EVT invasion, whereas anti-$\beta 1$ antibody did inhibit invasion. When combined, these antibodies acted synergistically. In contrast, anti-Fn antibodies stimulated rather than blocked invasion. Thus, the EVT–ECM interaction that subsequently arouses integrin conversion seems to be important in controlling EVT phenotype.

The significance of normal placentation of CT differentiation is highlighted by the fact that in pre-eclampsia, in which both interstitial and endovascular invasion are abnormally shallow, CT cells show significant defects in differentiation.[8,13–15] Furthermore, CT cells in women with pre-eclampsia increase expression of the $\alpha 5\beta 1$ subunit, but fail to both up-regulate $\alpha 1\beta 1$ and down-regulate α6b4.[5,15] Thus, the cells appear arrested in their differentiation and express an ECM receptor phenotype that may not be optimal for invasion.[16] Taking all these findings together, it is likely that expression of these integrin subunits is involved in the regulation of normal EVT differentiation.

Alteration of adhesion molecules during endovascular invasion

Angiogenesis plays a crucial role in both normal physiological and pathological conditions including placental development. During invasion, EVT finally replaces the endothelial cells in uterine vessels. Moreover, EVT cells also intrude into the vascular muscles. This endovascular differentiation induces remodeling of spiral arteries to increase blood flow toward the intervillous space, which is covered by ST, the other form of differentiated CT. As in the case of interstitial invasion, integrin subunits expressed in EVT dramatically change. Along with endovascular differentiation, the adhesion molecule repertories change in a comprehensive manner that mimics the pattern for endothelial cells.[16] Zhou *et al.*[16] reported that EVT *in vivo* showed reduced staining for adhesion receptors characteristic of stable monolayer epithelial cells and showed enhanced staining for adhesion molecules characteristic of endothelial cells. CT in cell columns show reduced E-cadherin

staining and express VE-cadherin, PECAM-1, VCAM-1, and α4-integrins. EVT cells in the uterine interstitium and maternal vessels start to express $\alpha V\beta 3$ integrin. These molecules ($\alpha V\beta 3$ and VE-cadherin) enhance CT invasiveness.[16] In a later report, Zhou *et al.* showed that pre-eclamptic CT does not stain for most of the endothelial-type adhesion molecules that are expressed by control CT cells.[17] Inhibitors of $\alpha V\beta 3$ or $\alpha V\beta 5$ show anti-angiogenic activity in many models.[18] Indeed, a humanized version of LM609, a monoclonal antibody that blocks $\alpha V\beta 3$ signaling, has entered clinical trials for use in treatment.[19] Although genetic studies in mice have provided several controversial points, it is believed that these integrins play an important role in angiogenesis.[20] Thus, these endothelial-cell-related molecules are considered to play an important role in endovascular differentiation in EVT.

The vascular endothelial growth factor (VEGF) family members and their receptors (VEGFR) seem to have important actions during the initial stages of angiogenesis.[21] EVT cells in early gestation express VEGF-A, VEGF-C, placental growth factor (PlGF), VEGFR-1, and VEGFR-3. When binding of VEGF-A, PlGF, and VEGF–PlGF heterodimer to VEGFR-1 is inhibited, tube-like formation on matrigel is impaired and expression of integrin $\alpha 1\beta 1$ is decreased. This effect is enhanced when VEGF-C binding to endogenous VEGFR-3 is blocked. This result suggests that the signal from VEGFR1/3 is involved in the alteration of integrin switching. The same research group also reported that CT responds to VEGF ligands by the autocrine system.[22] Dunk *et al.*[23] reported that angiopoietin 1 and angiopoietin 2 can act as a mitogen and stimulate nitric oxide release from first-trimester trophoblast, as well as VEGF.[23–26] These angiogenic factors also influence the angiogenic state of maternal blood vessels.[27]

Effect of cytokines and growth factor on EVT invasion (Table 62.1)

Interleukins

Interleukin-1 (IL-1) increases MMP-9 secretion and stimulates MMP-9 activities.[28,29] IL-1 or its receptors are important for implantation of the blastocyst.[30] Thus, IL-1 is a positive regulator of trophoblast differentiation along the invasive pathway.[31] IL-6 activates MMP-2 and MMP-9 in trophoblasts.[32] Circulating levels of IL-6 are increased in patients with pre-eclampsia.[33,34] IL-10 down-regulates MMP-9 activity and EVT invasiveness. IL-15 increases ETV invasion and migration, as well as MMP-1 production by Jeg-3 cells.[35] IL-10 and IL-15 seem to regulate trophoblast invasiveness by autocrine mechanisms.[35–37] Wang *et al.* reported lower levels of expression of IL-8 and IL-15 in pre-eclamptic placentas.[38]

Transforming growth factor

Transforming growth factor beta (TGFβ) stimulates the synthesis of matrix glycoproteins[39] and TIMP secretion through down-regulation of urokinase, plasmin, and plasminogen activator.[40–42] TGFβ inhibits cellular proliferation and migration,[37,43,44] whereas TGFα promotes EVT differentiation through the invasive pathway.[42]

Tumor necrosis factor alpha (TNFα)

TNFα levels are elevated in patients with pre-eclampsia,[45,46] and TNFα has been shown to regulate progesterone, estradiol, and human chorionic gonadotropin (hCG) production in CTs.[47] TNFα stimulates trophoblastic MMP-9, MMP-1, and MMP-3 production in human chorionic cells,[48] whereas TNFα decreases TIMP secretion.[32,49] TNFα induces apoptosis,[50] integrin subunit conversion, and functional activation in EVT cell lines.[51]

Insulin-like growth factors and relatives

Insulin-like growth factor (IGF)-II promotes trophoblast differentiation along the invasive pathway. Hamilton *et al.*[52] showed that IGF-II promotes cell migration. IGFBP-1 increases trophoblast cell migration,[42] invasion,[52] TIMP-1 secretion, and gelatinolytic activity.[53]

Other soluble factors

Leukemia inhibitory factor (LIF) is important for implantation of the blastocyst.[30] LIF inhibits the gelatinolytic activity of trophoblasts bearing an Ln receptor.[54]

TNF, VEGF, and ECM as collaborative regulators in EVT differentiation

As discussed above, many growth factors and cytokines have been shown to have an ability to produce certain effects on trophoblast function; however, the mechanism to regulate integrin subunit conversion has been unclear. Fukushima *et al.*[51] reported that TNFα suppressed α6 integrin expression and enhanced α1 integrin expression in a dose-dependent manner in a human EVT cell line; TNFα also induced apoptosis, which is suppressed by signals via integrin β1, with aggregation also induced by TNFα (Figure 62.3). Because integrins comprise a large family of cell surface receptors that recognize a variety of ECM components,[55] these results suggest that TNFα and ECM might collaboratively regulate EVT differentiation through integrin signaling (Figure 62.4). EVT cells alter their integrin expression in parallel with varied ECM distribution during invasion.[4,5] Thus, it has been

Table 62.1 Summary of biological effects of soluble factors on cytotrophoblast

	Biological effect on cytotrophoblast (and/or EVT)	References
IL-1	Promotes invasion	Lala and Lysiak,[31] Librach *et al.*[29]
	Increases MMP9 secretion	Meisser *et al.*[28]
	Promotes differentiation in invasive pathway	
IL-6	Increases circulating level in pre-eclamptic patients	Conrad and Benyo,[33] Conrad *et al.*[34]
	Activates MMP2 and 9	Meisser *et al.*[32]
IL-8	Lower level of expression in pre-eclamptic placenta	Wang *et al.*[38]
IL-10	Inhibits invasion	Roth *et al.*,[36] Roth and Fisher[37]
IL-15	Lower level of expression in pre-eclamptic placenta	Wang *et al.*[38]
	Increases invasiveness	Zygmunt[35]
TNF	Progesterone, hCG, estradiol synthesis	Li *et al.*[47]
	Stimulates MMP1, 3, 9, decrease TIMP	So *et al.*,[48] Takahashi *et al.*,[49] Meisser *et al.*[32]
	Induces integrin subunit conversion	Fukushima *et al.*[51]
	Induces apoptosis	Levy and Nelson[50]
	Elevates circulating level and expression in pre-eclamptic patients and placenta	Hamai *et al.*,[45] Rinehart *et al.*[46]
TGFβ	Stimulates matrix glycoproteins	Feinberg *et al.*[39]
	Inhibits cellular proliferation and migration	Graham *et al.*,[43] Khoo *et al.*,[44] Roth and Fisher[37]
	Stimulates TIMP secretion by down-regulation of urokinase, plasmin, plasminogen activator	Graham and Lala,[40] Graham *et al.*,[41] Irving and Lala[42]
TGFα	Promotes differentiation	Irving and Lala[42]
LIF	Inhibits gelatinolytic activity	Bischof *et al.*[54]
IGF2	Stimulates differentiation and migration	Irving and Lala[42]
IGFBP1	Increases cell migration, invasion, TIMP-1 secretion and gelatinolytic activity	Irving and Lala,[42] Hamilton *et al.*,[52] Bischof *et al.*[53]
VEGF	Increases proliferation and NO release	Charnock-Jones *et al.*,[18] Athanassiades *et al.*,[25] Ahmed *et al.*[26]
	Involves in tube-like formation in matrigel (VEGFR)	Zhou *et al.*[22]
Ang2	Increases proliferation and NO release	Dunk *et al.*[23]

IL, interleukin; TNF, tumor necrosis factor; TGF, transforming growth factor; LIF, leukemia inhibitory factor; IGF, insulin-like growth factor; IGFBP, IGF binding protein; VEGF, vascular endothelial growth factor; Ang, angiopoietin.

suggested that the alteration of integrin expression during differentiation of EVT may be responsible for mediating distinct signals to EVT upon adhesion to ECM. In other words, ECM regulates EVT differentiation; however, at the same time, this is an adaptation for EVT.

We should note physiological microenvironments surrounding EVT during early pregnancy. Hypoxia and oxidative stress caused by hypoperfusion and transient ischemia affect cytokine production.[56–58] Placental VEGF expression is up-regulated by hypoxia.[59] Hypoxia also induces proinflammatory cytokines including TNFα.[60] TNFα plays a pivotal role in pregnancy[61] and seems to be necessary for fetal development because it is expressed in normal tissues of a wide range of organs in the human fetus.[62] Zhou *et al.*[22] suggested that the signal from VEGF–VEGFR is involved in the alteration of integrin switching. We have found that TNFα and VEGF induce integrin αVβ3 expression and aggregation in an immortalized human EVT cell line.[63] It might be assumed that signals via αVβ3 integrin receptor and VEGFR are involved in endovascular differentiation. TNFα induces expression of VEGF in several kinds of cells.[64,65] Thus, there could be sequential and synergistic effects between TNFα and VEGF together with ECM in the physiological regulation of EVT differentiation. This hypothesis might explain biological communication between the maternal microenvironment and fetal trophoblast. As an immunological defending response, maternal cells secrete TNFα. Although some trophoblast cells are eliminated by apoptosis, at the same time, ECM could act as a survival factor for trophoblast cells through

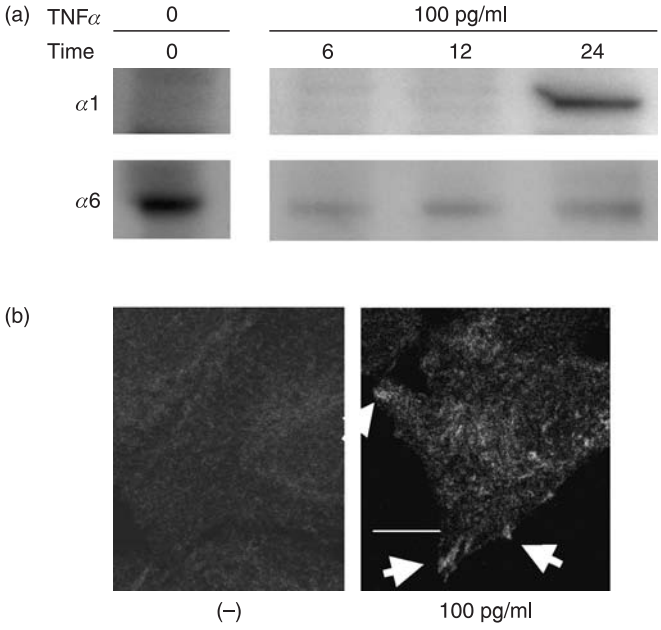

Figure 62.3 TNF induces integrin subunit switching in TCL1 cells. (a) Immunoblot analysis using anti-1 and -6 integrin subunits. TCL1 cells were seeded and grown at 37°C. After 1 day of incubation, the medium was replaced with fresh, complete medium containing 10% fetal calf serum and 20 or 100 pg/ml TNF for the indicated times. Cellular proteins were extracted and then analyzed by immunoblotting. Reproduced from Ref. 51. (b) TNF strengthens integrin adhesive functions. TCL1 cells were seeded on collagen type I-coated coverslips. The cells were incubated with or without 100 pg/ml TNF for 24 h. Cells were then fixed and stained with an anti-1 integrin subunit monoclonal antibody. The white arrows indicate integrin 1 subunit aggregation. Reproduced from Fukushima *et al*.[51]

integrin signaling if they can successfully convert phenotype. TNFα also enhances the formation of a number of endothelial cell molecules.[66] If excessive hypoxia and/or inflammation develop, such regulation might be impaired with induction or failure of both cellular survival and EVT differentiation. Indeed, when cultured under hypoxic conditions, CT cells fail to differentiate.[67]

In this chapter, we have presented research findings along with EVT invasion, which has been implicated as one of the 'key phenomena' in the normal placentation and hypothec paradigm. TNFα together with VEGF-systems might be key players in this differentiation adaptation with ECM. Of course, there have been suggestions that many other soluble factors could be involved in the regulation of trophoblast phenotype, and there are probably other key molecules that are essential for invasive phenotype, e.g. regulation of MMP secretion and activity. It is necessary to take into account cross talk among these molecules in the course of a normal pregnancy. Much more data are needed in order to integrate the current pieces of research evidence for this very interesting field.

63 Trophoblast dysfunction and maternal endothelial cell dysfunction in the pathogenesis of pre-eclampsia

K. Tsukimori, K. Fukushima and H. Nakano

The etiology and pathogenesis of pre-eclampsia remain poorly understood. Several investigators have suggested that poor placentation is an important predisposing factor of pre-eclampsia and that endothelial cell dysfunction underlies disease manifestations.[1–4] In response to reduced placental perfusion due to poor placentation, the placenta may promote the release of various factors that initiate systemic endothelial cell dysfunction, leading to an increase in both vascular resistance and arterial pressure and activation of the coagulation cascade associated with pre-eclampsia. In this chapter, we focus on functional abnormalities of the placenta and trophoblast in pre-eclampsia, as well as the potential cellular and molecular mechanisms that contribute to the maternal endothelial cell dysfunction seen in this disorder.

Poor placentation

During early pregnancy, cytotrophoblast (CT) cells invade the uterus and its spiral arteries (in interstitial and endovascular invasion, respectively). As a result of endovascular invasion, CT cells replace the endothelial layers of spiral arteries with destruction of the medial elastic, muscular, and neural tissue. This replacement substantially decreases vascular resistance, resulting in increased blood flow toward the intervillous space.[5,6] In pre-eclampsia, extravillous trophoblast (EVT) cell invasion of the uterus is shallow, and endovascular invasion does not progress beyond the terminal portion of the spiral arteries (Figure 63.1).[5] Myometrial segments of these arteries remain anatomically intact and undilated; in addition, adrenergic nerve supply to the spiral arteries is not affected. The mean external diameters of the uterine spiral arteries in women with pre-eclampsia are less than one-half the diameters of similar vessels from uncomplicated pregnancies. The failure of EVT invasion in pre-eclampsia results in a reduction in uteroplacental perfusion. Because the process of EVT invasion of spiral arteries is normally completed by weeks 20–22 of gestation,[7] a critical underlying lesion in pre-eclampsia is the failure of EVT to invade the myometrial portion of the muscular spiral arteries.

Normal trophoblast invasion requires meticulously regulated expression of specific adhesion molecules for both cell–cell interactions as well as cell–extracellular matrix (ECM) interactions.[8] In pre-eclampsia, CT cells increase expression of adhesion molecules present in the initial proliferative phenotype, $\alpha5\beta1$, but fail both to upregulate adhesion molecules that promote invasion, $\alpha1\beta1$, and to down-regulate molecules that inhibit invasion, $\alpha6\beta4$ (Table 63.1).[9–12] Thus, the cells appear arrested in their differentiation and express an ECM receptor phenotype that may not be optimal for invasion.[12] In addition, endovascular invasion seems to require the ability of endovascular trophoblast cells to alter phenotype to resemble vascular endothelial cells.[13] In pre-eclampsia, trophoblast cells in decidual vessels do not express the endothelial antigens vascular adhesion molecule-1 (VCAM-1) and platelet endothelial adhesion molecule-1 (PECAM-1).[12] When these data are considered together, this overall dysfunctional expression of adhesion molecules may be responsible for the pathological findings of impaired interstitial and endovascular invasion in pre-eclampsia.

Factors involved in poor placentation

Hypoxic environment

Several studies suggest that oxygen tension can modulate trophoblast differentiation. Fox and Path

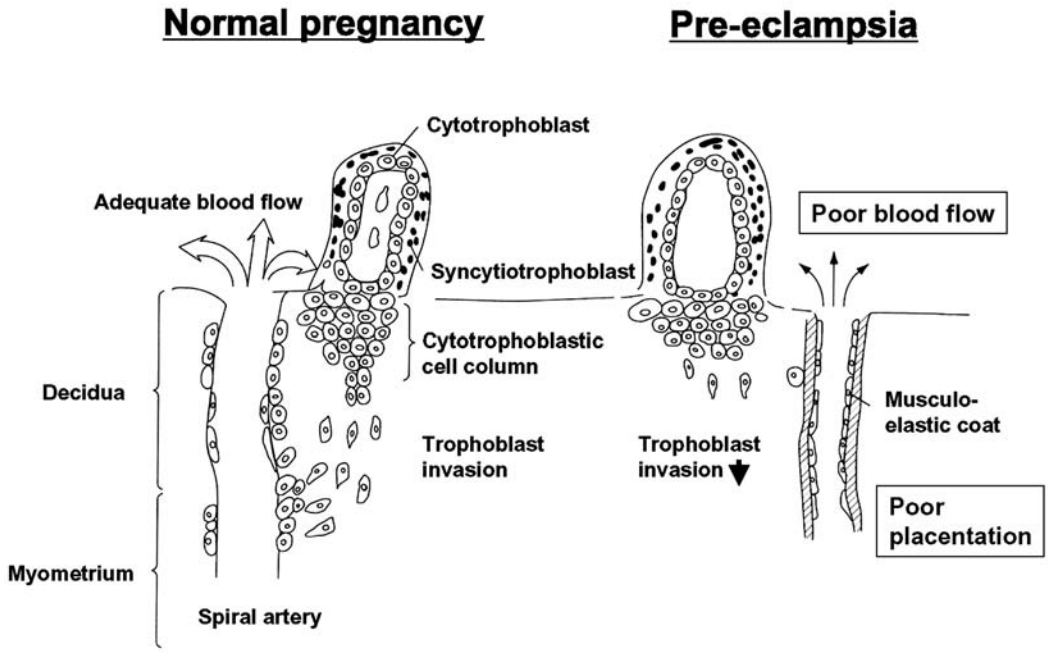

Figure 63.1 Trophoblast invasion in normal and pre-eclamptic pregnancies. Modified from Saito *et al.*[23] with permission.

Table 63.1 Integrin expression by cytotrophoblast cells in normal and pre-eclamptic pregnancies (modified from Zhou et al.[12])

Integrin receptor	ECM ligands	Functional link	Change from villus to placental bed	
			Normal pregnancy	Pre-eclampsia
$\alpha6/\beta4$	BM ligand (Ln ?)	Inhibit invasion	Down-regulated	Unchanged
$\alpha5/\beta1$	Fn	Initial proliferation	Upregulated	Up-regulated
$\alpha3/\beta1$	Ln, Fn, Col	Proliferation	Uniformly expressed	Uniformly expressed
$\alpha1/\beta1$	Ln, Col IV, Col I	Promote invasion	Up-regulated	Not expressed (weakly expressed)

ECM, extracellular matrix; BM, basement membrane; Ln, laminin; Fn, fibronectin; Col, collagen

reported that placental villi cultured under hypoxic conditions showed variable syncytial degeneration and a marked increase in the number and growth-promoting activity of CT cells.[14] More recently, using an *in vitro* organ culture model, CT maintained under hypoxic conditions failed to express integrin $\alpha1$ and VE-cadherin.[15,16] These findings suggest that under hypoxic conditions CT cells enter a proliferative pathway and do not differentiate to the invasive phenotype. The adhesion molecule phenotype of these cells mimics that of CT from women with pre-eclampsia.[12]

In vitro, hypoxia stimulates the production of inflammatory cytokines and other mediators such as tumor necrosis factor-α (TNF-α), Interleukin (IL)-1α, IL-1β,[17] and transforming growth factor-β (TGFβ)[18] by trophoblasts. TNF-α induces apoptosis,[19] integrin subunit conversion, and functional activation in an EVT cell line.[20] TGFβ also inhibits cellular proliferation and migration.[21–23] In addition, trophoblasts under hypoxic conditions increase production of soluble fms-like tyrosine kinase 1 (sFlt-1), an antagonist for both vascular endothelial growth factor (VEGF) and placental growth factor (PlGF).[24] The enzyme sFlt-1 is involved in an alteration of integrin switching that decreases cell invasiveness.[25] In placentas from women with pre-eclampsia, there is increased production of TNF-α,[17] TGFβ,[18] and sFlt-1,[25,26] as well as decreased production of VEGF.[25] Taken together, this evidence suggests that hypoxia induces production of inflammatory cytokines and/or growth factors and then modulates cytotrophoblast differentiation and adhesion antigen expression, resulting in the inadequate invasion seen in pre-eclampsia.

Immunologic factors

Epidemiological evidence indicates that first pregnancy, change of partner, donor insemination, and use of barrier contraceptives all increase the risk of pre-eclampsia, suggesting that a prior immune response to foreign or paternal antigens protects against development of pre-eclampsia.[27–29] In pre-eclampsia, human leukocyte antigen (HLA)-G, a surrogate auto-antigen known to prevent recognition by natural killer (NK) cells, is not expressed in trophoblasts.[30,31] HLA-G down-regulates NK cell-mediated cytotoxicity[32] and suppresses IL-2–induced cell damage.[33] The soluble HLA-G1 isoform also down-regulates CD8-positive T cell (cytotoxic T cell) reactivity.[34] These findings suggest that invasive trophoblast lacking HLA-G is attacked by NK cells and cytotoxic T cells, resulting in the inadequate trophoblast invasion seen in pre-eclampsia. Recently, Saito and colleagues reported that pre-eclampsia is associated with a Th1 predominant immunity.[35] Th1-type cytokines such as IL-2, IFN-γ, TNF-α, and TNF-β activate cytotoxic T cells and NK cells. Activated cytotoxic T cells and NK cells can attack invading trophoblasts, causing a failure of trophoblast invasion.

Genetic factors

There is evidence of an increased incidence of pre-eclampsia among sisters, mothers, and daughters. Some studies have implicated several genes as risk factors for pre-eclampsia including angiotensin,[36] endothelial nitric oxide synthase (eNOS),[37] TNF-α,[38] the factor Leiden mutation,[39] and hyperhomocysteinemia.[40] Recent data focused on fetoplacental rather than maternal acting genes suggest that fetoplacental genes may carry an associated risk. These could be genes encoding factors associated with CT invasion. The risk of pre-eclampsia increases with a change in partner,[41] implying the importance of paternal genes. By following both men and women who were products of pre-eclamptic pregnancy, it has been suggested that both maternally and paternally inherited genes play a contributory role,[42] possibly by contributing to the genetic constitution of the placenta.

Biological changes of placental function

Poor placentation causes a reduction in uteroplacental perfusion, causing placental ischemia/hypoxia. Placental ischemia/hypoxia is known to induce several mediators such as reactive oxygen species (ROS) and inflammatory cytokines. Several biochemical abnormalities have been reported in placentas obtained from women with pre-eclampsia (Table 63.2).

Increased oxidative stress

Increased superoxide (O_2^-) synthesis rates have been noted in placentas from women with pre-eclampsia.[43,44] The expression of xanthine oxidase, which is an important source of O_2^- generation, is also enhanced in placentas from women with pre-eclampsia.[45] As an indirect indication of excessive generation of ROS, nitrotyrosine content, a stable marker for peroxinitrite ($ONOO^-$), is increased in placentas from women with pre-eclampsia.[46,47] When oxygen free radicals are not eliminated by antioxidants, lipid peroxide formation is induced.[48] Placental levels of lipid peroxidation products, as well as other markers of oxidative stress such as malondialdehyde (MDA),[49,50] 8-iso-PGF2α,[51] and protein carbonyl[52] are increased. *In vitro* production of lipid peroxides is also increased in trophoblasts from women with pre-eclampsia.[51,53,54] Placental antioxidant levels such as vitamin E, as well as the activities of glutathione peroxidase,[55] and both mRNA expression and enzyme activity for Cu/Zn-superoxide dismutase (SOD), are decreased in pre-eclampsia.[44] Thus, the placenta represents a state of oxidative stress in pre-eclampsia.

Altered cytokine production

Expression of inflammatory cytokines such as TNF-α and IL-1β is increased in pre-eclamptic placentas.[56,57] However, Benyo and colleagues failed to observe increased mRNA levels of both TNF-α and IL-1β in pre-eclamptic placenta.[58] Placental levels of IL-8,[59] IL-10,[60] and IL-15[61] are decreased in pre-eclampsia. Thus, although the picture is not entirely clear, placental cytokine production is altered in pre-eclampsia.

Increased vasoconstriction

Placental thromboxane production is increased, whereas placental PGI_2 production is decreased in pre-eclampsia.[62,63] Endothelin (ET)-1 expression and production are increased in trophoblasts obtained from women with pre-eclampsia.[64,65] Regarding nitric oxide (NO) production, Napolitano and colleagues reported that inducible nitric oxide synthase (iNOS) expression, which represents the main source of NO, is decreased; conversely, endothelial nitric oxide synthase (eNOS) expression is increased in trophoblasts obtained from women with pre-eclampsia.[64] In contrast, other investigators have failed to observe increased eNOS activity[66] and eNOS immunostaining levels.[67] Page and colleagues reported that expression of neurokinin (NK) B is increased in trophoblasts from women with pre-eclampsia.[68] Thus, in pre-eclampsia placental vasoconstrictor production is increased, whereas placental vasodilator production is decreased.

Table 63.2 Biological changes in pre-eclamptic placenta

Marker or activity	Location	Reference no(s).
Increased oxidative stress		
Increased superoxide synthesis	Placental tissue and trophoblast cells	43, 44
Increased xanthine oxidase expression	Invasive cytotrophoblast	45
Increased nitrotyrosine immunostaining	Invasive cytotrophoblast	46, 47
Increased MDA level	Placental homogenate	49, 50
Increased 8-isoprostane level and production	Placental tissue pieces	51
Increased protein carbonyl level	Placental and decidual homogenate	52
Increased lipid peroxide production	Trophoblast cells and villous tissue	51, 53, 54
Decreased glutathione peroxidase activity	Placental homogenate	55
Decreased vitamin E level	Placental homogenate	55
Decreased Cu/Zn-SOD activity and mRNA expression	Trophoblast cells	44
Altered cytokine production		
Increased TNF-α production and mRNA expression	Placental tissue	56, 57
Increased IL-1β mRNA expression	Placental tissue	56
No change for inflammatory cytokine (TNF-α, IL-1α, IL-1β, IL-6) mRNA expression	Placental homogenate	58
Decreased IL-8 production	Placental villous tissue	59
Decreased IL-10 immunostaining	Villous trophoblast cells	60
Decreased IL-15 production	Placental tissue and trophoblast cells	61
Increased vasoconstriction		
Increased thromboxane production	Placental tissue and cytotrophoblast	62, 63
Increased ET-1 production and mRNA expression	Trophoblast cells	64, 65
Increased NKB mRNA expression	Outer syncytiotrophoblast	68
Decreased prostacyclin production	Placental tissue and cytotrophoblast	62, 63
Decreased iNOS mRNA expression	Trophoblast cells	64

MDA, malondialdehyde; TNF, tumor necrosis factor; IL, interleukin; ET, endothelin; NKB, neurokinin B; iNOS, inducible nitric oxide synthase

Maternal endothelial cell dysfunction in pre-eclampsia

Several pieces of evidence indicate that adverse changes in structure and function of the maternal vascular endothelium account for the altered vascular reactivity, activation of the coagulation cascade, and multisystem damage that occurs in pre-eclampsia.[69,70] Pathologic changes in endothelial cells that line the renal glomerular capillaries (glomerular endotheliosis) are a consistent feature in women with pre-eclampsia.[71–73] Structural changes of the endothelium have been found in uteroplacental vessels.[74] In addition, functional evidence of endothelial alteration has been reported. The level of the endothelial prostanoid prostacyclin (PGI_2) is reduced weeks before as well as during clinically evident pre-eclampsia.[75–77] Vessels removed from women with pre-eclampsia manifest reduced endothelial-mediated vasodilator function.[78–80] A variety of substances indicative of endothelial dysfunction are increased in the blood of women with pre-eclampsia including cellular fibronectin (cFN),[81–83] von Willebrand factor,[84,85] thrombomodulin,[86,87] and VCAM-1.[88,89] Many of these substances including serum soluble VCAM-1[90] and cFN[83] are elevated weeks before pre-eclampsia becomes clinically evident.

Linkage between placental dysfunction and maternal endothelial dysfunction

To link placental dysfunction with the generalized endothelial dysfunction seen in pre-eclampsia, the existence of factor X, released from the placenta into the maternal circulation, was proposed. Indeed, we and other investigators have reported that serum from women with pre-eclampsia has a cytotoxic effect on cultured endothelial cells.[91,92] The factor seems to modulate endothelial cell function rather than damage the cells directly. In response to serum or plasma from women with pre-eclampsia, production of PGI_2[93,94] and NO[95–97] is altered, and increases are seen in cFN production,[98,99] mitogenic activity,[100,101] uptake of fatty acids,[102] and expression of platelet-derived

growth factor (PDGF).[103] Many of these activities are not only elevated weeks before pre-eclampsia becomes clinically evident, but, as with the clinical signs of the syndrome, they disappear shortly after delivery.[91,99–101] Initially, Factor X was thought to be a single factor, but increasing evidence suggests the presence of several interacting factors. Several candidate factors have been proposed, including oxidative damage products, proinflammatory cytokines, syncytiotrophoblast microvesicles (STBM), and angiogenic factors.

Oxidative damage products

Circulating levels of lipid peroxidation products such as MDA[104–106] and 8-iso-PGF2α[50,107] are increased in pre-eclampsia. As described above, these products are elevated in concentration in trophoblasts from women with pre-eclampsia. Increased lipid peroxidation increases endothelial monolayer permeability to protein[108] and increases incorporation of fatty acids into endothelial cell membranes.[109] Free 8-iso-PGF2α is also a biologically active vasoconstrictor *in vivo*.[110] Nitrotyrosine staining, a stable marker for $ONOO^-$ is increased in sera from women with pre-eclampsia[111] and in pre-eclamptic placenta.[46,47] The free radical $ONOO^-$ is one of the most potent reactive species, and it can lead to increases in lipid peroxides and direct or indirect cellular damage.[112]

Proinflammatory cytokines

Proinflammatory cytokines such as TNF-α and IL-1β can produce endothelial dysfunction either directly or by activating maternal leukocytes.[3,113,114] In pre-eclampsia, circulating levels of IL-6, TNF-α,[115–117] and its two soluble receptors (p55 and p75 TNF-R)[117] are increased. Expression of placental cytokines including TNF-α and IL-1β is also increased in pre-eclampsia.[56,57] In contrast, Benyo and colleagues demonstrated that placental levels of inflammatory cytokines (e.g., TNF-α, IL-1α, IL-1β, and IL-6) are not altered,[58] suggesting that tissues other than the placenta, such as activated leukocytes or endothelium, may be involved in the elevation of inflammatory cytokines found in the circulation of women with pre-eclampsia. Hung and colleagues reported that hypoxia–reoxygenation of placental tissue *in vitro* increases production of TNF-α and causes endothelial dysfunction,[118] suggesting that a local inflammatory response can induce systemic endothelial dysfunction either directly or by activating maternal leukocytes during their passage through the placenta.

Syncytiotrophoblast microvesicles (STBM)

Circulating STBM are detected in the plasma of normal pregnant women, but they are present in significantly increased amounts in women with pre-eclampsia.[119] STBM induce ultrastructural endothelial cell injury[120,121] and reduce endothelial cell-mediated vasodilation in isolated human arteries.[122] Hung and colleagues reported that *in vitro* hypoxia–reoxygenation stimulates apoptotic changes within syncytiotrophoblasts in normal third-semester placentas, suggesting that aponecrotic processes secondary to reduced placental perfusion can lead to deportation of STBM into the maternal circulation.[123]

Angiogenic factors

VEGF is a well-known promoter of angiogenesis, and it also induces nitric oxide and vasodilatory prostacuclins in endothelial cells suggesting a role in decreasing vascular tone and blood pressure.[124,125] Decreased concentrations of circulating free VEGF have been noted in women with clinical pre-eclampsia,[26] and decreases have even been detected before clinically evident pre-eclampsia developed.[126,127] Recent studies have demonstrated that sFlt-1, an antagonist for VEGF, is increased in serum[26,128–130] and placenta[25,26] from women with pre-eclampsia. Levine and colleagues reported that increased levels of sFlt-1 predict subsequent development of pre-eclampsia.[129] In addition, animal model experiments have recently demonstrated that exogenous sFlt-1 administered to pregnant rats induces hypertension, proteinuria, and glomelural endotheliosis.[26] Nagamatsu and colleagues reported that trophoblasts under hypoxic conditions *in vitro* increase production of sFlt-1.[24] Interestingly, recent evidence suggests that TNF-α also stimulates the release of sFlt-1 from placental explants.[131]

Maternal and placental interactions in pathogenesis of pre-eclampsia

Abnormal placentation is not uniquely associated with pre-eclampsia. For example, infants with intrauterine growth restriction[132] and one third of infants with preterm birth[133] manifest abnormal features of placentation identical to those seen in pre-eclampsia. It has been proposed that abnormal placentation must interact with maternal factors to cause the clinical features of pre-eclampsia. Maternal constitutional factors, such as genetic, behavioral, and environmental factors would predispose to pre-eclampsia. These constitutional factors, likely influenced by the unique physiological changes of pregnancy, would interact with placental factors induced by placental ischemia/hypoxia to bring about the pathophysiological changes of pre-eclampsia.[1,134]

Constitutional factors

Preexisting hypertension, diabetes, obesity, and increased insulin resistance, as well as African descent

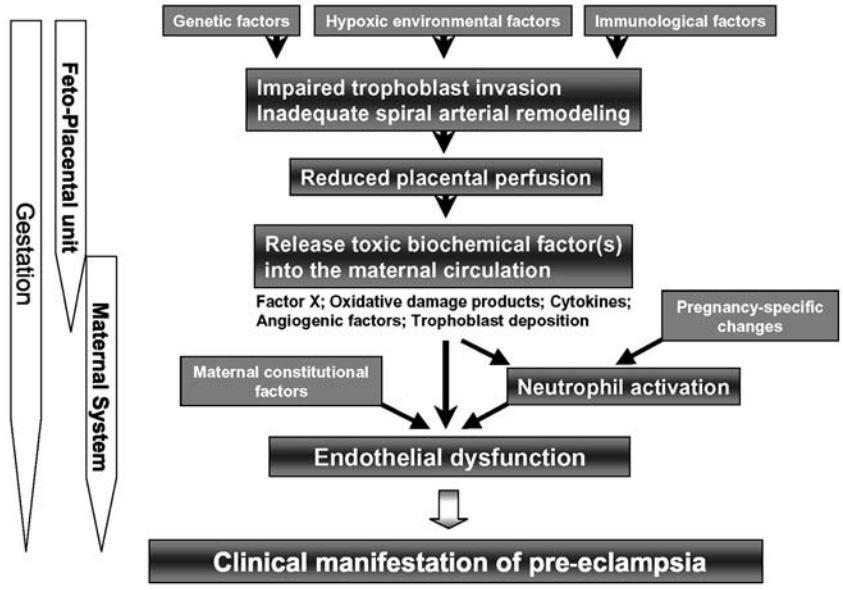

Figure 63.2 Proposed linkage between poor placentation and maternal endothelial dysfunction in pathogenesis of pre-eclampsia. See text for detail.

and increased blood homocysteine concentration, are already known to be predisposing factors.[135] Interestingly, these are also risk factors for other endothelial diseases, in particular atherosclerosis. The concept of common risk factors for the two disorders is supported by the relationship of pre-eclampsia to cardiovascular disease in later life.[136,137] In addition, pre-eclampsia and atherosclerosis share common alterations of lipid profile including elevated triglycerides,[104] reduced HDL-cholesterol,[138] and increased small dense LDL-cholesterol.[139] LDL particles are smaller than those of normal controls, which may facilitate their oxidation.[140,141]

Pregnancy-specific changes

It is well known that a neutrophilic leukocytosis occurs in pregnancy.[142] Sacks and colleagues used whole blood flow cytometric techniques to report that normal third-trimester pregnancy is characterized by remarkable activation of peripheral blood leukocytes, an activation that is further increased in pre-eclampsia.[143] We and other investigators have demonstrated that isolated neutrophils from women with pre-eclampsia synthesize more superoxide than those of normotensive pregnant women.[144-146] In an investigation of the mechanism of extreme neutrophil activation in pre-eclampsia, Aly and colleagues demonstrated that STBM, which are present in blood in elevated levels in pre-eclampsia,[119] lead to activation of maternal neutrophils.[147] Maternal neutrophils could also be locally activated during passage of maternal blood through the placenta.[117,148] In addition, we have reported that sera from women with pre-eclampsia enhance superoxide production of neutrophils *in vitro*.[144] The interaction of these activated neutrophils with endothelium would then result in the release of reactive oxygen species and endothelial injury.[149] Taken together, this evidence suggests that activated neutrophils, occurring as a usual component of maternal response to pregnancy, could provide a link between the placental dysfunction and maternal endothelial cell dysfunction seen in pre-eclampsia.

Conclusion

The two central pathophysiological themes of pre-eclampsia are placental trophoblast dysfunction and endothelial cell dysfunction within the maternal systemic vasculature. As discussed above, it has been proposed that multiple factors (e.g., hypoxic environmental, genetic, and immunological factors) may lead to impaired trophoblast invasion and inadequate spiral arterial remodeling (Figure 63.2). This, in turn, results in reduced placental perfusion. In response to this ischemic and/or hypoxic state, affected placentas secrete or elaborate substances into the maternal circulation that directly or indirectly cause systemic vascular endothelial cell dysfunction. In addition, pregnancy-specific changes (e.g., activation of neutrophils) combined with maternal constitutional factors (e.g., genetic disposition and circulating lipoproteins) are also involved in

development of pre-eclampsia. It is necessary to clarify the mechanisms involved in placental and maternal endothelial dysfunction and to identify the factor(s) connecting them in order to understand, treat, and eventually prevent pre-eclampsia.

64 Basic aspects of trophoblastic disease

N. Wake, K. Asanoma, T. Matsuda and H. Kato

Genetics of hydatidiform moles

Hydatidiform moles that have grossly swollen villi are divisible into two entities: the classical complete mole and the partial mole. The complete mole presents as a rapidly progressing hydatidiform change affecting the whole placenta, with widespread and gross trophoblastic hyperplasia in the absence of an embryo and its covering amnion. The majority of complete moles have a 46, XX karyotype. Inspection of the karyotype of a mole and its parents readily reveals that both members of chromosome pairs of the complete mole are traceable to one paternal chromosome. Thus, these moles result from duplication of a paternal haploid set in a functionally empty ovum, a process called androgenesis. Most probably, these moles develop from fertilization of an empty ovum by a haploid sperm followed by the duplication of its chromosomes.[1–6] The maternal nuclear complement is either eliminated or inactivated in an empty ovum. This mechanism would account for the preponderance of XX moles, because their YY counterparts are probably lost during early cleavage stages.

The rare 46, XY moles can also be found.[7–9] Estimates of the total number of these moles range from 4% to 20% in a small series. Southern blots of polymerase chain reaction (PCR) products clearly demonstrate that both alleles shown in the mole derive from the two paternal alleles in some gene loci, whereas the allele derives from one of two paternal alleles in the remaining loci. The genetic features shown in these moles are compatible with fertilization of an empty egg by two spermatozoa. Dispermy would result in an XX, XY or YY sex chromosome constitution, in a 1:2:1 ratio. Again, YY moles are lethal.

In addition to androgenesis, occasional complete moles that are diploid but biparental in origin have been described. While androgenetic complete moles are usually sporadic, biparental complete moles are associated with a predisposition to recurrent molar pregnancies and frequently occur in more than one member of a family. Women with a biparental complete mole have a much greater risk of having more complete moles than women with an androgenetic complete mole or partial mole, and have an appreciable risk of persistent trophoblastic disease. The biparental complete mole arises from an unusual pregnancy associated with a failure to set maternal imprints within the ovum. The gene, mutated in the woman with a biparental complete mole, shows an autosomal recessive mode of inheritance and has been mapped to chromosome 19q 13.4.

In the partial moles there is a slow hydatidiform change that affects only some of the villi. There is focal, moderate, trophoblastic hyperplasia, irrespective of the survival of the embryo. An accumulation of cytogenetic data has shown that dispermic triploids that were products of an intact ovum fertilized by two spermatozoa were responsible for these partial moles.[10–13] We have encountered unusual cases of partial moles in the course of systematic cytogenetic studies of partial moles, each with a tetraploid karyotype. These rare partial moles result from the combination of a haploid ovum with three paternal haploid sets as a result of trispermic fertilization.[14–16] The majority of partial moles result from dispermic triploids. Tetraploids with one maternal and three paternal haploid sets provide unequivocal morphological examples of partial moles. In addition to these, complete moles that involve the whole placenta in hydatidiform changes are androgenetic in origin. These findings illustrate an intriguing correlation between a molar phenotype and the ratio of paternal to maternal genome in the conceptus. In this connection, the fact that benign ovarian teratomas are parthenogenetic in origin leads to the possibility that the maternal and paternal genomes are not functionally equivalent. The teratoma that consists of embryonic tissue elements in the absence of extraembryonic tissues has two maternally derived haploid sets. These findings point to some dependence of the extraembryonic tissues, notably trophoblast, on the paternal genome, while some maternal genes are

apparently required for the development of the embryo proper. Only male plus female diploid combinations of pronuclei would give rise to normal embryos. Particular sets of genes undergo a separate specific imprinting during oogenesis and spermatogenesis. Most probably, disruption of imprinted regulation for a particular set of genes in complete and partial moles contributes to the formation of molar phenotypes, but these remain to be identified. Histopathological criteria to differentiate between partial and complete moles are inconsistent among countries. In addition, histological features overlap significantly between these moles, especially when the moles are evaluated in the early gestational stage. These indicate the necessity of genetic demonstration of each class of moles.

Malignant trophoblastic neoplasms with different modes of origin

It is well known that the complete mole has a propensity to malignancy. However, there has been no direct proof in the majority of patients that choriocarcinoma indeed derived from a complete mole. The androgenetic origin of complete moles provides us with a method for determining the origin of choriocarcinomas. The genome of choriocarcinoma should reflect that of the pregnancy from which the tumor arose. After a live birth or spontaneous abortion, both maternal and paternal contributions to the genome should be present in the tumor genome. Choriocarcinoma after complete mole conceptions should carry only the paternal genome. The absence of a paternal contribution in the tumor genome is a feature of non-gestational choriocarcinoma. Based on these genetic backgrounds, a small number of choriocarcinomas have been examined so far.[17–23] However, the number of cases reported is too small to show whether there is a predominant association of complete mole with choriocarcinoma or not. Thus, we examined the genetic origin of a relatively large number of trophoblastic tumors in order to demonstrate the propensity to malignancy of the complete mole.

Genomic DNAs obtained from 24 fresh or paraffin-embedded tumors were successfully amplified by PCR.[24.] Based on pregnancy history, these tumors included (1) 9 postmolar trophoblastic tumors, (2) 12 tumors preceded by live birth or abortion and (3) 3 non-gestational tumors. PCR polymorphism data revealed the absence of a maternal genome in eight postmolar trophoblastic tumors (Table 64.1). This was contrasted with the presence of a maternal genome in all 12 tumors preceded by live birth or abortion and in the three non-gestational tumors. Thus, these eight postmolar trophoblastic neoplasms developed from malignant transformation of complete moles. Six tumors were homozygous at three or more gene loci in which the partners were heterozygous. A female sex chromosome constitution was anticipated because PCR failed to amplify any fragment specific to the *SRY* (which is specific to the Y chromosome) gene sequence in these tumors. These genetic features may be compatible with those of the complete mole that results from fertilization of an empty egg by an X-bearing sperm. The heterozygosity was recognized in two tumors at a few gene loci. The 240-base-pair (bp) PCR product specific to the *SRY* gene sequence was present in one tumor but not in the other. It seemed likely that the two tumors originated from an XX or XY dispermic, androgenetic mole (Figure 64.1).

The remaining choriocarcinoma contained an allele derived from the patient at a few gene loci. This finding is compatible with the assumption that the tumor did not arise from a complete mole. A full-term delivery prior to a complete mole conception would explain this tumor development.

All 12 tumors in class (2) had alleles of both paternal and maternal contribution. However, discordance of sex between the antecedent pregnancy product and the tumor was recognized in three choriocarcinomas. The absence of a paternal contribution suggested a parthenogenetic origin for the three non-gestational choriocarcinomas. The findings that PCR polymorphisms were either homozygous in certain loci or heterozygous in others may mean that the tumor was derived from a germ cell after meiosis I. As a result, at least three subtypes with different modes of origin were demonstrated in the 24 trophoblastic tumors. Although more than half of the trophoblastic tumors collected here had a maternal contribution to their genomes, the data still support the suggestion that of all forms of pregnancy that predispose patients to choriocarcinoma, the most likely is the complete mole.

Molecular mechanisms associated with trophoblastic diseases

Gene expression profile in complete moles

Kato *et al.*[25] used microarray analysis to investigate the expression profiles of 589 genes committed to cell growth control, in order to characterize the regulatory circuitry for cell proliferation in complete moles. Complete moles are characterized by hyperplastic trophoblasts and have a high propensity to cause choriocarcinoma. Characteristic alterations in gene expression profiles were observed when compared with normal villi. A total of 57 genes were significantly up-regulated in complete moles. These involved the Ras/mitogen-activated protein kinase III, Janus kinase/STAT5 and Wnt signal pathways, implicating growth factor- or cytokine-mediated signal pathways in the trophoblastic hyperplasia of complete moles.

Table 64.1 PCR-polymorphism analysis of choriocarcinomas and invasive mole (antecedent pregnancies were complete moles) and parents

P, paternal DNA; T, tumor DNA; M, maternal DNA; ND, not determined. Bold type indicates a heterozygous pattern in the tumor DNA.

*Invasive mole

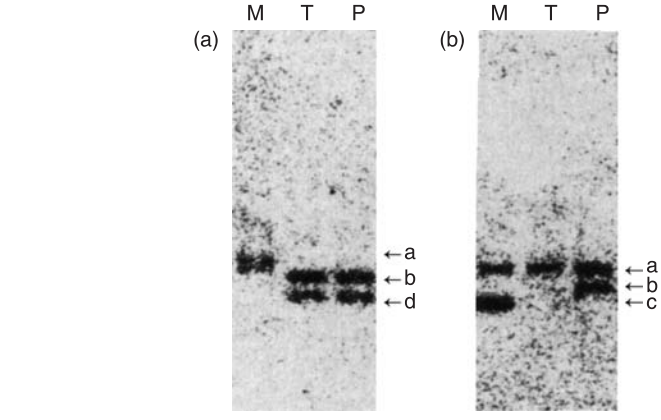

Figure 64.1 PCR–polymorphism of two chonocarcinomas. The tumor showed two bands that were absent in maternal DNA, suggesting an androgenic origin. P, PCR products from paternal DNA; T, PCR products from tumor DNA; M, PCR products from maternal DNA; VNTR, variable number of tandem repeats.

Several genes associated with antiapoptosis, cell structuring and/or cell attachment were also up-regulated in complete moles. In contrast, relatively fewer genes were down-regulated and these involved insulin growth factor binding proteins, Versican, interleukin-1, tumor necrosis factor receptor, CD44 and Rad 52. The genes identified as being up- or down-regulated may help to elucidate the regulation mechanisms of trophoblastic proliferation and the mechanisms causing a pathological phenotype in complete moles (Figure 64.2).[25]

Silencing of NECC1/Hop expression in choriocarcinoma

Choriocarcinoma is a highly invasive tumor consisting of markedly anaplastic trophoblasts totally lacking in residual villous structures. Demonstration of a predominant association between a complete mole and choriocarcinoma suggests that the molecular events of mole and choriocarcinoma development are related, since the putative forerunner carries unique genetic features (as mentioned previously). The

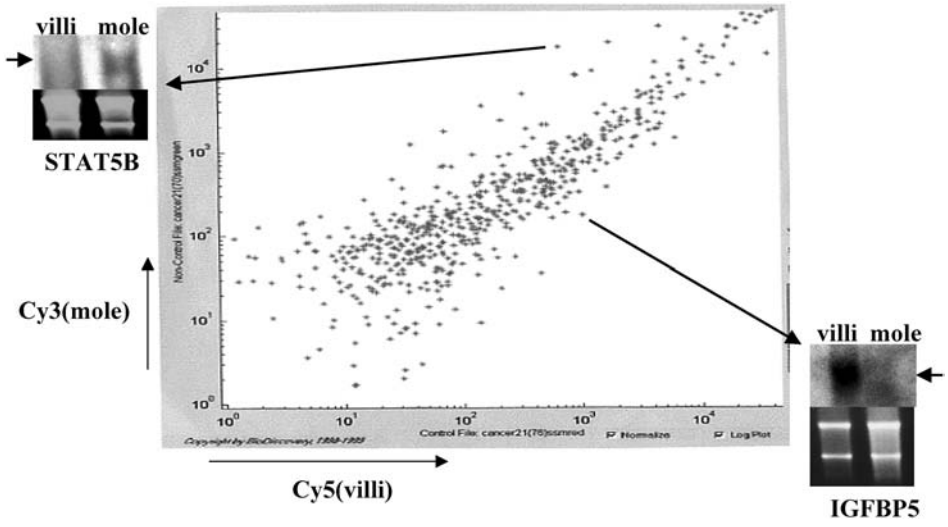

Figure 64.2 A log plot of a microarray experiment demonstrating distribution of 425-gene expression in normal and molar villi. Fluorointensity of Cy-3, which is labeled to mRNA from a complete mole, is plotted vertically. Fluorointensity of Cy-5, from normal villi, is plotted horizontally. Up-regulation of STAT5B expression and down-regulation of 1GFBP5 expression in mole are shown. *x*: Control file: mole red Cy3; *y*: non-control file: norma, villi green Cy5.

monoallelic contribution shown in the complete mole would render a certain gene susceptible to functional inactivation by 'one-hit' kinetics. Alternatively, uniparental transmission of genes that are subject to parental imprinting in humans would impair their regulation. Thus, the features exhibited by a complete mole would be associated with inactivation of particular tumor suppressor genes, contributing to the propensity to malignancy.

Many tumor suppressor genes are inactivated by intragenic mutations in one allele, accompanied by the loss of a chromosomal region containing the remaining allele; this is termed loss of heterozygosity. Mapping of such deleted regions has been used to identify sequences involved in malignancies. However, the monoallelic contribution exhibited by the complete mole and its transformant would mask the chromosomal region where the allelic loss frequently occurs. To resolve this difficulty, Asanoma *et al.*[26] constructed a PCR-subtracted fragmentary cDNA library between normal placenta villi and the choriocarcinoma cell line (CC1) and isolated a candidate choriocarcinoma suppressor gene. This gene comprised an open reading frame of 219 nucleotides encoding 73 amino acid residues and contained a homeodomain as a consensus motif, being identical with homeodomain-only protein (HOP), which is essential for cardiomyocyte development.[27,28] This gene, designated as *n*ot *e*xpressed in *c*horiocar*c*inoma clone 1 (*NECC1*),[26] is located on human chromosome 4q11–q12. *NECC1* expression is ubiquitous in the brain, placenta, lung, smooth muscle, uterus, bladder, kidney and spleen. Normal placental villi expressed *NECC1*, but all of the choriocarcinoma cell lines examined and most of the surgically removed choriocarcinoma tissue samples failed to express it. Asanoma *et al.*[26] transfected this gene into choriocarcinoma cell lines and observed remarkable alterations in cell morphology and suppression of *in vivo* tumorigenesis. Induction of chorionic somatomammotropin hormone 1 (CSH1) and a remarkable alteration in cell morphology including multinucleation by *NECC1* expression suggested the differentiation of choriocarcinoma cells to syncytiotrophoblasts (Figure 64.3).

The tumor suppressive ability of *NECC1* does not require the third/fourth helix and the C-terminal domain. The inhibitory effect of mutant *NECC1*, which deletes the third/fourth helix and the C-terminal domain, on choriocarcinoma cell growth properties is analogous to that of wild-type *NECC1*. The results imply that the DNA binding capability of *NECC1* is not required for choriocarcinoma cell differentiation and the resultant tumorigenic suppression. This unexpected finding may be supported by the previously reported evidence that several homeobox genes exhibit their biological functions in the absence of DNA binding. The data suggest that loss of *NECC1* expression is involved in the malignant conversion of placental trophoblasts.

Human chromosome 7 carries a putative tumor suppressor gene involved in choriocarcinoma

To determine which chromosome carries a putative tumor suppressor gene, microcell hybrids were isolated following fusion of choriocarcinoma cells with

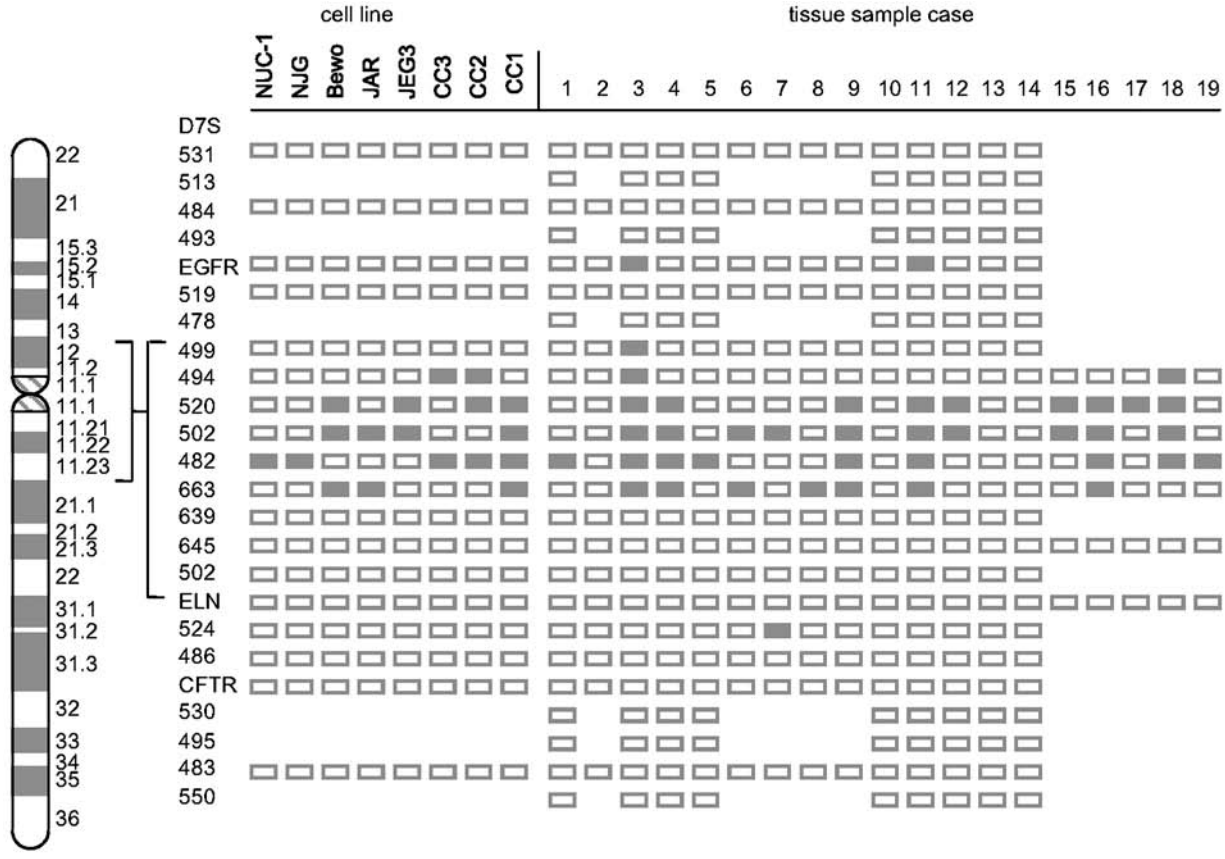

Figure 64.3 Map of homozygous deletions on chromosome 7. Close squares represent homozygous deletions. Open squares indicate the retention of a single or both alleles.

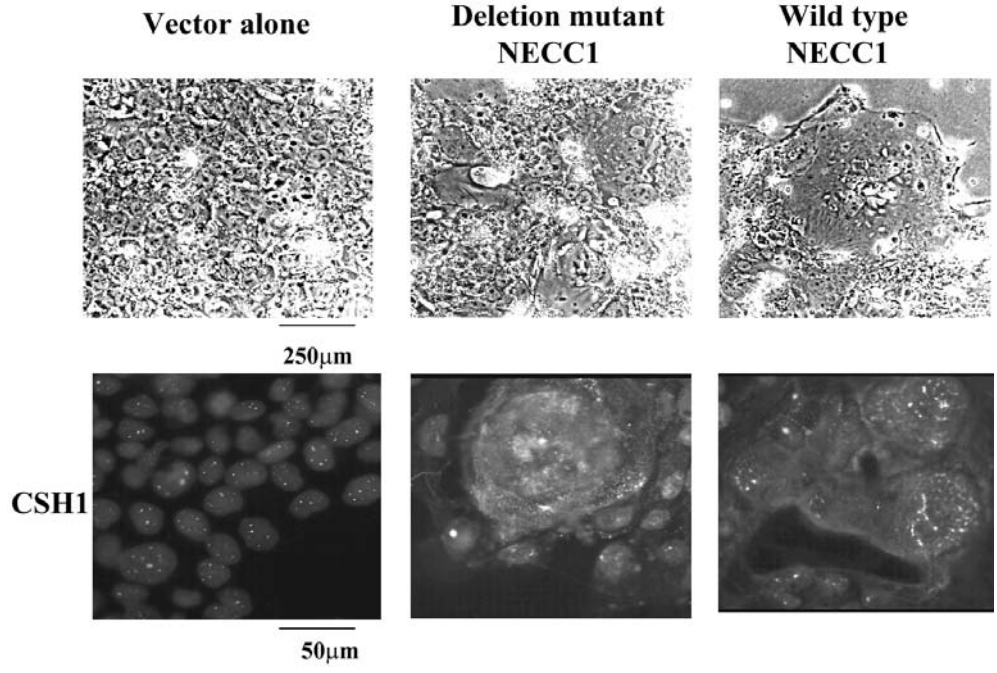

Figure 64.4 Morphology and immunofluorescent staining of NECC1 transfected BeWo cells. BeWo cells transfected with vector only, deletion mutant NECC1, and wild-type NECC1 were photographed using phase-contrast microscopy at 40. Lower photographs are immunofluorescent staining of CSH1. NECC1 deletion mutant and wild-type transfectants expressed abundant CSH1. CSH1, choriomammotropin hormone 1.

microcells from mouse A9 cells containing a single human chromosome, 1, 2, 6, 7, 9 or 11. Microcell hybrids with the introduction of chromosome 7 were suppressed or modulated for tumorigenicity and exhibited altered *in vitro* growth properties. Introduction of chromosomes 1, 2, 6, 9 or 11 had no effect. Tumorigenic revertants isolated from microcell hybrids with the introduced chromosome 7 contained reduced numbers of chromosome 7. These findings suggest that chromosome 7 contains a putative tumor suppressor gene for choriocarcinoma. Changes in the phenotypes seen in microcell hybrids were not associated with the presence of either the *ERV3* or the *H-plk* locus on the introduced chromosome 7, indicating that the putative tumor suppressor gene is outside the *ERV3* and *H-plk* gene loci. Furthermore, we obtained evidence for defining a critical region on chromosome 7 (7p12–7q11.23) that was frequently lost in surgically removed choriocarcinoma tissues and cell lines. Using a panel of microsatellite markers, biallelic deletions were observed, which strongly suggests the presence of a tumor suppressor gene within this critical region (Figure 64.4).[29]

Genome imprinting

It has been clearly established that both paternal and maternal contributions are necessary for maintaining a balanced development of both embryonic and extraembryonic tissues, and the disruption of such a balance may lead to hyperplastic proliferation of the trophoblast, which characterizes molar pregnancies. Based on this hypothesis, it is likely that genomic imprinting, which is disrupted in the androgenetic mole, may play a pivotal role in the development of choriocarcinoma. *H19* and *IGF2* are two classic examples of related imprinted genes. A high level of *H19* expression, in contrast to a considerably lower level of *IGF2* expression, was demonstrated in choriocarcinoma.[30] $P57^{KIP2}$ may also play a role in the pathogenesis of gestational trophoblastic disease (GTD).[31] $P57^{KIP2}$ is a cyclin-dependent kinase inhibitor and is imprinted with the maternal allele being expressed. $P57^{KIP2}$ was found to be highly expressed in proliferating trophoblasts of the normal placenta, but was expressed at a low level in the complete mole and choriocarcinoma. This is in accordance with what is expected on the basis of the imprinting of the maternal allele. However, at present, their exact role and diagnostic usefulness are not clear.

Other molecular events involved in trophoblastic diseases

Malignant transformation in the hydatidiform mole is a multistep process involving the accumulation of several genetic events, including activation of oncogene and/or loss of tumor suppressor genes. A small number of oncogenes and tumor suppressor genes have been found to play putative roles in the pathogenesis of GTD. For example, the oncogenes *c-myc*, *c-erb-B-2*, *bcl-2* and *mdm-2*,[32] the guanosine triphosphatase-activating protein genes, *p53*, *p21 WAF1/KIP1* and *Rb* and the tumor suppressor gene *DOC-2/hDab2*[33] have all been listed as candidates.

There are reports of increased *c-fms* RNA in the complete mole compared with the normal placenta[34] and *c-myc* and *ras* RNA in choriocarcinomas.[35] The significance of such simple quantitative changes in proto-oncogene expression by abnormal trophoblast is hard to evaluate since several proto-oncogenes are already expressed at high levels in normal placentas.

Epidermal growth factor receptors (EGFR) are expressed more strongly in molar placentas than in normal placentas of similar gestational age. Tumors with a histological diagnosis of invasive mole and choriocarcinoma show very strong binding of EGFRs. EGFR expression has been associated with the secretion of human chorionic gonadotrophin. Following exposure to chemotherapy, EGFR binding sites have been noted to be diminished in choriocarcinoma cells.[36]

Summary

The complete mole is androgenetic in origin. The vast majority of complete moles result from the fertilization of an egg devoid of nuclei (an empty egg) by a haploid spermatozoon. Fertilization of an empty egg by two spermatozoa is responsible for a rare class of complete mole. The genome of choriocarcinoma should reflect that of the pregnancy from which the tumor arose. Thus, the predominant association of the complete mole with choriocarcinoma suggests that the molecular events for the formation of a complete mole and the malignant conversion of trophoblasts are related. The monoallelic contribution shown in the complete mole would render a certain gene susceptible to functional inactivation by 'one-hit' kinetics. Alternatively, uniparental transmission of genes that are subject to parental imprinting in humans would impair their regulation. Loss of *NECC1* expression, biallelic deletions at the critical (7p12–7q11.23) region and enhanced *H19* expression in choriocarcinoma would reflect the genetic features exhibited by the putative forerunner, the complete mole. In addition, alterations in gene expression profiles accompanied by malignant conversion of trophoblasts would facilitate choriocarcinogenesis from the complete mole. In the future, identification of molecular targets down- or up-regulated in choriocarcinoma will provide us with the management tools for GTDs.

65 The placenta

K. Benirschke

The normal placenta

In the idealized menstrual cycle of 28 days, fertilization takes place on day 14, the developing blastocyst develops in the fallopian tube, travels through the tube to the endometrial cavity and implants on approximately day 6.[1] It usually implants on the anterior or the posterior surface of the upper endometrium, invades the decidualizing endometrium by ingesting its cells through trophoblastic activity and becomes interstitially implanted, that is to say, it becomes completely surrounded by the endometrium. At first, mostly trophoblastic proliferation takes place around a large cavity, the blastocystic cavity that contains a gel and the tiny embryo. From the gradually developing embryo, the three layers (ectoderm, mesoderm and endoderm) develop; the mesoderm expands into the future umbilical cord, and then comes to line the blastocystic cavity, thus making it the future chorionic membrane, and hence the mesoderm proliferates into the gradually developing villi, from inside outward. The trophoblast, initially polyploid, differentiates into cytotrophoblast from which the syncytiotrophoblast develops on the villous surfaces. The cytotrophoblast differentiates into two components, the villous cytotrophoblast (also called 'Langhans' layer') that underlies the syncytium, and the extravillous trophoblast. It is the latter group of cells that assume the infiltrative arm of the expanding shell; it infiltrates the decidua and, somewhat later, the endometrial (spiral) arterioles. This infiltration stops before the myometrium is reached, thus it normally leaves a thin layer of decidua basalis to remain between the villi and myometrium. It is at this interface where the Nitabuch and Rohr fibrinoid layers are produced, eosinophilic substances that are produced by the extravillous trophoblast. The latter cells, because of their formerly uncertain origin (maternal or fetal), have also been called the 'X-cells'; they often produce small cysts containing major basic protein (MBP). The MBP is similar to that found in the granules of eosinophilic polymorphonuclear cells, and it is secreted into the maternal circulation, like the human chorionic gonadotropin. Its function is completely unknown.

The embryo then lengthens and folds. From the edges of its ectodermal plate the amnionic cavity forms, which then gradually fills with clear fluid. As the embryo folds in all directions, the edges of the ectoderm and amnion come to meet over the developing umbilical cord mesenchyme and the amnion fuses with this mesenchyme tightly. As the amnion fills with fluid (perhaps derived from that contained in the extraembryonic coelom), it expands and gradually becomes passively attached to the inner surface of the chorionic membrane. It completely fuses with this membrane at about 12 weeks of gestation.[2] Prior to that fusion, it is being held in position by the gel of the extraembryonic coelom (Figure 65.1).

It is important to realize that the amnion has an inner epithelial layer that rests on a complex connective tissue layer, but it does not contain blood vessels. Moreover, the amnion can usually be dislodged from the chorionic surface of the placenta

Figure 65.1 Eight weeks conceptus *in utero*. The arrows denote the edge of the expanding amnion. Note that the dome of the placental membranes is not attached to the opposite side of the uterus.

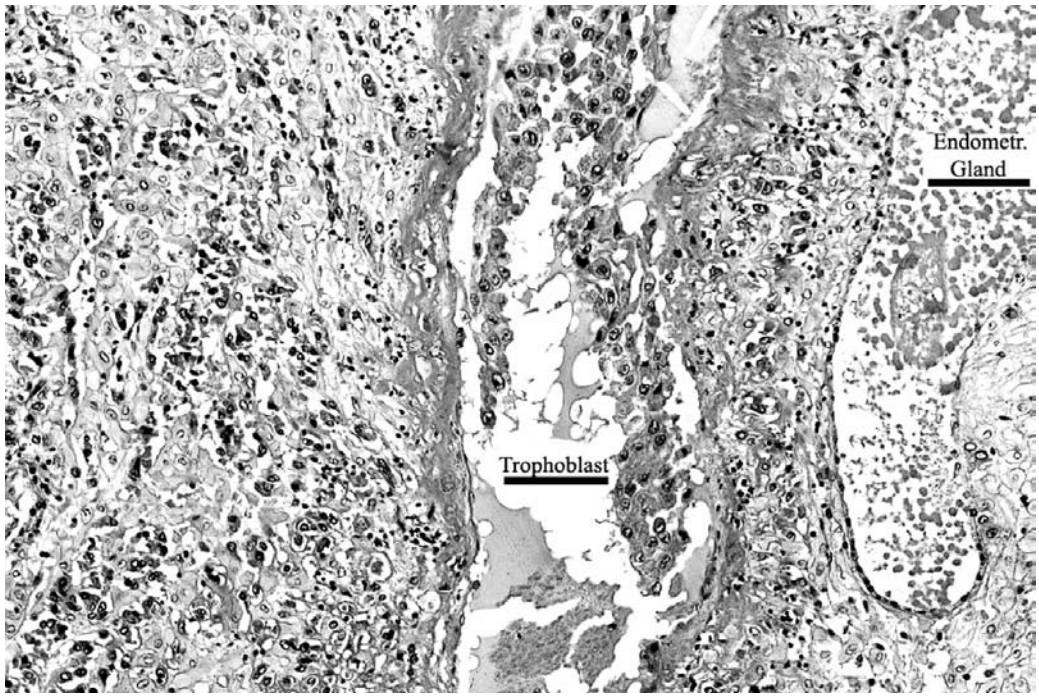

Figure 65.2 Extravillous trophoblast growing within a decidual spiral arteriole.

and is thus often disrupted by the manipulations at delivery. Furthermore, if the amnion were to disrupt prior to becoming affixed to the chorion (before 12 weeks), then amnionic bands may form, which ultimately can disrupt parts of the fetus.[3]

From the endodermal layer of the embryo develops the yolk sac. Its epithelium provides the precursors for liver, hematopoietic cells and germ cells, apart from producing the intestines after the embryo has folded. Having folded, the rotation of the intestines inside the embryo gradually pulls the yolk sac into the fetal abdominal cavity; there, it is connected to the possible remains of Meckel's diverticulum. Also from the distal part of the yolk sac, a small, temporary extension develops into the developing umbilical cord, the primitive allantoic diverticulum. It is very transitory in humans while a true sac develops in many other mammals and serves as a receptacle for fetal urine. In human placentation, the fetal urine accumulates in the amnionic cavity. Blood vessels infiltrate the villi and establish the fetal circulation somewhat later in the expansion of the villous tissue. It is not quite certain whether these vessels also differentiate *in situ* in the placental villi or whether they progress only from the fetus toward the periphery. Thus, ultimately two umbilical arteries progress from the fetus through the umbilical cord to the villous circulation, ramifying over the chorionic plate of the placenta. They are readily distinguished as arteries or veins by their position: the major arterial branches pass over the veins. They are virtually indistinguishable histologically. The vessels can be followed toward the periphery, where they are seen to dip into the villous tissue and, generally, a single vein returns to the same location as the arterial branch. Each such branch establishes a single fetal cotyledonary district whose circulation does not merge with the adjacent cotyledons.[4]

The extravillous cytotrophoblast arrodes the maternal arterioles, grows into them and there causes the 'physiologic change', altering these maternal arterial blood vessels by removing their musculature and depositing fibrinoid. At first, thick columns virtually occlude the lumens, later they hollow out and the complete intervillous circulation is then established (Figures 65.2 and 65.3). Needless to say, fetal and maternal circulations are separated by the trophoblast and a thin layer of connective tissue.

Gross examination

The placenta should be inspected after the baby is delivered and some minimal observations should be charted. It is our practice also to save the placenta in a refrigerator for several days, as its examination may be valuable for pathologists in cases where the infant is abnormal or fails to thrive. The important observations to be made at the time of delivery are the following features: (1) the length and insertion of the umbilical cord should be ascertained; (2) the presence or absence of retroplacental clot (abruptio placentae) needs to be looked for; (3) the color of the fetal surface (meconium staining or opacification from chorioamnionitis) needs to be charted and (4) the color of the villous tissue should be inspected. The last

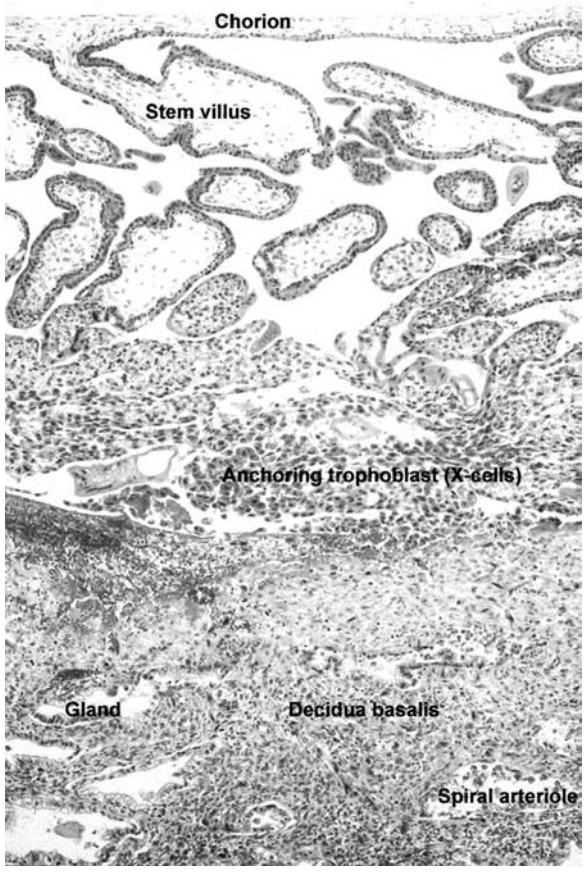

Figure 65.3 The placental floor in early implantation. The darker cells are extravillous trophoblast that intermingles with the decidual cells.

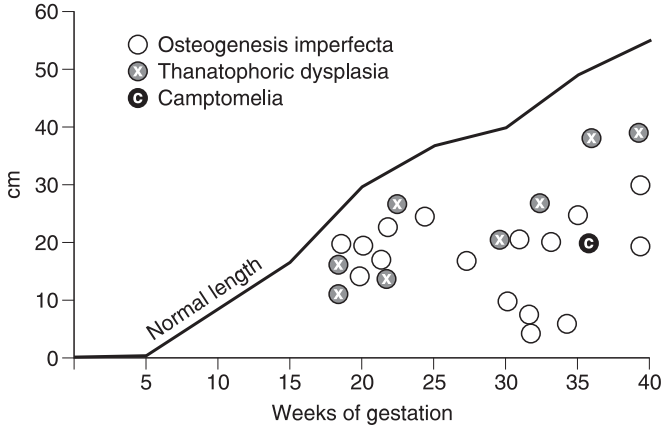

Figure 65.4 Length of umbilical cord in excessively short cord syndromes. The line represents the normal length.

observation is important as it can denote whether a baby has lost blood through transplacental hemorrhage. The color of the villous tissue is almost totally a reflection of the fetal hemoglobin content. Thus, an anemic neonate has a very pale villous tissue that may reflect erythroblastosis, parvovirus B19 infection, hemoglobinopathy or, importantly, significant fetal blood loss. If it is unusually pale (and the obstetrician of course needs to be acquainted with the normal colors), then a maternal blood film should be made immediately, which needs to be studied by the Kleihauer–Betke technique.[3] If infarcts or other unusual findings are made, the placenta should be sent for pathologic examination. Special circumstances are to be observed in multiple pregnancy and these are discussed in a subsequent section.

Umbilical cord

The normal cord insertion is somewhere near the center of the placental disk. In about 5% of normal gestations it inserts at the placental margin, and in ~1% of placentas it is located in the membranes ('velamentous insertion'). The latter is of significance in that it is often a cause of fetal growth restriction and also because the fetal vessels ramifying in the membranes have lost their protection by Wharton's jelly and may become disrupted, leading to massive fetal hemorrhage. The length of the umbilical cord is important and it can rarely be reassessed after the placenta is sent for study. Thus, it should at least be estimated, if not measured, at the time of delivery. In the normal-term gestation, the umbilical cord is approximately 55 cm long, and 85% have a counterclockwise (left) twist. The reason for this 'chirality' is unknown, but I suspect that it relates to the fetal movements because immobile fetuses, such as those found with osteogenesis imperfecta cases, have usually no twists. The cord in those cases is also unusually short (Figure 65.4). In contrast, when knots in the cord exist or when there are nuchal cords, it is often significantly lengthened. This may be the result of excessive fetal movements. It is also important to ascertain in unusually long cords whether there is excessive twisting of the cord on the surface of the fetus, the place where it inserts on the abdomen. It is not uncommon that excessive twisting leads to fetal demise, even abortions (Figure 65.4). In addition, one may find 'false knots' which represent redundancies of vessels or excess Wharton's jelly, unimportant features.

The normal umbilical cord contains three blood vessels, two arteries and one vein. In some 1% of neonates only one artery is found [single umbilical artery (SUA)] and this is frequently associated with congenital anomalies (~45%) and also with fetal trisomies. While the presence of SUA may signal the neonatologist that special attention should be paid to possible internal anomalies (heart, kidney), it is important to realize that many babies with SUA are entirely normal. True knots in the umbilical cord usually form early during development and they are now often recognized sonographically. They may lead to complete obstruction of blood flow and to fetal demise. In other cases, true knots have so impeded the venous (oxygenated blood) return from

the placenta that surface thrombi will be observed on the placenta, which can even be calcified. Obviously, such features may determine whether major sequelae develop in the fetus, such as central nervous system (CNS) destruction and cerebral palsy.

The membranes

The free membranes are referred to as the chorion laeve but, in the older placental literature, all of the placenta and its membranes were referred to as the membranes or 'secundines'. The 'free' membranes as we know them now have an outer layer of deciduas capsularis, which is followed by atrophied villi in between extravillous trophoblast, then comes the chorion and innermost is the amnion. When the membranes have a measurable portion between the site of rupture and the placental disk, then it cannot have been a placenta previa if it is delivered vaginally. At the site of rupture one often finds blood clot and some inflammation can occur here from the processes of labor. Histologically, there is then deciduitis, and thrombosis may be present in the decidual blood vessels. While this may be grossly interpreted as representing an abruptio placentae, that is not quite correct, as the blood is accumulated only behind the membranes, not behind the villous tissue. Of course, since chorioamnionitis is so much more common in immature placentas, these features are much more frequently found in such births. For the pathologist, the study of the deciduas capsularis is best undertaken when a membrane roll is made so as to increase the chances of finding abnormalities. These are principally findings of 'atherosis' (alterations of decidual arteries in pre-eclampsia to be discussed below) aside from the inflammation. Since atherosis is so frequently found in these vessels, this has raised the question of where the vascular supply of the deciduas capsularis originates. It is usually assumed that the expanding membranes are merely pressed against the deciduas vera of the opposite side of the uterus and that there is perhaps no ingrowth of decidua vera into the decidua capsularis, but definitive studies have not been made. Macroscopic findings of early placentas negate this suggestion of true ingrowth from the deciduas vera (Figure 65.1).

It is important for the pathologist to recognize that the amnion consists of a single layer of epithelial cells (that occasionally have patches of squamous metaplasia) that are situated on a dense, avascular connective tissue membrane. When the amnion disrupts spontaneously before it attaches to the chorion in early pregnancy, the amnion fails to grow subsequently and may become entangled in fetal extremities when the fetus moves about. This is the mechanism for amnionic bands and its many complications, primarily digital amputations. The cause of such disruptions is unknown but does not usually relate to trauma or any antecedent event that has been elucidated. In such cases, one can invariably find a rim of amnion at the reflection of the umbilical cord, as it is here firmly affixed to the mesenchyme of the cord. Amnion nodosum is the other pathological condition worthy of note. In the absence of amnionic fluid (as in renal agenesis, polycystic kidneys, urethral obstruction, etc.) fetal urine fails to fill the sac and focal degeneration of the amnionic epithelium takes place. Amnion nodosum is most pronounced on the placental disk, never on the cord and only rarely on the free membranes. At the sites of this epithelial disruption, vernix caseosa embeds and forms microscopic nodules, the amnion nodosum. This is of course possible only after the fetus has made sufficient vernix to be embedded, and it is thus not found in very immature fetuses with renal agenesis (Figure 65.5).

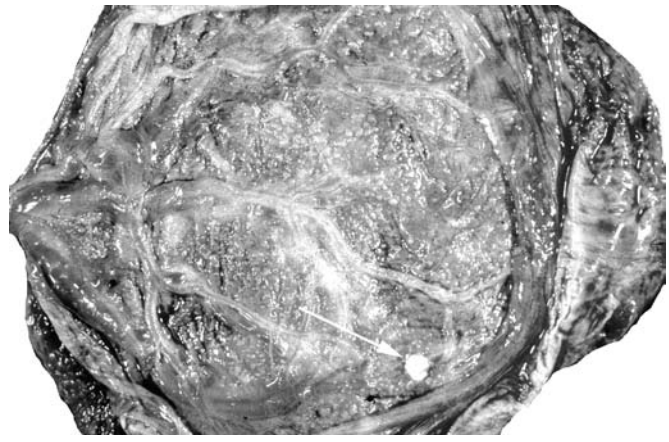

Figure 65.5 Placental surface in renal agenesis with amnion nodosum; at the arrow is the degenerated, calcified remains of the yolk sac (a normal feature).

Meconium staining of the membranes is common. It occurs in nearly 15% of our placentas and is usually the result of post-term gestations. Numerous clinical impressions have suggested that meconium discharge is the result of fetal hypoxia, but other studies indicate that this may not be so. For instance, most stillborn fetuses, assuredly having died from hypoxia, are not stained. Moreover, elevated levels of motilin (the gastrointestinal hormone that regulates bowel movements) are present. Meconium can be recognized histologically in the macrophages of amnion and chorion by their yellow pigmentation and enlargement. It must be cautioned also that this pigment disappears quickly when slides are exposed to light. Slides must thus be examined soon after their preparation. Moreover, the pigment may also be due to hemosiderin from chronic bleeding somewhere in the gestational sac; it must therefore be critically appraised.

Villous tissue

The villous tissue changes with the maturation of the placenta. In young organs, the villi are relatively

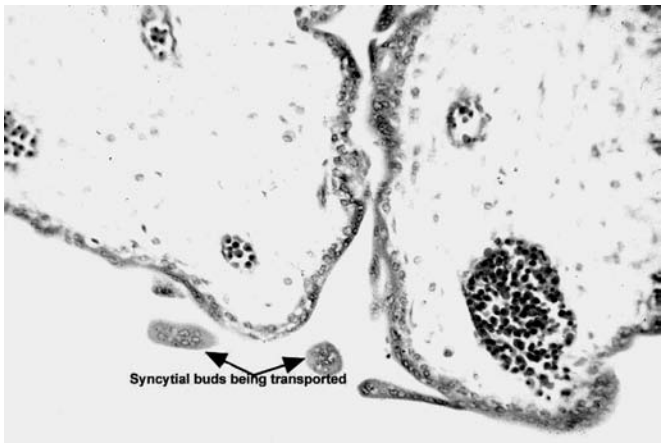

Figure 65.6 Immature villi with numerous NRBCs within the capillaries. The stroma is 'loose' and appears edematous, but that is normal. A few syncytial buds are in the process of detaching. The cytotrophoblastic Langhans' layer is visible beneath the superficial syncytium.

large, have numerous cells and the fetal capillaries are dispersed peripherally beneath the trophoblast. The villi look 'edematous' and this changes with maturity as more villi sprout peripherally (Figure 65.6). In the term placenta then the most peripheral villi are small and contain mostly three to four capillaries with few connective tissue elements. There are also some macrophages within the villi, the so-called Hofbauer cells, which are more readily seen in immature organs. They are important cells in the elimination of antigens and assist in the removal of focal hemorrhage as they occur, for instance, in cytomegalovirus (CMV) infections. They may then contain hemosiderin.

The surface of the villi is covered by trophoblast. There is an inner layer of cytotrophoblast (Langhans layer) in which mitoses occur, which produce the cytoplasm and the nuclei for the covering syncytiotrophoblast. The syncytium, however, is the actual organ of exchange. It is a single, uninterrupted membrane covering all villi, has no cell borders and the nuclei have become incapable of mitosis. The syncytiotrophoblast has a fine brush border of microvilli and its cytoplasm possesses numerous transport vesicles, and its surface has many receptor sites for nutrient exchange. Importantly, the syncytium expresses no human leukocyte antigen (HLA) antigens that could potentially excite a maternal rejection process. So far as is now known, only HLA-G is expressed and this is not antigenic to the mother. The cytotrophoblast is easily visible in young placentas, but it is difficult to recognize these cells at term, although they are always there when studied by the electron microscope. Since cytotrophoblast continues to produce new syncytium, the cells and cytoplasm of the latter bunch up and form the so-called knots, or sprouts. These increase in number toward term and then they are recognized on about 30% of peripheral villi. They also often detach and are carried away in the intervillous (maternal) circulation and swept to the maternal lung. Here they die, as they have no reproductive capacity. When the villi shrink, as is the case in pre-eclampsia, because of deficient water transfer to the fetus, there is more 'buckling' of the syncytium and more knots are found; this is referred to as the 'Tenney–Parker' change.

A number of conditions cause histologically recognizable changes in villi, the most important and frequent of which is infarction. Death of villi, usually of larger districts, is caused by the obliteration of spiral (decidual) arterioles. This occurs most commonly in pre-eclampsia and may be associated with abruption of the placenta from bleeding into the deciduas basalis. But infarcts are also common at the edge of the placenta and then they are usually without consequence. Edema of villi is a frequent finding in fetal anemia (erythroblastosis, hemoglobinopathy) and of course in hydatidiform moles. In addition, one may find inflammatory cells within the villi in the condition known as 'villitis of unknown etiology' (VUE), in CMV infections and in syphilis.

Finally, there may be too many capillaries within the terminal villi. This condition, known as chorangiosis, is seen in chronic hypoxia (e.g. in placentas from high altitude), in the Beckwith–Wiedemann syndrome, associated with chorangiomas, and a few other conditions (diabetes). When such alterations are found, one should also look for the presence of nucleated red blood cells (NRBCs) in the fetal capillaries; they are not present in placentas after about 25 weeks and, when present, they may also signal prolonged intrauterine hypoxic states.

Infections

One of the most important aspects of obstetrics today is the ascending infection with chorioamnionitis and premature birth ensuing. This is an especially important feature for the 20–30-week gestations as the often associated severe prematurity may lead to fetal infection and, most importantly, to CNS damage with cerebral palsy, the outcome. Chorioamnionitis is common and it often recurs in subsequent pregnancies. I believe that it results mainly from the deficiency of endocervical mucus that normally protects the intrauterine environment from vaginal organisms. This, in turn, probably reflects severe chronic endocervicitis. While septic distribution of some maternal organisms occurs (listeriosis, cytomegalovirus infection, toxoplasmosis), these are, numerically speaking, unimportant entities.

The endocervical canal produces copious amounts of dense mucus in normal pregnancy that contains abundant antibodies and protective immunocytes. The canal is also normally closed and narrow till labor commences. When organisms are allowed to cause endocervicitis and proliferate here, the inflammatory process generates enzymes (mainly a phospholipase)

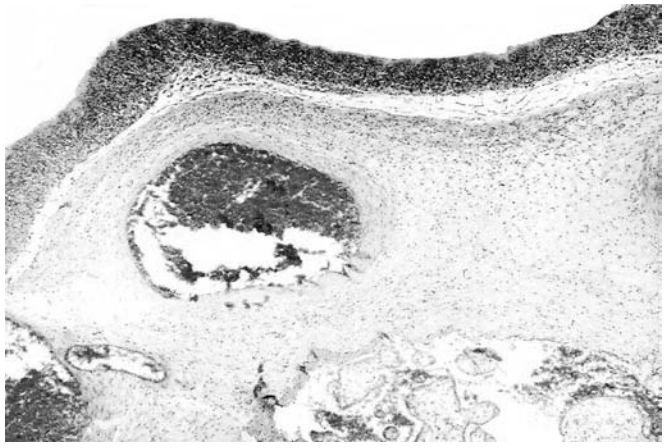

Figure 65.7 Placental surface in marked, long-standing chorioamnionitis. The dense leukocytic infiltrate is seen beneath the amnion.

that lead to the local production of prostaglandins with dilatation of the cervix followed by lower uterine segment. This, in turn, leads to deciduitis of the 'forelying' decidua capsularis and the organisms may enter the amnionic cavity, with or without the rupture of membranes. Once they are in the amnionic cavity, the leukotactic property of the organisms leads to a series of inflammatory sequelae, first on the surface of the placenta, then on the umbilical cord and, when inhaled, the infection may cause fetal pneumonia (Figure 65.7). The first effect is the emigration of maternal leukocytes from the intervillous space beneath the chorionic surface of the placenta; then inflammation of surface vessels follows; thereafter, umbilical phlebitis and finally umbilical arteritis take place. This pus that obscures the fetal surface of the placenta and makes it to be 'cloudy' (opaque) is thus of mixed origin, maternal and fetal. Studies of gastric aspirates and lung exudate have shown this admixture definitively. In time, after days of aspiration of this infective material, the fetal lung reacts with infiltration of a lymphocytic response. Often, it is possible to identify some bacterial organisms, but this is generally uncommon. The reason for our inability to recognize organisms histologically lies in the nature of the inciting antigens. They are frequently not visible in histologic sections (such as *Trichomonas*, *Mycoplasma*, *Ureaplasma*, *Chlamydia*) but they can be cultured if efforts are made. An exception is found in the infections with group B streptococci. Because of their toxins (hemolytic and cytolytic), one may identify numerous organisms, but only relatively little inflammation is found with this common infection.

Numerous attempts have been made to treat this ascending infection when it is recognized by a dilating cervix or by maternal fever, but that is usually too late in the course of the disease. Moreover, most efforts to treat the fetus *in utero* with administration of antibiotics to the mother have been unsuccessful. Thus, it becomes more important to anticipate the infection, especially its recurrent nature, and treat with antibiotics prior to the dilatation of the cervix. The pathologist observes placentas with an opacified (cloudy) fetal surface and, histologically, by the presence of numerous polymorphonuclear leukocytes in chorion and amnion (Figure 65.7). Later, there is exudation from the umbilical vein and then the arteries. The remainder of the placenta, especially its villous structures, is entirely normal, but usually immature. The membranes, however, are markedly altered. The deciduitis and often decidual necrosis are severest near the point of membrane rupture, which is very close to the endocervical canal. There may be a fresh clot attached at this site and it is occasionally mislabeled as representing an abruption. In twin gestations, it is invariably twin A, lying closest to the endocervix that has the infection and severest inflammation. Chlamydial organisms are the commonest cause of genital infection nowadays, causing urethritis, salpingitis (with infertility ensuing), cervicitis and occasionally a disseminated infection. Since this organism is not visible in routine preparations of histologic slides, it must be considered when chorioamnionitis is present.

Disseminated infections represented by lesions in the placenta are found in listeriosis. This gram-positive coccobacillus causes maternal sepsis and disseminates into the fetus most commonly via abscess formation in the placenta. Numerous epidemics have been described, which have usually been of a food-borne origin, as the organism is widespread and proliferates well in the refrigerated state. The placenta may show small abscesses and many organisms are commonly found on the placental surface. When the fetus is thus infected, the condition known as 'granulomatosis infantiseptica' may result with disseminated abscesses, meningitis, dermatitis and other sequelae. Since the organism is highly susceptible to ampicillin, early diagnosis is essential.

Toxoplasma organisms of placenta and fetus are commonly acquired parenterally from the fecal contamination originating from cats. In felines, the intestines propagate the organism and, when feces are dry and subject to dust contamination, the pregnant mother may become infected. That is an important reason for cleaning litter boxes while the fecal material is still moist. Toxoplasma cysts of a congenital infection may be seen in the chorion and even more commonly in Wharton's jelly of the umbilical cord, but they are sparse. The fetus may develop hydrocephalus and a variety of other pathologic states. The infection is easily preventable but difficult to treat once it is diagnosed.

CMV infection is also common and it may be sexually transmitted at times. It infects the villi of the placenta and can then disseminate into the fetus. The outcome is highly variable, but is often associated with growth restriction, cerebral manifestations,

jaundice and other complications. The usually small placenta may show characteristic changes. In early infections, one finds inclusion bodies within villi, thrombosis of capillaries and occasional villous hemorrhages. Plasma cells that are otherwise very unusual features of normal placentas then infiltrate; eventually, the villus atrophies and hemosiderin pigment deposit in Hofbauer cells. The antigen is easily demonstrated with modern techniques of antibody-marked histologic staining, as is of course the case also with the determination of serum antibodies. When the infection is longstanding and when it is severe, thrombi may develop even in the larger surface vessels (Figure 65.8), and these may be calcified as well.

Only a few other disseminated infections are of importance. Thus, varicella infection has been described rarely, hepatitis antigens can cross the placenta, Coxsackie viruses have been transmitted with few placental lesions visible and the placenta may also contain numerous intervillous malaria organisms during a malaria attack. Transmission to the fetus transplacentally, however, of the widespread malaria infection is extremely rare.

A final comment must be made about a reasonably common condition known as VUE. This condition is frequently found in the placenta of growth-restricted fetuses and in stillbirths. Worse, it often recurs in subsequent pregnancies. When large districts of the placenta are so affected, fetal demise is common but there are no abnormal findings of any infectious nature in the fetal tissues. The villi in VUE are probably infiltrated by maternal T-cells and macrophages. They here cause an obliteration of the capillary beds and the restrictive cause of fetal growth is therefore readily understood. But the precise cause of why the maternal lymphocytes invade the placenta is as yet unknown. It has been speculated that this is akin to a 'rejection' phenomenon, but why the fetal HLA type should be recognized by the mother's immune cells is so far obscure.

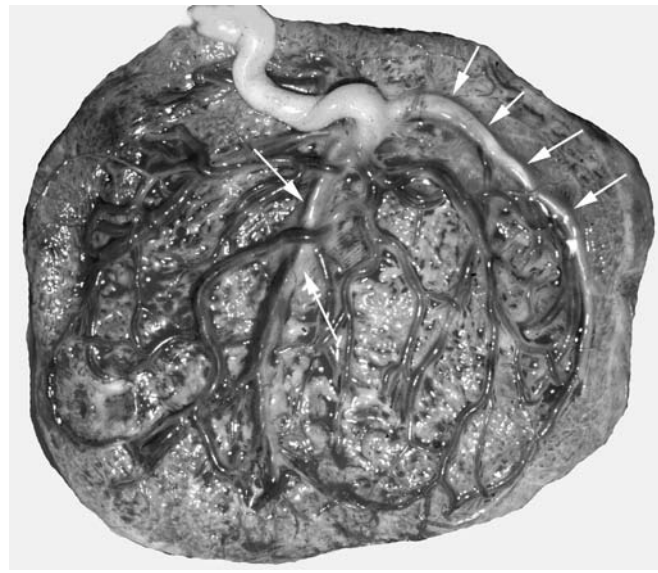

Figure 65.8 Placenta in severe CMV infection with extensive venous thromboses at arrows. The thrombi were at least partially calcified.

Figure 65.9 Large chorioangioma bulging from the placental surface at left.

Tumors and microchimerism

The commonest tumor of the placenta is the chorangioma.[6] It is frequently found only accidentally in sections prepared at random. Angiomas occur in villi as an expansion of the fetal capillary and mesenchymal cells; they form nodules that can be seen grossly and which are easily shelled out of their beds. Interestingly, their surface is usually covered by a single layer of trophoblast that suggests the expansion of fetal vessels being very focal in nature. Chorangiomas occur more frequently at high altitude and are often also associated with 'chorangiosis', an increase of the normal number of capillaries in the peripheral villi. They are benign tumors despite their frequently great cellularity. In fact, chorangiomas have been mislabeled in the past as being sarcomas, mesenchymomas or have been assigned other appellations, but they have never metastasized. Large chorangiomas may protrude on the fetal surface (Figure 65.9); they may be one cause of hydramnios and they may also infarct from thrombosis resulting in cessation of the hydramnios. Recent studies have shown that they are at least in part the result of increased angiopoietin expression.[7] On rare occasions, the angioma may be associated with an excessive degree of trophoblastic proliferation. This condition has been labeled 'chorangiocarcinoma', but its true nature and degree of malignancy are still poorly defined.

Maternal tumors have also been found to have set metastases in the placenta occasionally, perhaps

most commonly the carcinoma of the breast. They may focally destroy placental tissue but most of them do not disseminate into the fetus. This only contrasts with the occasional metastatic melanomas, which can travel into the fetus, but here the metastases are usually rejected in neonatal life. Maternal B-cell lymphomas have been described recently as having disseminated into villi and they have caused neonatal deaths from tumor dissemination. Most maternal leukemias, however, do not spread to villi or to fetus. The situation differs with fetal cells disseminating into the mother transplacentally. It is now recognized that fetal cells often traverse the placenta in small numbers. These are mostly RBCs, but nucleated elements have also reached the maternal circulation, perhaps even fetal stem cells. In the maternal organism, these elements may live for many years and, perhaps as determined by their antigenic expression, they may be destroyed in the mother. Recent studies, however, have also shown that some of these fetal cells themselves may impart an antibody/rejection response against the mother. This microchimerism is now thought to be the cause of some maternal autoimmune diseases, such as systemic sclerosis and postpartum thyroiditis. Indeed, it has been shown that the maternal thyroid epithelium may on occasion be replaced by fetal cells when postpartum thyroiditis has occurred.

Choriocarcinoma *in situ* has been described a few times in otherwise normal placentas and this tumor has even been disseminated into the mother. Macroscopically, such tumors have given the impression of being infarcts, and only histologic preparations have shown them to be malignant neoplasms. In some cases, the tumor has caused villous destruction with exsanguination of the fetus into the mother. This entity is completely unrelated to the usual cause of choriocarcinoma that may follow the presence of a hydatidiform mole, and its chromosomes have not yet been studied. The reason for their occurrence is obscure.

Moles

When the villi swell up with much fluid from the intervillous space by transport through the syncytium, they swell and may become so swollen as to take on a grape-like configuration that is grossly visible. We refer to this as hydatid swelling and it is doubtlessly related to the deficient movement of the accumulated fluid to the fetus because the fetus has died and the fetal placental circulation has ceased. The result is the formation of (a) 'hydatid degeneration' of the placenta in abortion and (b) hydatidiform moles (mole merely means mass). Because the entire placental tissue may not have become transformed into grape-like masses, we speak of 'partial hydatidiform moles' (PHM) and also of 'complete hydatidiform moles' (CHM). The former may represent a variety of conditions; triploidy of the conceptus is the commonest antecedent condition, but PHM may also be due to a set of twins, the placenta of one having become truly molar, i.e. a CHM.

The differentiation of these two types of moles is not always easy, but it should be attempted. When two separate masses or a distinctly divided placenta is present, twinning is the most likely origin. But the differentiation of PHM and CHM may often present difficulties for the pathologist and a strong recommendation has been made to submit some of the abnormal tissue for ploidy analysis that is most efficiently done by flow cytometry, or for cytogenetic study. Flow cytometry is the easiest and the quickest way for this differential diagnosis. It quickly identifies triploidy ($3n$) from diploidy ($2n$) and this is relevant primarily because triploid moles are only exceptionally rarely followed by gestational trophoblastic neoplasms (GTNs).

Partial moles (PHM) are most commonly the result of fertilization of one oocyte by two spermatozoa. This imbalance leads to defective fetal development and, usually, the embryo dies early while the placenta continues to grow and accumulates fluid. It is much less common that a polar body (two maternal components – gynogenic) provides the additional set of chromosomes. In such pregnancies, there is considerably better fetal development. Nevertheless, the embryo develops somewhat abnormally and shows numerous anomalies that are invariably lethal soon after birth. One of the more characteristic anomalies is the fusion of two fingers and often also of toes. The placentas of PHM are enlarged, irregularly molar and the villi have scalloped borders that often lead to trophoblastic inclusions. These inclusions are not truly invasive features, but represent tangential sections through infolded surfaces.

The CHM is similarly enlarged but more uniformly (Figure 65.10). The distension is mostly within the terminal villi and these can often be traced to thinner and firmer structures represented by the former stem villi that do not participate so much in the swelling. The amount of trophoblastic development varies greatly in CHM; at times it is massive and suspicious of tumor development. But the former method of 'grading moles', depending on the amount and nature of trophoblastic proliferation, has been abandoned as it has proven to have little prognostic significance. The villi of CHM have no capillaries, in contrast to what is often the case in PHM. Since the revolutionary insight gained by Kajii and Ohama,[8] it is now accepted that CHM is 'androgenetic'. That is to say, their chromosomes are derived only from the spermatozoon. They are also $2n = 46$,XX because a Y-bearing sperm would lead to a $2n = 46$,YY conceptus and those cells are not viable. Thus, one can easily understand the development of a CHM by visualizing the fertilization by an X-bearing spermatozoon of an 'empty' egg, i.e. an oocyte that has lost its nucleus. The 23,X chromosomes (from the spermatozoon) of

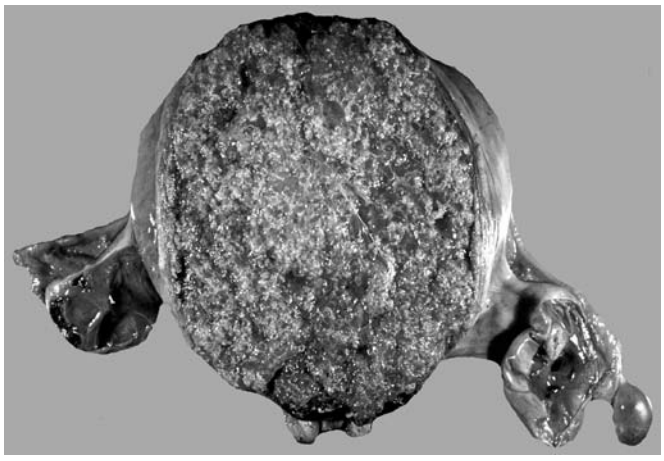

Figure 65.10 Uterus filled with a CHM. The ovaries are enlarged because of gonadotropin stimulation.

the newly fertilized oocyte would then duplicate. But, because of imprinting features, an ovum fertilized by only male chromosomes does not develop a functional embryo; it can only produce a placenta. When early complete moles have been carefully examined, diminutive embryos are found occasionally; they are severely stunted and would soon have vanished. Thus, CHMs have generally no fetus and no vasculature, and there is also no recognizable amnionic cavity. For the sake of completeness, it must be mentioned that a few exceptions have been reported. Thus, a rare gynogenic mole has been found; also rarely, a diploid spermatozoon has led to the formation of moles and, equally amazing, a small number of CHMs fertilized by two sperms were found to be $2n = 46$,XY. These aberrations from the usual, however, have not had different sequelae.

Because the swelling of terminal villi and the enlargement of a molar placenta obviously take time to develop, really early CHMs may be difficult to identify; they may appear to be spontaneous abortions, i.e. 'blighted ova'. In addition, spontaneous intermixtures of normal villi and molar villi have been observed in chimeras. However, all of these are uncommon features. They merely indicate that detailed study may be needed to unravel what is otherwise a great biologic complexity. Furthermore, nobody has described an empty egg, which we hypothesize as being the starting point for molar development. We thus assume that some abnormality in the maternal oocyte nucleus exists that prevents it from participating in embryonic development. What this is, is being studied. Occasional chromosomal errors and genetic defects have thus been identified, but that is in a minority of cases so far. We may need more information on the reasons for the great geographic/racial differences in the occurrence of CHMs to attain a better understanding of its real causes. Genetic errors have been identified on occasion as the basis for familial moles. But why it is that CHMs occur in European/American stock with a frequency of ~1:2000 and in the Japanese population, for instance, as commonly as in ~1:350 is not known now.

Trophoblastic tumors

Choriocarcinoma is the most malignant, albeit uncommon, outcome of hydatidiform moles. But other neoplastic entities are now recognized (epithelioid trophoblastic tumor; placental site nodule; exaggerated placental site) so that they have now all been grouped as GTNs. Nevertheless, the choriocarcinoma is the best recognized and the most frequent of these tumors. It is composed solely of trophoblast, cytotrophoblast and syncytiotrophoblast, and most commonly it follows complete moles. Because the choriocarcinoma continues to produce chorionic gonadotropin, it is easily screened for and the follow up of moles is usually undertaken with serial determination of gonadotropin levels. The other unusual feature of these tumors, especially the choriocarcinoma, is that it is highly susceptible to methotrexate and actinomycin D therapy. Even metastatic lesions are mostly treated successfully now when they are recognized early enough.

While choriocarcinoma most commonly follows a CHM, it may also arise from abortions, even from ectopic pregnancies. It may be present accidentally in an otherwise normal placenta and is then referred to a choriocarcinoma *in situ*. It then looks like some bland infarct, but may of course have serious sequelae. What causes choriocarcinoma to develop is uncertain, although it would appear that excessive proliferation of trophoblast is a precursor, as it is engendered often in moles. The tumor is usually very hemorrhagic and metastases occur anywhere but they are most feared when they occur in the brain.

The other tumorous lesions referred to above are more characteristically produced by the extravillous trophoblast, the X-cells whose main purpose is the invasion of the uterus and the modulation of the uterine vessels. By and large, these tumors are much less common; they usually behave in a less malignant fashion and can often be treated by excision.

Multiple pregnancies

Twinning is common and monozygotic (MZ) – 'identical' – and dizygotic (DZ) – 'fraternal' – twins occur (Figure 65.11). When higher than twin multiple pregnancies take place, MZ and DZ multiples may be admixed. In order to understand the placenta of monozygotic twins it is necessary that one visualizes the stages at which the 'splitting' of the developing embryo can occur (Figure 65.12). Thus, when segregation of blastomeres takes place very early (during the first 3 days), then the two entirely separate placentas

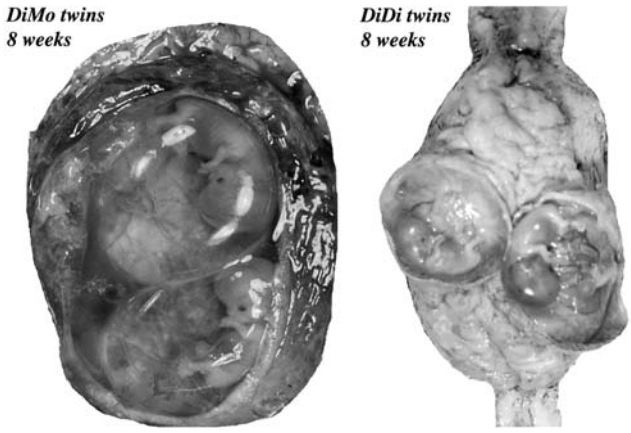

Figure 65.11 Two uteri within which are 8-week-old twin fetuses. At the left are monochorionic (identical) twins with their amnionic sacs. At the right are two fraternal, dichorionic twins within adjacent placental implantations.

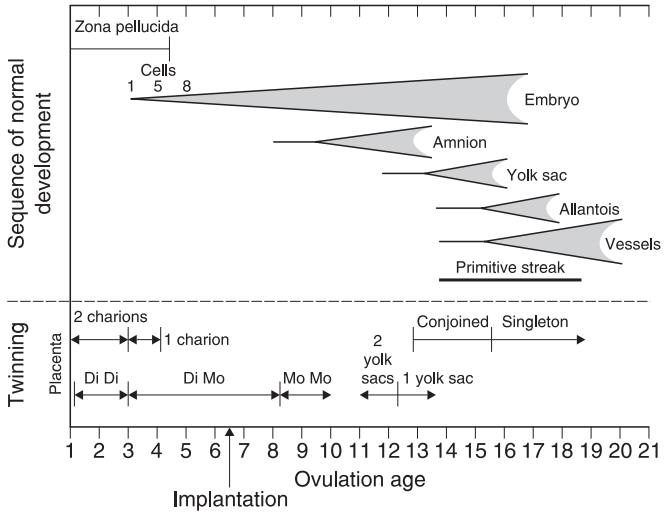

Figure 65.12 Conceptual drawing of early splitting of embryos/placentas in the process of producing monozygotic twins.

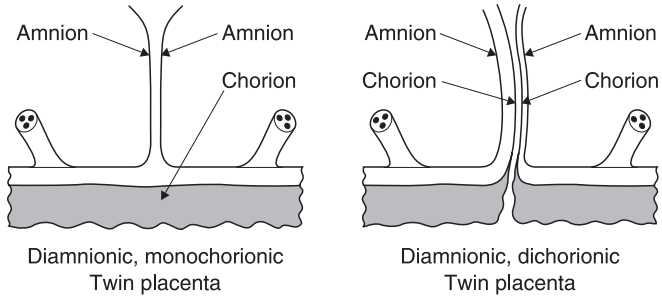

Figure 65.13 Diagram to show the membrane relationship in monochorionic twin placentas (left) and dichorionic twin placentas (right).

may develop; but when it occurs later, a single chorion and two amnions develop; and when it occur later still, a monoamnionic sac can be produced. Eventually, after 13 days of development, twinning becomes impossible or else conjoined twins would develop. Therefore, the placenta of MZ twins may be dichorionic (20%) or monochorionic (80%). This is what is actually found and it is important as the classification of twins may depend on this; and so does the formation of blood vessels that may connect the two fetal circulations. The anastomotic connections then occur only in MZ and monochorionic twins; DZ twins virtually never have such anastomoses and are worthy of being reported.

The frequency of DZ twins depends largely on the genetic factors that control polyovulation. Polyovulation is controlled by maternal FSH levels; it is very high in the Nigerian Yoruba tribe, but much lower in Oriental people. Therefore, the percentage of MZ twins is much higher in Japan than it is in African or European populations. The consequences of this are significant also as most problems in the placentation of twins occur with monochorionic (MZ) twins.

The placenta of dichorionic twins is easy to understand (Figures 65.11 and 65.13). The two blastocysts implant either side by side in the uterus or on opposite surfaces. Two fused placentas may thus arise, having a diamnionic, dichorionic 'dividing membrane'. Sonographically, this is commonly recognized by the thickness of the membrane and by a small elevation of the placental tissue at the meeting point of the chorionic surface. The pathologist observes that these membranes are thicker, less translucent and that atrophied blood vessels may be apparent in the dividing membranes. Anastomoses between the two fetal circulations do not occur or are so rare that they warrant a case report. The umbilical cords of both types of twins are much more often marginally (or membranous–velamentous) inserted. That is also the case of occasional singleton placentas, but in twins it may be the consequence of competition for space in an expanding placenta. Alternatively, it may be the result of improper early central implantation but the precise mechanics are undetermined. Importantly, such abnormal cord insertion may also be found on the dividing membranes and the velamentous vessels then represent a danger of disruption when these are ruptured during delivery.

Monochorionic placentas in contrast nearly always have blood vessel connections on the fetal surface. These take essentially three forms: most common is an artery-to-artery communication (Figure 65.14); the next most common are artery-to-vein connections and vein-to-vein anastomoses are least often found. The connections are readily identified in the delivered placenta. One may stroke blood back and forth in an artery–artery (AA) anastomosis; the recognition of artery–vein (AV) connections is much more difficult and it is also the most important and troublesome

Figure 65.14 Monochorionic twin placenta with a single large artery-to-artery anastomosis (at arrows).

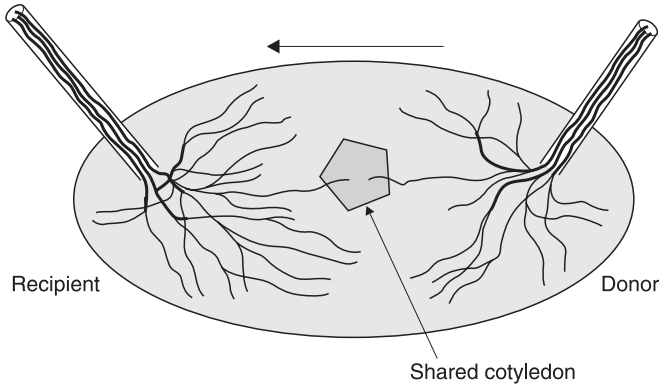

Figure 65.15 Drawing to show the shared cotyledon in a monochorionic twin placenta with the TTTS.

connection. Injection with milk or other fluids makes it easy to recognize the type of anastomosis, and it is usually necessary to undertake such injections if the AV anastomosis of the twin-to-twin-transfusion syndrome (TTTS) is to be understood. As has been said earlier, arteries generally cross over the veins, especially in the larger vessels. They are thus easily recognized and their course can be followed by careful gross inspection. Generally speaking, in the normal placenta an arterial branch distributes blood to a single cotyledon. When this branch is followed to its end, the artery suddenly stops, bends down into the villous and then perfuses one cotyledon. Nearby, a vein emerges from this cotyledon and sends blood back to the umbilical vein. In the TTTS, however, this vein sends blood back to the other twin, thus establishing the basis for the TTTS. One needs to inject these suspect terminal arterial branches, fill the cotyledon completely and see the injected material emerge in the vein of the 'recipient' twin in order to establish the basis for the TTTS. There may be several such 'common districts' (they have been referred to as the 'third circulation') and they may even have different directions. Their net size determines the severity of the TTTS; it is generally held now that the coexistence of an AA communication prevents this syndrome in its worst states.

In such monochorionic twin placentas (the majority are diamnionic, monochorionic – DiMo), the dividing membranes are composed of two amnions; they are translucent and lack the remnants of former vessels.

The most important and frequent complication of MZ twinning is the TTTS. It comes about by the presence of a single 'shared (common) cotyledon' (Figure 65.15). An artery from the donor enters one cotyledon and this is drained to the recipient who becomes fluid-overloaded and because of excessive urination develops hydramnios. That is how the syndrome usually becomes symptomatic, most frequently between 20 and 30 weeks of gestation. The donor urinates little or not at all and becomes the 'stuck twin'. Hydramnios usually terminates the pregnancy unless it is treated by the modern method of laser obliteration of the offending vessels. In order to do this surgery, one requires considerable knowledge of the vascular features of the placental surface and it should not be attempted unless this detailed knowledge is acquired. It must also be appreciated that even large intertwin anastomoses may have other serious sequelae. Thus, when one DiMo twin dies *in utero*, blood may be transferred rapidly from the surviving twin back into the now dead fetus. This can lead to an at least temporary deficient CNS perfusion in the survivor and thus, cerebral palsy in one of the surviving twins is relatively common. Such a mechanism is also implored in understanding the death of the later-dying original 'Siamese' twin pair (Eng).

Monoamnionic twins are always monochorionic (MZ) and thus suffer the possibility of entangling of their umbilical cords. Complex knots may develop early in fetal life and they may become constrictive and cause fetal demise (Figure 65.16). At times, one finds thrombi in such umbilical cords or in blood vessels of the chorionic surface from the chronically restricted blood flow during intrauterine life. Moreover, chorangiosis is often observed in such placentas.

Acardiac twins occur in many forms; some are nearly perfectly formed babies, but most are severely abnormal and they may even grossly appear as though they were skin-covered teratomas. Most acardiacs also have a single umbilical artery. They are always MZ, or identical, although they represent the worst possible congenital abnormality imaginable. The formation of acardiacs is best explained by the presence of both an AA and a VV anastomosis in the surface of the placenta (Figure 65.17). We believe that in very early embryonic development, the normal twin causes a

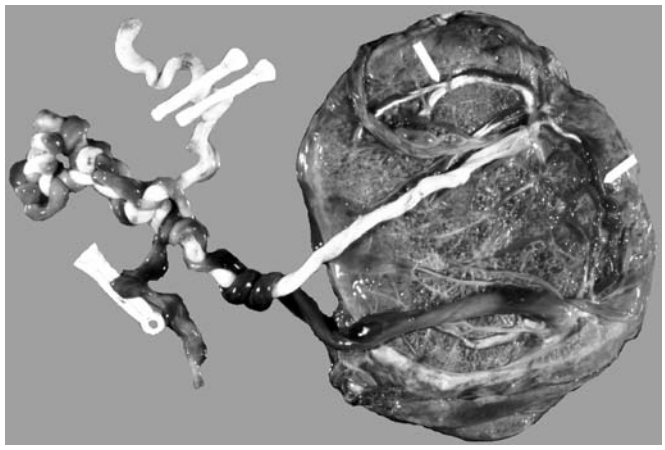

Figure 65.16 Monoamnionic twin placenta with extensive entangling of umbilical cords that led to fetal demise.

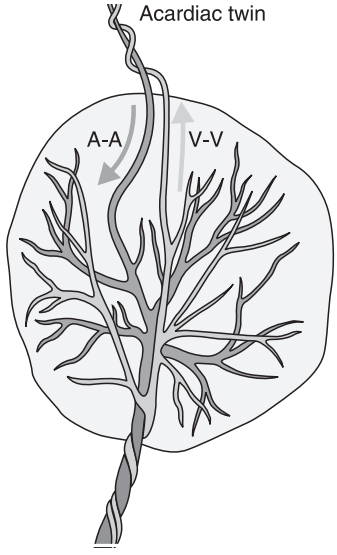

Figure 65.17 Drawing to show the setup of the vascular connections that lead to the development of an acardiac twin.

reversal of blood flow through the AA connection and the VV, thus returning the blood in the opposite direction; perhaps, they were then already of different sizes. Because blood from the artery now enters the developing acardiac fetus at its abdomen, the legs develop more adequately, while the cephalic end is usually most deficiently developed. And, because of the reversal of flow, the heart of the acardiac develops poorly (it may be two-chambered) or not at all. These acardiac fetuses are chromosomally generally normal and of the same sex as the cotwin. It might be mentioned also that such acardiacs have been reported quite accidentally in many different species.

When many more fetuses are implanted, a condition that is now much more common with the practice of 'assisted reproductive technology' (ART), the placentas may be closely packed and have no blood vessel connections. They generally have abnormal cord insertions and, depending on their number, many are born prematurely. It has also been our observation that frequently one or more of the fetuses are surgically eliminated by KCl injection and a fetus papyraceus is then found in the membranes with a markedly atrophied placenta. What is amazing in such specimens is the marked spiraling of their cords, as this must have originated very early in development. Finally, the placentas of such ART pregnancies present challenging problems in that more fetuses and placentas may be found than embryos originally implanted into the uterus. Thus, monochorionic twins are admixed and can only be explained by assuming that one embryonic precursor has split early in gestation. Perhaps, the practice of embryonic culture *in vitro* for several days is responsible for this spontaneous MZ twinning event.

Abortions

Spontaneous abortions are very common in human development. They are much more common than in most species that have been studied in detail. The vast majority occurs during the first 3 months of gestation and the majority is due to chromosomal errors. Generally, a deformed or macerated embryo is found on examination of the specimen but equally often, especially in the earliest abortions, the amnionic sac is empty and the fetal vasculature of the placenta has atrophied; these specimens are often referred to as blighted ovum. The placenta is otherwise atrophied and may have focal hydatid changes of the villi. The trophoblast is unremarkable or atrophied. Occasional retroplacental hemorrhages accompany these specimens. A frequent cause of spontaneous abortion is the presence of an excessively long umbilical cord with severe twisting (Figure 65.18). The causes of the twisting and excessive length of the cord are unknown but I speculate that this is the result of excessive movements in early life. It often leads to severe twisting on the surface of the umbilical cord insertion on the abdominal surface, which must be observed to understand this cause of embryonic demise.

Placental and fetal hydrops

The placenta of hydropic fetuses is much enlarged and most often very waterlogged. The villi are swollen and often contain prominent Hofbauer cells (macrophages). There are many causes for hydrops and depending on their nature, the histopathology differs. In erythroblastosis and in the placentas of the fetal thalassemias, the capillaries contain NRBCs in profusion. In transplacental infection with parvovirus B19, one may find characteristically nuclear inclusion bodies that are found most often within the nucleated red cells. But, at later stages, they may be

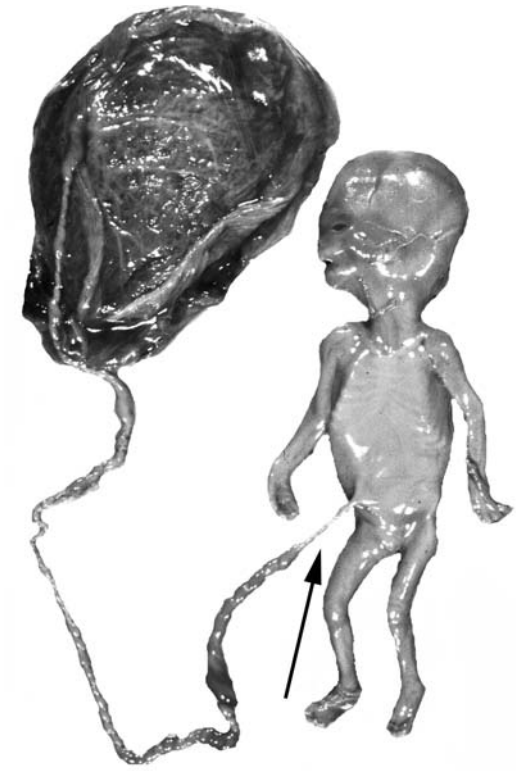

Figure 65.18 Abortus with an excessively long and heavily twisted umbilical cord and the even more excessive twisting on the abdominal surface of the fetus.

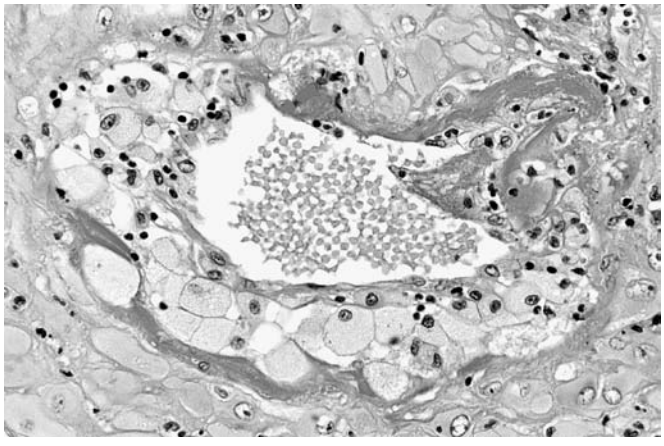

Figure 65.19 Atherosis in the spiral arteriole of a patient with severe pre-eclampsia.

inconspicuous and identification of the etiology of hydrops will commonly depend on serologic findings or on staining the tissue with specific antibodies. When the hydrops is caused by fetal anomalies, such as left heart hypoplasia, cystic adenomatous malformation of the lung, sacrococcygeal teratoma, etc., the placenta is merely large, edematous and pale. Some of the other fetal conditions that lead to hydrops are summarized below.

Maternal and fetal diseases affecting the placenta

Pre-eclampsia

The cause of pre-eclampsia [or pregnancy-induced hypertension (PIH)] is still unknown, but speculations about its origin abound. Less controversial are the placental sequelae in PIH. Generally speaking, the placenta is smaller and exhibits what is called 'advanced maturation'. This is a misnomer, however, and merely applies to the histologic features of such placentas as having smaller villi; they appear to be more mature than would be expected at the usually immature gestational age. The villi are not only smaller but also have less mesenchymal fluid content. As a consequence, the superficial cover of trophoblast buckles and more knots or 'sprouts' of syncytium become apparent. This is referred to as the Tenney–Parker change, after the first authors to describe this feature. This increased number of sprouts (more than 30% of terminal villi) also leads to their more frequent deportation in the maternal circulation and was thus witnessed as a peculiarity of women dying in eclampsia as they had more such elements in their pulmonary capillaries.

Pre-eclampsia is associated characteristically with the presence of atherosis in the maternal, decidual spiral arterioles. It is conceived that the normal transformation of these blood vessels does not occur because of inadequate extravillous trophoblastic infiltration in early development. The atherosis is reasonably characteristic for PIH and may be found in the decidua basalis and also (often easiest) in the decidua capsularis of the membranes. But, not in all cases of even severe PIH can one find this change; it can also be associated with thrombosis. Atherosis affects only the maternal arterial bed; it spares the veins. Characteristically, it consists of the deposition of foam cells (cholesterol-laden macrophages) in the lumen and wall of the arterioles (Figure 65.19). This lesion may obstruct blood flow, as thrombosis would also do and thereby lead to placental/fetal hypoxia and typically to placental infarcts. When infarcts are of recent origin, they still have fetal blood remaining and they are red. As infarcts age, they lose the fetal hemoglobin and become pale and, eventually white. They are firm and sharply delimited from the spongy adjacent placenta tissue. In contrast to the more common marginal infarcts seen in normal placentas, infarcts of PIH are distributed centrally. They also may surround focal intervillous thrombi, which are characterized by a laminated appearance due to the 'lines of Zahn' in a thrombus. The occlusion of maternal spiral arterioles also causes the degeneration of decidua basalis and destruction of maternal veins. This may lead to hemorrhages and the condition is known as abruptio placentae (Figure 65.20). While abruption is commonest in PIH, it also can occur in traumatic injuries to the placenta. For instance,

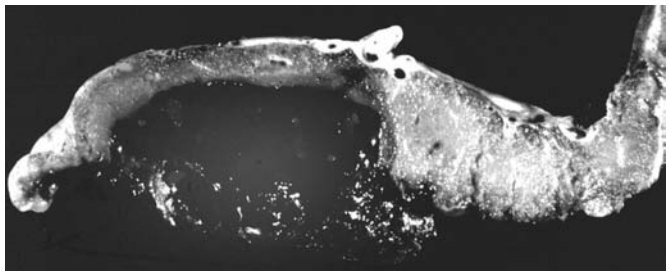

Figure 65.20 Abruptio placentae with fetal demise in pre-eclampsia. Note the compression of nearly one-half of the placenta. Infarcts are also present.

amniocentesis occasionally needs to be done by trespassing the placental tissue and that can disrupt major blood vessels. More common though is abruption of the placenta in automobile accidents, for instance, when a seat belt injures the pregnant uterus. Very rarely, an abruption was caused by external version of a breech presentation; thus, it needs to be borne in mind that this can occur when versions are attempted. It is not uncommon that small retroplacental hematomas are found on careful examination, especially adjacent to placental infarcts. When they are as large and sudden as shown in Figure 65.20, however, they are lethal for the fetus.

One feature of placental infarcts differs from infarcts occurring in other organs (e.g. the kidney), namely, the dead tissue does not become 'organized' in the usual sense. That is to say, blood vessels from the adjacent tissues do not enter the infarct and the dead tissue is also not removed by macrophage activity.

Placenta percreta

It is normal for placentation that a small amount of decidua basalis separates the villi from the myometrium. It is not fully understood why it is that the trophoblast stops invading or destroying the endometrium at that point, as one can readily find X-cells in the myometrium underlying most placental sites and they are found in myometrial blood vessels beneath the placenta. Only when there is insufficient decidua present does the villous portion of the placenta attach itself to the myometrium and then form a placenta accreta. I believe that this occurs most commonly because prior disease (e.g. tuberculosis or chronic endometritis) has destroyed the endometrium and endometrial repair does not take place by lateral growth of endometrium. Thus, when a placenta implants over a prior curettage site, the development of focal placenta accreta may occur. It is generally witnessed only by the disruption of the placental floor when the placenta is examined or clinically by postpartum bleeding. Thus, when placental tissue remains attached to a focus of myometrium, a placental 'polyp' may form, which is composed of fragments of placental tissue enmeshed in blood clot and is occasionally accompanied by inflammation. Also, because of insufficient decidualization of the higher endocervical canal, placenta previa is often associated with focal placenta accreta.

When deeper infiltration of the myometrium by placental tissue has occurred, we speak of placenta increta and when it has penetrated, we refer to it as placenta percreta. These terms are frequently misinterpreted to mean that the placenta has actually invaded the myometrium to destroy it and 'grow through the endometrium', to emerge on the peritoneal surface. This is really true only of ectopic pregnancies in the fallopian tube. When they rupture, this is due to placenta percreta but primarily so because there is only minimal or absent decidualization, thus ensuring that a placenta percreta can form; and because of the thinness of the tubal wall, rupture may occur when the conceptus enlarges. It must be said, however, that ever so rarely a full-term gestation takes place in the tube. Moreover, all abdominal implantations are placentas accreta and it is for that reason that the placenta will not detach on delivery. It has also recruited an enormous blood supply from the neighborhood.

Placenta percreta has become more common in recent years and it is now often diagnosed sonographically. Virtually, invariably this is the result of a prior cesarean section. When the uterus is sutured, usually by a single layer of resorbable fibers, the edges of the prior incision are poorly aligned and since there is no new growth of myometrium to connect the edges, repair occurs by connective tissue. When a new pregnancy takes place, this scar widens and thins; when a placenta is attached directly over the site, it may appear as though it has penetrated the uterus, but that occurs only by separating the myometrial edges from the prior cesarean section. Thus, having implanted on connective tissue (instead of the normal decidua), the placenta may even attach itself to the posterior surface of the urinary bladder. On occasion, some bladder wall is removed at the excision of such specimens and it appears as though a true invasion has taken place. But that is no more than the usual infiltration of extravillous trophoblast into the uterine musculature that occurs in all pregnancies. In other words, while it is theoretically possible that an occasional placenta may truly invade, the common placenta percretas are the result of insufficient healing of a prior section scar. It might be mentioned parenthetically that, when a pathologist has the opportunity to examine the hysterectomy specimens of such percretas, the endocervical canal is tough to cut, it is firmly closed and it is filled with that sticky mucus that normally prevents ascending infection of the amnionic cavity.

Fetal storage diseases

Numerous storage diseases of the fetus, the so-called 'errors of metabolism', affect the placental morphology.

One of the first to be recognized was 'I-cell disease' in which the trophoblastic cells show diffuse vacuolation. The same is true for many other storage diseases and, to differentiate among them, it is necessary to undertake enzyme studies. Fetal leukemia occurs occasionally and can be recognized by the circulating nucleated cells, but care must be taken not to overinterpret these as they may be a transitory phenomena, for instance, in Down's syndrome. More important are fetal neuroblastoma and sacrococcygeal teratoma; both may present as hydrops with typical swelling and edema of the villi. In neuroblastoma, however, the neuroblasts are seen to plug many capillaries and occasional rosettes may be identified.

66 Clinically significant pathology of the placenta

B. Hargitai and T. Marton

Introduction

Histopathological examination of the placenta can contribute to the determination of the causes of fetal demise, growth restriction, or neonatal condition. Recently, several guidelines[1–3] and books have been published in the subject of placental pathology.[4,5] The ever-growing evidence-based knowledge requires recapitulation of the clinicopathological correlation. The benefits of placental examination include recognition of maternal conditions having an effect on subsequent pregnancies (autoimmune disease, antiphospholipid syndrome, thombophylia) or that may have medicolegal implications (e.g. concerning the etiology of long-term neurodevelopmental sequelae or the approximate timing of an intrauterine death.[6,7] Timing of the lesions and fetal damage can be estimated and possibly vital clues obtained concerning the etiology of the fetal or neonatal condition. Many features of the placenta can be judged only in the clinicopathological context, partly because of the occasionally loose correlation between the histological changes and the clinical symptoms and partly because of the large reserve capacity of the placenta. It is also apparent that satisfactory clinical information improves the rate of recognized histological features, which underlines the importance of the clinical information submitted to the pathologist.[8]

This chapter attempts to highlight clinicopathological associations bearing great importance in everyday obstetrical and neonatal care.

Placenta referral to the histopathology laboratory

The increased workload of perinatal pathology departments would not allow examination of all placentas, which is not even necessary, except those well-defined conditions when placenta referral is indicated. This 'minimal list' can be extended in selected centers with specific research project. Referral is decided at the delivery suit. The indications of placenta referral are as follows.[1]

Fetal conditions, when referral is indicated

Intrauterine growth restriction (IUGR) (birth weight below 2.5 kg or third percentile), prematurity (less than 37 weeks of gestation), placental abruption, fetal hydrops, fetal developmental abnormality, chromosome aberration, stillbirth, severe fetal distress requiring admission to neonatal unit, rhesus (and other) isoimmunization, morbidly adherent placenta, twins/other multiple pregnancy (complicated or uncomplicated), abnormal placental shape (if clinically relevant, including placental tumors) or other postnatally diagnosed disorders of the placenta (hematoma, too large or too small placenta, infarction, discoloration of membranes), umbilical cord containing two vessels, premature rupture of membranes (PROM) (more than 36 h).

Diseases of the neonate with possible intrauterine origin

These include neonatal infection (pneumonia, or sepsis within 72 h) and neonates with neurological signs.

It is also recommended to examine the placentas from pregnancies with maternal diseases that might have consequences in the neonate. These are maternal pyrexia and maternal group B streptococcus, pre-eclampsia, hypertension, severe diabetes, including gestational diabetes, maternal thrombopathies–thrombophilias, other metabolic disease, maternal autoimmune disease, maternal tumor and storage disease.

Generally, referral *is not indicated for* cholestasis of pregnancy (with no further complication), hepatitis B, HIV infection (seropositivity with no manifest disease), other maternal disease with normal pregnancy outcome, normal pregnancy, placenta previa, postpartum hemorrhage.

In the pathology laboratory, placentas are selected for pathological examination

A full examination of the placenta includes macrosocopic and histological examination of representative

samples of the placenta, membrane and umbilical cord. The indications for examination of the placentas are as follows.[1]

Rhesus isoimmunization with admission to the neonatal unit, in any intrauterine death/stillbirth (even if a postmortem examination of the baby does not take place), anemia requiring intrauterine transfusion, morbidly adherent placenta, maternal pyrexia, neonatal infection, prematurity (<34 weeks and not PET/IUGR), severe fetal distress, any admission to the neonatal unit, IUGR, prematurity (<34 weeks) due to PET/IUGR, severe PET, abruption, hydrops and fetal anomaly. The goal in this group is to demonstrate the placental consequences of the clinical condition, in other instances to identify the etiology.

The rest of the placentas belong to a risk group for neonatal disease, so storage is recommended (in unfixed state, for 2 weeks, 4°C, urgent examination on clinical request). These placentas are from pregnancies with PROM, prematurity (34–36 weeks), uncomplicated gestational diabetes, rhesus negative mother, maternal group B streptococcus and uncomplicated pre-eclampsia.

The normal placenta

Normal human placenta has a range of features that are dependent on many factors including maternal size, ethnic origin, geographic area, age, parity, etc.

All placentas are examined at the delivery suit after birth macroscopically.

The *membranes* can lose their transparency, become mat/murky and thickened in chorioamnionitis, subchorionic hemorrhage. Small, white-gray granular nodules appear in oligohydramnios and this alteration is referred to as amnion nodosum, which can be confused with squamous metaplasia macroscopically, but the latter is a normal variant.

Circumvallate placenta presents with a yellow-whitish rim on the fetal surface. Its significance is uncertain, some correlate it with IUGR.

The normal *placenta* is ovoid, and the fetus to placenta weight ratio is 7 at term, growing gradually from 1 at 14/40 weeks of gestation. Normal thickness is approximately 1.5–2.5 cm. Irregular placental shape, multilobed placenta can be a sign of disturbed implantation, or developmental abnormality of the uterus. The placental weight correlates with the fetal weight and a small placenta is prone to result in placental insufficiency and subsequent fetal demise. A large placenta is usually associated with fetal overgrowth syndromes and genetic disorders (Beckwith–Wiedemann syndrome, congenital nephrosis syndrome of the fetus). Other underlying conditions are maternal diabetes, maternal and fetal anemia and fetoplacental hydrops.[9]

The fetal surface has to be searched for vessels leaving the disk, but not returning to it, because that can be a sign of a retained cotyledon. Generally, the fetal surface reflects the changes that can be seen in the membrane or on the subchorionic surface. The color of the normal placenta varies between red and dark red, which depends on the time of clipping the umbilical cord. In a normal placenta, palpation is spongy and homogenous and does not suggest any focal lesions (except for small, peripheral infarcts or perivillous fibrin deposition in term placentas).

After turning the placenta, the maternal side has to be checked for completeness. The *umbilical cord* length is 40–70 cm at term, with one coil over 5 cm on an average.[10] The normal umbilical cord has three vessels and is inserted on the placental disk, preferably in central or paracentral position.

Twin placentas

It is essential to determine the chorionicity of twin placentas, because of the increased morbidity and mortality rate of the monochorionic gestation. The commonest type is the dichorionic placenta. It can have a single disk (either fused or non-separated) or two separated disks. While dichorionic twins can be both di- and monozygotic, monochorionic twins are always monozygotic. Monochorionic, diamniotic twins represent the second most frequent twinning. There is always a single placental disk. Chorionicity can be easily identified with the help of two forceps: the septum needs to be separated into two layers. In case of two thin, equally translucent webs the twin placenta is monochorionic, whereas in uneven separation, having one smooth, opaque, thin layer and a thicker one with uneven surface, the pregnancy is dichorionic.

The rarest finding is the monochorionic, monoamniotic twin placenta (with a single placental disk).

Clinicopathological correlations

Umbilical cord

The umbilical cord is short by definition if it measures less than 40 cm. A short umbilical cord carries an increased risk for fetal/neonatal morbidity or mortality and there is an increased rate of neurological abnormality. The cord is considered to be long if it is longer than 70 cm. A long umbilical cord has a correlation with maternal factors, such as systemic diseases, delivery complications and increased maternal age. According to Baergen *et al.*, fetal factors included non-reassuring fetal status, respiratory distress, vertex presentation, cord entanglement, male sex and increased birth weight. Other frequently observed placental features were increased placental weight, overcoiled cord, true knots and congestion. Cord prolapse causing fetal distress also occurred more often with a long umbilical cord.[11]

Marginal cord insertion shows correlation with IUGR, stillbirth, neonatal death, premature birth and low birth weight. A possible explanation is that a disturbed implantation is behind the atypical cord

insertion. The same is true for velamentous cord insertion.

Over- or undercoiling of the cord has an increased risk for fetal demise, fetal intolerance to labor, IUGR, and chorioamnionitis.[10] It is apparent that an extremely overcoiled umbilical cord has an elevated vascular resistance, and vascular obstruction is often behind the fetal loss in these cases.

A true knot can cause fetal death (associated with perinatal mortality of 10%), whereas a loose knot *per se* does not cause harm to the fetus (Figure 66.1). Long umbilical cord is a risk factor for both knot and increased coiling.

Single umbilical artery[12] has an association with fetal malformation and chromosome aberration in 25–50%. In normally formed infants, IUGR is frequent and there is also an increased perinatal mortality.

Thrombosis of the umbilical vessels has a very poor prognosis,[4] but survival can also occur.

Besides the well-known consequences of intrauterine infection (see below), umbilical cord vessel vasculitis and funisitis are associated with cord vessel thrombosis and vasospasm of cord vessels.[5] Necrotizing funisitis is a rare form of umbilical inflammation usually seen with acute chorioamnionitis. Candida, streptococci, herpes and syphilis are reported to play a role in the pathogenesis of necrotizing funisitis (Figure 66.2).[4]

Figure 66.1 Tight knot of the umbilical cord.

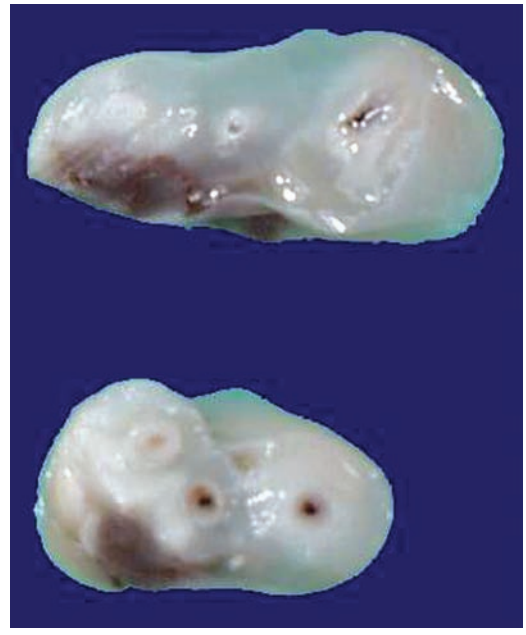

Figure 66.2 Necrotizing funisitis. See the whitish necrotic areas in the umbilical cord.

Membranes

Acute chorioamnionitis (including 'subchorial intervillositis') has a strong association with premature rupture of the membranes and preterm delivery.[13] Fetal intrauterine infection may occur. Maternal pyrexia and tachycardia are described as maternal effects, but may be asymptotic. Recently, chorioamnionitis has been implicated as a risk factor for periventricular leukomalacia and cerebral palsy.[14]

Chronic chorioamnionitis has been observed in prolonged rupture of membrane and herpes virus infection.[4]

Amnion epithelial vacuolization can be artifact, but lipid containing droplets in the epithelium are specific for gastroschisis.[4]

In contrast to the common belief, pigmented macrophages and the presence of meconium staining are not necessarily associated with adverse fetal outcome. Meconium staining indicates the danger of meconium aspiration and with other histological signs of fetal distress may underline the diagnosis. Vasospasm of cord vessels and fetal chorionic vessels are reported as a consequence of meconium exposure.[15]

Acute and chronic deciduitis and decidual necrosis in the parietal decidua are frequently associated with ascending infiltrations of the placental membranes, which may be non-significant in isolation. In retroplacental hematoma, severe, necrotizing acute deciduitis is a common finding. The significance of chronic deciduitis with scattered infiltration of lymphocytes is uncertain.[4]

Placenta

Macroscopic alterations of the placenta

Low placental weight, below the 10th percentile for gestational age occurs in IUGR, pre-eclampsia, increased intervillous fibrin deposition, villitis of unknown origin and trisomies.[9] Placental weight shows correlation with the fetal weight; a small fetus has a generally smaller placenta than a large fetus, but a small placenta may lead to growth restriction.

The placenta is thin (the medical term is placenta annulare or placenta membranacea) by definition if the average thickness is less than 2 cm and the placenta has a large membranous area. While the fetal outcome is usually favorable, there is a risk of maternal bleeding, placenta previa, placenta accreta. Often premature delivery occurs and possibly it is more frequent in IUGR.[16]

The hemorrhages of the placenta include retroplacental hematoma. A large retroplacental hematoma causes a crater (Figure 66.3) and extensive infarction involving a sufficient proportion of villous tissue with secondary fetal hypoxia and/or perinatal death. An early separation (placental abruption) can be lethal if extensive. An elevated maternal serum alpha-fetoprotein level can be associated with old hematomas.

Subchorionic hematoma (Figure 66.4) usually has no clinical significance when patchy, focal or present as a thin diffuse layer. Although rarely, in extreme cases, a massive hematoma (massive subchorial thrombosis, Breus' mole) can result in abortion.

Placenta previa is usually diagnosed by ultrasound before delivery. If undetected and if it causes bleeding, it can be life threatening for both mother and fetus.

Placenta accreta, increta and percreta are potentially life-threatening clinical conditions, causing uterine rupture, and massive postpartum hemorrhage, or leading to cesarean section if prenatally diagnosed. Placenta creta is often an indication of postpartum hysterectomy because of the excessive bleeding. To make the pathological diagnosis of a placenta accreta, examination of the entire uterus is necessary as a posthysterectomy specimen.

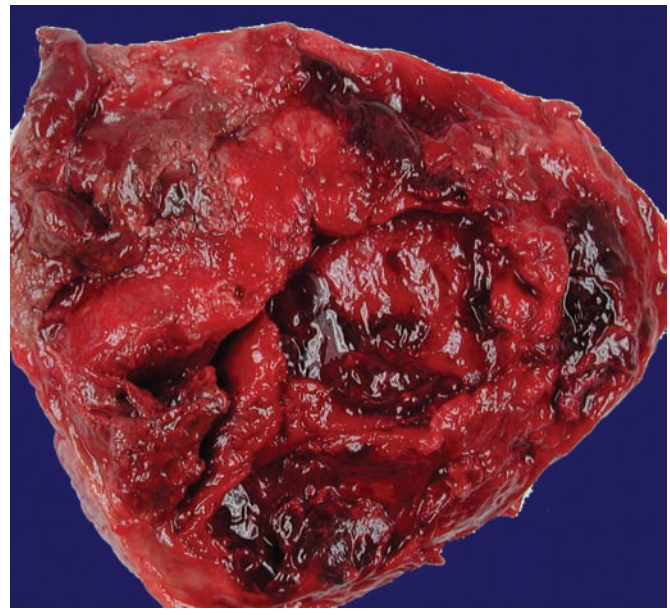

Figure 66.3 The crater in the middle of the placenta was caused by a retroplacental hemorrhage.

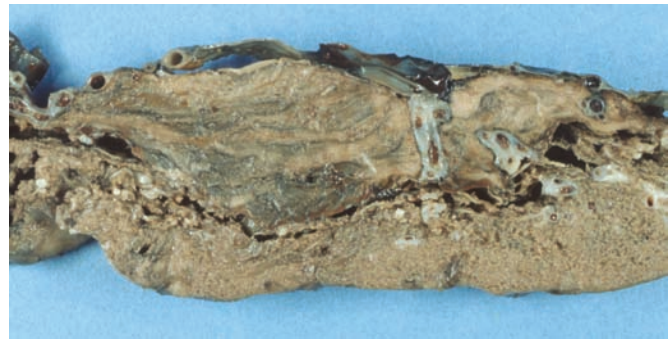

Figure 66.4 Lamellated, large subchorionic hematoma can be seen on the fetal surface of this placenta.

Microscopic alterations of the placenta

- Abnormalities of the placental chorionic villi, the intervillous space and chorionic vessels that result in a reduced functional capacity of the placenta:
  (1) A *placental infarct* (Figure 66.5a and b) has no significance if it is single, marginal and/or involves less than about 5% of the villous tissue. If a placental infarction involves more than 10% of the placental volume it is regarded as extensive infarct and can have serious clinical consequences such as fetal hypoxia, IUGR, stillbirth, pregnancy-induced hypertension, abruptio placentae, neurological abnormalities because of the reduced size villous tree.[4]
  (2) *Extensive perivillous fibrin deposition*, involving more than 20–30% of the villous tissue and functional placenta, is an important histological entity, associated with IUGR and fetal death. In these cases often 70–80% of villous population is enveloped by fibrin. The maternal serum AFP can be extremely elevated.[17,18]
- There are two special patterns of the fibrin deposition: massive basal plate perivillous fibrin deposition is termed as '*maternal floor infarct*' and is known to be associated with high mortality and IUGR.[4,5,19,20]
- The massive perivillous fibrin deposition in a net-like pattern (Figure 66.6a and b) is the '*gitter infarct*'. 'Gitter infarct' and 'maternal floor infarct' are historical names, none of them a true infarct, but a special type of perivillous fibrin deposition.
  (3) *Abnormalities of the fetal vessels*: Fetal chorionic vessels and fetal stem vessels of the placenta may contain fresh or organized thrombus. The organized thrombus can calcify, or contains small vascular spaces if recanalized. Obstruction of fetal vessels (Figure 66.7) is associated with groups or fields of hyalinized, *avascular villi*. These villi cannot take part in the blood gas exchange for the complete lack of capillaries. Presence of extensive avascular villi (Figure 66.8), due to fetal vessel thrombosis, was reported in association with stillbirth, IUGR, maternal and fetal coagulopathy and fetal thromboembolic disease leading to cerebral palsy.[7] *Intimal fibrin cushion*, a non-symmetric intimal swelling with endothelial disruption, is described in neonatal asphyxia, in association with disseminated capillary thrombi of fetal vessels. The severity of the fetal

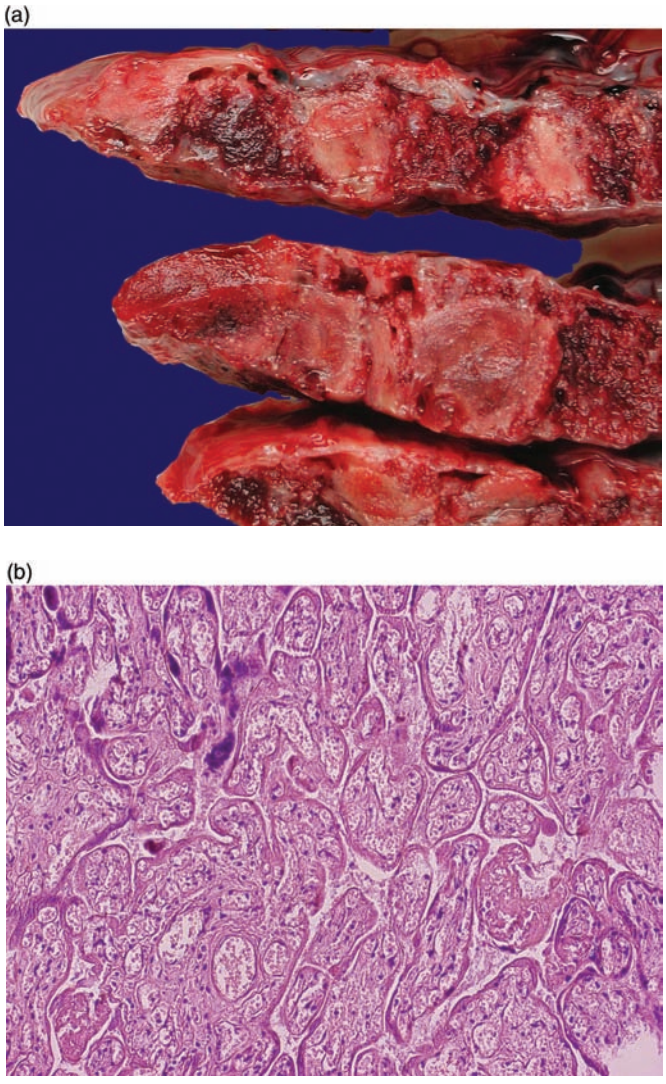

Figure 66.5 Multiple fresh infarcts in a term placenta: (a) macroscopic picture and (b) microscopic image representing necrotic villi.

consequences depends more on the accompanying vascular lesions, mainly on fetal vessel thrombosis.[15] If there are large areas of avascular villi, the prognosis is dependent on the proportion of the placenta as described above.

- *Hemorrhagic endovasculitis* (HEV) is a controversial entity, which was reported to be a postmortem artifact and was doubted as being a specific disease. The histological appearance is characterized by thrombotic-recanalized stem vessels and extravasated, fragmented red blood cells (Figure 66.8). HEV was found to be associated with meconium staining and postmaturity. Earlier report revealed association with stillbirth, IUGR, neurological disability and maternal hypertension. HEV was reported also in livebirths, associated with perinatal complications, fetal distress and IUGR.

- Interlesional relationships exist between thrombotic, chronic inflammatory and chronic vaso-occlusive lesions.[4]

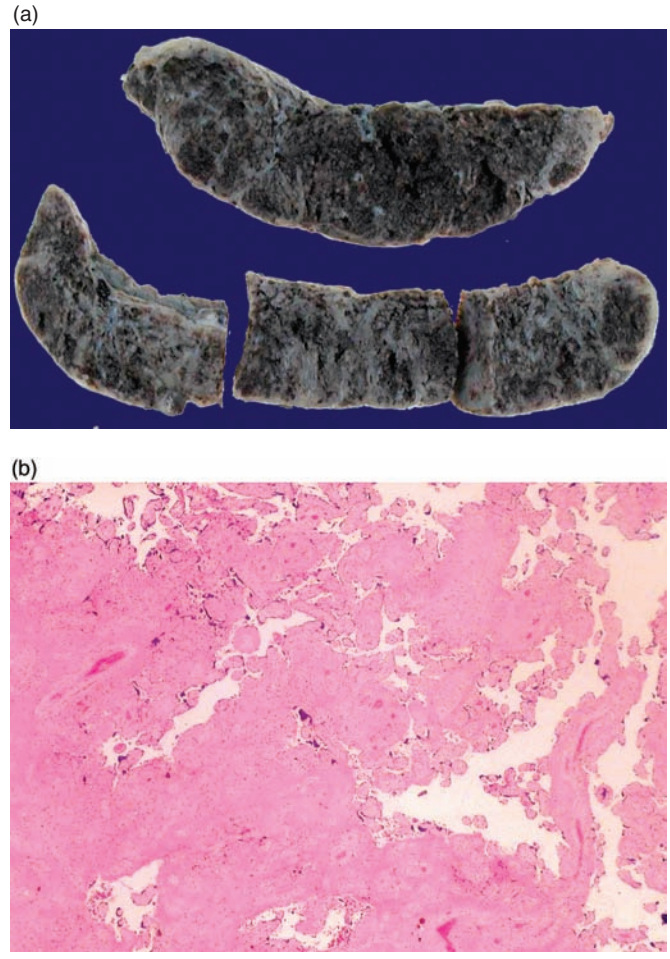

Figure 66.6 Net-like fibrin deposition in the placenta: (a) macroscopic picture and (b) microscopic image shows villi entrapped by fibrin.

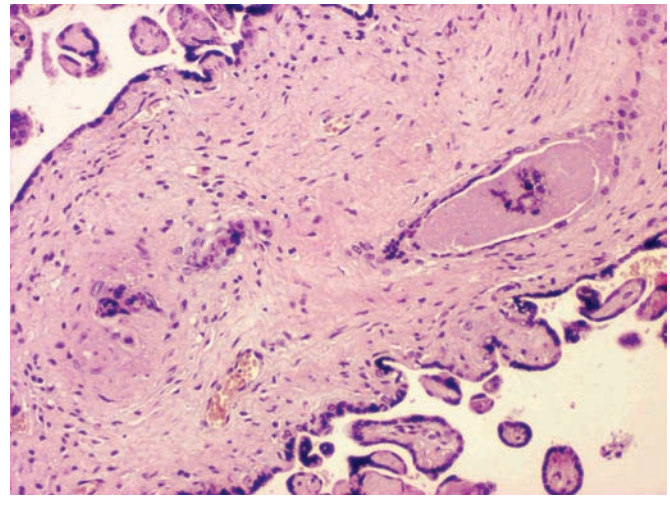

Figure 66.7 Stem vessel occlusion with small avascular villi.

(4) Most frequently, *intervillous hemorrhage* and *thrombus* are related to maternal vessel lesion and are of maternal origin. Small and focal lesions have no clinical importance. Large and multiple lesions may cause fetal compromise or demise depending on the functional placental

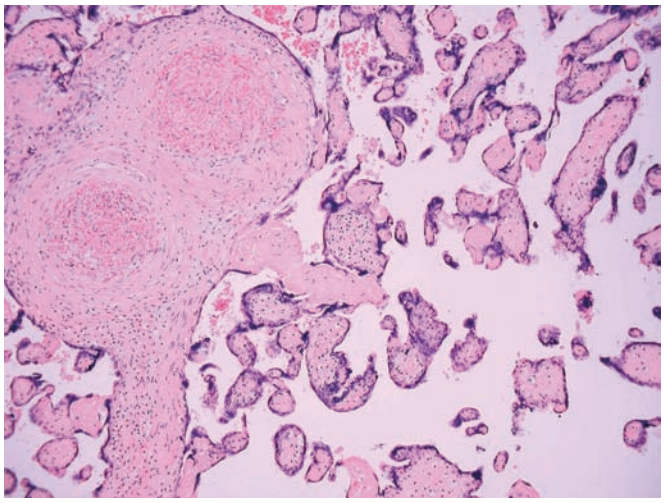

Figure 66.8 A group of avascular villi around a stem villus. The stem villi show hemorrhagic endovasculitis.

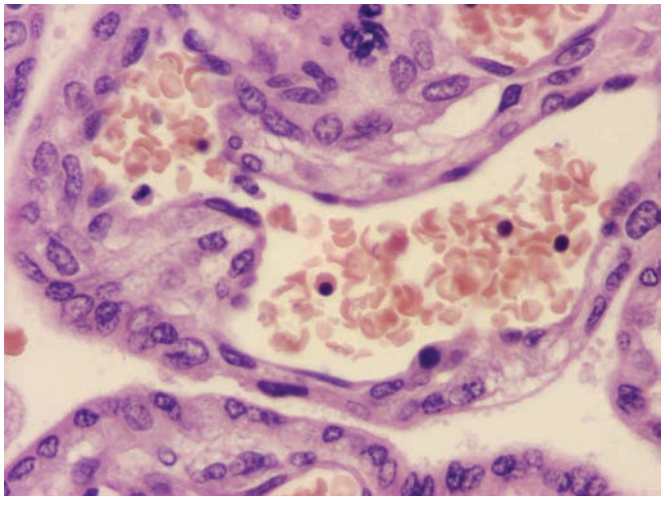

Figure 66.9 Nucleated red blood cells in a fetal capillary.

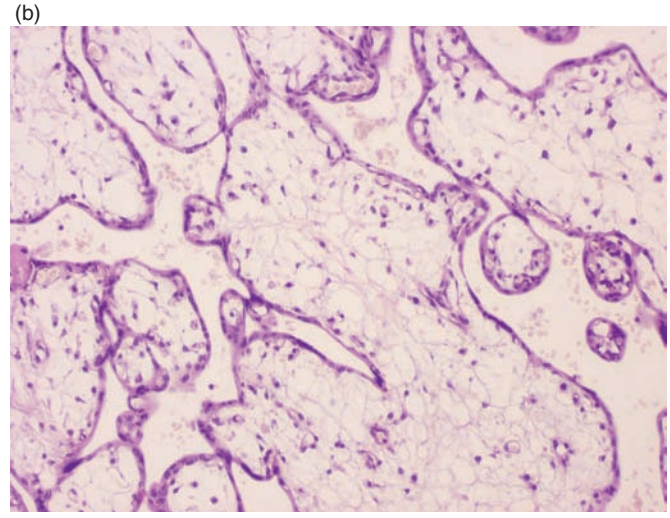

Figure 66.10 Placental edema: (a) macroscopic picture – the bulky placenta and (b) edematous terminal villi.

parenchyma loss and the rest of the unaffected placenta. Quite often they can be seen in pre-eclampsia and is surrounded by infarct as a rim. In some cases intervillous hemorrhage and thrombus are signs of fetal bleeding into the maternal circulation as described by Kline. Only a minority of these alterations leads to a large amount of fetal blood loss and stillbirth or severe anemia followed by ischemic lesions of parenchymal organs.

- Changes of the chorionic villi secondary to pre-eclampsia, intrauterine hypoxia or fetal conditions and maternal spiral artery changes:

  (1) Increased number of *syncytial knots* occurs in pre-eclampsia, hypertension, diabetes mellitus, maternal anemia and pregnancy at high altitude. It can also be seen in a thick histological section (artifact). Despite the fact that it occurs in pre-eclampsia, the correlation between increased syncytial knotting and fetal hypoxia has not been proved. Excessive increase of syncytial knotting may be due to reduced fetal perfusion and placental hypoxia or can be the sign of accelerated maturation if the duration of pregnancy was less than 40 weeks.

  (2) *Elevated number of nucleated red blood cells* (NRBCs) may occur in many causes of chronic hypoxia (Figure 66.9), IUGR, stillbirth, acute and chronic fetal blood loss or anemia, maternal diabetes and erythroblastosis fetalis.[4]

  (3) An increase of vasculo-syncytial membrane (VSM) is described in pregnancies at high altitude, pre-eclampsia, maternal heart failure and maternal anemia. *VSM deficiency* was reported in pre-eclampsia, materno-fetal rhesus incompatibility, maternal diabetes, low birth weight and stillbirths.[4,5]

  (4) *Extensive stromal fibrosis* occurs in terminal villous deficiency, in IUGR, and in avascular villi due to fetal stem vessel thrombosis.

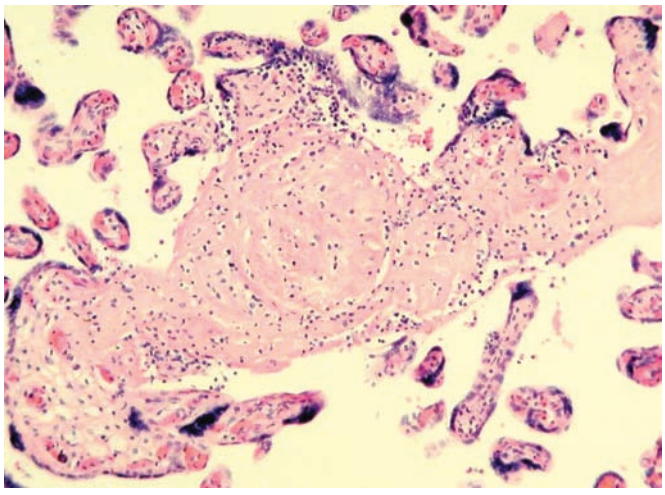

Figure 66.11 Villitis of unknown etiology (VUE). Chronic inflammatory cells infiltrate the villus, the chorionic epithelium is damaged.

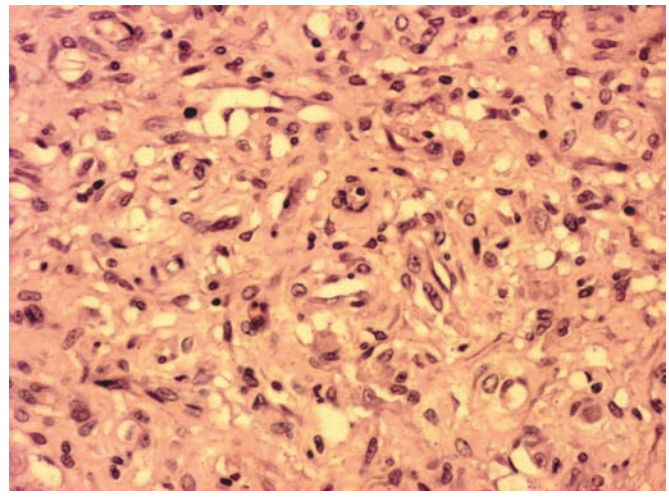

Figure 66.12 Microscopic appearance of chorangioma with small capillary-like vessels and sinusoids.

(5) Placentas from pregnancies with hydrops fetalis may show a combination of immaturity and edema. *Villous edema* occurs also in infections (syphilis, CMV, toxoplasma, parvovirus) (Figure 66.10a and b) and in hydatidiform moles. Edema may be within normal limits, when focal.[4]
(6) A *failure of villous maturation* was found to be associated with fetal hypoxia, IUGR, maternal diabetes and materno–fetal rhesus incompatibility. Maturation failure may lead to intrauterine death.[5,21]
(7) *Accelerated villus maturation* (maturitas precox)[4] can be observed in prematurely delivered placentas in pre-eclampsia and the features are related to chronic ischemia.
(8) *Abnormalities of the maternal vessels* are usually associated with pre-eclamptic toxemia. *Uteroplacental* or *decidual arteriopathy* is a failure of physiological adaptation of maternal vessels. Uteroplacental vessel fibrinoid necrosis, acute atherosis and uteroplacental vessel thrombosis are closely related with pregnancy-induced hypertension, maternal essential hypertension, pre-eclampsia resulting in fetal complications such as IUGR, SGA and stillbirth. It is associated with APA, systemic lupus erythematosus and thrombophilia.[4,5,22]

- Inflammatory processes involving the placental villi or intervillous space:

(1) *Acute villitis* is usually associated with severe maternal infection, preterm delivery and might lead to intrauterine infection and intrauterine death (IUD).[4]
(2) The etiology of *chronic villitis* is usually not known (villitis of unknown origin, VUO, or villitis of unknown etiology, VUE) (Figure 66.11). In about 15% of cases CMV, toxoplasma and syphilis infection are the underlying causes of chronic villitis.

- Chronic villitis is associated with IUGR and/or stillbirth. Chronic villitis of unknown etiology is associated with IUGR and preterm birth, and tends to recur during subsequent pregnancies.[4]

(3) *Chronic histiocytic intervillositis* (chronic perivillositis) is characterized by dense histiocytic intervillous infiltrate, and is reported in association with elevated maternal serum AFP, recurrent abortion, IUGR and preterm delivery. Malarial infection should be excluded.[23]

- Miscellaneous conditions of the chorionic villi:

(1) *Mesenchymal dysplasia* is the hallmark of Beckwith–Wiedemann syndrome.[24]
(2) Perinatal death, congenital malformation and cerebral palsy were found to be associated with *chorangiosis* as a response to low-grade tissue hypoxia. Although others have supported this observation, the question still remained as to how chronic hypoxia results in increased vascularization. The significance of this alteration needs further investigation.[25]
(3) *Chorangioma* is a tumor-like lesion, resembling infantile hemangiomas (Figure 66.12). It is most likely of hyperplastic origin, arising from the subtrophoblastic reticular tissue of the immature stem villi. Large lesions can lead to cardiac failure, hydrops and death of the fetus due to high-output cardiac failure. Other possible complications are transplacental bleeding, and feto–maternal transfusion leading to anemia. Chorangioma was reported to be associated

with pre-eclampsia, multiple gestation, premature delivery, fetal thrombocytopenia and fetal angiomas (Kasabach–Merritt syndrome).[4]

(4) *Umbilical cord hemangioma* is a rare entity and its complications are related to the size of the lesion. It can be associated with elevated AFP level; fetal disseminated intravascular coagulation, fetal hydrops as well as fetal demise have been described.[26]

Conclusion

In conclusion, we would like to emphasize the importance of placental referral to the pathology laboratory and the placenta examination. We would also like to encourage communication between clinicians and pathologists to discover further clinicopathological correlations for the benefit of the patients.

67 Non-invasive prenatal diagnosis: maternal blood

O. Lapaire, B. Zimmermann, X. Yan Zhong, S. Hahn and W. Holzgreve

Abstract

One of the major topics of prenatal research today is the genetic analysis of fetal cells or fetal DNA/RNA, which can be accumulated from the blood of pregnant women. It is the intention of the clinician and scientists of the laboratory to offer a risk-free diagnostic method for pregnant women in order to reduce the number of invasive interventions [e.g. amniocentesis (AC), chorionic villi sampling (CVS)] and the procedure-related risk of fetal loss, as well as to provide additional markers for prenatal screening programs and for prenatal diagnosis. Until now the technical problems of cell enrichment has prevented routine use of fetal cell sampling. In contrast, cell-free fetal DNA in maternal plasma can now be used for the extremely reliable identification of fetal genetic traits, clearly distinguished from maternal sequences (e.g. the fetal rhesus status) or inherited polymorphism. Only recently, a new field of investigation has been opened by the demonstration of the cell-free form of fetal RNA in maternal plasma, which is surprisingly stable and holds promise for non-invasive screening for fetal aneuploidies or pregnancy-associated disorders.

Introduction

Routine clinical prenatal diagnosis with a view to identify fetal genetic disorders was started in the 1970s. Since its inception, the reason for prenatal diagnosis is the detection of fetal aneuploidy and malformations. The overall risk of fetal chromosomal disorders is continuously rising due to the increasing average age of pregnant women in the Western world, especially in Europe. The maternal age alone as a screening marker has a low sensitivity of 30–40% for trisomy 21 (M. Down), dependent on the age distribution of the studied population. Down's syndrome is the most common chromosomal abnormality among live births and is the most frequent form of mental retardation caused by a chromosomal aberration. Prenatal protocols for Down's syndrome screening have been introduced for several reasons:

- Trisomy 21 has a high prevalence (1 in 700 births in the absence of prenatal intervention)
- The high morbidity and mortality in affected fetuses and the consecutive socioeconomic costs
- The area-wide availability of diagnostic tests to detect this chromosomal abnormality
- The availability of safe and accessible interventions to introduce abortions of affected fetuses

As a whole, the society desires Down's syndrome screening to be done as early as possible in pregnancy, despite the effectiveness of second-trimester serum screening. First- or early second-trimester diagnosis of fetal abnormalities allows more time for decision making, greater privacy and safer methods of pregnancy termination. However, a number of issues must be addressed before earlier screening can be offered on a general population basis. These issues include the availability and acceptability of early invasive diagnostic methods (e.g. chorionic villus sampling and amniocentesis), as well as clinical effectiveness.

Three screening markers, two serum and one fetal ultrasound marker have been shown to be effective for first-trimester screening for Down's syndrome.[2,3] The two serum markers in combination with the maternal age constitute a first-trimester maternal serum screening test that achieves a sensitivity of 63% at a 5% false-positive rate.[2]

An improved performance can be attained by the addition of sonographic analysis for increased fetal nuchal translucency (NT) (Figure 67.1). NT by itself is a strong marker of Down's syndrome and is associated with detection rates between 60% and 70% at a 5% false-positive rate.[4] When it is combined with the pregnancy-associated plasma protein A (PAPP-A),

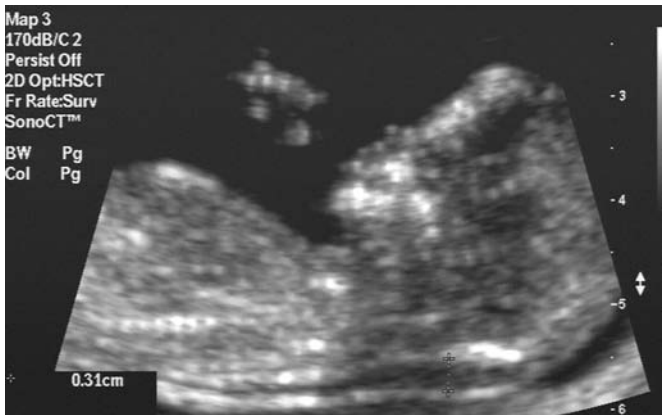

Figure 67.1 Transabdominal measurement of the fetal nuchal translucency (3.1 mm) at the end of the first trimester.

free beta-human chorionic gonadotrophin (beta-hCG), and the maternal age, an overall sensitivity rate of approximately 85% at a 5% false-positive rate can be obtained.[5–7]

The combination of serum and ultrasound markers at the end of the first trimester is better than any of the second-trimester serum tests that are nowadays available and, at least in a hypothetical model, are more cost-effective (screening plus liveborn costs).[8] However, the performance of NT as a screening marker has not been consistent from study to study, probably because of the variability of the operator's experience and training.[9] Further studies as well as proper training and ongoing quality management are necessary before a widespread use of this screening regimen can be implemented.[10]

In case of a suspicious result (in Switzerland: overall risk for trisomy 21 > 1:380), invasive testing, with either amniocentesis (AC) or CVS, is advised during a profound genetic counseling. AC is the commonly used ultrasound-guided technique for withdrawing amniotic fluid from the uterine cavity, using a needle via a transabdominal approach. CVS refers also to the invasive procedures for prenatal diagnosis of genetic disorders, in which small specimens of the placenta are achieved for chromosome or DNA analysis. Two approaches are available for obtaining chorionic tissue, a transcervical and a transabdominal CVS, depending on the routine of the performer and the location of the placenta. However, due to the procedure-related risk of fetal loss, which is estimated to be 0.5–1% of all interventions, a rising percentage of pregnant women opt not to have any invasive diagnostic procedures. Thus, the rate of procedure-related unaffected fetal loss is estimated to be 44–45 per 100,000 women screened when either first-trimester screening (NT, free beta-hCG, and PAPP-A) or a second-trimester quadruple test has been performed.

For that reason international projects have been set up in the field of prenatal medicine research for effective, risk-free, and reliable alternative methods and additional markers. The object of the research is to obtain fetal tissue, with either the enrichment of fetal cells or cell-free DNA, and recently RNA, extracted from the maternal blood. Fetal cells have been found in the maternal blood, though in very low quantities. Therefore, the primary step was their detection, enrichment, and characterization with molecular biologic methods.[11] Besides fetal cells, cell-free fetal DNA and fetal RNA, independent of fetal gender and genetic polymorphism status, were found in the maternal plasma. With the progress in prenatal research and technical advances, some results of non-invasive prenatal medicine research have already come into the clinical setting: as a diagnostic tool, fetal DNA, extracted from maternal plasma, can now be used for the extremely reliable identification of fetal genetic traits that are absent in the maternal genome (e.g. the fetal rhesus status or patients with an elevated risk for X-chromosomal inherited disorders, e.g. hemophilia, fragile X-syndrome).

To examine fetal DNA, nowadays a polymerase chain reaction (PCR) is normally used as the first step in the vast majority of DNA analyses. In a few hours, an automated PCR can amplify a single DNA molecule a millionfold. The greatly amplified target DNA is subsequently analyzed via other techniques.

The recent detection of fetal RNA in the plasma of pregnant women has led to new opportunities. Unlike fetal DNA, quantitative analysis of fetal RNA with PCR methods has the advantage of being applicable to all gravidae, irrespective of fetal gender and genetic polymorphism.[12]

To analyze fetal RNA, a reverse-transcriptase PCR (RT-PCR) is used for transforming messenger RNA (mRNA) into complementary DNA (cDNA) by an RNA-dependent DNA polymerase, specified as RT. The cDNA complex is then changed into a double stranded DNA, thus becoming the template for a subsequent PCR reaction.

The main source of fetal RNA is thought to be the placenta. Fetal RNA is surprisingly stable in the maternal plasma. Data indicate that the measurement of circulating placental RNA may provide a new method for non-invasive prenatal diagnosis and monitoring. The future clinical application of this technology would be the application of RNA as an additional screening tool for chromosomal aneuploidies and other pregnancy-associated disorders.

Non-invasive clinical diagnostics using fetal cells in maternal blood samples

A long sought goal of prenatal medicine has been the reduction of invasive diagnostic procedures for fetal cell sampling, and its procedure-related risk of miscarriage, by isolating fetal cells from the maternal blood.

In the 1990s, the first report about successful enrichment of fetal cells, extracted from maternal blood, was published. The cells could be analyzed for possible aneuploidies by fluorescent *in situ* hybridization (FISH).[13] FISH can identify different chromosomal mutations including deletions, duplications, aneuploidy, and the presence of derivative chromosomes with specific DNA probes. However, small mutations, including small deletions and insertions as well as point mutations, cannot be identified with the FISH technique. When the DNA probes are designated with a fluorochrome, fast detection of the fluorescent signal is possible via fluorescence microscopy. The main difficulty of this method has been the very low concentration of fetal cells in the maternal serum. It could be shown that only two to six cells per milliliter of maternal blood are present.[14] Fetal cells can be found in the blood of pregnant women from the first trimester on. However, a rapid, simple, and consistent procedure for their isolation for prenatal non-invasive testing has not been found. Almost any procedure available in experimental cell research for cell enrichment has been used to isolate fetal cells out of maternal blood. For the multistep enrichment, the density gradient centrifugation is always used as the first step,[15] fluorescence-activated cell sorting (FACS)[16] or magnetic activated cell sorting (MACS) (see Figure 67.2)[17] follow as the second step after the attachment of magnetically labelled or flourescent antibodies for specific fetal cell surface markers. A major effort has been made during the last years to standardize and validate these processes among different laboratories.

The latter method is easy to perform and has a higher turnover of samples, as well as a higher sensitivity than FACS (see Figure 67.3). The third step includes FISH, culture, or PCR. However, the cell culture, with or without enrichment, as well as the multistep enrichment procedure itself requires many manipulations in which a certain amount of cells may be lost. New methods, such as automatic scanning, are needed to install the cell enrichment in the routine clinical use. Different populations of fetal cells can be enriched from the maternal blood; CD34 + hematopoietic progenitor cells and cells from the trophoblast are used.[17] Each of these cell lines has some specific disadvantages. For example, it is not possible to cultivate nuclear erythrocytes. This fact does not allow a metaphase analysis for chromosomal testing. On the other hand CD34 + cells can be cultivated. However, they persist postpartum in the maternal blood circulation and make a prenatal testing in the next pregnancy more difficult. Furthermore, cells are not constantly present in the maternal circulation. The isolated cells have been investigated using cytochemistry, soret band absorption microscopy, monoclonal antibodies for ε- and γ-chain-hemoglobin, monoclonal antibody for i-antigen, and FISH. In summary, the enrichment of fetal cells from the maternal blood is too laborious to be a serious alternative in the clinic and to supersede prenatal invasive diagnostic procedures. Today, the international research has partially turned its attention to the cell-free fetal DNA and RNA.

Non-invasive prenatal diagnostic tests with fetal DNA

The first publication about cell-free fetal DNA, extracted from maternal blood, dated from 1997.[18] Quantitative investigations showed that the concentration of fetal DNA during pregnancy is much higher than that of fetal cells.[18] Quantitative levels can be measured with

real-time PCR. Real-time PCR has several advantages over conventional PCR: the data collection is done during amplification. The accumulation of PCR products over time is measured directly, without post-PCR modifications. Therefore, it is less prone to contamination, as the results are analyzed automatically without having to open the PCR reaction vessel, and there is no post-PCR work. It also permits the rapid analysis of numerous samples in one analytic run and is therefore better for automation.

The quantitation of fetal DNA may provide additional knowledge regarding the outcome of pregnancy. Fetal DNA is elevated in specific pregnancy-associated disorders like pre-eclampsia,[19] hyperemesis gravidarum,[20] or trisomy 21.[21] In case of pre-eclampsia, it could be demonstrated that the severity of the disease correlates with the level of cell-free fetal DNA in the blood of affected pregnant women.[22] Furthermore, cell-free fetal DNA can be used as an additional marker for Down's syndrome. Although its sensitivity is lower than that of other biochemical screening-markers, like alphafetoprotein (AFP), unconjugated estriol (uE3), hCG or Inhibin A, predominantly due to its width of distribution, it shows a 21% detection rate (with a set 5% false positive rate), when cell-free fetal DNA from maternal plasma/serum is singularly used as marker for Down's syndrome.[23] These studies suggested that an elevated concentration of fetal DNA may be a valuable marker for pregnancy-associated diseases.[23] As the majority (more than 90%) of free DNA in maternal serum is derived from the mother, it is difficult to differentiate the origin. Previously, it was possible only to examine genetic traits that are not present in the maternal genome. However, with this non-invasive and risk-free method it is now possible to detect Y-specific sequences in pregnancies with an elevated risk for X-chromosomal inherited disorders (e.g. hemophilia, fragile X-syndrome). Approximately, 15% of Caucasian pregnancies are potentially at risk of severe intrauterine hemolytic disease, mainly due to rhesus D incompatibility. The need to know the rhesus constellation, as well as the large number of X-linked disorders, has prodded several groups to develop non-invasive risk-free methods for diagnostic tests.

With the highly specific real-time PCR method, it is nowadays possible to detect these fetal genetic traits with an almost 100% sensitivity and specificity. A few laboratories offer routinely the detection of the fetal rhesus status. This is a success in the 15-year-old international research on this topic.

A recently published work of our laboratory demonstrated that fetal DNA can be separated from maternal DNA, due to the difference in its size.[24] A majority of fetal DNA has a size of < 0.3 kb, whereas the maternal DNA, which constitutes more than 90% of the amount of circulating DNA in the maternal blood, shows a size of > 1 kb.[25] The difference in size may account for the different origin. Fetal DNA derives predominantly from the placenta, whereas maternal DNA has its main origin in the hematopoietic system.[26,27] After size separation of the fetal DNA, it is possible to detect fetal microsatellite markers with fluorescent PCR.[24] Until now, this new technology has been used for the determination of many disorders like myotonic dystrophy,[28] achondroplasia,[29] and beta-thalassemia.[30]

Non-invasive prenatal screening tests with fetal DNA

The current focus in research on fetal DNA investigates its use as a maternal serum marker in the second trimester for fetal Down syndrome and other pregnancy-associated disorders. The quantitative measurement of fetal DNA could complement the second-trimester serum markers. By increasing the specificity of the screening, it could help to prevent a considerable amount of unnecessary invasive procedures. The median of fetal DNA concentration is reported to be approximately twofold higher in pregnancies with Down's syndrome, compared with unaffected pregnancies, but the data are disputed by other reports and larger sample numbers, and meticulously accurate, standardized quantification are demanded to allow final conclusions.

In order to use the fetal DNA as a screening marker, a gender-independent fetal DNA marker that can be assayed by real-time PCR is needed. Polymorphic sequences are presently used in the clinical samples that are investigated for fetal rhesus status to ascertain the presence of adequate amounts of fetal DNA. Although a number of sequences have to be examined in each pregnancy to ascertain distinction between fetal and maternal DNA, this approach is still relatively easy to implement.

The presence of fetal DNA in maternal plasma has revealed significant clinical potential for the prenatal diagnosis of fetal genetic diseases and pregnancy-associated complications.

A caveat of the approach is that the DNA present in the circulation is predominantly of maternal origin and interferes with molecular analysis of the fetal DNA. Hence, paternally inherited fetal loci that are clearly different from maternal genomic sequences can be readily examined. Paternally inherited mutant genes in compound heterozygous genetic disorders may also be detected if the paternal mutation is dissimilar from the maternal allele. In general, the detection of fetal single gene disorders is at least cumbersome and sometimes impossible with current methods. Our group was able to detect four paternal inherited mutations of the β-globin[31]. The detection rate was 86%, 100%, 100% and 81%, respectively. Only one false positive result was seen in one of the four examined point mutations. The continuing use of mass-spectroscopy will allow the detection of specific alleles, point mutations or

even differences in single nucleotides (single-nucleotide polymorphism).

Most studies generate data from pregnancies with male fetuses as sequences on the Y chromosome are unique DNA markers, which are absent in the maternal genome. This approach is only applicable to approximately 50% of the pregnancies, but is straightforward to perform. An impediment in the generation of accurate data is the low number of fetal sequences in the plasma, such that the samples quantified by the real-time PCR have copy numbers close to the detection limit and therefore the results of a study may be limited by this fact.

Non-invasive prenatal diagnosis and screening with fetal RNA from maternal plasma, expressed from the placenta

A new development in prenatal screening research constitutes the measurement of fetal RNA in the maternal blood. It gives the possibility to screen for sex-unspecific disorders.[12] Fetal RNA in maternal plasma is surprisingly stable and holds promise for non-invasive gene expression profiling.[32–34] Unlike fetal DNA, extracted from maternal serum or plasma, fetal RNA can be used for prenatal testing irrespective of fetal gender and genetic polymorphism status. To date, only a few reports present quantitative data on this phenomenon. They indicate that fetal RNA extracted from maternal plasma represents a gender independent marker, which may be used for non-invasive gene-expression profiling and may be a suitable additional screening tool for pregnancy associated pathologies. In the case of preeclampsia, not only elevated levels of cell-free fetal DNA, but also elevated levels of fetal RNA were detectable in maternal plasma.[35] The presence of fetal RNA in maternal plasma/serum gives the possibility of investigating the expression of certain genes in analogy with the presently used RNA markers in oncology.[36]

The fast progress and success in non-invasive prenatal research may give a future prospect for valuable alternatives in regard to invasive prenatal diagnostic tests.

68 Multiple gestations: pregnancy evaluation by ultrasonography

S. Tercanli, D. V. Surbek, R. Zanetti-Dällenbach, I. Hösli and W. Holzgreve

Introduction

Since the introduction of ultrasound in prenatal medicine, the prognosis of multiple pregnancies has improved dramatically. Early and appropriate diagnosis of multiplicity and chorionicity, detection of discordant fetal growth, evaluation of fetal well-being by biophysical scoring and Doppler sonography as well as planning of delivery mode by determination of fetal presentation are some of the most important diagnostic advances that represent the basis of adequate clinical management. Multiple pregnancies are at increased risk for several complications during pregnancy and childbirth like prematurity, fetal growth retardation, twin–twin transfusion syndrome (TTS), pre-eclampsia, stillbirth and malpresentation. Therefore, early diagnosis of multiple pregnancies and in particular determination of chorionicity is mandatory for the appropriate assessment of risk factors, for intensive prenatal care and early detection as well as for treatment options of complications. Before the introduction of prenatal ultrasound, detection rate of twin pregnancies before delivery was lower than 50%,[1] while in countries where routine ultrasound in pregnancy is performed, the rate is close to 100%.[2] Consequently, this has led to decreased perinatal morbidity and mortality in twin and higher multiple gestations in the past 30 years.

In the following chapter we will give an overview of the most important clinical issues of multiple pregnancy where ultrasonography plays a major role in the diagnostic procedure.

Early diagnosis of multiple pregnancies

Why should a multiple pregnancy be diagnosed early? First, the number of fetuses, which can be confirmed by ultrasound, is a strong determinator of prognosis of a pregnancy, which is generally best for singletons and gets worse with higher-order multiplicity. As in singleton pregnancies, gestational age can be confirmed by an early ultrasound during the first trimester using growth charts of crown–rump length corresponding to gestational age.[3] In the first and second trimesters of pregnancy, growth charts for singleton pregnancies can be used appropriately for twin pregnancies.[4] More importantly, early ultrasound allows for definitive diagnosis of chorionicity, which itself is also a strong predictor of fetal outcome.

Usually, early diagnosis of multiple pregnancy by transvaginal sonography is easy.[5] After the fifth week of pregnancy (from the last menstrual period), different gestational sacs are visible in multichorionic gestations, whereas in monochorionic twins only one chorionic cavity is visible. From the sixth or seventh week of pregnancy, it is possible to identify the number of embryos and yolk sacs in multichorionic as well as monochorionic gestations (Figure 68.1a and b). As soon as two or more embryos with heart activity are discernible, the diagnosis of multiple gestations is confirmed. Although a false diagnosis of a singleton pregnancy may be made if a hurried scan is performed by an inexperienced examiner, the diagnosis at this stage is virtually error-free. Possible pitfalls may be chorial hematomas or a decidual pseudosac mimicking a second or third gestational sac, or conjoined twins mimicking a singleton pregnancy (Figure 68.2a and b).

Another issue in early diagnosis is the phenomenon of vanishing twins, which seems to occur in a significant proportion of twin gestations[6,7] and might be the reason for discordant diagnosis in subsequent ultrasound examinations. This phenomenon of 'vanishing embryos' is especially well established from *in vitro* programs such as those shown in Table 68.1, which summarizes data obtained in pregnancies after *in vitro* fertilization (IVF) where intact heart action of the embryos was the intake criterion for the prospective study. Vanishing embryos is the spontaneous abortion of a multiple gestation member in the first trimester either by expulsion or – more often – by complete resorption of the embryo (Figure 68.3). In many cases it remains asymptomatic, though sometimes it is accompanied by vaginal bleeding.

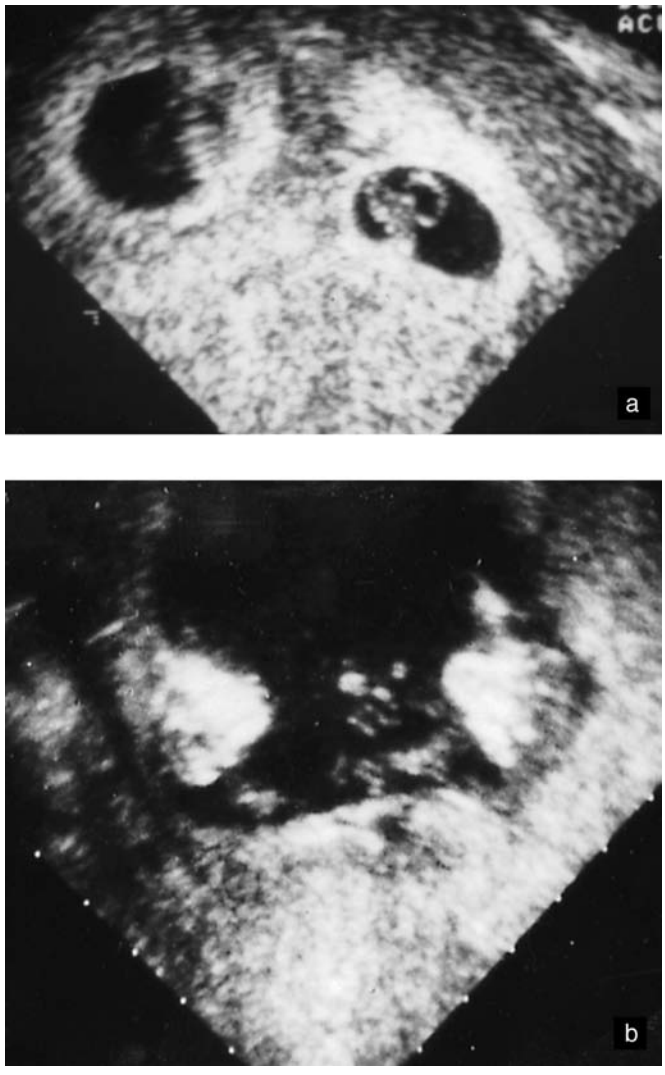

Figure 68.1 Transvaginal sonograms of pregnancies in the first trimester. (a) Dichorionic twin pregnancy with clear separation of the chorionic cavities. (b) Monochorionic twin pregnancy with both embryos anencephalic.

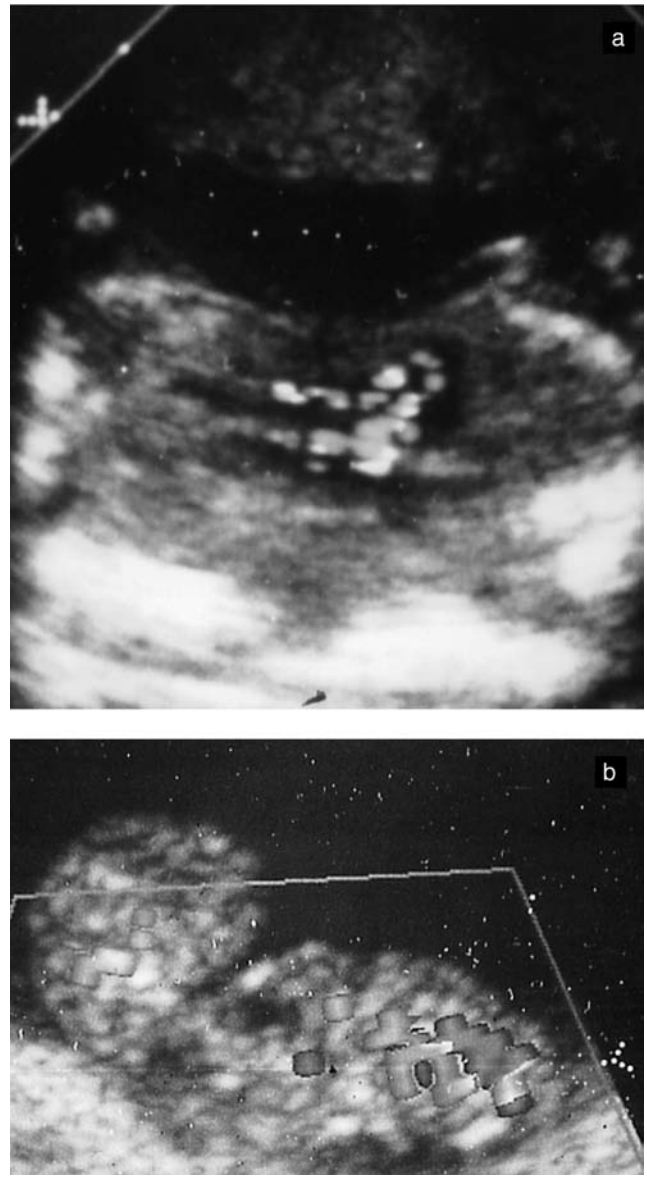

Figure 68.2 Conjoined twins mimicking a singleton pregnancy. Color-coded Doppler sonography. (a) A common fetal heart. (b) Two independent fetal hearts.

Prognosis for the surviving twin seems excellent, although recently it has been hypothesized that unexplained cerebral palsy might be the consequence in the survivor of a vanishing twin pair.[8,9]

Prenatal diagnosis of zygosity, chorionicity and amnionicity

Dizygotic twinning results in dichorionic–diamniotic pregnancies, even though the placentae may be fused (Figure 68.4). In contrast, monozygotic twinning may result in dichorionic–diamniotic, monochorionic–diamniotic or monochorionic–monoamniotic placentation, depending on the age of division. The division of the embryo results in the following constellations: from day 1 to day 3 after fertilization, dichorionic–diamniotic twins; from day 4 to day 6, dichorionic–monoamniotic twins; from day 7 to day 9, monochorionic–monoamniotic twins. If the division takes place after day 9,

Table 68.1 Vanishing embryos in pregnancies with multiples. The 'intake criterion' was intact heart action. All pregnancies are from the *in vitro* fertilization program of Dr. Robert Fischer, Hamburg

Initial scan	Cases	Second trimester
Twins	52	34 twins 18 singletons
Triplets	22	8 triplets 11 twins 3 singletons
Quadruplets	4	2 quadruplets 2 triplets

Figure 68.3 Dichorionic twin pregnancy with a 'vanishing embryo'. After spontaneous abortion of the twin in the upper left corner of the uterus, the amniotic fluid in this sac has almost disappeared and the embryo is getting almost 'resorbed'.

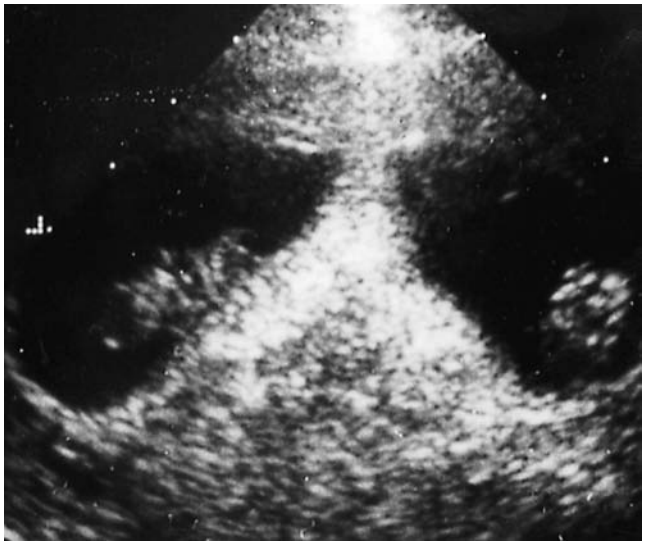

Figure 68.4 Dichorionic twin pregnancy where both chorion frondosum areas are so close to one another that the two placentae seems to be 'fused'.

Figure 68.5 Twin pregnancy with (a) discordant growth and (b) intrauterine fetal demise. The sonogram shows the head of the survivor in the lower left and the dead fetus in the upper right corner.

conjoined twins result. Dichorionic placentation is found in 30% of monozygotic pregnancies.[10] As a rule, dizygous twins are always dichorionic, although this dogma has recently been disproven.[11,12]

Virtually all monochorionic twins, which represent about 20% of all twin pregnancies, have vascular anastomoses in the placenta, whereas almost none of the dichorionic (fused) placentas shows such cross-circulation.[13] These vascular shunts usually remain balanced, but occasionally they might become functional, leading to typical monochorionic twin complications like discordant growth (Figure 68.5a) and TTS.[14] Alternatively, in situations with one intrauterine fetal demise (Figure 68.5b) complications from vascular anastomoses might arise in the surviving twin. These include severe conditions like multicystic encephalomalacia and renal infarctions. In earlier publications, several authors postulated that embolization of thromboplastin-like material across the shared circulation followed by disseminated intravascular coagulation is the cause of this phenomenon, which is also called the twin disruption syndrome. More recent evidence, however, suggests another pathophysiological mechanism, which is based on the assumption that a sudden blood pressure gradient may occur at the moment of fetal demise, followed by severe hypotension and exsanguinations in the surviving fetus, leading to acute hypoxic organ damage predominantly in the brain in

Figure 68.6 Twin–twin transfusion sequence in monochorionic and monoamniotic twin pregnancy. The right fetus has a beginning ascites in the abdomen as a sign of cardiac failure.

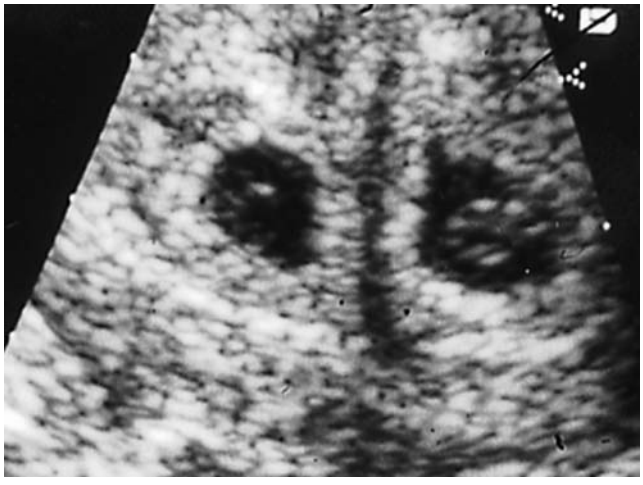

Figure 68.7 Dichorionic twin pregnancies. The two sacs are clearly separated.

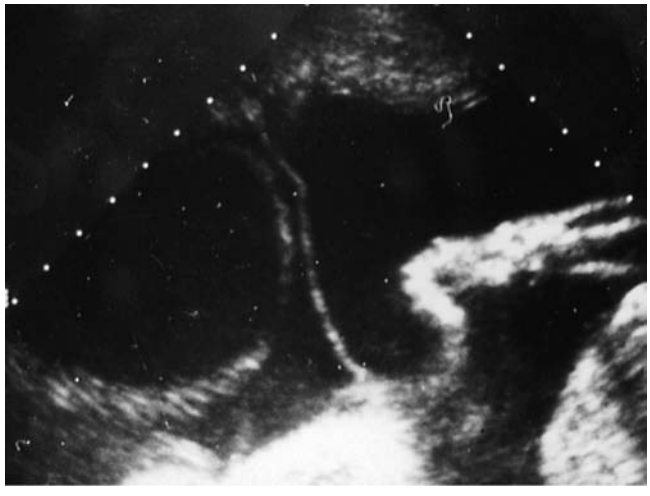

Figure 68.8 Biamniotic twin pregnancy with two discernable amniotic membranes surrounding the embryo.

up to 20% of survivors.[15] This phenomenon could be called an acute TTS.[16]

These complications occur only in monochorionic gestations (Figure 68.6). In particular, the fetal loss rate in monochorionic pregnancies is up to four times higher as compared to dichorionic twin pregnancies. Chorionicity is thus the most important factor influencing the outcome of twin pregnancies. Consequently, accurate prenatal diagnosis of chorionicity is of predominant importance for the clinical management of twin pregnancies.

As outlined above, monochorionic twins usually have a separating membrane, and thus are diamniotic. Fewer than 2% of twins are monoamniotic. Besides complications of monochorionicity, these pregnancies are at high risk for cord accidents during pregnancy and birth, resulting in an extremely high fetal loss rate of 50–75%. Delivery by early elective cesarean section is therefore one of the most important features of the management of monoamniotic twins.

Determination of chorionicity and amnionicity before birth is done by ultrasonography. In early pregnancy during the first trimester, it is usually easy to differentiate the type of placentation by transvaginal sonography. If two gestational sacs with two embryos are identified, the diagnosis of dichorionic twins can be made with certainty (Figure 68.7). On the other hand, if there is only one gestational sac with two embryos, monochorionic twins are diagnosed. To separate monoamniotic from diamniotic gestation, it is necessary to discern two amniotic membranes surrounding the embryos (Figure 68.8), or, at a later stage, to identify a partition membrane between the fetuses (Figure 68.9). If there is no membrane visible, the sonographer has to be cautious as a separating membrane might exist but might be hardly visible on ultrasound scan (Figure 68.10a), particularly in cases of severe oligohydramnios or anhydramnios of one twin combined with polyhydramnios in the other (Figure 68.10b), as it is typically present in TTS ('stuck twin').

Later in the first trimester, from about 10 to 14 weeks' gestation, the key to the differentiation of mono- and dichorionic–diamniotic twins is the 'twin peak' sign or lambda sign (Figure 68.11) used to predict dichorionic twins if present.[17] The latter finding consists of chorionic tissue extending between layers of the interfetal septum close to the placenta.

In the second or third trimester of gestation, other criteria become important in the determination of chorionicity. A reliable diagnosis of chorionicity can only be made if the fetuses are of opposite sex (dizygotic) or there are clearly two separated placentae visible, which is often not the case in dichorionic twins (Figure 68.12). Entanglement of umbilical cords represents a reliable sign confirming the presence of a single amniotic cavity in monoamniotic gestation.[18] In cases with the same fetal sex, with one non-separated placenta and with a dividing membrane between the fetuses, determination of chorionicity is difficult after

Figure 68.9 Biamniotic twin pregnancies with the partition membrane between the fetuses. A twin–twin transfusion syndrome is indicated by severe ascites in the left twin.

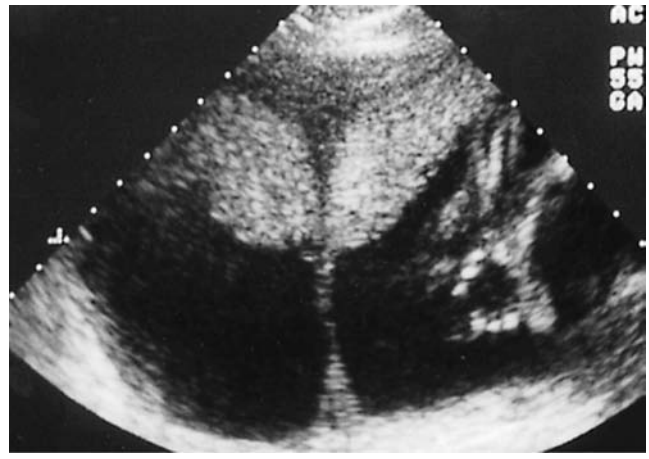

Figure 68.11 'Twin peak' sign in a dichorionic twin pregnancy.

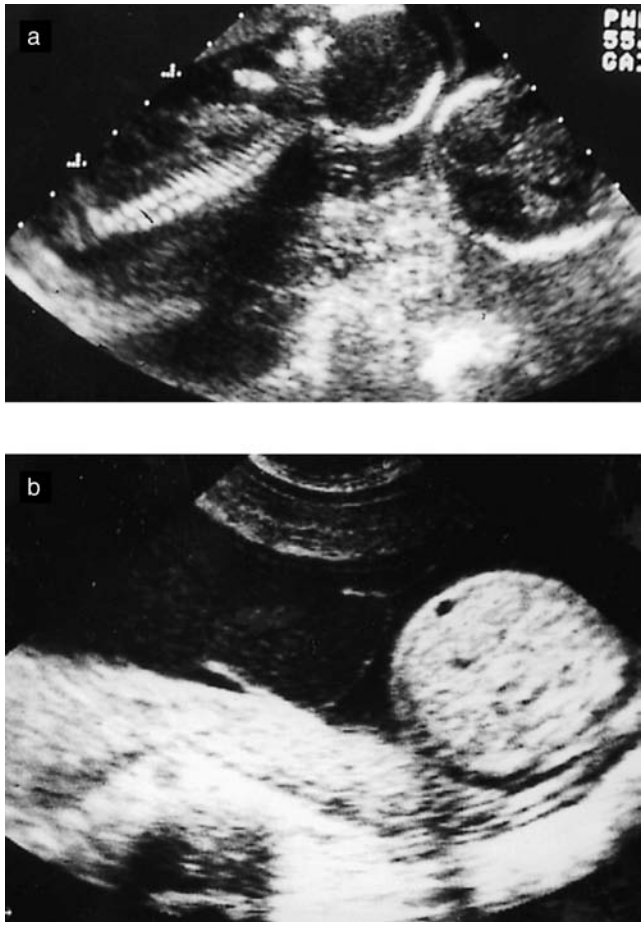

Figure 68.10 Biamniotic twin pregnancies. (a) The separating membrane can hardly be seen on top of the head of the left, smaller fetus. (b) Polyhydramnios is visible in the left, oligohydramnios in the right sac.

the first trimester of gestation and requires other criteria. Thickness of the dividing membrane (Figure 68.13) measured by ultrasound is one criterion that is able to predict chorionicity, using a cutoff level of 2 mm.[19] Another important sonographic feature is the number of layers identified in the dividing membrane.[20] While not always technically possible, it remains a reliable criterion of dichorionic placentation if three or more layers are present. Probably the best approach is the combination of these criteria, reaching excellent predicting values in the determination of chorionicity.[21]

Fetal malformations and chromosomal anomalies in multiple pregnancy

Twins, above all monozygotic twins, are known to be at increased risk for malformations – not only because the presence of two fetuses in one pregnancy doubles the chance of a defect.[22] The incidence of malformations is higher in monochorionic than in dichorionic twins and the highest in monoamniotic twins. Furthermore, the incidence of chromosomal aneuploidy seems to be higher in twin gestations as compared to singletons.[23,24] A detailed study of fetal morphology in

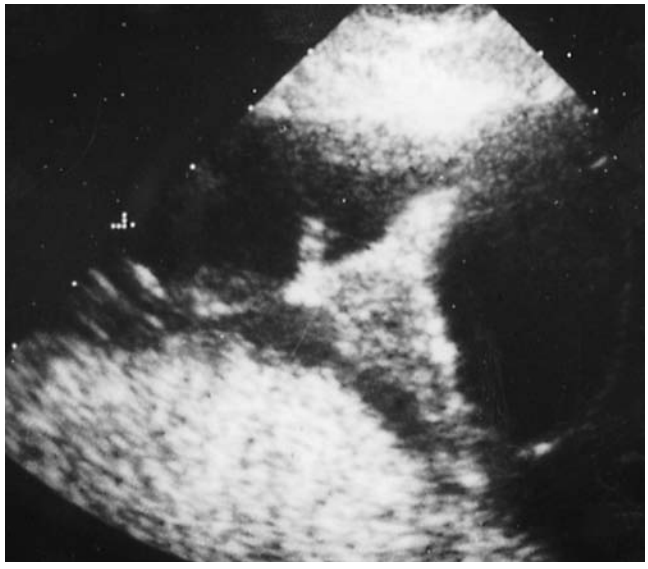

Figure 68.13 Dichorionic twin pregnancies. The thickness of the dividing membrane is more than 2 mm.

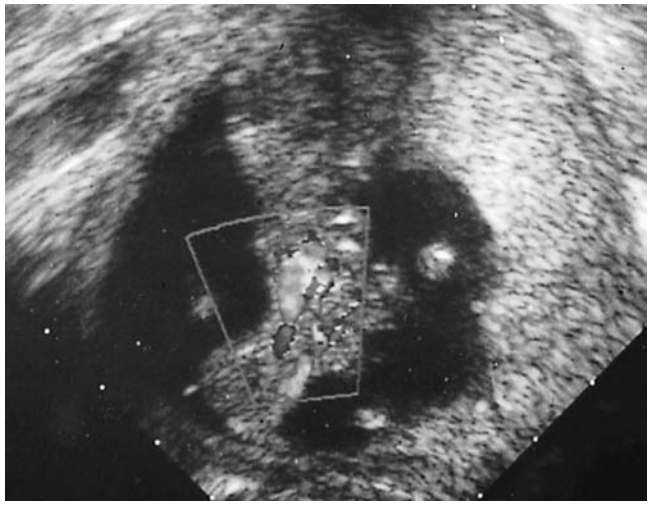

Figure 68.14 Sonogram of conjoined twins with two separate hearts.

multiple pregnancy by ultrasound is time-consuming and sometimes much more difficult than in singletons, but it should be done during routine ultrasound surveillance. Emphasis should be put not only on typical anomalies unique to the twinning process, but also on other anomalies known to be increased in twin pregnancies.

Congenital anomalies specific to multiple gestation occur infrequently but are usually severe. The rate of conjoined twins (Figure 68.14) is 1 in 50,000 births.[25] Prenatal diagnosis by ultrasonography including determination of type of anomaly and of shared organs (Figure 68.15) is important for the optimal management of those pregnancies in terms of appropriate determination of prognosis and plan of delivery route (cesarean section) and postnatal care. In severe cases diagnosed early, termination of pregnancy is an option that many parents choose. Ultrasonographic criteria for the detection of conjoined twins have been proposed: a missing separating membrane, a fixed position of the twins toward each other and a lack of separate visualization of the fetuses in a specific anatomical region. Different patterns of physical joining exist, resulting in different prognosis of the pregnancies. The symmetric complete form of conjoined twinning is present when two fetuses are anatomically almost 'complete' except the part of the body where they share a certain amount of tissue. These 'diplopagi' are described after the body structure that is joined, namely, craniopagi, thoracopagi (accounting for 57% of diplopagi, Figure 68.16), omphalopagi and pygopagi. Postnatal separation is often possible in diplopagi except in cases where gross parts of the heart or central nervous system are shared. The symmetric incomplete forms are represented by twins with one trunk and a single lower part of the body together with two heads (dicephalus) or by twins with one head and upper trunk and a double lower body (dipygus). Asymmetric forms are conjoined twins, one of which is severely malformed and often rudimentary (parasitic twin) while the other is normally developed.

An extreme form of twin-specific asymmetric malformation is the so called acranius–acardius, also known as chorangiopagus parasiticus, or twin reversed arterial perfusion (TRAP) sequence. Numerous theories about pathogenesis of this syndrome, which occurs in a frequency of 1 in 35,000 births, have been subject to discussion in the literature. Typical features are functional vascular anastomoses between not-joined twins with reverse arterial perfusion of the lower part of the malformed twin leading to varying degrees of upper body reduction including acardia and acranius.[26] Doppler sonography may be helpful in identifying cardiac structures, reversed perfusion and vascular anastomoses.[27] A different theory of pathogenesis is the primary existence of acranius–acardius malformation, which is supported by the fact that the malformed twin has been found to have a high prevalence of chromosomal anomalies. Mortality in the reversely perfused twin is 100%. The other fetus, the so-called 'pump-twin', is usually severely compromised by a high-output heart failure, which leads to a mortality of 50%. An intervention might be necessary and indicated, which includes ligation/coagulation of the cord or of intra-abdominal blood vessels of the acranius–acardius twin.

Congenital anomalies not specifically related to multiple gestations have the same ultrasonographic features as in singleton pregnancies. These malformations affect mainly the tracheoesophageal anatomy, the genitourinary and central nervous systems (e.g. neural tube defects), and the cardiovascular system.

Chromosomal anomalies are also increased in multiple gestations. The risk of chromosomal anomalies

Figure 68. 15 Sonogram of conjoined twins with one heart.

Figure 68.16 Almost completely conjoined twins. Thoracopagus anomaly.

in a twin pregnancy can be calculated using maternal age, zygosity and nuchal translucency of the twin fetuses. In dichorionic twins, the detection rate of nuchal translucency measurements for chromosomal anomalies is similar to that in singletons, whereas in monochorionic twins there are more false positives due to placentation-specific alterations of the nuchal translucency. In particular, care must be taken if a large difference in nuchal translucency is found in monochorionic twins because this could be an early manifestation of TTS and not of a karyotype anomaly. In monozygous twins, the karyotype is the same in both twins, and calculations are used for both. In dizygous twins, the risk must be calculated separately for each of the twins. Biochemical parameters such as free β-HCG and PAPP-A (in the first trimester) or α-fetoprotein, free β-HCG, estriol and inhibin (in the second trimester) can be used but are less useful, yielding a lower detection rate of chromosomal anomalies in twins.[28] Simple use of normative values from singleton pregnancies is not possible as medians are different. Current studies are evaluating the validity of twin pregnancy-adjusted normative values.

If the parents want prenatal karyotyping, chorionic villus sampling (CVS) or amniocentesis (AC) can be performed as possible options.[29–32] The parents must be informed in detail about the difficulties and risks of karyotyping in multiple pregnancies. The procedure might be technically difficult, leading to incomplete results (i.e. karyotyping of only one fetus in twins). On the other hand, difficulties might arise if one fetus turns out to be healthy while the other is affected by a severe chromosomal anomaly. In multiple gestations, CVS imposes specific problems due to a missing safeguard in proving that identical karyotypes represent monozygotic twins rather than sampling from the same chorion frondosum. In multichorionic gestations, the placentas might be close to each other, leading to difficulties in separate sampling (Figure 68.17). Furthermore, contamination of one sample with the villi of the other might happen. If fetal sex is different, it could be safely determined that both fetuses have been karyotyped. When suspicion arises, 'follow-up' amniocentesis should be offered. Consequently, CVS in twins should only be performed if individual samples can be guaranteed. Amniocentesis is the alternative procedure, often preferred in multiple gestation. After the puncture and retrieval of amniotic fluid of one amniotic sac, indigo carmine is injected before the needle is retracted. In the following puncture of the second amniotic cavity, the aspirated amniotic fluid is checked in color to exclude re-entry of the amniotic cavity of the same fetus. With this technique, amniocentesis in twins with a correct diagnosis of fetal karyotypes is feasible in most twin pregnancies[33] and has a somewhat lower loss rate as CVS. As a rule, the higher the risk for chromosomal anomaly in a twin, the earlier the diagnosis should be made, ideally by CVS. The reason for this is that if one twin is affected and the parents opt for selective termination, the risk of the latter procedure for the surviving twin is lower, the earlier the selective feticide of the co-twin is performed.

If in a multiple pregnancy one child is proven by prenatal diagnosis to be affected with an untreatable condition, e.g. trisomy 18 or 13 or a severe malformation, a selective feticide can be performed by applying KCl directly to the fetal heart.[34] This technique, however, may exclusively be used if monochorionic

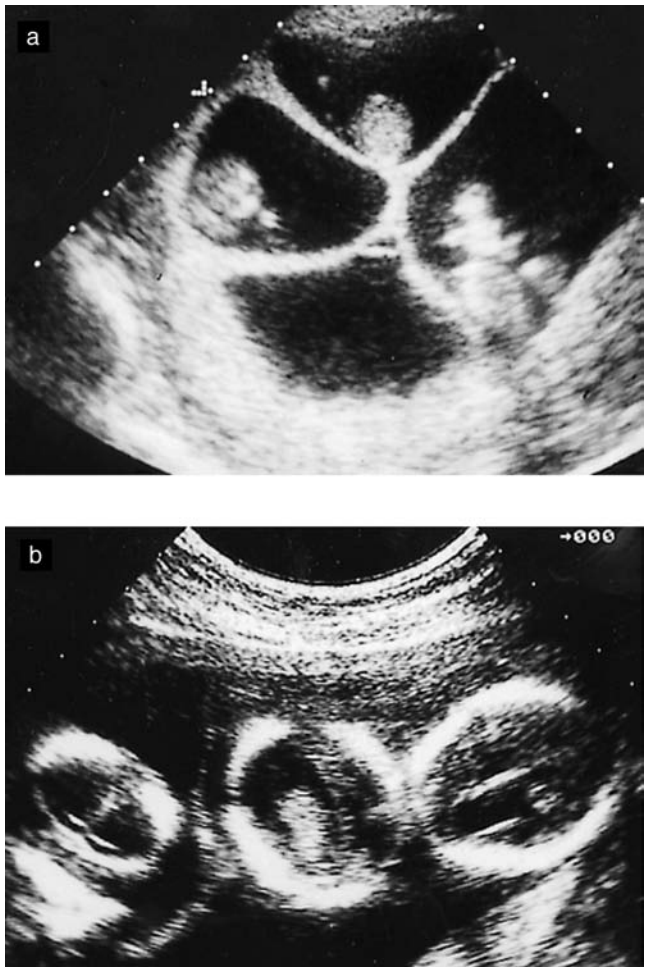

Figure 68.17 High multiple pregnancies. (a) Quadruplet pregnancy in the first trimester. The placentae are so close to each other that they cannot be easily sampled separately. (b) Triplet pregnancy in the third trimester. The separating membranes are more difficult to be seen than in the first trimester.

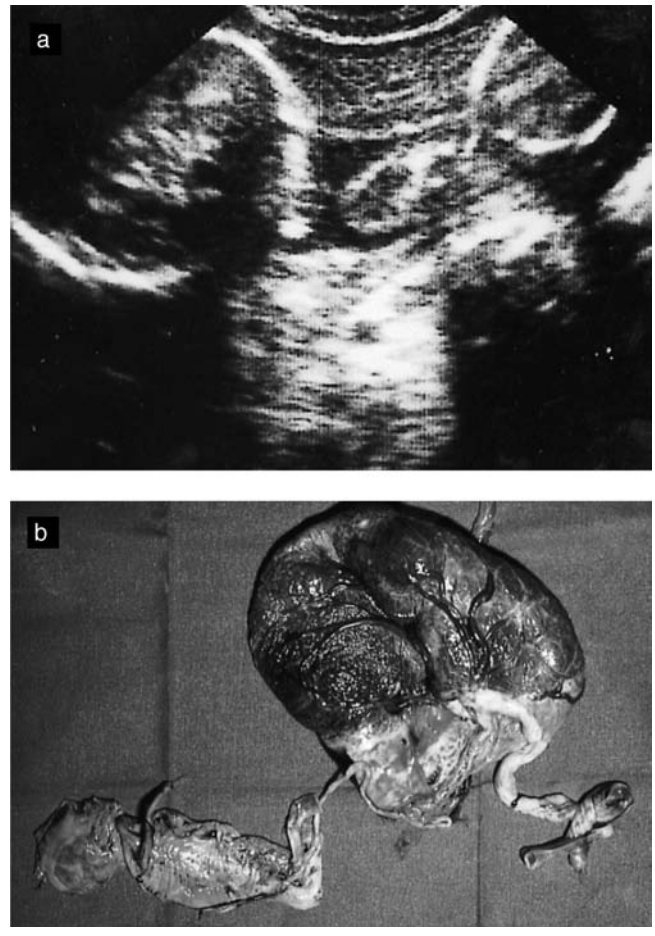

Figure 68.18 Situation after selective feticide. (a) Sonogram shows the small dead fetus in the upper right corner of the picture. (b) After delivery the 'fetus papyraceus' and the 'dead part' of the placenta can easily be seen.

placentation is excluded. The selective fetocide is ethically not much different from a termination of a whole pregnancy in singletons, except for the fact that the pregnancy *per se* continues and the dead fetus usually follows after the livebirth of the co-twin together with the placenta (Figure 68.18a and b).[35]

In pregnancies with very high multiples, e.g. octuplet pregnancies (Figure 68.19a and b), this would be bound to fail (Figure 68.20a and b), so that a 'reduction' of the number of living fetuses has been performed in order to avoid loss of the whole pregnancy spontaneously or through termination. This procedure is called multifetal pregnancy reduction and is performed by intracardiac injection of KCl in 'multiple-chorionic' multiples; again, monochorionicity must be excluded. The outcome of the pregnancy after this procedure depends significantly on the starting number of fetuses, the finishing number and the operator's experience.[36] The primary aim, however, must be to avoid iatrogenic higher-order multiple pregnancy, e.g. by controlled use of ovulation inducing drugs or by restriction of the number of transferred embryos to two during IVF procedure.

Fetal growth in multiple pregnancies

As in all pregnancies, the appropriate dating of pregnancy is important in terms of determination of fetal growth to differentiate growth restriction from normal growth. Dating is best done in the first or early second trimester by combining the date of the last menstrual period with fetal ultrasound measurements.

We mentioned before that in twin pregnancies, growth charts of singletons can be used at least up to the beginning of the third trimester, because normal growth in twins is the same as in singletons. Only after 28–30 weeks of pregnancy does intrauterine growth gradually decrease compared to singletons.[4,37] It has been estimated that after 32 weeks of pregnancy, weight gain of both fetuses in twin pregnancy equals the weight gain of one singleton.

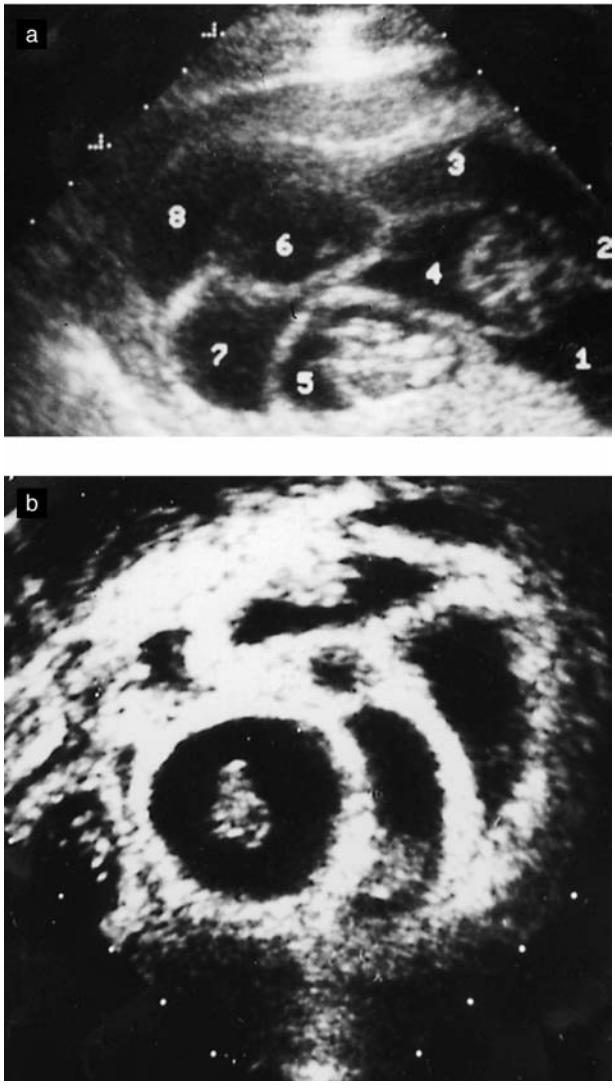

Figure 68.19 (a, b) Two independent octuplet pregnancies which both occurred after ovulation induction by gynecologic practitioners.

Figure 68.20 Complication of high multiple pregnancies. (a) Triplet pregnancy at 26 weeks of gestation. (b) Placenta of sextuplet pregnancy after spontaneous abortion.

Assessment of fetal growth in twin pregnancies has been performed initially by measurements of biparietal diameter,[38] though it has been shown later that biparietal diameter is not an appropriate measurement for detection of discordance in twins.[39] Possible explanations for these difficulties might be different fetal positions and overlaying fetal parts of the other twin. Better estimates of fetal growth and prediction of discordance are accomplished by femur length and abdominal circumference,[40–43] where technical difficulties in measuring seem to be of minor importance.

If discordant growth in twin pregnancy (defined by an estimated weight difference of 20–25% between the fetuses) is diagnosed by prenatal ultrasound, several possibilities exist. The most common cause for the weight discordance is a constitutional weight difference in normal dizygotic twins. In contrast, pathologic causes might result in often severe growth difference between twins. The prevalence of intrauterine growth restriction is up to 10 times higher in twins than in singletons, in particular in monochorionic twins. Pathologic conditions include intrauterine growth retardation affecting one or both twins, because of local uteroplacental factors (which might happen in dichorionic or monochorionic pregnancies) or TTS (Figure 68.21a and b). In some cases, congenital anomaly of only one

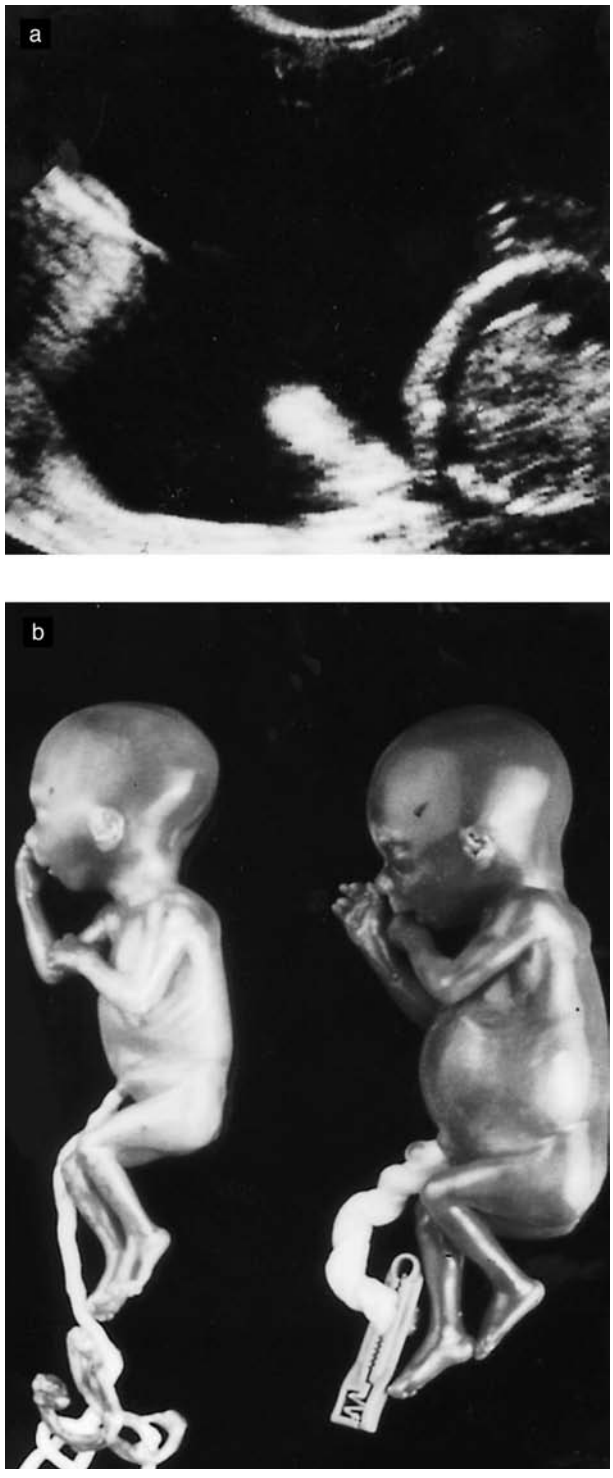

Figure 68.21 Twin–twin transfusion syndrome. (a) Sonogram showing severe polyhydramnios and non-immune hydrops in the recipient twin. (b) Fetus after spontaneous abortion. The right one is plethoric, whereas the left one (donor twin) is anemic and smaller.

fetus might also lead to discordant growth. An important question in discordant twins is chorionicity and amniotic fluid amount. Overall, perinatal morbidity and mortality besides later intellectual sequelae are increased in twin pregnancies, irrespective of the underlying cause.[44]

Doppler velocimetry has proved to be predictive of fetal hypoxia in growth-retarded singletons.[45] Similarly, this technique might be used in twins as an additional measure for detection of growth discordance and fetal compromise.[46,47] Furthermore, with color Doppler, placental anastomoses in twin–twin transfusin syndrome can be detected, which might be helpful for intrauterine treatment by fetoscopic laser ablation of placental vessels (see below).[48]

As in singletons, an individual biophysical profile including non-stress testing should be applied in both twins in growth restricted twin pregnancies as an important tool for assessment of fetal well-being.[49]

Twin–twin transfusion syndrome

TTS is a condition that develops in about 10–25% of monochorionic twin pregnancies. The underlying cause for this syndrome is imbalance of vascular anastomoses between the placental circulation of both twins within the single (monochorionic) placenta. This imbalance leads to decreased feto-placental blood volume in the donor and increased volume in the recipient. The definition of TTS includes the polyhydramnios–oligohydramnios sequence (POS). Typical sonographic features include in the donor fetus oligohydramnios or anhydramnios ('stuck twin' phenomenon), small or absent bladder and growth restriction, whereas the recipient shows polyhydramnios and a large bladder. In both twins, the condition can lead to cardiac decompensation, detectable by ultrasound (including tricuspid regurgitation and negative ductus venosus A-wave in the recipient, pericardial effusion and hydrops). Doppler flow measurements in umbilical arteries can be pathologic in both twins (absent or reversed end-diastolic flow). Ultimately, fetal death in one or both twins can occur. Severe TTS has a 90% mortality and a high rate of neurologic long-term morbidity (handicap) in survivors if untreated.

The severity of TTS can be assessed by ultrasound, which correlates with the prognosis. Several criteria for classification have been proposed, the Quintero staging system being the most widely used.[50]

Management options depend on severity of TTS, gestational age and women's preference and include expectant management with close follow-up (in mild TTS), repetitive amniodrainage, needle septostomy or endoscopic laser coagulation of anastomoses. Cohort studies[51] and a recent multicenter randomized trial[52] suggest that laser treatment in severe TTS is superior to repetitive amniodrainage regarding neonatal mortality as well as morbidity. With regard to the current evidence, laser treatment seems to be the treatment of choice in severe TTS, but the long-term neurologic

outcome results of the randomized trial are still awaited.

Ultrasonography for prediction of preterm deliveries in multiple pregnancies

Twin gestations are known to have a significantly increased risk of preterm delivery as compared to singletons. Early diagnosis of preterm contractions and individual preterm delivery risk assessment is therefore particularly important. Cervical ultrasound has recently been shown to be predictive of preterm delivery. Initial studies measuring cervical length by transabdominal ultrasonography found a significant correlation of a shortened cervix with preterm delivery. As shown by different examiners, transabdominal measurement of cervical length has the disadvantage of being biased by the degree of bladder filling, which led to the increased use of transvaginal ultrasound probes in pregnancy.[53] Besides the cervical length, dilatation of the internal cervical os, protrusion of membranes in the cervical canal, length of funneling and thickness of the wall of the lower uterine segment have been used more or less successfully to diagnose cervical incompetence and to predict preterm birth. Ultrasonographic determination of cervical morphology has been shown to be superior to digital examination of the cervix for the prediction of preterm birth if there is no overt cervical dilatation of 2 cm or more. While some studies have used transvaginal ultrasound for the prediction of the likelihood of preterm delivery in patients with preterm labor, a recent multicenter study proved a correlation of cervical length measured in the second trimester in asymptomatic patients with the risk of preterm delivery.[54] A major finding in this study was that cervical length did seem to be a continuous variable rather than a dichotomous variable, suggesting that cervical function might be a continuum, in contrast to the earlier belief that the cervix is either 'competent' or 'incompetent'. Other studies have shown that ultrasonography of the cervix might be used as well in the follow-up after cervical cerclage, measuring the distance between the cerclage suture and the internal cervical os.[55]

Though some of these studies have excluded multiple pregnancies, others have specifically determined the predictive value in twin pregnancies.[56] One may conclude that ultrasonographic determination of the cervix and the lower part of the uterus is an important additional tool in predicting preterm delivery in multiple gestations, where the risk of prematurity is especially high.

Intrapartum ultrasonography in multiple gestation

There is considerable controversy in the literature around intrapartum management of multiple gestations.[57] Multiple pregnancies of higher order are usually delivered by cesarean section. In twins, the single most important question is the route of delivery in different subsets of twins and, additionally, in different clinical situations like prematurity, growth retardation or pre-eclampsia. Above all, the management plan for delivery has to take presentation of the twins into consideration, which includes all possible combinations of vertex, breech, transverse and oblique presentation of the first and second twins.[58] Ultrasonography can be reliably used for detection of these different presentations before onset of labor, during labor, after delivery of the first twin or after interventions like external or internal version of the second twin. Again, ultrasound examination is the most important tool in the peripartum management of twin pregnancies.

Conclusions

The aim of this chapter was to discuss the most important clinical applications of ultrasonography in multiple gestations. Beginning with early gestation, diagnosis of multiplicity, zygosity, chorionicity and amnionicity are predominant tasks for determination of the risk of complications later in pregnancy. Typical complications of monochorionic twins with vascular anastomoses are being explained. Fetal congenital anomalies in multiple gestations are different in many ways from singletons and represent another problem of primary importance in routine medical care. Multiple gestation-specific anomalies like conjoining can be discerned from non-specific congenital malformations, which exist as well in singletons. Invasive procedures for prenatal chromosomal analysis are briefly discussed, which are more difficult than in singletons as one has to deal with more than one maternal and one fetal karyotype.

Discordant fetal growth is a major complication in multiple gestations. The diagnosis is usually confirmed by ultrasonography; at the same time, the underlying pathology like growth restriction based on fetal malformation of one twin or TTS might be evaluated. Cervical change assessed by vaginal ultrasonography has been shown to be predictive of spontaneous preterm delivery in singletons; similarly this might be applicable in multiple gestations. Finally, peripartum ultrasonography for the detection of presentation is crucial in planning delivery and possible intrapartum intervention in twins.

69 Chromosomal abnormality screening

M. I. Evans, J. N. Macri, R. Snijders and R. S. Galen

Introduction

Principles of screening tests

Screening for any disease process requires a fundamental understanding of the differences between diagnostic and screening tests. Diagnostic tests are meant to give a definitive answer to the question – Does the patient have this particular problem? They are often complex and require sophisticated analysis and interpretation. They are usually performed only on patients felt to be 'at risk'. Because they tend to be expensive, in contrast, screening tests are typically performed on healthy patients and are often offered to the entire relevant population. They, therefore, need to be cheap, easy to use, and interpretable by everyone; their function is only to help define who, among the low risk group, is, in fact, at high risk (Table 69.1). Screening test results are, by definition, not pathonomonic for the disease.[1] Their role is to delineate who needs further testing.

Table 69.1 Screening tests vs. diagnostic tests

Diagnostic tests	
	Performed only on 'at risk' population
	Commonly expensive
	Commonly have risk
	Give definitive answer
Screening tests	
	Offered to general population of patients
	Healthy patients
	Cheap
	Easy
	Reliable
	Quick
	Define 'at risk' population
	Do not give definitive answer

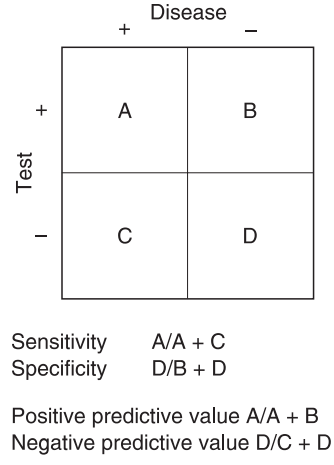

Figure 69.1 Two-by-two table of disease and tests.

There are four key measures used in the evaluation of screening tests (sensitivity, specificity, positive predictive value, and negative predictive value) (Figure 69.1). Sensitivity and specificity fundamentally address the question from an epidemiologic viewpoint. For example, of all the people with the disease, what percentage was identified by the test? This is the definition of sensitivity. Specificity is the converse, i.e. of all the people who do not have the disease process, what percentage of the patients test negative? Physicians are generally more interested in different questions, however, because only after a positive test does the patient usually get interested. Of all patients who have a positive test, what percentage of them actually have the disease? This is the positive predictive value. The negative predictive value is just the opposite, i.e. of all the people who have a negative test, what percentage of them are actually negative?

A key point to remember is that, in general, sensitivity and specificity do not vary as a function of prevalence, unless there is an influence of other factors on the equation. However, positive and negative predictive values do vary (Figures 69.3 and 69.4). In a population in which the prevalence is very low, the proportion of positives that will be false positive will be much higher than in a population in which the prevalence is very high. In the former case the vast

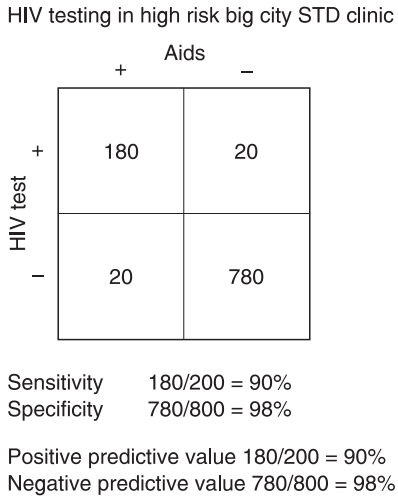

Figure 69.2 Two-by-two table in high-risk population for sensitivity and predictive values.

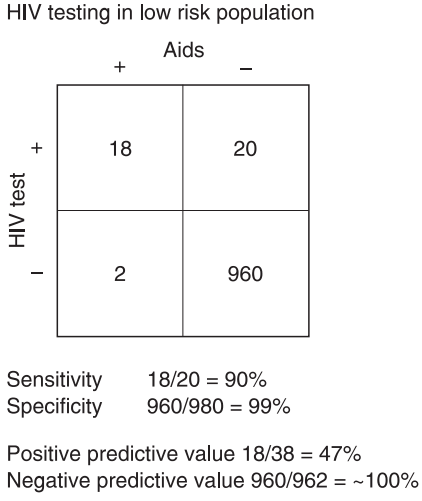

Figure 69.3 Two-by-two table in low-risk population for sensitivity and predictive values.

majority of positives will, in fact, be false positives. In both high and low prevalence areas, the sensitivity and specificity of the tests should be the same. However, the positive and negative predictive values will be widely different. If a test is absolutely useless (no better than chance), then the predictive value after testing will be the same as the population risk (prevalence) before testing. When this occurs, the test performs no better than a coin flip, and the sensitivity and specificity add to 100%.

The past few years have seen continued advancement in attempts to refine the sensitivity and specificity of chromosomal screening, and to reduce the overall costs of the screening programs *per se*.[2,3] The goal is to reduce the need for expensive costs of invasive testing that follow a positive screening, and also, although not commonly mentioned, to reduce the cost

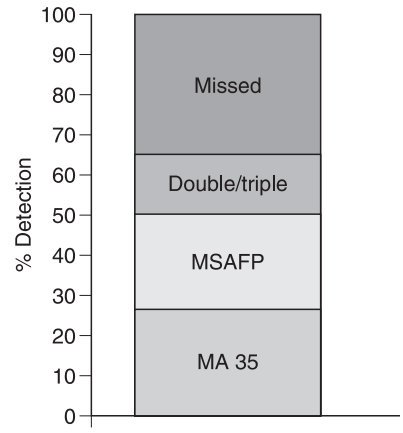

Figure 69.4 Maternal age 35 identifies about 25% of Down's syndrome pregnancies. Low AFP brings the total to about 50%. Double or triple screening raises that number to about 60%. Half of the 80% of cases occurring in women under 35 are detectable.

of the care of abnormal newborns who might as a result of screening be detected and terminated at the wishes of the parents.[1–5]

Screening for chromosome abnormalities

Merkatz *et al.* first published the association of low maternal serum alpha-fetoprotein (AFP) with an increased risk of chromosome abnormalities, particularly Down's syndrome in 1984.[6] Subsequently, there was a gradual acceptance of the association, as well as an eventual understanding that Down's syndrome is not the only aneuploid condition association with low maternal serum AFP. For example, trisomy 18 usually has even lower AFP values.[7]

The adoption of wide scale screening with maternal serum AFP effectively doubled the potential detection of chromosome abnormalities in the population. Before the massive explosion of infertility therapies, only about 20% of Down's syndrome babies were born to women over age 35 (Figure 69.5). More recent data suggest that the proportion of births to women over 35 has gone from about 5% to nearly 15%, and the proportion of Down's syndrome cases in women over 35 is now more than 30%.[8] The addition of a well-coordinated maternal serum AFP screening program as developed in the late 1980s could detect approximately 30% of the 75% of cases that are born to women under age 35. The detailed mechanics of biochemical screening, i.e. with adjustments for gestational age, race, diabetic status, multiple gestation status, maternal weight, and adjustments via a different database or correction factors for maternal race, have been published previously and will not be repeated here.[9]

In 1988, Wald *et al.* suggested that a combination of parameters including AFP, beta-human chorionic gonadotrophin (β-hCG), and unconjugated estriol (uE3)

could significantly increase the detection frequency of Down's syndrome to approximately 60% of the total.[10] Multiple studies have corroborated the increased efficacy of multiple marker screening as opposed to AFP alone in detecting chromosome abnormalities, particularly Down's syndrome.[11–14]

Despite overwhelming data and recommendations of national organizations such as the American College of Obstetricians and Gynecologists that multiple numbers be offered, by the millennium still nearly 20% of patients in the United States who had screening were still just having AFP alone (M. I. Evans, unpublished data).

Evans *et al*. have investigated many of the 'dogmas' of three decades of biochemical screening and found that many of these are no longer valid. We believe that the wide variance in results reported from around the world is largely due to subtle, and sometimes not so subtle, differences in laboratory methodologies.[15–19] For example, the bitter arguments about double vs. triple screening are in part explained by wide differences in assays among laboratories that particularly affect estriol. When the methods are 'standardized', much of the variability disappears and will allow for an 'apples vs. apples' as opposed to 'apples vs. oranges' comparison.[19] Similarly, much of the other reported variations in the literature likewise disappear with standardization, and the diabetic correction factor becomes unnecessary with proper accounting for the fact that diabetic patients are of higher maternal weight,[15] and maternal weight correction, *per se*, continues to be important.[16,17]

Over the past several years there have been numerous papers that have attempted to refine methodologies of sample collection[20,21] and more precisely explored the impact of various factors such as more precise dating or the efficacy of Down's syndrome detection rates.[22,23] Likewise with an ever increasing proportion of pregnancies resulting from infertility therapies, questions have risen as to whether modifications of risk or screening strategies are required.[24]

A number of papers have suggested dimeric inhibin A as an excellent marker that may raise the sensitivity by 3–7% for a given screen positive rate.[25–28] Out of this data have come calls for 'quadruple' screening, and various combinations of biochemical and biophysical (ultrasound) data. There are also paradigms that include different parameters at different times combined. While preliminary data do suggest a high sensitivity with improved specificity,[29,30] hiding results from patients for up to a month is ethically problematic in our opinion. No doubt there will be multiple approaches to screening that emerge, and there will be no one uniform standard approach.[31]

A two-step approach has been the so- called 'integrated' test.[28–31] This is a combination of first-trimester blood and ultrasound. The first-trimester results are not communicated to the patient, who then waits for second-trimester blood results before a risk assessment is completed. Two studies, the 'SURUSS' trial and the 'FASTER' trial have data that suggest a reduced false-positive rate for comparable sensitivity, but the trade-off is the need for patients to wait as much as 6 weeks for start to finish of the screening process.[29,30] For patients who do not particularly care about the results, the delay may be fine, but our experience suggests that many anxious patients would find such a delay intolerable.[32–35]

As reproductive techniques have dramatically increased the proportions of multiple pregnancies, questions about the efficacy of screening tests have emerged. We and others have debated the data of biochemical screening on twins or more. There have been several papers that have promoted 'pseudo risks' for twins by biochemical data. We continue to be concerned about the accuracy of these tests and believe that in multiple pregnancies biophysical data are more likely to be accurate.[36–39]

First trimester

The future of screening for Down's syndrome (and other anomalies) lies in the first trimester. Substantial evidence now shows that free βHCG is reliably elevated and PAPP-A is diminished in Down's pregnancies.[39,40] Data from multiple laboratories have been consistent in suggesting 70% to even 90% detection rates. In combination with ultrasound nuchal translucency (NT) measurements, almost all publications in which the ultrasound component was performed in a technically sound fashion have shown at least a 70% sensitivity.[41]

Several large-scale studies – particularly the King College group in London and the NICHD funded 'BUN' and 'FASTER' trials – all essentially confirmed that first-trimester data will be at least equal to routine second-trimester double or triple screening.[29,40]

Measurement of fetal NT thickness

Guidelines for measurement of fetal NT thickness have been drafted by the Fetal Medicine Foundation (FMF). More than 300 centers around the world have adopted the FMF guidelines and they take part in the quality control scheme. Quality control of ultrasound scans involves assessment of the distribution of NT measurements and assessment of randomly selected images in terms of magnification, section (sagittal or oblique), caliper placement, skin line (nuchal only or nuchal and back), and visualization of the amnion separate from the nuchal membrane.[34]

The ability to measure NT and obtain reproducible results improves with training; good results are achieved after 80 scans for the transabdominal route and 100 scans transvaginally.[41] The ability to achieve a reliable measurement of NT is dependent on the motivation of the sonographer. Results were compared from hospitals that used NT in clinical practice

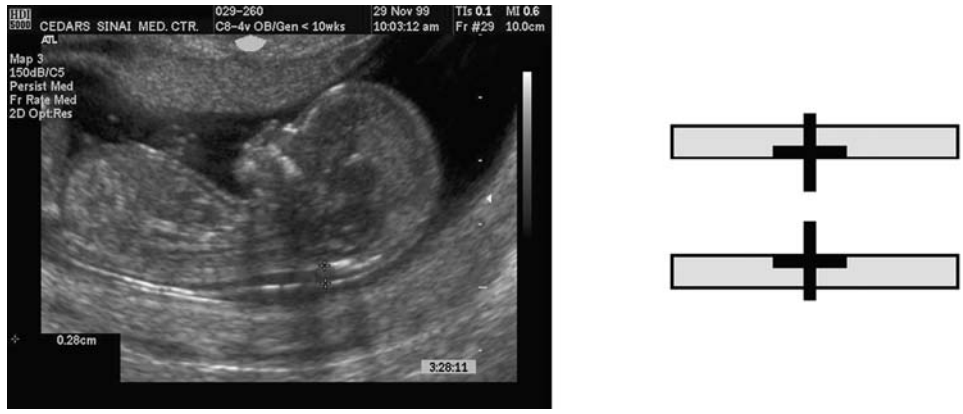

Figure 69.5 Ultrasound measurement of the fetal neck at 12 weeks.

(interventional) to those obtained in hospitals that recorded the measurements but did not act on the results (observational). In the interventional group, successful measurement of NT was achieved in 100% of cases and the measurement was >2.5 mm in 2.3% of cases; the respective percentages in the observational group were 85% and 12%.[42,43]

Guidelines

- Equipment to measure up to 0.1 mm and time allocated for each scan at least 10 min.
- Transabdominal or transvaginal route. The transabdominal route gives a success rate of 95%; in 5% of cases it is necessary to perform vaginal sonography.
- Gestational age between 10^{+3} and 13^{+6} weeks [crown–rump length (CRL) 38–84 mm, biparietal diameter <27 mm]. At these gestations the success rate for obtaining a measurement is more than 98%. From 14 weeks onward the fetal position (vertical) makes it more difficult to obtain measurements.[44]
- Good sagittal section of the fetus, as for measurement of fetal CRL. An optimal measurement is obtained when the fetus is in a neutral position (neither in flexion nor in extension).
- Magnification so that the fetus occupies at least three-quarters of the screen and that each increment in the distance between callipers is only 0.1 mm.
- Distinguish between fetal skin and amnion (both appear as thin membranes!) by waiting for spontaneous fetal movement away from the amniotic membrane. Alternatively, the fetus may be bounced off the amnion by asking the mother to cough and/or by tapping the maternal abdomen.
- Measure the maximum thickness of the subcutaneous translucency between the skin and the soft tissue overlying the cervical spine by placing the calipers on the lines as shown in Figure 69.5.

The umbilical cord may be round the fetal neck in 5–10% of cases and this can produce an increased NT as it adds about 0.8 mm to the measurement.[45] Measurements of NT above and below the cord will be different and in the calculation of risk it is appropriate to use the smaller measurement. It is well established that NT normally increases with gestational age.[46–51] Therefore, the difference from the normal median for gestation is used to determine the factor by which the age-related risk is adjusted.

Increased NT and chromosome defects

Studies that report on first-trimester fetal NT thickness and chromosome defects can be divided into four groups. Initial observational studies examined the prevalence of chromosome defects in fetuses with increased NT. Subsequent observational studies examined in (high risk) pregnancies prior to invasive testing the proportion of Down's syndrome and normal fetuses that present with increased NT. Implementation studies then reported on the feasibility of introducing screening by NT in routine practice and, finally, centers that introduced the test reported experience with screening based on the combination of maternal age, gestational age, and fetal NT thickness.

Observational studies

In the early 1990s, several reports on fetuses with increased NT demonstrated a possible association between NT and chromosome defects in the first trimester of pregnancy (Table 69.2).[52–65] The mean prevalence of chromosome defects in 14 series involving 1457 patients was 28%. However, the percentage ranged from 19% to 88%. This variation in results presumably reflects differences in the maternal age distributions and differences in the definition of minimum thickness of the abnormal translucency, ranging from 2 to 10 mm.

In subsequent studies NT thickness was assessed immediately before fetal karyotyping, mainly for advanced maternal age (AMA). Detection rates for trisomy 21 varied from 30% to 84% (Table 69.3)[66–71] with false-positive rates ranging from 1% to 6%. Detection rates were relatively low if measurements were taken before 10 weeks of gestation, and/or machines measured whole millimeters only.[49,50]

Table 69.2 Summary of reported series on first-trimester fetal nuchal translucency (NT) providing data on gestational age (GA) in weeks, criteria for diagnosis of increased NT thickness, and the presence of associated chromosome defects (T21 = trisomy 21, T18 = trisomy 18, T13 = trisomy 13)

Increased NT and normal karyotype

Souka *et al*.[72] recently presented findings in 4116 chromosomally normal fetuses with increased NT together with a review of the literature. There are at least five conditions that may underlie increased NT and these include heart defects or heart failure, intathoracic compression, altered composition of the dermis, abnormal lymphatic system, and neuromuscular abnormalities.

Heart defects

Two fetal echocardiographic studies at 10–16 weeks of gestation reported that 16 (80%) of the 20 fetuses with cardiac defects had an abnormal collection of nuchal fluid.[72,73] In addition, a study of 29,154 pregnancies demonstrated that the prevalence of cardiac defects increases with increasing NT. In fetuses with an NT < 95th percentile, it was 0.8 per 1000 compared to 15 per 1000 in the group with increased NT

Table 69.4 Prevalence of major cardiac defects in chromosomally normal fetuses with increased NT thickness

NT thickness	*N*	Cardiac defects
$< 95^{th}$ percentile	27,332	0.8/1000 (~1 in 1250)
95th percentile–3.4 mm	1507	5/1000 (~1 in 200)
3.5–4.4 mm	208	29/1000 (~1 in 35)
4.5–5.4 mm	66	91/1000 (~1 in 10)
≥ 5.5 mm	41	195/1000 (~1 in 5)
Total	29,154	1.7/1000

thickness (Table 69.4).[74,75] Examination of chromosomally normal pregnancies with an NT of 3.5 mm or more (1% of the population) at 15–20 weeks by an echocardiographer identifies approximately 40% of significant cardiac defects.

Public policy

Why then has not first-trimester screening already replaced the second-trimester testing? The answers are complex, but can be divided into several different categories. First, many patients do not come for prenatal care until the second trimester. It is well known that there are universal correlations between socioeconomic status and gestational age at the first visit for prenatal care. No matter how good a first-trimester test is, it does no good for a patient first seen at 24 weeks.[76]

Second, even in 2001 with voluminous articles and college opinions touting multiple markers, 20% of patients were still getting the 1980s model of AFP alone (M. I. Evans, unpublished data). Significant professional education will be needed to leapfrog the practice in first-trimester screening.

Third, until immediate invasive testing is readily available and accepted, first-trimester screening results would be worse than no screening if the patient then had to wait a month to have an amniocentesis for a definitive answer.[34–65] We see this as very problematic for the 'integrated' test that combines first- and second-trimester laboratory results and ultrasound. Chorionic villus sampling (CVS) has long since proven to be safe and effective in experienced hands. As the so-called limb reduction defect scare has been shown to be false at appropriate gestational ages, hopefully, the availability of CVS and acceptance will swing the pendulum back toward the desire for first-trimester screening for testing, which has many advantages for the patient. We actually expect the concept of maternal age as a stand-alone variable to be phased out over the next several years.[76]

Trisomy 18

Although screening has generally focused on trisomy 21, our data and those of others have always shown a varied pattern of anomalies detected by screening.[77] A different pattern of analyte levels has been observed in trisomy 18. The values of AFP, hCG, and uE3 appear to be very low.[78] This suggests a different pathophysiology than for Down's syndrome. In Down's syndrome, the low AFP and uE3, and high hCG can be explained as reflecting inappropriate immaturity or dysmaturity of the fetus, i.e. all values are consistent with a younger gestational age. In trisomy 18, however, that explanation does not work.[79] We have previously shown that there are different patterns of genomically directed intrauterine growth retardation in different aneuploidies[77] but how this translates into serum markers is unclear. Nevertheless, some reports have shown that an algorithm can be used to identify the majority of trisomy 18 cases while adding about 0.75% to the population being offered amniocentesis.[79,80]

The end of AMA

The association of AMA with increasing risks of chromosomal abnormalities, particularly Down's syndrome, has been appreciated for decades.

The choice of age 35 at least in the United States was an arbitrary compromise determined in part by naivety in data collection. Cohorts of Down's syndrome risk were usually reported in 5-year groupings, and there was clearly a big jump from the 30–34 to 35–39 age group. It was only later when data were reported on a year–age-specific curve that the slope of the curve was shown to be changing before age 35. Furthermore, the difference from one year to the next was obviously nowhere as dramatic as suggested in the 5-year cohorts.[9]

Another dramatic development of the 1970s was changing laws in the United States concerning a woman's right to end a pregnancy. New York and California were among the first states to repeal laws that made abortion virtually impossible to obtain legally. In 1973 the US Supreme Court ruled that in the first trimester a state had very little right to interfere with a woman's defined right of privacy in terminating a pregnancy.[81,82] In the second trimester the state's interests were primarily only in ensuring the safety of the procedure. It was only in the third trimester that the state could exert a compelling interest in protecting the 'rights' of the fetus over the mother's wishes.

The combination of new technology plus the ability to terminate abnormal pregnancies led to a surge of interest in prenatal diagnosis. As with most new technologies, utilization was initially highest among patients of upper socioeconomic status who had the knowledge of the availability of the technology as

well as the means to travel to far-off centers to obtain such services.[83]

The evidence that first-trimester screening followed by first-trimester diagnosis by CVS can bring about a substantially higher sensitivity and specificity within the same time frame than CVS in AMA is overwhelming. The question thus reduces to how and when to update the accepted 'culture' in the United States to be consistent with the current scientific knowledge base.

There has to be the understanding that age is not being discarded, but will merely become one of a number of variables that can be assessed to give the most accurate assessment of risk possible. With education, the ultrasound portion of the equation will become more standardized to laboratory levels of quality assurance. Non-profit organizations such as the Fetal Medicine Foundation in London and the Fetal Medicine Foundation in America, as well as others, will certainly help coordinate the transition and training needed to make such a reality.

It is also not realistic to expect a shift of 'standards' and practice to change on a single day. Thus, there will have to be a short phase-in period, under which either the old or the new approach will be considered acceptable. However, it is also reasonable to expect the insurance companies, which will have to pay for such tests, to vociferously and clearly articulate to their subscribers and physicians that they are not about to vastly increase the number of patients having tests. Thus, the right will be likely the 'right' to pay out of one's own pocket for testing for AMA, *per se*.

It is time for AMA, as a stand-alone criterion for having invasive testing, to go the way of the buggy whip. The principal objection to screening as entry to testing has been removed. It can all now be done in the first trimester. The science has evolved. It is now time for the culture and the standards to follow.

70 Amniocentesis

S. Tercanli, P. Miny and W. Holzgreve

Introduction

Midtrimester amniocentesis is the most commonly performed invasive technique in prenatal diagnosis. Valenti *et al*. reported the first successful diagnosis of Down's syndrome in 1968.[1] Since that time the number of midtrimester amniocentesis has increased dramatically and amniocentesis is nowadays an established standard tool in the assessment of pregnancies that are at risk for a variety of chromosomal disorders, single gene defects, biochemical analysis and fetal infections. Chromosome analysis and tests related to risk screening for aneuploidy remain by far the most common laboratory procedures in prenatal diagnosis worldwide. Conventional chromosome analysis has maintained its role as a gold standard for the primary exclusion of aneuploidy from amniotic fluid cells. Frequent indications listed in Table 70.1 for offering second-trimester amniocentesis are pregnancies considered to be at an increased risk.

Prior to any prenatal invasive test, patients should be counseled. The risks and benefits of all invasive and non-invasive tests must be discussed as well as the limitations of any procedure. In the case of specific risk factors or abnormal ultrasound findings the information should be as complete and appropriate as possible. Considering the current developments in prenatal diagnosis by performing advanced methods for individual risk calculation, e.g. nuchal translucency measurement and biochemical serum marker screening, counseling of pregnant women will become more and more important. It can be assumed that in this context a more selective approach to invasive testing may result in the next few years. One of the significant problems in counseling pregnant women is still how to explain to women (e.g. socioeconomic, ethical and cultural variability) the complex implications of risk calculation. Our own experiences showed that appropriate individual counseling is more time-consuming and requires more appropriate methods.

Table 70.1 Common indications for amniocentesis

Advanced maternal age (=35 years)
Family history for chromosome anomalies, single gene defects, etc.
Abnormal maternal serum screening in the second trimester
Increased risk for chromosomal anomalies following first trimester screening – if chorionic villus sampling is not available
Abnormal ultrasound findings
Maternal infections potentially affecting the fetus

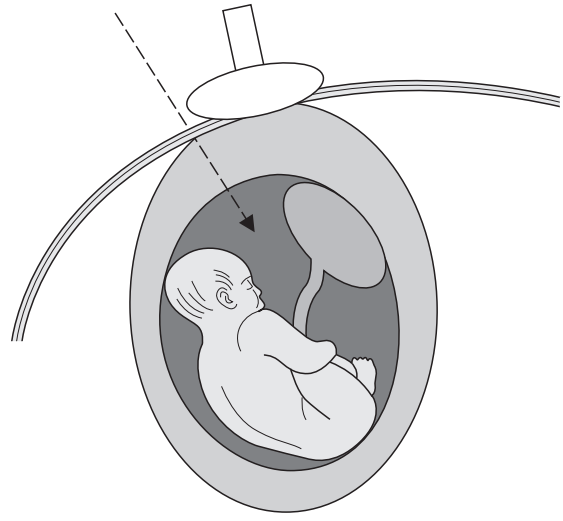

Figure 70.1 Diagram of amniocentesis. Transplacental perforation should be avoided if possible.

Technique

Midtrimester amniocentesis is commonly performed between 15 and 16 weeks of gestation (Figures 70.1 and 70.2). Prior to the procedure of ultrasound, evaluation of the uterus (e.g. exclusion of fibroids), the fetus, amniotic fluid volume and position of the placenta is recommended, because the failure rate can be reduced by avoiding the removal of bloody fluid or multiple injections.[2–4] Patients' anxiety may be reduced if adequate information is given to them during the procedure at each step. After disinfection of the maternal abdomen, amniocentesis is performed under direct ultrasound guidance generally using an

Figure 70.2 Second-trimester amniocentesis under ultrasound guidance.

18–20-gauge needle. The amniotic fluid volume obtained should not be more than 1 ml per gestational week. The first 2 ml of amniotic fluid should be rejected in order to avoid maternal cell contamination. If bloody amniotic fluid is aspirated, the analysis of the chromosomes from cultured cells will take a longer time and there might be a slightly higher risk of misdiagnosis due to the risk of culturing maternal cells from any tissue other than blood cells. In women with Rh-negative blood group Rh-immune globulin must be administered, if the father of the child is Rh-positive or his blood group is unknown. Following the procedure it seems helpful to demonstrate the fetus again to the mother by ultrasound evaluation. There is no clear evidence in the literature that ultrasound guidance itself will reduce the fetal loss rate, but it may reduce the maternal fears. In contrast, it is assumed that the abortion rate increases if the placenta is perforated.[5] Operator experience may also prejudice the fetal loss rate but this has not been definitively determined.[6] However, there is a general agreement that the operators performing genetic amniocentesis need to be trained, and maintaining stable ongoing expertise is recommended.[7–9] Especially in multiple pregnancies, amniocentesis should be performed by trained investigators. Amniocentesis in twin pregnancies consists in obtaining of amniotic fluid from both cavities. As recommended in the past, dye injection into the first punctured sac was performed routinely.[10] Advanced ultrasound technology allows the evaluation of both fetuses and makes dye injection obsolete in experienced hands. Controversy is ongoing whether both amniotic sacs should be injected in cases of monochromic diamniotic twins. In diachronic twins a single needle insertion technique is often favored, but may result in cytogenetic problems. On the other hand it is not known whether a single-needle technique may induce rupture of the membrane.

Cytogenetic aspects

Compared to other methods for prenatal karyotyping, the benefits of an amniocentesis are the simplicity of the implementation of the procedure and the convenience of the analysis for the cytogenetic laboratory. In clinical practice the level of alpha-fetoprotein (AFP) in amniotic fluid is determined routinely. Currently, it is debated that these may no longer be needed because high-resolution ultrasound is able to detect neural tube defects and abdominal wall defects. However, the detection of spina bifida depends on the experiences of the sonographer. Therefore, evaluation of AFP in the amniotic fluid is still recommended.

Cell culture as a prerequisite for conventional chromosome analysis on amniocytes causes a turnaround time of at least 1 week. In practice, the average processing time is probably close to 2 weeks in most of the laboratories. Ongoing trends in prenatal diagnosis aim at early and rapid diagnosis as well as at the improvement of risk screening for aneuploidy. Fluorescent *in situ* hybridization (FISH) on interphase amniocytes and quantitative fluorescence polymerase chain reaction (QF-PCR) are efficient tools for the rapid exclusion of selected aneuploidies.[11] Regarding the overall detection rate of unbalanced chromosome anomalies, the same limitations apply for both techniques with current approaches. It is suggested that QF-PCR is advantageous at least in all centers with access to the necessary hardware or those with large sample numbers. We believe, however, that for rapid karyotyping, if available, direct preparation from chorionic villi should be the method of first choice when there is an increased risk of unbalanced chromosome anomalies, i.e. after the ultrasound diagnosis of fetal malformations. This method carries a false-negative rate of below 1% as compared to up to 35% with interphase FISH or QF-PCR.[13] In conclusion, it can be stated that FISH and QF–PCR should be used as additional tests.

Particularly in blood-stained probes, maternal cell contamination of amniotic fluid cell is a rare but well-known cause of diagnostic error in the prenatal diagnosis of fetal disorders (<3/1000).[14] Using fluorescent-labeled microsatellites permits the differentiation between maternal and fetal cells. Mosaicism is one other remaining problem and is seen in 1/1000 of samples.[15]

Complications

The risks that may be associated with second-trimester amniocentesis include leakage of amniotic fluid, vaginal bleeding, contractions, chorioamnionitis, failure to obtain a sample, pregnancy loss and, possibly, fetal injury.[5,16–23]

Actual fetal loss rates related to genetic amniocentesis vary among randomized studies and may be comixed

Figure 70.3 Gestational and amniotic sac at 12 weeks demonstrating absence of fusion between amniotic membranes and the surrounding cavity.

by transplacental needle passage, multiple-needle insertion and use of larger needles sizes.[17–19]

The total fetal loss rate related to the procedure is often calculated to be around 0.5%.[24] But in many studies the source for this reported level of risk was non-distinctive, and the background risk of miscarriage was unaccounted for. In the three larger multicenter studies the risk of fetal loss following amniocentesis was approximately 1%, but bias due to selection cannot be excluded.[3,7,22] These results were comparable with the former findings in the only randomized controlled trial reported by Tabor.[5] Recently, Seeds reviewed 68,119 amniocenteses from both controlled and uncontrolled studies providing straightforward arguments for several conclusions.[25]

Currently, midtrimester amniocentesis under ultrasound guidance is associated with a procedure-related rate of excess pregnancy loss of 0.33% (95% CI, 0.09–0.56). Among only controlled studies, the risk is 0.6% (95% CI, 0.31–0.90). Adding the natural risk of loss of about 1.08% among control groups the total rate of losses can be determined to be around 1.6%.

Application of ultrasound guidance may reduce the number of injections and may also lower the incidence of blood-stained fluid. Analysis of only controlled studies shows that this trend remains, but is not statistically significant.

Injury of the fetus is rare and cannot be completely prevented by using ultrasound guidance, but may occur more frequently.

The earlier reported experience of higher risks due to placental perforation does not support an increased rate of miscarriage. As shown in the comprehensive overview, other complications (such as vaginal bleeding and infection or leakage of amniotic fluid) could not be analyzed due to the limited number of described terms or were not comparable.

Following the improvement in the technique and the laboratory methods there have been attempts in bringing forward the time of amniocentesis in the past by performing early amniocentesis, which is technically more demanding (Figure 70.3). Both the randomized studies designed to assess the safety and cytogenetic accuracy of early amniocentesis showed an increased rate of fetal losses as well as a higher rate of talipes, equinovarus and oligohydramnios. Also, more multiple-needle insertions were performed in early pregnancies compared to midtrimester amniocentesis. The rate of laboratory failures following early investigations was increased. Comparing early vs. late amniocentesis, it is suggested that the procedure in the second trimester is more favorable.[26,27]

71 Cordocentesis

C. P. Weiner

The development of high-resolution ultrasound made it feasible to clearly image the umbilical cord. In the early 1980s, Daffos performed the first intentional percutaneous umbilical blood sampling (cordocentesis) under ultrasound guidance spurred by a desire to accurately diagnose fetal toxoplasmosis.[1] The procedure rapidly gained favor with demonstration of its safety[2–4] and directly spurred the development of fetal medicine. A wide range of fetal norms (hematological, endocrinological, immunological, biochemical, and biophysical[5]) were developed, a crucial step in the evolution of fetal medicine. And while many early indications for cordocentesis have been supplanted by less invasive techniques, there remain several indications for fetal blood sampling. The most common presently are assessment and treatment of red cell and platelet alloimmunization, antenatal diagnosis of inherited blood or metabolic diseases, rapid karyotyping of malformed or severely growth-restricted fetuses in some countries, and rarely the determination of fetal acid–base status.

Methods

Cordocentesis is performed in the outpatient setting by a single operator with or without an assistant. There is no benefit of maternal fasting, sedation, prophylactic antibiotics, or tocolysis. Though it is technically more difficult prior to 20 weeks, and the loss rate is much higher prior to 16 weeks, cordocentesis can be performed as early as 12 weeks. The patient's partner is encouraged to attend both the counseling session preceding the procedure, and the procedure itself. The limitations and potential complications must be stated unambiguously before written informed consent is obtained, and a targeted ultrasound examination performed.

There are two methods for cordocentesis: freehand and the use of a fixed needle guide. The preferred location for umbilical cord puncture is the placental origin where it is relatively fixed regardless of technique. The first few centimeters of the fetal origin of the umbilical cord are innervated, and puncture there causes pain. The umbilical vein is the preferred target rather than the umbilical artery because of its lower association with complications discussed subsequently. A 'no touch' philosophy is essential. If you do not touch the shaft of the needle, you cannot contaminate it.

The freehand technique employs a 18–20-gauge spinal needle 8–12 cm long.[1] The subcutaneous and deep layers are infiltrated with a local anesthetic agent. The needle course is tracked by imaging the tip and shaft with the ultrasound transducer held either in the opposite hand of the operator or by the assistant. Since the needle is not fixed, the tip can move several centimeters in all axes should either the site of insertion be suboptimal or the fetus move during the procedure. The operator secures the needle after the vessel has been punctured and the assistant aspirates a series of 1-ml syringes. Preheparinization of the syringe is unnecessary unless a fetal blood gas is needed. The freehand technique remains most popular because of the flexibility it allows the operator.

I, however, prefer to perform cordocentesis using a fixed needle guide[2] attached to the base of the ultrasound transducer. Typically, the transducer is held by the operator's assistant. The predicted course of the needle, which can travel only in the vertical plane, is displayed on the ultrasound screen, allowing the operator to select a precise target for puncture. Deviation from the predicted path occurs when there is an abrupt change in the relationship between the puncture site in the maternal abdominal wall and the uterus as the needle traverses between the two. The most common causes are abrupt patient movement or inspiration and failure to hold the transducer surface flat against the maternal abdomen. Fetal movement is rarely an issue because of the speed of the procedure. A smaller-gauge needle such as a 22 or 25 is used because lateral movement of the needle is not possible. I prefer to target the umbilical cord longitudinally at the 'easiest' site for a direct approach. More than 50% of the time I target a free loop. Placental puncture is avoided whenever possible when the indication is alloimmunization (RBC or platelet) just as for amniocentesis. Local anesthesia is unnecessary for diagnostic procedures using a 22-gauge needle. A local anesthetic should be used when the procedure is lengthy (e.g.

intravascular transfusion). Prophylactic antibiotics are not indicated for either cordocentesis or intravascular transfusion. In my experience, amnionitis complicates less than 1 in 800 diagnostic procedures when the 'no touch' philosophy is rigorously adhered to and a needle guide is used (1 in 1200 procedures).

Fetal movement while the needle is intraluminal increases the risk of umbilical cord trauma; it may also either prevent a successful puncture or shorten the access time available regardless of technique. I keep prepared a neuromuscular antagonist such as pancuronium (0.3 mg/kg estimated fetal weight) on the sterile field for every procedure, and routinely use it to eliminate fetal movement when performing a mid-loop puncture. The pancuronium is given either intramuscularly into the fetal buttock, or preferably, intravenously as soon as the vein is punctured; the effect here is evident within seconds. Vercuronium is preferred over pancuronium for simple diagnostic procedures because its shorter half-life allows a more rapid return of fetal movement and heart rate variability.[6] In contrast, pancuronium is preferred for fetal transfusion because it maintains fetal cardiac output despite the volume load.

The volume of blood removed depends on the gestation and indication for sampling. Five milliliters is typical, and adequate for a karyotype, umbilical venous blood gas, and complete blood profile with Kleihauer–Betke testing, with 2 ml remaining for use.

Table 71.1 Complications of cordocentesis

Bradycardia or asystole
Premature rupture of membranes
Premature labor

Fetal to maternal hemorrhage

Table 71.2 Risk factors for cordocentesis

Umbilical artery puncture (associated with bradycardia)
Fetal hypoxemia (associated with bradycardia)
Technique – freehand vs. needle guide
Gestational age – prior to 20 weeks, both techniques
Number of punctures (freehand technique only)
Duration of procedure (freehand technique only)
Experience (freehand technique only, presumably because of #4, 5)

Major complications and risk factors for cordocentesis

The major complications of cordocentesis are listed in Table 71.1. They include all complications associated with amniocentesis plus fetal bradycardia, umbilical cord laceration, and thrombosis. Risk factors for cordocentesis are noted in Table 71.2.

Bradycardia is the major complication of cordocentesis. Essentially, all emergency cesarean deliveries and most perinatal losses are associated with a fetal bradycardia. Umbilical artery puncture and hypoxia are the major risk factors for bradycardia. In the absence of profound anemia or fetal heart failure, fetal hypoxia is associated with an elevated umbilical artery resistance index and it can be used as a risk marker. The incidence of bradycardia with absent and/or reversed diastolic flow approaches 25%. Umbilical artery puncture increases the risk of fetal bradycardia 5- to 10-fold.[3,7,8] The presence of either oligohydramnios or a two-vessel cord increases the risk of arterial puncture.

The observation that the bradycardia is associated with an elevated resistance index in one but not both umbilical arteries suggests localized vasospasm is the cause. Pancuronium reduces the prevalence of bradycardia in appropriately grown but not growth-restricted fetuses.[8] It is possible some episodes of bradycardia occur when fetal movement tugs on the umbilical cord causing needle trauma and irritation to the underlying vascular smooth muscle. Bradycardia after umbilical vein puncture may reflect disruption of the adjacent umbilical artery smooth muscle as the tip traverses the cord.

In the event of a bradycardia, vigorous fetal stimulation by palpation is beneficial as the heart will speed up and then slow again if the manual stimulation is stopped too early. A variety of chronotropes (e.g. atropine) and bicarbonate have also been given as part of the fetal resuscitation without predictable effect.

Umbilical cord laceration and thrombosis are associated with freehand procedures and are not reported to date when a needle guide was used.[7] Though bleeding from the umbilical puncture site is common, prolonged bleeding with sequelae is uncommon.

Even when performed at a midloop, the fetus does 'react' to the cordocentesis. Umbilical artery resistance typically declines after either a diagnostic procedure or a fetal intravascular transfusion.[9] The higher the 'normal' baseline resistance index, the greater the decline. The decrease is associated with prostacyclin release from the vascular endothelium.[10,11] Endothelial adaptation to hypoxia also explains why hypoxemia is a risk factor for bradycardia.[8] Rizzo *et al.* demonstrated that endothelin is released upon umbilical vein puncture

of growth-restricted but not appropriately grown fetuses.[12] Fetuses who develop bradycardia release more endothelin.

It was generally accepted that the technique selected was a matter of operator preference and had no impact on outcome. There is now evidence to challenge this concept. The first line of evidence is indirect. The often stated 'advantage' of the freehand technique, its flexibility, may also increase risk. Analogous to a lever, a small movement at the hub of the needle amplifies the distance the tip moves. In association with this inescapable fact, freehand cordocentesis produces a significantly greater increase in the MSAFP than amniocentesis after controlling for placental puncture.[13] In contrast, the incremental change in MSAFP when a needle guide is used is similar to amniocentesis.[14] Further, the association between fetal thrombocytopenia and bleeding from the umbilical puncture site after a freehand cordocentesis is high enough to have prompted a recommendation that all fetuses at risk for alloimmune thrombocytopenia receive a prophylactic platelet transfusion at cordocentesis.[15] Yet, there is no relationship between the fetal platelet count and the bleeding time from the puncture site when a needle guide is used.[16] The latter may reflect either less lateral movement of the needle after puncture or the thinner gauge needle, or both. The loss rates reported after second trimester amniocentesis are lower when thinner needles are used.[17] Not surprisingly, there are also reports that suggest that an amniocentesis performed with a needle guide is safer than one performed freehand.[18]

Though no single center has adequate volume for a randomized trial, and comparisons of loss rates sustained by groups using the freehand and needle guide techniques are problematic since it is hard to separate procedure-related losses from those secondary to the natural progression of disease, there is evidence to suggest many losses are technique-dependent. I examined the role of technique by combining our experience with that of Professor Okamura of Tokohu University, who also uses a fixed needle guide for all procedures.[7] Over 25 operators with varying levels of experience performed 1260 diagnostic cordocenteses at a mean gestational age of 29 weeks. The umbilical vein (confirmed by the blood pressure reading) was punctured in 90% demonstrating that the desired vessel can be targeted. A procedure-related loss was defined as any loss within 2 weeks of the procedure except those resulting from elective pregnancy termination. Overall, there were 12 losses (0.9%) (Table 71.3).

Though there are more recent studies, Ghidini *et al.* provided adequate information for stratification and that the low level of experience reported by the involved centers may be more reflective of today's reality.[19] After deleting my experience from the analyses, the overall loss rate was 7.2% (96/1328) with the freehand method.[19] This rate was significantly higher than the overall loss rate when a needle guide was used (0.9%, 12/1260; $P < 0.00001$). But this is a superficial comparison.

Table 71.3 Frequency of major complications of cordocentesis when a needle guide is used

Final diagnosis	GA (weeks) at cordocentesis	Percent emergency delivery*	Percent death within 2 weeks**
RBC alloimmunization	28 ± 4	0.2	0.2
Uteroplacental dysfunction	32 ± 4	5.0	0.9
Chromosome abnormality	29 ± 6	7.7	9.9
All others	28 ± 6	0.3	0.2

*From Weiner, unpublished; **from Weiner and Okamura;[7] fetuses with a chromosome abnormality delivered by cesarean section were delivered before the karyotype was completed

To exclude the contribution of the underlying pathology to the loss rate, procedures may be divided into high and low risk with the latter excluding chromosomal abnormalities, non-immune hydrops, intrauterine growth restriction (IUGR), and fetal infection. Such exclusions virtually eliminate all abnormal fetuses that might be at risk for a loss *unrelated* to the procedure. The perinatal loss rate for these low-risk procedures using the freehand technique was 3% (20/660). This rate is 15 times the needle guide rate (0.2%, 2/1021; $P < 000001$), which *includes* fetuses with infection, hydrops, and structural malformations.

Donner et al. reported 759 diagnostic cordocenteses *with a known outcome* using the freehand technique.[20] Acknowledging several limitations (final diagnoses were not necessarily reported and 87% (34/39) of their perinatal losses were excluded as being unrelated to the procedure), their stated loss rate was 0.8% including 94 therapeutic terminations in the denominator. Subtracting the terminations from their total yields a loss of 1.1% (7/665). Of these pregnancies, 160 were sampled because of severe early IUGR. We can identify their low-risk group by excluding the IUGR fetuses and assuming that all fetuses with chromosomal abnormalities were either in the growth-restriction group, therapeutic termination group, or the one fetus with trisomy 18 noted in the paper. This leaves a low-risk group of 504 in which there were six fetal/neonatal losses (1.2%). This rate is significantly higher than that achieved in a similar group using a needle guide ($P = 0.03$).

These findings strongly suggest that many of the procedure-related losses associated with cordocentesis are technique-dependent. And while a few skilled operators might duplicate the results obtained with a

needle guide, the majority of practitioners who perform only a few cordocenteses per year would benefit from the use of a guide.

Indications and applications for cordocentesis

Antenatal diagnosis of blood disorders

The use of recombinant DNA techniques on placental biopsy material in the first trimester of pregnancy or amniocytes in the second for the diagnosis has supplanted cordocentesis for the diagnosis of many of these conditions.[21] Cordocentesis is still needed for a phenotype diagnosis, in those patients requiring confirmation of normality based on a linked probe, those who lack key affected relatives, those who are not informative by any of the available probes, and those in whom DNA analysis is not feasible because of late referral.

Antenatal diagnosis of metabolic disorders

Antenatal diagnosis of over 100 of these disorders is now possible by the analysis of amniotic fluid, placental tissue, or fetal blood. Cordocentesis is particularly useful when the gestational age is close to the local limit for abortion, as with late prenatal care or after failed chorionic villus or amniotic fluid techniques.

Red blood cell alloimmunization

Cordocentesis is not indicated in most instances of maternal RBC alloimmunization for fetal blood typing. Accurate typing can now be accomplished by applying polymerase chain reaction to either trophoblast or amniocytes obtained in the early second trimester when the risk of exacerbating sensitization is lower.[22,23]

Fetal blood sampling made it possible to better understand the pathophysiology of this disease and allows for an improved method of assessment and treatment.[24–29] The net result of improved understanding is an improved perinatal outcome. The most important advancement in the non-invasive management of RBC alloimmune disease was the recognition that most severely anemic fetuses have an elevated peak flow velocity in the middle cerebral artery.[30,31] Previously, the severity of fetal hemolysis was estimated from: (1) the history of previously affected pregnancies; (2) the level of maternal hemolytic antibodies in a first sensitized pregnancy; (3) the amniotic fluid bilirubin concentration; (4) the altered morphometry of fetus and placenta; and (5) the presence of pathological fetal heart rate (FHR) patterns. However, the scatter of values around the regression lines describing the relationships between fetal anemia and the data obtained from these indirect methods of assessment was wide.[32] And though the vast majority of fetuses with an elevated peak velocity in the middle cerebral artery are anemic, a sizable percentage of anemic fetuses have normal velocities, and the relationship between velocity and the magnitude of the hemoglobin deficit varies greatly among fetuses.

The only accurate method for determining severity is blood sampling by cordocentesis with the measurement of fetal hemoglobin concentration, reticulocyte count, blood type, strength of the direct Coombs test and total bilirubin concentration. However, the timing of the first cordocentesis remains less than concrete. Invasive procedures should be minimized not only because of the fetal risk, but also because transplacental puncture enhances the risk of fetomaternal hemorrhage,[14,33] increases maternal antibody titer, and worsens disease. I prefer to avoid cordocentesis until the peak middle cerebral artery flow velocities are abnormal in those pregnancies under 20 weeks' gestation. However, since as many as half the fetuses with mild to moderate anemia have normal velocities, it is reasonable depending on referral patterns and distances to consider sampling all women with a history of severe disease, those with high antibody titers, and fetuses with pathological FHR patterns.

A fetal blood sample is obtained, the hemoglobin concentration measured, and an intravascular blood transfusion given as necessary.[34] The goal of the first transfusion is to correct the hemoglobin deficit completely unless there is hydrops. Immune hydrops in the human fetus is almost always characterized by an elevated umbilical venous pressure (UVP), which is consistent with high output heart failure or left ventricular dysfunction perhaps secondary to the low oxygen carrying capacity.[35] These fetuses tolerate the first intravascular transfusion poorly, and should be corrected initially to a hemoglobin level of no more than 8–9 g/dl. (We routinely monitor the fetal UVP to avoid over-transfusion.) The second transfusion is performed a few days later at which time the target hemoglobin for this and all subsequent transfusions is 18 g/dl. Subsequent transfusions are given at 3- to 4-week intervals until 34 to 36 weeks' gestation, their timing based on the findings in the middle cerebral artery and the knowledge that following a fetal blood transfusion the mean rate of decrease in fetal hemoglobin is approximately 0.3 g/dl/day.[34] Currently, the survival rate of red cell isoimmunized pregnancies treated with cordocentesis exceeds 90% in experienced hands, and virtually all losses are associated with immune hydrops fetalis.[34] Importantly, we have demonstrated normal long-term neurodevelopment despite the profound anemia prior to treatment.[36]

How often to repeat cordocentesis in the occasional affected fetus which is not anemic is determined by the change in the peak flow velocity in the middle cerebral artery and by the 'hemolysis pattern' determined at the first sampling.[37] This prospectively validated grading scheme is based on the reticulocyte count and the strength of the positive direct Coombs

test. Most fetuses do not require a second sampling. That said, non-anemic sensitized fetuses remain at risk for postnatal hyperbilirubinemia that is in direct correlation to their antenatal bilirubin levels.[38,39]

Platelet alloimmunization

Immune thrombocytopenia (ITP) is not an indication for cordocentesis.[40] The assumed risk of fetal intracranial hemorrhage during labor is not supported by the aggregate experience of the last two decades. There is no more than one *fetal* loss documented in the literature secondary to an intrapartum fetal hemorrhage.[40] Most losses attributed to ITP were associated with a maternal connective tissue disorder or a neonatal bleed. In almost all other instances, either the cause of death or the timing of death is either not stated or not known. ITP is the most common autoimmune disorder of reproductive age women; if true, there should be no controversy that thrombocytopenia secondary to ITP posed a significant fetal risk during labor. Yet, the loss rate from cordocentesis in the best hands for a 'low risk' fetus is 0.2%.[7] Further, there is no direct or indirect evidence that cesarean section for autoimmune thrombocytopenia improves neonatal outcome.

There has been significant progress in the management of severe fetal alloimmune thrombocytopenia.[41,42] It is clear that medical therapy consisting of primarily high doses of intravenous gammaglobulin (1–2 g/kg/week) with a prednisone rescue for suboptimal responders is an effective treatment for the majority of affected pregnancies.[43] At-risk pregnancies begin the weekly infusion between 10 and 20 weeks depending on past history. Most undergo a single cordocentesis around 28 weeks to confirm normal platelet counts. When secondary to Pl(A1) platelet antigen incompatibility, fetuses with platelet counts >20,000 at the initiation of therapy are predicted to maintain their platelet count at the second fetal blood sampling at >20,000. The history of the previous sibling does not predict the initial fetal blood sampling, the second fetal blood sampling, or the response to treatment.[44] Even suboptimal fetal responders have a dramatic decrease in the risk of antenatal hemorrhage. Fetal platelet transfusion is associated with a high loss rate when used for primary therapy (up to 17%[45]). Its role is now secondary, indicated for those fetuses with extremely low platelet counts or those with a count <50,000 prior to a planned vaginal delivery. There is no relationship between the fetal platelet count and bleeding from the puncture site when a needle guide is used.[16]

Evaluation of non-immune hydrops fetalis

Cordocentesis is central to the complete evaluation of non-immune hydrops since it allows the separation of cardiac from non-cardiac etiologies.[46] The UVP is a surrogate for the central venous pressure. Studies of human fetuses[47] indicate that it is very similar to right-sided heart pressure. An elevated UVP is consistent with myocardial dysfunction whether caused by anemia (e.g. parvovirus infection, hemolytic disease), myocarditis, or obstructed cardiac return (thoracic mass effect). Successful treatment of cardiogenic hydrops is associated with normalization of the UVP before the hydrops resolves. Hydrops that is responsive to shunting is caused by a shift of the mediastinum, which then obstructs cardiac return. An elevated UVP also predicts that the fetus with hydrothorax and hydrops will be cured by a thoracoamniotic shunt. If the UVP is neither elevated nor normalizes after draining the chest, a shunt will not help. The underlying problem lies elsewhere.

Miscellaneous

Not yet accepted but a likely valid indication for cordocentesis is presence of maternal thyroid stimulating antibody (TSiG) or active maternal Graves disease.[48,49] Emerging evidence suggests even mild degrees of thyroid dysfunction is associated with impaired long-term neurodevelopment.[50–52] While there is a relationship between the degree of maternal and fetal thyroid suppression with such agents as propylthiouracil (PTU), it is common to find the fetus being significantly over- or under-treated despite the mother being euthyroid. For fetal hyperthyroidism, the maternal PTU dose is increased and the woman is given thyroxine replacement. For hypothyroidism, the fetus can be given thyroxine intra-amniotically on a weekly basis.[53] Women with a history of Graves disease who have undergone thyroid ablation should be screened for the presence of TSiG. The fetus is at minimal risk if the TSiG study is negative.

72 Perinatal Rh hemolytic disease and other alloimmunizations: screening and treatment

L. S. Voto

Severe hemolytic disease due to rhesus (Rh) incompatibility still constitutes a source of concern for obstetricians and pediatricians. In Argentina, as well as in most developing countries, this disease is one of the main causes of fetoneonatal morbidity and mortality due to the lack of appropriate prophylaxis with postpartum anti-D γ-globulin and inadequate prenatal control.[1]

Perinatal hemolytic disease (PHD) represents one of the most significant examples in medicine of successful management of a disease and adequate prophylaxis.

By the first half of the century, PHD accounted for 45% of all perinatal deaths. Nowadays, this rate has significantly decreased to 5%, as a result of in-depth understanding of the etiology and pathogenesis of the disease, the advances in perinatal technology, the creation of sophisticated centers for high-risk perinatal care and, mainly, from its prophylaxis.

The Rh blood group antigens

Biochemistry and molecular genetics

A group of non-glycosylated hydrophobic transmembrane proteins of 30–32 kDa are known to carry the Rh blood antigens (D, Ce, and Ee series). These proteins, which are not found in the red cells of rare Rh_{null} individuals with membrane defects, are erythroid-specific and have a distinctive sequence homology. The Rh_D and non-D proteins show 92% sequence identity and a similar predicted membrane topology.

The Rh proteins D and Cc/Ee are encoded by the RHD and RHCE genes, respectively. These genes are arranged in tandem on chromosome 1p34–p36 and probably result from the duplication of a common ancestral gene.

The human RH locus is considered a two-gene model where all Rh-D positive haplotypes have two structural genes (namely, RHD and RHCE) and most Rh-D negative ones have only one structural gene (namely, RHCE). D protein is encoded by the RHD gene, whereas the C/c and E/e proteins are encoded by the RHCE gene. The relationship between blood group D epitopes and the amino acid polymorphisms of the Rh proteins still remains unclear, but it has been found that the molecular basis for the C/c (Ser→Pro) and E/e (Pro→Ala) specificities result from amino acid polymorphisms at positions 103 and 226, respectively. In the Rh system, polymorphism and gene diversity seem to be produced mainly by gene conversion. But cases of gene deletion have also been observed in the Rh system. Rh_{null} phenotypes have been found to be caused by a mechanism of transcriptional regulation, which has not been clearly described yet.

In the cells of the Rh_{null} individuals, morphological and functional abnormalities of cation transport as well as phospholipid asymmetry have been observed and are thought to lead to severe clinical conditions. Also, Rh proteins and other glycoproteins (such as Rh50 glycoprotein, CD47, glycophorin B, Duffy, LW) are either not present, or their quantity is markedly lower in the Rh_{null} individuals' cells, which might mean that Rh proteins form a multimeric complex with these glycoproteins.[2]

Etiology and pathogenesis of Rh–Hr incompatibility

The antigens of the Rh system are located on the surface of the erythrocyte, although they are also thought to be part of the trophoblast.[3]

Rh system's anti-D antibodies are responsible for the majority of clinically detectable PHD cases. This situation is observed in Rh-negative mothers whose husbands are Rh-positive, and whose immunization occurred during pregnancy, abortion, postpartum or incompatible transfusion.

There are other Rh–Hr system's antibodies that are capable of producing a clinical disease. They are listed in order of frequency as follows: anti-c (of Hr), anti-C (of Rh), anti-e (of Hr) or the combination of any of them with factor D.

In Argentina, 13% of couples are Rh-incompatible, and it is estimated that there is 1 PHD case every 150 deliveries. On the other hand, according to different statistics, the immunization rate is between 7% and 14%.

Rh sensitization mechanism

The passage of fetal red blood cells to maternal circulation is considered normal during pregnancy. Using the Kleihauer–Betke technique, it was established that the passage of fetal red blood cells is not higher than 0.1–0.2 ml. In this case the competent immunological system would not be activated; however, the chances of it being stimulated are much higher if transplacental hemorrhage is greater than the established values.

There are certain obstetric events that can increase the risk, such as placenta previa, ruptured placental membranes, external version, cesarean section, manual removal of placenta, and – in the early stages of pregnancy – abortion, and ectopic pregnancy.

All invasive procedures during pregnancy cause passage of fetal red blood cells. Chorionic villus sampling performed during the first trimester of pregnancy, which is frequently used nowadays, has been associated with very severe cases of hemolytic disease even with hydrops. Amniocentesis causes fetomaternal hemorrhage in 2–3% of the cases. Spontaneous or induced abortion is also associated with transplacental hemorrhage.

Antigen D has already developed by the 35th to 45th day of gestation, which explains why 4–5% of postabortion patients may become sensitized. Intravenous drug abuse can also lead to isoimmunization.

When an Rh-negative person receives Rh-positive blood, an immunologic response takes place in 50% or more of the cases.

The primary immunologic response is usually weak. The initial antibodies are of immunoglobulin M (IgM) nature, with a high molecular weight and are unlikely to cross the placenta. As a result, they do not produce fetal hemolysis labely in pregnancy, the IgG antibodies cross the placenta and produce hemolysis.

The IgG antibodies involved in the etiology and pathogenesis of PHD due to anti-D are mainly subtypes IgG1 and IgG3. The former crosses the placenta early in pregnancy, and therefore have a role in the most severe cases of PHD.

In our experience, the frequency of immunization in Rh-negative patients during their second pregnancy with compatible Rh-positive fetuses is 12–15%.

ABO incompatibility in an Rh-negative patient provides partial protection against primary anti Rh-isoimmunization, but not against a secondary immunologic response. In the former, the anti-A or anti-B incompatibility immunized blood cells are captured by the liver, which is not an immunologically active organ and does not produce anti-Rh antibodies. On the other hand, in a secondary immunologic response, the spleen receives the blood cell stroma and produces anti-Rh antibodies. Therefore, there is a higher incidence of Rh hemolytic disease in children whose parents are HBO compatible.

Pathogenesis and physiopathology of perinatal hemolytic disease

According to different studies, the rate of active transport of human IgG varies in the course of normal gestation; before 12 weeks of pregnancy this transfer is very low, but it has been demonstrated that, in severe Rh disease, the direct antiglobulin test on the fetal (Rh-positive) red cells may be positive as early as 6–10 weeks. The IgG antibodies rise exponentially until term. Sometimes, IgG levels in the infants could be higher than in the mother. The placental transport of IgG1 and IgG3 in women with Rh (D) immunizations is not diminished compared with normal pregnancy. The placental transport of IgG3 is significantly higher in pregnancies at risk of hemolytic disease of the newborn with IgG3 concentrations in normal pregnancy.[4]

The pathogenesis of PHD lies in the hemolysis of fetal erythrocytes caused by maternal antibodies. Hemolysis then results in fetal anemia.

According to the severity of hemolysis, PHD will be anemic, icteroanemic, or hydropic. In hydropic PHD, the hepatic parenchyma is replaced partially with secondary erythropoiesis tissue, which causes a portal and umbilical venous hypertension syndrome, as well as alterations in the metabolism of proteins, and decreased albumin. Both clinical conditions cause edema and ascitis, which are characteristic of hydrops.

Frequently, fetal cardiac failure secondary to severe anemia is observed. The other two forms of PHD, anemic and icteroanemic, are the result of a less severe hemolysis that does not compromise either the cardiocirculatory system or the protein metabolism.

Early fetal gene diagnosis

The use of polymerase chain reaction (PCR) for detection of the RHD gene can measure the RHD gene status for unborn babies at risk for hemolytic disease of the newborn. The occurrence of D gene variants has led to errors in prenatal typing. The effectiveness of using PCR in a clinical setting has been reported. It verifies the importance of testing more than one region of the gene and also the need for a testing strategy where both maternal and paternal testing for RHD gene dosages are performed.[5]

In the present time, it is possible to determine the fetal DNA in maternal serum during the first trimester

of pregnancy. The advantage of this method is its non-invasive nature.[6]

Follow-up of the Rh-negative patient

The anamnesis will focus on relevant data such as: number of previous deliveries, history of anti-D prophylaxis, history of perinatal morbidity and mortality attributable to hemolysis, history of previous transfusions, and history of neonatal exchange transfusions or luminotherapy in previous deliveries.

If an indirect Coombs test does not detect anti-D antibodies, it should be repeated every 4 weeks until immediate puerperium.

If the test is positive we will proceed as follows:

- Study of husband's zygosity. If he is heterozygous, the fetus might not be Rh-positive
- Serial titration of anti-D antibodies every 3 weeks with the purpose of drawing a curve
- Serial ultrasonographic follow-up to evaluate fetal growth or detect characteristic signs of the disease: polyhydramnios, hepatomegalia, ascitis, soft tissue edema
- Doppler measurement of middle cerebral artery (MCA) peak systolic velocity provides a non-invasive modality for determining moderate or severe fetal anemia. The sensitivity of an increased peak systolic velocity in the MCA for the prediction of moderate or severe fetal anemia is 100% either in the presence or the absence of hydrops fetalis, and the false-positive rate is 12%.[7,8] The study of amniotic fluid (AF) is another very good predictive tool in the evaluation of fetal anemia.[9]

Many methods have been used to evaluate AF by detecting fetal hemolysis. Liley plotted curves of AF $\triangle$OD450 values based on gestational age and derived three zones of severity of fetal disease. Therefore, from the Liley curves, fetal condition can be predicted based on the AF $\triangle$OD450 value:[10,11]

- AF spectrophotometry, in accordance with a previous history of Rh disease and levels of anti-D antibodies in relation to the patient's gestational age
- If the patient's antibody titer is just at the critical level and the patient has not had a baby with PHD, the initial amniocentesis can be done at 28–29 weeks' gestation. If the titer or the history suggests that the PHD may be more severe, then amniocentesis can be performed earlier. In this way, a fetus that needs an intrauterine transfusion can be identified.

  Many methods have been used to evaluate AF by detecting fetal hemolysis. Liley plotted of AF ΔOD450 values based on gestational age and derived three zones of severity of fetal disease. Therefore, from the Liley curves, fetal condition can be predicted according to the AF ΔOD450 value[10,11]

  At present, however, Doppler measurement of middle cerebral artery peak systolic velocity constitutes the method of choice for the follow-up of fetal anemia
- Cordocentesis for the prediction of the severity of fetal anemia through the analysis of fetal blood started to be used when high-resolution ultrasound was developed. However, cordocentesis is currently not recommended for the evaluation of fetal anemia. It should be used as a route for transfusional therapy. Cordocentesis is only indicated in cases either requiring assessment of fetal anemia < 26 weeks gestation (anti-D titers $> 1/128$) or showing AF spectrophotometric analysis in the Upper Zone B or Zone C of Liley's chart, anterior placenta, and a poor obstetric history[12]
- Antenatal fetal monitoring as soon as it is reliable to assess fetal vitality and specially sinusoid patterns.

Treatment of severe maternal–fetal Rh-incompatibility

In 1963, Liley described intrauterine transfusion as the only possible way to prevent intrauterine fetal death of severely affected Rh-positive fetuses. When pregnancy interruption is indicated, fetal prematurity becomes an aggravating factor, which conspires against successful results.

The purpose of all the procedures described below is to allow the fetus to reach viability.

Intrauterine fetal transfusion

Intraperitoneal route

It is estimated that the total amount of blood transfused into the peritoneal cavity flows into the fetal bloodstream within 7–10 days after being injected.

This technique relies on the absorption capability of the fetal peritoneum and subdiaphragmatic lymphatic system, and it is not usually indicated before the 24th week of gestation. Ultrasound plays an essential role in this procedure: it locates the fetal abdomen and shows the precise point of entry.

The inferior portion of the peritoneal cavity is then accessed, considering the bladder as a reference point to prevent injury to the liver or spleen.

Type O, Rh-negative blood – compatible with maternal blood – with a hematocrit concentration not less than 75% should be transfused. Blood should have been recently extracted (not more than 48 h before the procedure).

Ascites, if present, should be evacuated before the procedure, although in this case the intravascular route is always preferred.

The use of uterine inhibitors is recommended, and the administration of antibiotics in order to prevent possible infections is controversial.

The procedure should be repeated, according to the patient's evolution, every 14 days or more, until fetal viability is achieved.

The amount of blood to be transfused should be estimated as follows: gestational age in weeks minus 20, multiplied by 10. For example, in a 28 week pregnancy, $(28-20) \times 10 = 80$, a total of 80 ml of erythrocytes should be transfused.

Intravascular fetal transfusion

Indications to use this approach are especially in case of fetal hydrops or very severe fetal anemia. This technique, which may be used as from 18 weeks of pregnancy, involves access to an umbilical vessel near its placental insertion, in the intrahepatic portion of the umbilical vein, or in the fetal heart (fetal rescue operation).

Nowadays, this procedure is superior to the former because it allows the immediate reversal of fetal anemia as it is possible to obtain a sample of fetal blood and determine its hematocrit and hemoglobin values. Also, a faster remission of fetal hydrops is observed in most of the cases.

The amount of blood to be transfused depends on the patient's gestational age, and blood donor's and fetal blood's hematocrit. The procedure should be repeated according to post-transfusion hematocrit values, until fetal extraction is indicated.

If no complications occur, this technique allows the lengthening of intrauterine fetal life until the fetus is viable, which results in a marked decrease in perinatal mortality rates.

High-dose intravenous IgG for the treatment of severe Rh alloimmunization

Intrauterine fetal transfusion, either by the intraperitoneal or intravascular routes, has shown to be an effective treatment of Rh-hemolytic disease. However, some fetuses are already severely compromised at an early stage when it is technically impossible to indicate the procedure.

In agreement with other authors, we have found that repeated invasive techniques result in an important increase in anti-D titers owing to the variable amounts of fetomaternal bleeding inevitably caused by the procedure itself. As a result of this, a moderate Rh disease in a present pregnancy can often become a severe one in the subsequent gestation.

It has been reported that transfusional therapy before 32 weeks of gestation is associated with a higher fetal mortality rate.[13] The early treatment in the first weeks of pregnancy would reduce the severity of fetal anemia, decreasing the fetal morbidity and mortality. That is why we started a protocol of treatment with high doses of γ-globulin.[1]

The use of high doses of intravenous immunoglobulin (IVIG) in the treatment of immunologic diseases both in children and adults and recurrent intrauterine fetal loss has been frequently reported in the literature with varying degrees of effectiveness.

Although the mechanisms of action of IVIG remain unclear, several explanations have been proposed during pregnancy: feedback inhibition of antibody synthesis, competition for macrophage or Fc receptors of target cells, and blockade of Fc-mediated antibody placental transport. We have used IVIG therapy in a prospective study in order to analyze its effectiveness in the antenatal treatment of severe Rh-hemolytic disease.

The only immunoglobulin that is transferred into the fetal circulation is IgG; the other classes of maternal immunoglobulins are either not transferred or only cross the placenta in small quantities. The mechanisms involved in the active transfer of IgG across the human placenta are not yet known. Brambell *et al.*'s studies in rabbits suggest that the transport of IgG molecules across the placenta is mediated through a receptor for the Fc part of the molecule. Further studies have clarified the role of Fc as a placental Fc receptor for IgG. This receptor has been demonstrated on the surface of the trophoblast at 10 weeks and at term.

The mechanisms of placental transfer of exogenous IgG infused into the mother are still to be elucidated. It must be emphasized that transplacental IgG transfer is a slow process and requires an intact Fc portion of the IgG molecule. Gitlin *et al.*'s studies demonstrated that when labeled IgG was injected into pregnant women at various intervals before delivery, even after 12 days, the concentration in the infant's serum was only about 40% of that in the mother. Studies performed by Contractor *et al.* about IgG transport in perfused placentas suggest that the trophoblast absorbs a substantial amount of human IgG and all bovine IgG, both broken down into small fractions by a mechanism of non-specific endocytosis, and transmits these fragments to the fetal circulation. A small amount of human IgG, however, would escape this process of lysosomal destruction by diverse protective mechanisms, and would be released intact on the fetal side.

There are very few cases in the literature reporting the treatment of severe Rh-hemolytic disease with high doses of IVIG and the findings are too dissimilar to allow for conclusive generalizations. Rewald and Berlin *et al.* obtained satisfactory results with the combined use of plasmapheresis and IVIG in 4 cases of severe Rh-hemolytic disease. De la Cámara *et al.* reported the successful treatment of two cases with repeated doses of IVIG throughout gestation. Scott *et al.*, on the other hand, used a combined protocol of IVIG and repeated intrauterine transfusions in one case of hemolytic disease.

We have administered IVIG as the only treatment in 24 severely Rh-sensitized patients with a previous history of affected fetuses and/or neonates, with elevated anti-D titers, and a high degree of intrauterine hemolysis. Patients in group 1 (< 20 weeks, $n = 8$) fulfilled the first two of these inclusion criteria, whereas

in groups 2 (20–28 weeks, $n=7$) and 3 (> 28 weeks, $n=9$), IVIG treatment was indicated on the basis of intrauterine hemolysis.

IVIG was infused at a daily dose of 0.4 g/kg maternal body weight for 4–5 consecutive days, and repeated every 21 days until delivery.

Group 3 also included those patients who attended the antenatal clinic very late in pregnancy; as a consequence of this delay, the fetuses in these cases were highly compromised because of the advanced stage of the hemolytic disease, and they evidenced major neonatal depression and severe fetal anemia at birth, requiring – in almost all cases – exchange transfusions.

Initial mean anti-D level was significantly higher in group 1 (25.9 ± 12.9 IU/ml) than in the other two groups, whose values were, however, higher than 10 IU/ml. AF total bilirubin levels before the onset of therapy were pathologic and in 55% of the cases they coincided with Zone 3 of Liley's chart. Hydrops fetalis at the onset of treatment accounted for the only three fetal deaths in groups 1 and 2. None of the fetuses developed hydrops during treatment. Six of the nine neonates in group 3 were depressed at birth (1-min Apgar below 7). However, at 5 min only one newborn showed an Apgar below 7. Mean birth weight was over 2500 g in all the cases. Neonatal hematological condition in group 2 (50% of the babies required only phototherapy) was better than in the other two groups (transfusional therapy).

The decrease in pre- vs. post-treatment anti-D antibody quantification, the reduction in intrauterine hemolysis and the strongly positive direct antiglobulin test in all neonates may indicate that the mode of action of high doses of IVIG in Rh-hemolytic disease is (1) feedback inhibition of antibody synthesis and (2) partial blockade of Fc-mediated antibody transport across the placenta. No adverse effects from the drug were observed in the mother or neonate.

Our findings show that IVIG treatment was effective in both groups 1 and 2, where IVIG was administered before the 28th week of gestation and the fetuses were not hydropic at the onset of therapy. In group 3, however, where fetal anemia was already advanced at the time of treatment, intrauterine transfusions and prompt fetal extraction should have been the treatment of choice.

The analysis of the series including only the 13 most severely affected cases as judged by their history of fetal/neonatal death, demonstrated again the effectiveness of IVIG treatment. It can be inferred from the results in this particular group of patients that (1) after 28 weeks' gestation the administration of IVIG does not elicit significant reductions in anti-D titers and intrauterine hemolysis, thus intrauterine transfusion is the therapy of choice, and (2) IVIG treatment is not indicated in case of hydrops fetalis. Except for these two indications, it is in this series with the poorest history, the highest antibody level and failure of transfusional therapy in previous gestations, where we find the most encouraging therapeutical results of IVIG treatment.

The high cost of IVIG therapy is immediately outweighed by the highly satisfactory perinatal results obtained in our population of extremely severe Rh-sensitized patients. Moreover, babies born after treatment with intrauterine transfusions, as well as those prematurely delivered because of their severe disease, require a prolonged stay in the neonatal intensive care unit (a mean of 60 days in the latter case), the cost of which greatly exceeds that of IVIG therapy.

To conclude, the results of our study, which to the best of our knowledge is the largest reported in the literature, show the value of high doses of IVIG in the treatment of severe Rh incompatibility when administered repeatedly before 28 weeks' gestation and in the absence of hydrops fetalis.

High-dose γ-globulin (IVIG) followed by intrauterine transfusions: a new alternative for the treatment of severe fetal hemolytic disease

Intrauterine fetal transfusion (IUT) is currently the therapy of choice in cases of severe anti-D isoimmunization. However, its efficacy is reduced in patients with early severe hydrops fetalis due to the technical difficulties in performing this procedure before 20 weeks' gestation and because the fetuses are already anemic at that time.

The purpose of this study was to determine whether early onset of high-dose γ-globulin therapy followed by IUTs is more effective than IUTs alone in the treatment of very severe isoimmunized fetuses.

The population studied in this retrospective clinical research was assigned to one of the following two groups: (1) Gamma group: 30 patients receiving γ-globulin therapy before 21 weeks' gestation and IUTs after 20 weeks or (2) IUT group: 39 patients receiving IUT treatment starting at a gestational age of 20–25 weeks.

Both groups were statistically similar regarding history of perinatal deaths and anti-D antibody titers. The number of hydropic fetuses at the first IUT and of fetal deaths were significantly higher in the IUT than in the Gamma group. No significant differences were observed between the groups in fetal hematocrit at first IUT and at birth. However, the percentage of severely anemic fetuses was higher in the IUT group. Fetal mortality rate was 36% less in the Gamma group.

In summary, in very severe cases of Rh-isoimmunization:

(1) the development of fetal hemolysis in the first 20 weeks of gestation increases the risk of fetal death;
(2) the early onset of invasive fetal therapy is only partially effective and potentially harmful; and

(3) according to the present study, those patients who received high-dose intravenous γ-globulin in the first 20 weeks of pregnancy seem to have a better fetal outcome.

Our results show that high-dose γ-globulin therapy followed by IUTs improves fetal survival in these severe cases.[14] Conventional treatment has also been modified by the administration of immunoglobulin to the neonate.[15]

Neonatal treatment

Our studies suggest that the frequency of neonatal transfusion therapy can be reduced by a combination of conventional phototherapy with HDIVIG. Further studies are needed to determine the optimum timing and dosage of HDIVIG therapy.[16]

Other studies show that intravenous immunoglobulin is effective in decreasing the maximum bilirubin levels and the need for repeated exchange transfusions in Rh hemolytic disease of the newborn. There is, however, an increased need of blood transfusions for late anemia in the babies treated with IVIG.[17]

Other alloimmunizations

Routine antibody screening of Rh (D)-positive women is probably not warranted from a clinical cost–benefit perspective.[18]

Anti-c isoimmunization follow-up is similar to that of anti-D and, together with anti-E, they are the next in order of frequency as a cause of perinatal alloimmunization.[19]

The treatment for anti-E sensitization is similar to that of anti-D. AF is a weak indicator of the result, that is why the management of the disease remains questionable. It is not clear yet if the presence of anti-E implies the accummulation of a hemolytic effect with other antibodies.

Pregnancy follow-up in anti-Kell alloimmunization

It is identified by the presence of anti-Kell antibodies in maternal serum or previous fetal anemia. The search for hemolysis in AF through bilirubin concentration is not useful as the pathogenesis responds to fetal anemia due to the inhibition of erythroid progenitor and not to the destruction of the Kell-positive erythroid by the antibodies.

Therefore, cordocentesis should be chosen to obtain fetal blood and, in this way, be able to detect fetal anemia and make the Kell-serotyping by studying the fetal DNA when the father is K1 heterozygous.

Other studies show that fetal anemia due to anti-Kell isoimmunization might be due in part to erythropoietic suppression, but it is still largely a hemolytic process. The methods based on a hemolytic process, including use of a critical maternal serum titer of 1:32, serial AF analyses when the titer was in excess and liberal use of funipuncture, were successful in identifying severely affected fetuses.[20]

Natural and monoclonal anti-Kell antibodies inhibit the growth in the Kell-positive erythroid progenitor.

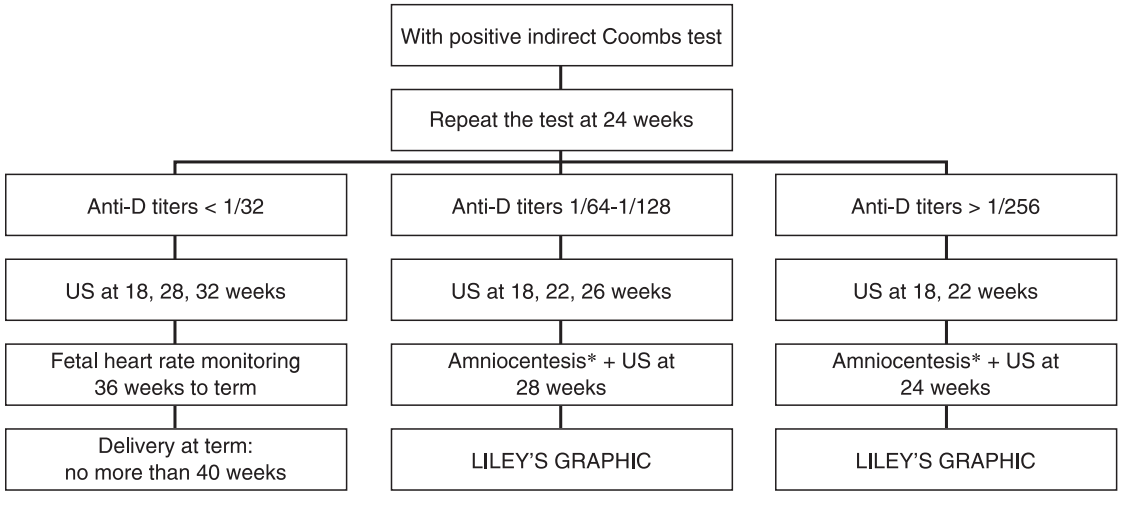
Fetal hematology

It shows just a few reticulocytosis and normoblasts compared to fetuses affected by anti-D, which suggests that erythroid suppression would be the mechanism responsible for fetal anemia, a mechanism that has been proved by Vaughan's studies.[21]

The treatment is similar to that of the anti-D. Needless to say, an ultrasound follow-up is very important.

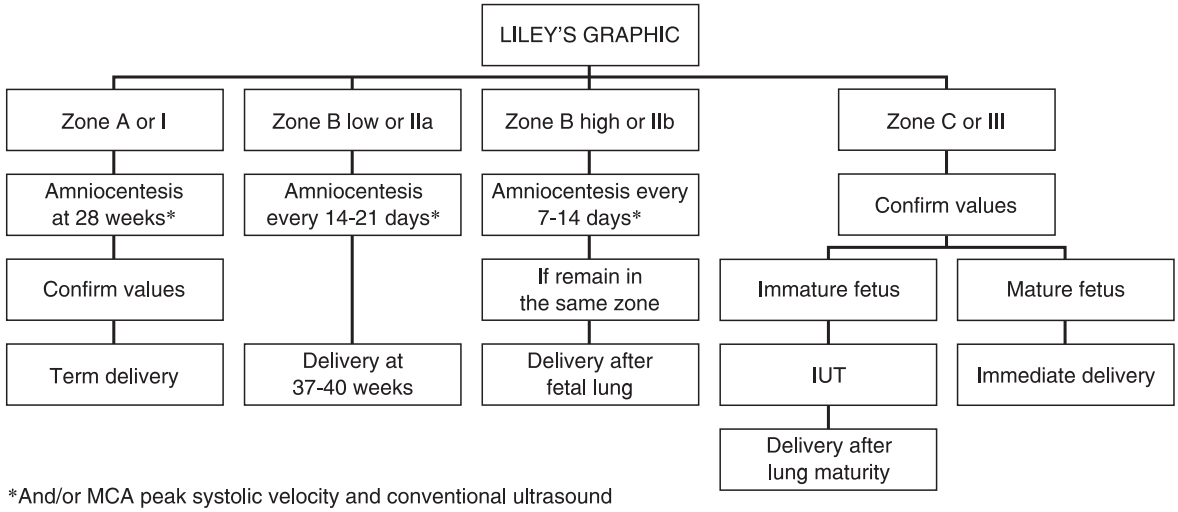
Summary: steps to follow

Rh-isoimmunization: patients with no maternal and/or perinatal history of the disease



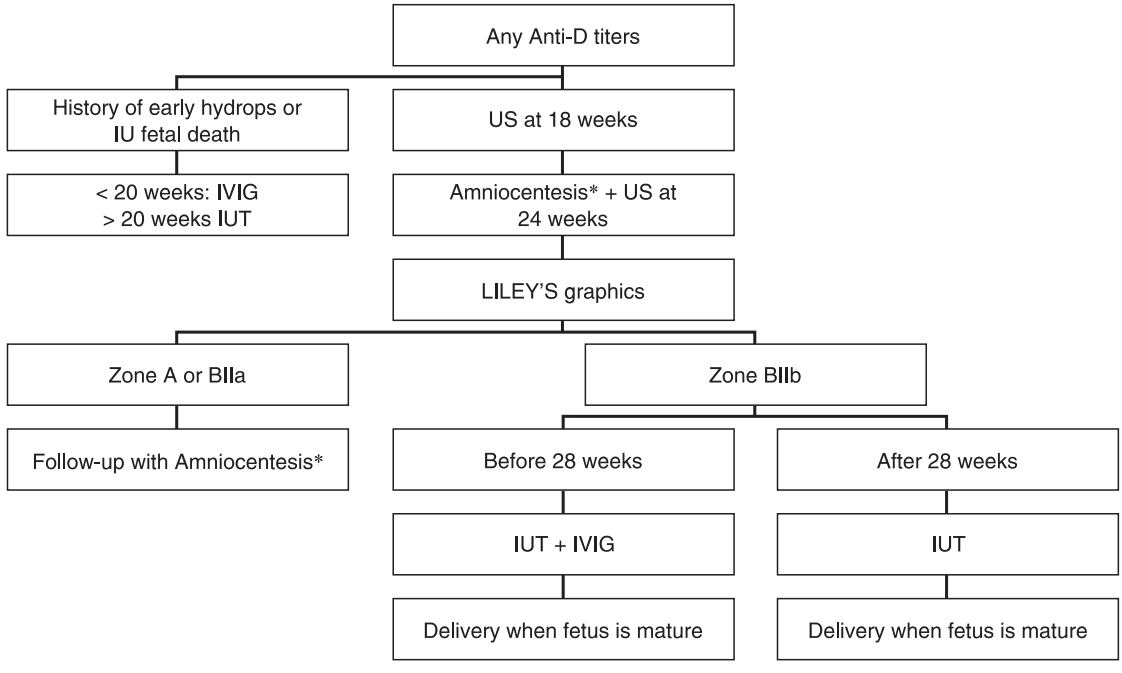
*And/or MCA peak systolic velocity and conventional ultrasound

Rh-isoimmunization: patients with no maternal and/or perinatal history of the disease



*And/or MCA peak systolic velocity and conventional ultrasound

Rh-isoimmunization: patients with maternal and/or perinatal history of the disease



*And/or MCA peak systolic velocity and conventional ultrasound

Prophylaxis

In 40–50% of pregnancies, the passage of fetal red blood cells to maternal circulation usually takes place during the last trimester. In the majority of the cases the amount of blood transferred is less than 0.1 ml.[22]

In 1977, there were 110 cases of stillbirths or postnatal deaths due to anti-D hemolytic disease in the UK. In 1992, the figure decreased to only nine cases. This decrease came as a result of the introduction of anti-D γ-globulin prophylaxis since 1969 but it is also subject to the application of public health policies for perinatal care, especially in developing countries.[23]

In 1969, the prophylaxis protocol consisted of anti-D γ-globulin administration only after the birth of an Rh-positive child, or after certain pregnancy events such as antepartum hemorrhage. Most of the deaths resulted from maternal sensitization between 28 and 40 weeks of the first pregnancy (third trimester) and during postpartum.

Further studies have determined that the percentage of sensitization decreases from 1.2% to 0.28% if antenatal prophylaxis is carried out.

In practice, the combination of antenatal and postnatal prophylaxis will prevent immunization in 96% of the high-risk cases. The remaining 4% corresponds to the absence or inappropriate administration of immunoglobulin when it is indicated.

Due to the fact that isoimmunization during pregnancy is caused by transplacental hemorrhage,[24] the risk of immunization increases after the following procedures:

(1) Spontaneous or induced abortion
(2) Amniocentesis
(3) Chorion villus sampling
(4) Cordocentesis
(5) Ectopic pregnancy
(6) Fetal manipulation: external version
(7) Antepartum hemorrhage
(8) Antepartum fetal death
(9) Positive blood transfusion

The standard postpartum dose of 300 μg contains enough anti-D to neutralize at least 15 ml of fetal red blood cells.

There are different methods to detect excessive fetomaternal hemorrhage:

- Kleihauer–Betke technique is, if carried out correctly, a very sensitive and specific method, but it is subject to laboratory and technological errors.
- Flow cytometry is also a very sensitive method, but difficult to perform and too expensive.
- The Rosette method is easy to carry out and very sensitive, but has low specificity and its results must be confirmed by Kleihauer–Betke method or flow cytometry.
- A gel technology method has been reported for the assessment of fetomaternal hemorrhage and determination of minimum necessary dose of RhIG. This technique works well in determining the appropriate dose of anti-D required to treat D patients with D+ newborns. There are potential cost savings in decreased use of RhIG, less direct technical time required and more rapid availability of results.[25]

Anti-D γ-globulin has very few adverse effects. Some fetuses yield with a slightly positive direct Coombs test at birth after antenatal administration. The presence of anemia or hyperbilirubinemia is very rare. All plasma involved in the production of anti-D immunoglobulin is carefully checked for infectious diseases.

There have not been any HIV cases due to contaminated plasma.

The American College of Obstetricians and Gynecologists recommends both typifying the pregnant patient and looking for antibodies in her first visit, and again at 24–28 weeks, offering anti-D γ-globulin to all Rh-negative, non-sensitized patients.

It has been found that transplacental hemorrhage occurs in 3%, 12%, and 45% of the cases during the first, second, and third trimesters, respectively.

The capacity of an antibody to eliminate D-red cells *in vivo* depends both on its avidity, and to a lesser degree, on its affinity for the D-antigen. Absorption is also a limiting factor.

Even though antepartum γ-globulin administration offers many additional benefits, some authors argue that, as the incidence of isoimmunization is relatively small, it makes medication 16 times less cost-effective than postpartum prevention programs. The *Cochrane Review* states that anti-D, given within 72 h after childbirth, reduces the risk of RhD alloimmunization in Rh-negative women who have given birth to an Rh-positive infant. However, the evidence on the optimal dose is limited.[26]

Unit equivalents

50 μg	250 IU
100 μg	500 IU
300 μg	1500 IU
225 μg	1250 IU

Route of administration

The route of administration is intramuscular through the deltoides muscle. In the gluteal area, it only penetrates to the subcutaneous tissue, thus absorption is prolonged.

Anti-D IgG use recommendations

- Dose: 500 IU or 100 μg every 4 ml of fetal red blood cells in maternal circulation.
- Indications
  - Postpartum, within the first 72 h = 300 μg
  - Prenatal
    - First trimester: abortion, ectopic pregnancy, chorionic villus sampling, or amniocentesis
    - Second trimester: suspected fetomaternal hemorrhage, invasive procedures
    - Third trimester: prophylactic: 500 IU at 28 and 34 weeks or only one dose of 300 μg between the above-mentioned weeks[27]

General and future management of RhD isoimmunization

Future therapy will involve selective modulation of the maternal immune system, turning the need for intrauterine transfusions into a rarity.[28]

When Rh_D sensitization occurs, careful follow-up of these mothers and judicious intervention can result in good outcomes for most pregnancies. Both Doppler assessment of middle cerebral artery peak systolic velocity and spectral analysis of AF at 450 nm (△OD450) are useful in the diagnosis and management of fetal anemia.[29]

73 Prenatal therapy of endocrine and metabolic disorders

G. Rosner, S. B. Shachar, Y. Yaron and M. I. Evans

Introduction

Our understanding of molecular and genetic basis of disease is ever-increasing. This has resulted in more and better ways for primary prevention. This is often achieved by prenatal diagnosis and termination of affected pregnancies and more recently, preimplantation genetic diagnosis. Some metabolic and endocrine disorders however, such as congenital adrenal hyperplasia and cardiac arrhythmias are amenable to pharmacological interventions.[1,2] This chapter describes different modes of intrauterine pharmacological therapy in the fetus with an endocrine or metabolic disorder. The use of folic acid supplementation for the prevention of neural tube defects will also be discussed.

Endocrine disorders

Adrenal disorders

Congenital adrenal hyperplasia

Treatment of congenital adrenal hyperplasia (CAH) in the fetus is an excellent example of pharmacological therapy during pregnancy. CAH is a group of autosomal recessive metabolic disorders characterized by an enzymatic defect in the steroidogenetic pathway. As a result of the enzymatic deficiency, there is a compensatory increase in adrenocorticotropic hormone (ACTH) secretion in order to maintain cortisol production. This leads to overproduction of the steroid precursors in the adrenal cortex, causing adrenal hyperplasia. The most common abnormality, responsible for $> 90\%$ of patients with CAH is caused by a deficiency of the 21-hydroxylase (21-OH) enzyme. Other, less common causes for CAH include deficiencies in 11β-hydroxylase, 17α-hydroxylase, and 3β-hydroxysteroid-dehydrogenase. Decreased 21-OH activity results in accumulation of 17-hydroxyprogesterone (17-OHP) which is converted via androstenedione to androgens, the levels of which increase by as much as several hundred-fold (Figure 73.1). The excess androgens cause virilization of the undifferentiated female external genitalia. The degree of virilization may vary from mild clitoral hypertrophy to complete formation of a phallus and scrotum. In contrast, genital development in males is normal. The excess androgens cause postnatal virilization in both genders and may manifest in precocious puberty.

The 'classical' form of CAH involves a severe enzyme deficiency or even a complete block of enzymatic activity, which is associated in more than half of the cases with a life-threatening salt-losing form. The classical form is easy to recognize in female newborns but may be overlooked in males, who may present at a later stage with severe dehydration and even demise. The 'nonclassical' attenuated form of 21-OH deficiency results in partial blockade of enzymatic activity and results in simple virilization in women only later in life. It is estimated to occur in ~3.5% in Ashkenazi Jews and ~2% in Hispanics.[3]

The gene for 21-OH is in close linkage to the human leukocyte antigen (HLA) major histocompatability complex on the short arm of chromosome 6.[4] The gene for 21-OH (CYP21B) has now been mapped, allowing direct mutation analysis in informative families.[5]

In the past, diagnosis of CAH was made by the finding of elevated levels of 17-OHP in the amniotic fluid. With the development of chorionic villus sampling (CVS) in the 1980s, linkage-based molecular diagnosis in the first trimester became available. Since the discovery and mapping of the gene, direct DNA mutation analysis has become the routine approach.

The fetal adrenal gland can be pharmacologically suppressed by maternal administration of dexamethasone.[6] The suppression can prevent masculinization of affected female fetuses in carrier couples. In the first attempt to prevent female genital birth defects in 1982, Evans *et al.* administered dexamethasone to a carrier mother beginning at 10 weeks of gestation.[6] Serial maternal estriol and cortisol levels indicated that adrenal gland suppression had been achieved. The female fetus was born at 39 weeks' gestation with normal external genitalia. Forrest and David then

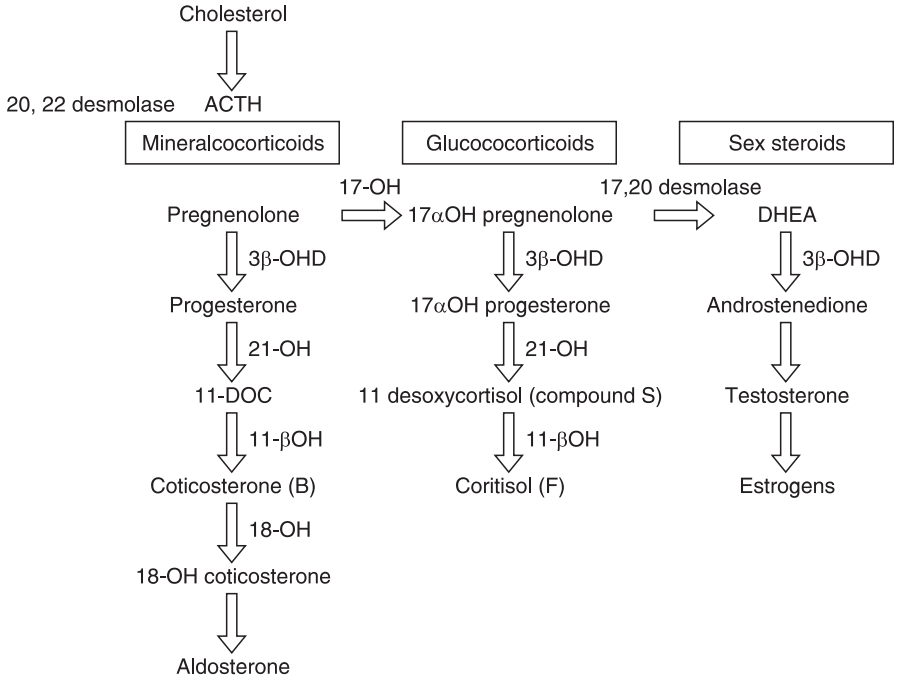

Figure 73.1 Steroidogenic pathway: androgen production in 21-hydroxylase deficiency (congenital adrenal hyperplasia).

employed a similar protocol beginning at 9 weeks' gestation to treat several fetuses at risk for CAH.[7] Female fetuses subsequently confirmed to be affected with severe CAH were spared masculinization of the external genitalia. Several hundred pregnant women and their fetuses have since been treated with prevention of masculinization in more than 85% of affected females.[8]

The differentiation of the external genitalia begins at about 7 weeks of gestation. Thus, diagnosis by amniocentesis or even CVS is too late to prevent masculinization. Therefore for carrier parents, pharmacological therapy has to be initiated prior to prenatal diagnosis: Therapy is administered to all patients at risk, despite the fact that the chance of an affected female fetus for carrier parents is only 1 in 8 (i.e., 1/4 affected $\times$ 1/2 female). Following molecular diagnosis, by CVS, in seven out of eight patients, therapy is discontinued if the diagnosis of a male is made or if CAH is ruled out. However, if the fetus is an affected female, therapy is continued throughout gestation. Stress-dose corticosteroids should be given to the mother during labor and tapered gradually postpartum.

No consistent untoward effects on fetuses have been reported. Greater weight gain, edema and striae were noticed in treated mothers but no increased risk of hypertension or gestational diabetes was noted.[8]

Inclusion criteria of the European Society for Paediatric Endocrinology and Wilkins Pediatric Endocrine Society[9] for prenatal treatment of CAH include: (1) a previously affected sibling or first-degree relative with known mutation causing classical CAH proven by DNA analysis; (2) reasonable expectation that the father is the same as the proband's; (3) availability of rapid and quality genetic analysis; (4) therapy started less than 9 weeks following the last menstrual period; (5) lack of intent for therapeutic abortion; and (5) reasonable expectation of patient's compliance.

There is an agreement that the treatment requires a professional team that includes an expert high-risk obstetrician, a pediatric endocrinologist, genetic counselor and a molecular genetic laboratory.

Thyroid disorders

Hypothyroidism

Congenital hypothyroidism affects about 1:3000 to 1:4000 infants.[10] About 85% of the cases are the result of thyroid dysgenesis, a heterogeneous group of developmental defects characterized by inadequate amount of thyroid tissue. Congenital hypothyroidism is only rarely associated with errors of thyroid hormone synthesis, thyroid-stimulating hormone (TSH) insensitivity, or absence of the pituitary gland. Fetal hypothyroidism may not necessarily manifest in a goiter before birth since maternal thyroid hormones may cross the placenta. Congenital hypothyroidism presenting with a goiter can be found in only about 10–15% of cases, with an estimated prevalence of 1:30,000–1:50,000 live births.[11] Fetal goiterous hypothyroidism is caused in most instances by maternal exposure to thyrostatic agents used to treat maternal hyperthyroidism.[12] These drugs include propylthiouracil (PTU), the inadvertent use of radioactive ^{131}I in the pregnant women or iodide exposure. Maternal ingestion of amiodarone (antiarrhythmic

drug) or lithium (drug for people with mood disorders) may also cause hypothyroidism in the fetus. Finally, fetal hypothyroidism may result from transplacental passage of maternal blocking antibodies (known as TBIAb or TBII) or rarely due to rare defects in fetal thyroid hormone biosynthesis.[11]

Fetal goiterous hypothyroidism may lead to severe fetal and neonatal consequences. An enlarged goiter may cause esophageal obstruction which may lead to polyhydramnios, which may result in preterm delivery or premature rupture of membranes. Rarely, a goiter may even lead to high-output heart failure due to high vascular flow in the goiter.[13] A large fetal goiter can cause extension of the fetal neck leading to dystocia in labor. The effects of the fetal hypothyroidism itself may be devastating. Without treatment, postnatal growth delay and severe mental retardation may ensue. Even with immediate diagnosis and treatment at birth, long-term follow up of children with congenital hypothyroidism has demonstrated that they have lower scores on perceptual-motor, visuospatial, and language tests.[14]

In suspicious cases, an extensive maternal and family history should be obtained. In patients with a positive history, maternal thyroid hormone levels, as well as blocking immunoglobulin levels should be measured. In addition, all women with a history of any thyroid disease (both hypothyroidism and hyperthyroidism) are advised to have monthly fetal ultrasound scans to screen for fetal goiter, polyhydramnios, or fetal tachycardia.[15]

Occasionally, fetal goiterous hypothyroidism may be identified by an ultrasound scan performed due to increased uterine size caused by polyhydramnios secondary to esophageal obstruction and impaired swallowing. Sometimes, a fetal goiter may incidentally be discovered on a routine scan. Before the advent of cordocentesis, amniotic fluid levels of TSH and FT4 (free thyroxine) were used as potential indicators of fetal thyroid function. However, these proved to be inconsistent.[16] With cordocentesis, fetal thyroid status can be directly and accurately evaluated; fetal response to therapy can therefore be reliably measured using available appropriate nomograms for fetal serum levels of FT4, total T4 (thyroxine), free T3 (triiodothyronine), total T3, and TSH.[15,17] *In utero* treatment was initially suggested by Van Herle *et al.* using intramuscular injection of levothyroxine sodium.[18] Subsequent studies however, have indicated that intra-amniotic administration of thyroxine may be superior and can lead to resolution of the polyhydramnios as well. The dose of the injected drug may be refined using the fetal thyroid profile in the amniotic fluid and the thyroid size.[19] The doses commonly used for treatment range from 200 to 500 mg intra-amniotic every week. With this regimen, fetal goiters have been shown to regress, the hyperextension of the fetal head have been shown to resolve and fetal and newborn TSH levels have normalized.[19]

Hyperthyroidism

Neonatal hyperthyroidism is rare with an incidence of 1:4000 to 1:40,000 live births.[10] Fetal thyrotoxic goiter is usually secondary to maternal autoimmune disease, principally Graves' disease or Hashimoto's thyroiditis. As many as 12% of infants of mothers with a known history of Graves' disease are affected with neonatal thyrotoxicosis, which may occur even if the mother is euthyroid.[20] As with hypothyroidism, inherent to the underlying mechanism is the transplacental passage of maternal IgG antibodies. In this case the antibodies, known as TSAb or (TSI), are predominantly directed against the TSH receptor.

Usually, the investigation of fetal hyperthyroidism begins only after the discovery of fetal goiter. Often, the goiter is diagnosed on ultrasound in patients referred due to elevated thyroid stimulating antibodies. In some cases, fetal goiters are realized serendipitously on routine ultrasonography. Others may be discovered in patients referred for scan because of polyhydramnios. Beside the risks related to the goiter itself, untreated fetal hyperthyroidism may be associated with a mortality rate of 12–25% due to high-output cardiac failure.[21] Once a fetal goiter is identified, biochemical evaluation is indicated. Historically, amniotic fluid levels of TSH and FT4 were used as potential indicators of fetal thyroid function. These, however, proved inconsistent in that amniotic fluid levels of these hormones do not always correlate with their serum levels. Some controversy still exists regarding their use, however, they may be of some benefit in centers that do not have available cordocentesis.[16] As stated previously, cordocentesis allows reliable assessment of fetal thyroid status TSH,[15,17] and treatment can be planned accordingly.

Once the diagnosis of fetal hyperthyroidism is confirmed, fetal treatment should be initiated. Authors have attempted treating fetal hyperthyroidism with maternally administered antithyroid drugs. Porreco and Bloch have reported maternal treatment of fetal thyrotoxicosis with the antithyroid drug propylthiouracil (PTU), which lead to a good outcome.[22] The initial dose used was 100 mg PO three times a day, which was later decreased to 50 mg PO three times a day. Wenstrom *et al.* described a favorable outcome using maternal methimazole to treat fetal hyperthyroidism in a patient who could not tolerate PTU.[21] Hatjis also treated fetal goiterous hyperthyroidism with a maternal dose of 300 mg PTU. This patient, however, required supplemental synthroid to remain euthyroid. There was good fetal outcome in this case as well.[23]

Inborn errors of metabolism

Methylmalonic acidemia

The methylmalonic acidemias (MMAs) are a group of enzyme-deficiency diseases inherited in an autosomal recessive manner resulting from one of several genetically distinct etiologies. Some cases are caused by

mutations in the gene encoding methylmalonyl-coenzyme A mutase while others are due to a defect that catalyzes the biosynthesis of adenosylcobalamin from vitamin B_{12}. The disease is characterized by a wide clinical spectrum ranging from a benign condition to a fatal neonatal disease. In the severe form, MMA is characterized by severe metabolic acidosis, developmental delay and biochemical abnormalities that include methylmalonic aciduria, long chain ketonuria and intermittent hyperglycinemia. Patients with defects in adenosylcobalamin biosynthesis may respond to administration of large doses of vitamin B_{12}, which may enhance the amount of active holoenzyme (mutase apoenzyme plus adenosylcobalamin). A proposed mechanism for the neurological abnormalities observed in methylmalonic acidemia was suggested by a group of Brazilian investigators who administered methylmalonic acid to rats during the first month of their life.[24] A significant diminution of myelin content and of ganglioside *N*-acetylneuraminic acid were noted in the cerebrum.

More than 20 years ago, Ampola and colleagues were the first to attempt prenatal diagnosis and treatment of a B_{12}-responsive variant of MMA.[25] They followed the pregnancy of a patient who had previously suffered the loss of a child to severe acidosis and dehydration at the age of 3 months. The diagnosis of MMA was made posthumously by chemical analysis of blood and urine. In the subsequent pregnancy, amniocentesis at 19 weeks revealed elevated methylmalonic acid in the amniotic fluid. Cultured amniocytes also demonstrated defective propionate oxidation and undetectable levels of adenosylcobalamin. When adenosylcobalamin was added, normal succinate oxidation and methylmalonyl-coenzyme A mutase activity were noted. These studies established that the fetus also suffered from MMA apparently due to deficient synthesis of adenosylcobalamin. It was already known that fetal MMA is associated with increased methylmalonic acid excretion in the maternal urine. Indeed, Ampola *et al.*[25] documented increased methylmalonic acidemia in maternal urine at 23 and 25 weeks gestation. Late in the pregnancy, cyanocobalamin (10 mg/day) was orally administered to the mother in divided doses. The treatment only marginally altered the maternal serum B_{12} level. However, there was a slight reduction of maternal urinary methylmalonic acid excretion that remained several fold above normal. At approximately 34 weeks gestation, 5 mg of cyanocobalamin per day was administered intramuscularly. The maternal serum B_{12} level then rose gradually to more than sixfold above normal and was accompanied by a progressive decrease in urinary methylmalonic acid excretion. Maternal urinary methylmalonate was only slightly above the normal range when delivery occurred at 41 weeks. Amniotic fluid methylmalonic acid concentrations were three times the normal mean at 19 menstrual weeks and four times the normal mean at term, despite prenatal treatment. Postnatally, the diagnosis of methylmalonic acidemia was confirmed. The infant suffered no acute neonatal complications and had an extremely high serum B_{12} level. Long-term postnatal management involved protein restriction; however, no continuous B_{12} treatment was required. In this instance prenatal treatment certainly improved the fetal and, secondarily, the maternal biochemistry. Whether there was any significant clinical benefit to the fetus by *in utero* treatment cannot be assessed adequately. It seems likely that reducing the fetal burden of methylmalonic acid should have some beneficial effect on fetal development and could reduce the risks in the neonatal period.

Andersson *et al.*[26] followed a cohort of eight children with MMA for an average of 5.7 years. Congenital malformations were described, reinforcing the deleterious effects of prenatally abnormal cyanocobalamin metabolism. Growth was significantly improved in most cases after initiation of therapy postnatally and in one case microcephaly resolved. However, developmental delay of variable severity was always present regardless of treatment onset. These data suggest that prenatal therapy of MMA may be effective and perhaps ameliorate some of the prenatal effects. Evans *et al.* have documented the changing dose requirements necessary over the course of pregnancy to maintain adequate levels of B_{12}. They sequentially followed maternal plasma and urine levels in a prenatal treated pregnancy.[27] Data such as these suggest that modulation of maternal-fetal pharmacological interchange of therapeutic drugs will be difficult to precisely control.

Multiple carboxylase deficiency

Biotin-responsive multiple carboxylase deficiency is an inborn error of metabolism caused by diminished activity of the mitochondrial biotin-dependent enzymes (pyruvate carboxylase, propionyl-coenzyme A carboxylase and α-methylcrotonyl-coenzyme A carboxylase). The condition may arise from mutations in the holocarboxilase synthetase (HCS) gene on chromosome 21q22.1 or the biotinidase gene localized to chromosome 3p25.[28–32] Affected patients present as newborns or in early childhood with dermatitis, severe metabolic acidosis, and a characteristic pattern of organic acid excretion. It has been demonstrated that metabolism in patients or in their cultured cells can be restored toward normal levels by biotin supplementation. Prenatal diagnosis can be made by demonstration of elevated levels of typical organic acids (3-hydroxyisovalerate, methylcitrate) in the amniotic fluid or in the chorionic villi. However, the existence of a mild form of HCS deficiency can complicate prenatal diagnosis as organic acids level in amniotic fluid might be normal.[33] Therefore, prenatal diagnosis must be performed by enzyme assay in cultured fetal cells in biotin-restricted medium.

Roth and colleagues treated a fetus without the benefit of prenatal diagnosis in a case in which two

previous siblings had died of multiple carboxylase deficiency.[34] The first had died within 3 days of birth and in the second, the diagnosis of biotin-responsive carboxylase deficiency was made posthumously. Since the mother was first seen at 34 weeks gestation, prenatal diagnosis was not attempted. Because of severe neonatal manifestations in previous offspring and due to the probable harmlessness of biotin – oral administration was begun at a dose of 10 mg/day. There were no apparent untoward effects; maternal urinary biotin excretion increased by a factor of approximately 100 during biotin administration. Nonidentical twins were subsequently delivered at term. Cord blood and urinary organic acid profiles were normal, and cord blood biotin concentrations were four to seven times greater than normal. The neonatal course for both twins was unremarkable. Subsequent study of the cultured fibroblasts of both twins indicated that the cells of twin B (but not of twin A) had virtually complete deficiency of all three carboxylase activities. Genetic complementation studies confirmed that despite the normal clinical presentation during the newborn period, twin B was homozygous for the disease mutation. Packman and colleagues have also reported prenatal diagnosis and treatment of biotin-responsive multiple carboxylase deficiency for a mother who had previously given birth to a male with the neonatal-onset form of this disease.[35] In the subsequent pregnancy, maternal urine organic acid profiles were normal. Carboxylases activities were assayed in cultured amniotic fluid cells obtained by amniocentesis at 17 menstrual weeks. In biotin-restricted medium, the amniotic cells demonstrated the characteristic severe reduction in carboxylase activities. Since these initial reports of prenatal administration of biotin to fetuses affected with this disorder, other cases have been published,[33,36,37] further providing compelling evidence that biotin administration antenatally is effectively taken up by the fetus and prevents functional deficiency of the carboxylases in an affected newborn. No toxicity from treatment was observed. However, because experience with this treatment is confined to a small number of cases, it is reasonably to carry out prenatal diagnosis and only then to initiate treatment with biotin in any affected fetus.

Smith–Lemli–Optiz syndrome

Smith–Lemli–Optiz syndrome (SLOS) is a dysmorphological syndrome first reported in 1964.[38] Features include characteristic facies, growth and mental retardation, and anomalies of the heart, kidneys, central nervous system, and limbs. Cleft palate, postaxial polydactyly, 2–3 syndactyly of the toes and cataracts are often seen in affected patients. The 2–3 syndactyly of the toes is very specific for this disorder and is seen in > 90% of affected patients. Affected patients typically present with a narrow forehead, ptosis, anteverted nares, low-set ears, and micrognathia.

Males may present with ambiguous genitalia. In contrast with CAH, patients with SLOS are deficient in cholesterol and therefore lack steroid precursors. This leads to the lack of androgens, which results in under-masculinization of the male genitalia. Patients with the severe form of the syndrome present not only with these dysmorphological findings but also with a high rate of neonatal mortality.[39] The incidence of SLOS is estimated to be 1:20,000–1:40,000 live births,[40] and it appears to be most common in Caucasians population of North European origin, with an estimated carrier frequency of 1:70.[41] In 1993, the etiology of SLOS was discovered to be an inborn error of cholesterol biosynthesis due to a deficiency of the enzyme 7-dehydrocholesterol-Δ^7 reductase.[38,41–44] The gene for 7-dehydrocholesterol-Δ^7 reductase has been localized to chromosome 11q12–13.[44]

As a result of this enzymatic defect, there is a characteristic biochemical pattern of reduced cholesterol levels and elevated 7- and 8-dehydrocholesterol levels (7-DHC and 8-DHC, respectively) in all body fluids and tissues including red blood cells, fibroblasts, amniotic fluid and chorionic villi. The values observed in affected patients may be extremely variable. The diagnosis is made primarily by the presence of the cholesterol precursor, 7-DHC, and not by the deficiency of cholesterol. Unaffected individuals have levels of 7-DHC and 8-DHC of less than 1 mg/dl whereas patients with SLOS usually have levels of 7–20 or greater. Clinical manifestations correlate with cholesterol levels. Severely affected patients have very low levels of total cholesterol (usually <10–15 mg/dl), while those with more mild manifestations may present with levels of 40–70 mg/dl. Prenatal diagnosis of SLOS has been available since 1994 by either amniocentesis or chorionic villus sampling.[45–47]

Since identification of the cholesterol metabolic defect in SLOS, a treatment protocol has been attempted providing exogenous cholesterol. This form of therapy has now been provided to many patients with SLOS for the past several years in many centers in the United States and internationally,[48–50] with the goal of raising cholesterol levels and decrease the precursors, 7-DHC and 8-DHC. It has been shown that dietary cholesterol supplementation can restore a normal growth pattern in children and adolescents with SLOS, alleviate behavioral abnormalities and improve general health.[48–50]

Fetal therapy strategies may theoretically include providing cholesterol to the mother or to the fetus. The former, however, is not possible because cholesterol does not cross the placenta well in the second trimester and there is lack of evidence that it crosses the placenta in the third trimester. Moreover, cholesterol is available only in a crystalline form, which cannot be given intravenously or intramuscularly. Furthermore, it is impractical to inject cholesterol into the amniotic fluid because it would precipitate.

However, cholesterol can be given to the fetus by giving fresh frozen plasma in the form of low-density lipoprotein (LDL)-cholesterol. The group at Tufts University has attempted treatment antenatally in several affected fetuses. In cases where treatment was started late in pregnancy, the results were inconclusive. Although few descriptions of fetal therapy for SLOS exist, the latest report of antenatal treatment comes from that same group of investigators.[51] Therapy was begun at 34 weeks of gestation and resulted in increased fetal cholesterol levels and red blood cell mean corpuscular volume with subtle improvement in fetal growth, as assessed by consequent fetal weight plots. However, no significant change in 7-DHC and 8-DHC levels was observed, further emphasizing the inconclusiveness of that treatment. However, the main point is that since significant development of the central nervous system and myelination occurs prior to birth it is a reasonably to assume that providing cholesterol to the fetus, as early as possible would result in the most clinical benefit.

Galactosemia

Galactosemia is an inborn error of metabolism caused by the diminished activity of the enzyme galactose-1-phosphate uridyltransferase (GALT). This causes a defective metabolism of the sugar galactose which is the constituent of lactose, the main carbohydrate of milk, resulting in accumulation of galactose in the bloodstream. It is inherited in an autosomal recessive manner and results in cataracts, mental deficiency, growth deficiency, and ovarian failure. Clinical symptoms appear in the neonatal period and can be largely ameliorated by elimination of galactose from the diet. Cellular damage in galactosemia is thought to be mediated by accumulation of galactose-l-phosphate intracellularly and of galactitol in the lens. The *GALT* gene, localized to chromosome 9p13, is the only known gene to be associated with galactosemia. Several disease-causing mutations are commonly encountered in classical galactosemia, the most frequently observed is the Q188R classical mutation. Mutational analysis is available usefully for the six classical galactosemia alleles (Q188R, S135L, K285N, L195P, Y209C, F171S) and for the N314D Durate variant mutation.[52] In cases in which disease causing mutation are not identified (as observed in 10–29% of classic galactosemia), GALT sequence analysis may be performed to detect private mutations. Galactosemia can be diagnosed prenatally by study of cultured amniocytes and chorionic villi.

There are suggestions that even the early postnatal treatment of galactosemic individuals with a low galactose diet may not be sufficient to ensure normal development. Some have speculated that prenatal damage to galactosemic fetuses could contribute to subsequent abnormal neurological development and to lens cataract formation. Furthermore, it has been recognized that female galactosemics, even when treated from birth with galactose deprivation, have a high frequency of primary or secondary amenorrhea because of ovarian failure. This is because oocytes have already been damaged irreversibly long before birth. There also may be some subtle abnormalities of male gonadal function.

Exposure to a high-galactose diet has been considered to represent an animal model for human galactosemia. Chen and colleagues have observed a reduction in the oocyte content of rat ovaries after prenatal exposure to a 50% galactose diet.[53] No analogous alterations in the testes were observed in prenatally treated males. Experiments in rats suggest that toxicity to the female gonads from galactose or its metabolites is most obvious during the premeiotic stages of ovarian development. Recently, impaired germ cell migration leading to the development of gonads with deficient initial pools of germ cells was proposed as the causal link between galactosemia and premature ovarian failure.[54]

These observations in animals and human beings have led to speculation that galactose restriction during pregnancy may be desirable if the fetus is affected with galactosemia. In the human female, ovarian meiosis begins at 12 and is complete by 28 menstrual weeks. Thus, ovarian damage, and perhaps neurological or lens abnormalities, might occur prior to the usual time when prenatal diagnosis by amniocentesis can be accomplished. Thus, anticipatory treatment in pregnancies at risk for having a galactosemic fetus might best be initiated very early in gestation or even preconceptually.

Despite these experiments and speculations, we are unaware of studies that adequately assess the impact of prenatal administration of a low-galactose diet to galactosemic fetuses. However, such data, especially controlled, will be difficult to obtain. Nevertheless, prenatal galactose restriction is probably desirable in galactosemia and should be harmless. There is little reason to suppose that galactose restriction would have adverse consequences, since galactosemic and normal fetuses are both capable of some endogenous galactose synthesis.

Multifactorial disorders

Neural tube defects

Neural tube defects (NTDs) are malformations secondary to abnormal neural tube closure between the third and fourth weeks of gestational age. The etiology is complex and imperfectly understood with both genetic and environmental factors involved. Animal studies suggest that NTDs can arise from a variety of vitamin or mineral deficiencies. There are historical data in humans suggesting increased NTD frequencies in subjects with poor dietary histories or with intestinal bypasses. Biochemical evidence of suboptimal nutrition is present in some women bearing infants

with NTDs. Analysis of recurrence patterns within families and of twin–twin concordance data provides evidence of a genetic influence in nonsyndromal cases, although factors such as socioeconomic status, geographic area, occupational exposure, and maternal use of antiepileptic drugs are also associated with variations in the incidence of NTDs.[55] In 1980, Smithells *et al.* suggested that vitamin supplementation containing 0.36 mg folate can reduce the frequency of NTD recurrence by sevenfold in women with one or more prior affected children.[56,57] For almost a decade, there has been a great deal of controversy regarding the benefit of folate supplementation for the prevention of NTDs.[58–61] Finally, in 1991, a randomized double-blinded trial designed by the Medical Research Council Vitamin Study Research Group demonstrated that preconceptual folate reduces the risk of recurrence in high-risk patients.[62] Subsequently, it was shown that preparations containing folate and other vitamins also reduce the occurrence of first time NTDs.[63] In response to these findings, guidelines were issued calling for consumption of 4.0 mg/day folic acid by women with a prior child affected with a NTD, for at least 1 month prior to conception through the first 3 months of pregnancy. In addition, 0.4 mg/day folic acid is recommended to all women planning a pregnancy to be taken preconceptually. The data on NTD recurrence prevention is now very well established, and became routine for high-risk cases. As of January, 1998, the United States Food and Drug Administration has mandated that breads and grains be supplemented with folic acid. The impact of food fortification with folic acid on birth prevalence of NTDs during the years 1990–1999 was evaluated by assessing birth certificate reports before and after mandatory fortification.[64] It was found that the birth prevalence of NTDs reported decreased by 19%. It is important to note that the continuing decline in NTDs rates are estimated to be due to the introduction and increased utilization of prenatal diagnosis, recommendations for multivitamin use in women of childbearing age, and the population-wide increases in blood folate levels since food fortification was mandated.[65]

Folate plays a central part in embryonic and fetal development because of its role in nucleic acid synthesis mandatory for the widespread cell division that takes place during embryogenesis. Folate deficiency can occur because of low dietary folate intake or because of increased metabolic requirement as seen in particular genetic alterations such as the polymorphism of the thermolabile enzyme methyltetrahydrofolate reductase (MTHFR). A metabolic effect of folate deficiency is homocysteine elevation in blood. As mentioned, the thermolabile variant of MTHFR 677TT, is a known risk factor for NTDs. However, evidence regarding a second polymorphism in the same gene, 1298A→C, does not support its role in NTDs.[66] Additionally, numerous studies analyzing MTHFR variants have resulted in positive associations with increased NTD risk only in certain populations, suggesting that these variants are not large contributors to the etiology of NTDs.[67] Therefore, it seems less likely to advise parents prospectively to test for MTHFR variants. Reinforcement to the assumption that additional candidate genes other than MTHFR may be responsible for an increase risk to NTDs comes from the NTD collaborative group of Duke University.[68] A total of 175 American Caucasian NTD patients and their families were examined for the thermolabile variant of MTHFR. Although a significant association has been found comparing patients and controls, no such association was found in patients' parents. Two other key enzymes in the metabolic pathway of homocysteine are methionine synthase (MTR) and methionine synthase reductase (MTRR). Recently reported, MTR and a specific (A66G) MTRR polymorphisms have been found to be associated with increased risk for NTDs. Interestingly, the NTDs risk was not influenced by maternal preconception folic acid intake at doses of 0.4 mg/day. However, due to limited sample size further studies are needed in order to draw meaningful inferences.[69] Other candidate genes suggested as risk factor for NTDs (mainly spina bifida), are polymorphisms in the mitochondrial membrane transporter gene UCP2.[70] Despite previous studies suggesting zinc deficiency to play a role in the etiology of NTDs,[71,72] further studies found this observation inconclusive.[73,74] Methionine deficiency might be involved in NTDs as 30%-55% reduction in the risk of having NTD associated pregnancy was reported when methionine intake was greater then the lowest quartile of intake, with further reduction in risk with greater methionine intake.[75] In conclusion, preconception intake of folic acid alone or as multivitamin supplementation reduces the risk of recurrence and first time NTDs. Additionally, folic acid-multivitamin supplementation reduces the occurrence of other congenital anomalies such as seen in the urinary tract (e.g., vesicorenal reflux, horshoe kidney, and others), in the cardiovascular system (e.g., conotruncal heart defects), and anomalies involving the limbs and face (orofacial clefting).

Pharmacologic approaches

It might be appropriate to consider suppressing excessive cholesterol production prenatally in severe hypercholesterolemia when a safe and effective agent for accomplishing this becomes available (although there is no clear evidence for hypercholesterolemic prenatal damage). If cysteamine or related agents were to prove an effective treatment for lethal variants of cystinosis, prenatal therapy might be considered, because excessive and possibly harmful cystine accumulation is evident even in cystinotic fetuses. Cysteamine levels have been detected in chorionic villi, and significant elevations even at 10 weeks' gestation have been hypothesized.

Inhibitors of gamma-glutamyl transpeptidase, if safe, would elevate intracellular glutathione levels and inhibit oxoproline production in glutathione synthase deficiency, thereby averting the characteristic neonatal acidosis. In theory, it would be desirable to minimize copper accumulation in Wilson disease as early as possible. If and when reliable prenatal diagnosis of Wilson disease is possible, cautious administration of penicillamine prenatally might be considered. This would be a double-edged sword, however, as the teratogenic potential of penicillamine would demand careful evaluation. Batshaw and colleagues[76] have treated certain urea cycle defects by administering arginine and benzoate. Since hyperammonemia in some of these entities develops very acutely after birth, it might be desirable to consider pretreating the fetus with these compounds just prior to or during labor to minimize postnatal hyperammonemia.[76] Conversely, it may be desirable to consider drug avoidance as an approach to fetal treatment. For example, fetuses with glucose-6-phosphate dehydrogenase deficiency are sensitive to a variety of drugs that induce hemolysis. It would probably be appropriate to avoid administering such agents to women carrying or known to be at risk for carrying fetuses deficient in glucose-6-phosphate dehydrogenase.

Umbilical cord catheterization under ultrasound guidance may lead to the development of other types of fetal treatment.[77] Systems such as gene replacement are being developed for certain lysosomal storage disorders. Progress is being made in postnatal experimental models on administration of thymic cells for certain immune deficiency states, bone marrow transplantation for a variety of genetic disorders, and gene transfer. The development of better and earlier techniques for prenatal treatment will be complex, especially with regard to gene transfer; but progress will be made, and access to the fetal vasculature may be required for these methods to have a chance for success.

Bone marrow transplantation or thymic cell infusion is actually only a specialized example of organ transplantation. In the future, fetal organ transplantation may become possible and may open many prospects for surgical treatment of certain biochemical genetic disorders.

One can also speculate about the therapeutic possibilities involving compounds administered directly into the amniotic fluid or into the fetal intestinal tract. It might be possible, for example, to administer thyroid hormone in this fashion or to prevent meconium ileus in cystic fibrosis by instilling not yet determined enzymes into the fetal intestinal tract.

Conclusion

While a multitude of metabolic disorders exist, prenatal treatment for most has never been attempted or considered. The discovery of new disease associated genes and prenatal carrier testing may in the future allow preconceptual carrier detection, without the tragedy of first having an affected child. This may provide targeted therapy in families who chose to continue the pregnancy and offer the prospect of improved outcome by ameliorating at least some of the prenatal deleterious effects of the metabolic disease.

74 Fetal surgical interventions

M. R. Harrison and M. I. Evans

Introduction

Over the last two decades, fetal therapy has evolved into four major areas: open surgical approaches, 'closed' endoscopic surgical approaches, pharmacologic therapy, and stem cell/gene therapy. Advances in the field have been characterized by dramatic successes, but also intense frustration at technical challenges and moving targets as ancillary therapies change risk/reward equations.[1]

If something can be treated safely postnatally, then there is no justification for prenatal intervention. However, for the conditions discussed below, profound and irreparable damage occurs before birth, making fetal intervention the best or sometimes only way to ameliorate the damage. Some procedures have been quite rare. Others are more common, but the expectation is that with improvements and increasing utilization of prenatal diagnosis, more women will consider the opportunities to treat fetuses before birth.[2]

Surgical therapy

In utero closed fetal surgery

The most efficacious percutaneous *in utero* fetal surgery has been for the evaluation and treatment of obstructive uropathy. Lower urinary tract obstruction (LUTO) is a heterogenous entity that affects 1:5000–8000 newborn males. Posterior urethral valves or urethral atresias are the most common causes for LUTO, although other etiologies, such as stenosis of the urethral meatus, anterior urethral valves, ectopic insertion of a ureter and tumors of the bladder, have been observed. LUTO can result in massive distention of the bladder with compensatory hypertrophy and hyperplasia of the smooth muscle within the bladder wall, leading to loss of compliance and elasticity and poor postnatal function generally requiring surgical reconstruction.[3] Elevated intravesicular pressures prevent urine inflow from the ureters and eventual distortion of the ureterovesicle angles contributes to reflux hydronephrosis. Progressive pyelectasis and calyectasis compress the delicate renal parenchyma within the encasing serosal capsule, leading to functional abnormalities within the medullary and eventually the cortical regions. Focal compressive hypoxia likely contributes to the progressive fibrosis and perturbations in tubular function resulting in urinary hypertonicity, which is observed. Obstructive processes can eventually lead to type IV cystic dysplasia and renal insufficiency.[4–7]

The effects extend beyond the genitourinary tract. Progressive oligo/anhydramnios leads to compressive deformations as seen in Potter sequence, including extremity contractures and facial dysmorphology. Absence of normal amniotic fluid volume also interferes with pulmonary growth and development. Constant compressive pressure on the fetal thorax leads to restriction of expansion of the chest through normal physiologic 'breathing movements'. Babies born with LUTO generally die secondary to pulmonary complications and not renal failure.

The prenatal sonographic diagnosis of LUTO includes dilated and thickened walls of the bladder, hydronephrosis, and oligohydramnios. (Figure 74.1) Urethral strictures or atresia, urethral agenesis, megalourethra, ureteral reflux, and cloacal anomalies may be present and have a very similar appearance on ultrasound. The typical 'keyhole sign' of proximal urethral dilation is secondary to urethral obstruction present in PUV or atresia. However, the precise diagnosis can only be made after birth.[7]

The prenatal evaluation and management of fetuses with the sonographic findings of LUTO are complex.[4–6] Ruling out other congenital anomalies, such as cardiac and neural tube defects, is necessary before intervention can be considered.

Karyotyping is needed to confirm a normal male chromosomal status, as cases of LUTO have an increased incidence of aneuploidy. Female fetuses almost always have more complex syndromes of cloacal malformations, which do not benefit from *in utero* shunt therapy. Because of the presence of oligo/anhydramnios, we commonly obtain karyotypes by transabdominal chorionic villus sampling, which gives reliable results within 5 days during which the remainder of the prenatal evaluation is under way. Fluorencence *in situ* hybridization can be used to get rapid status of chromosomes 13, 18, 21, X, and Y.[8]

Figure 74.1 Oligohydramnios and dilated bladder in a fetus at 17 weeks with good electrolytes.

Figure 74.2 Vesicoamniotic shunt with the proximal portion lying within the fetal bladder while the distal portion lies within the amniotic fluid space allowing diversionary draining of urine into the appropriate space.

Essential to the prenatal workup is the evaluation of underlying renal status in the fetus. Over the past 15 years, we have developed a multicomponent approach for the analysis of fetal urine that evaluates proximal tubular and possible glomerular status using sodium, chloride, osmolality, calcium, β-2 microglobulin, albumin, and total protein concentrations.[5] Predictive reliability has been shown to be significantly improved by sequential samplings at 48–72-h intervals.[6] Using such an approach, one can directly correlate the degree of impaired renal function and damage with the extent of urinary hypertonicity and proteinuria. As such, the ability to counsel patients about the renal status of their fetus and the long-term prognosis has been dramatically improved.

Vesicoamniotic catheter shunts bypass the urethral obstruction diverting the urine into the amniotic space to allow appropriate drainage of the upper urinary tract and prevention of pulmonary hypoplasia and physical deformations. (Figure 74.2) In fetuses with isolated LUTO, a normal male karyotype, and progressively improving urinary profile that meet threshold parameters (Table 74.1), intervention has been very successful in salvaging fetuses using percutaneous vesicoamniotic shunt therapy.

Experience in humans has been widely variable and appears to be related to the extent of prenatal evaluation prior to shunt placement, as well as the etiology of obstruction. Freedman *et al.* confirmed that Prune Belly infants, without complete urethral obstructions, have very good renal outcomes following vesicoamniotic shunt therapy.[7] They have also found significant improvement in survival and renal function in infants with posterior urethral valves treated by shunting; however, many have mild to moderate renal insufficiency at birth and several of these have progressed to renal failure, dialysis, and transplantation. The worst group of infants appears to be those with urethral atresia. However, there have been survivors with urethral atresia following early shunt intervention. These findings support animal studies, which indicated that early-onset complete obstructions resulted in more severe renal damage than later-onset or partial obstructions. Such data emphasize the necessity for early diagnosis, evaluation, and intervention in such cases.

Table 74.1 Upper threshold values for selecting fetuses that might benefit from prenatal intervention

Sodium	< 100 mg/dl
Chloride	< 90 mg/dl
Osmolality	< 190 mOsm/l
Calcium	< 8 mg/dl
β-2 microglobulin	< 6 mg/l
Total protein	< 40 mg/dl

More recently, data from our experience over the past 15 years suggest that patients having bladder shunts had a 91% survival rate, but that long-term renal function was not guaranteed. Just under half had 'normal renal function', and about a quarter had mild impairments. The experience depended highly on the exact etiology of the disorder with posterior urethral value having the best outcomes and urethral atresia the worst. The experience suggests that close pediatric urologic/renal function assessment is essential. The Paris group has found

that about 25% of children had serious, long-term renal impairments and about 15% actually developed end-stage renal disease requiring transplant. (M. Dommergues and F. Mueller, unpublished data).

Although vesicoamniotic shunting has clearly improved survival and renal function in cases of early obstructive uropathy, complications of this procedure remain unacceptably high. We found in the 1980s and 1990s that in 40% of our cases the shunts became physically displaced into the amniotic or intraperitoneal space, or became obstructive with loss of drainage function, necessitating replacement. On balance, intervention for LUTO has saved fetuses that would otherwise have surely died. Many have normal to moderately impaired renal function. A carefully balanced approach in counseling is required for patients to determine what is right for them.

Other shunts

In the late 1970s, shunting was attempted for obstructive hydrocephalus.[9] Attempts in the late 1970s and early 1980s at *in utero* ventriculoperitoneal shunting were nearly uniformly disastrous. However, in retrospect, most of the operated patients were, in fact, very poor candidates for intervention. Many had multisystem syndromic disorders, including aneuploidy, and hopeless congenital anomalies, such as holoprosencephaly.

Accordingly, ventriculoamniotic shunts were abandoned since the early 1980s. With a better understanding of the poor natural history of the anomaly, and better, more accurate diagnostic techniques, we have speculated that there may eventually be limited applications for prenatal neurologic shunting in cases of early-onset, isolated, progressive obstructive hydrocephaly.

The other use of percutaneously placed shunts has been for thoracic abnormalities.[10,11] The macrocystic form of congenital cystic adenomatous malformation can present with a very large intrathoracic mass with a dominant macrocyst that causes cardiac and mediastinal shift and comes with its potential hemodynamic changes, as well as pulmonary compression and risk of lung hypoplasia. Such dominant cysts can be approached using pleuroamniotic shunts to chronically drain these structures, reducing their volume, and diminishing their space-occupying effects within the thoracic cavity.

Isolated pleural effusions can also accumulate to the point of causing hemodynamic changes and onset of generalized hydrops as well as pulmonary compression, which interferes with normal lung development increasing the risk of hypoplasia. Small, unilateral effusions generally do not warrant intervention, but must be followed closely as they have the potential for rapid progression and development of generalized hydrops.[11]

As with all fetal interventions, prenatal evaluation prior to intervention is critical for appropriate case selection. Seemingly isolated effusions may be the first sign of a cardiac malformation, aneuploidy, anemia, or an infectious process. Thoracoamniotic shunting is effective in carefully evaluated cases when the risk of pulmonary hypoplasia from large effusions early in gestation is present, or early signs of progressive hydrops (unilateral–bilateral effusion, skin or scalp edema, ascites, pericardial effusion) appear. Fetal anemia, *per se*, is not an indication for thoracoamniotic effusion shunting, as hydropic changes will usually resolve with timely fetal transfusion therapy. Also, if one waits to intervene until the fetus develops significant ascites, the prognosis even with successful shunt intervention diminishes considerably.[11] However, several cases with suddenly progressive pleural effusions and the onset of generalized hydrops (skin/scalp edema, pericardial effusion, and moderate ascites) have been treated with complete resolution of all hydropic complications and normal postnatal infants.

Open surgical approaches

For a limited number of indications, open fetal surgery has been performed for about 20 years.[2] Appropriate concerns for maternal risk, rigorous selection criteria, and somewhat frustrating results have limited its use. There have been continuing innovation and development of instruments and techniques motivated by the clinical necessity to improve the safety of open fetal surgery for both the fetus and the mother.

Congenital diaphragmatic hernia (CDH)

The fetal approach to CDH has undergone continuous evolution since the first attempted CDH repair in 1986 and the first success in 1989.[12–15] Definitive repair of CDH by reduction of viscera from the chest, diaphragmatic patch placement, and abdominal silo construction (to reduce intra-abdominal pressure) had unacceptable mortality, particularly after a clinical trial showed open fetal repair was no better than postnatal repair, when the liver was herniated into the chest.[16,17] The definitive repair was abandoned as an option for CDH; *in utero* tracheal occlusion took its place.[17–24] (Figure 74.3) Tracheal occlusion leads to an increase in lung size through accumulation of pulmonary secretions, which reduces the herniated viscera from the chest and decreases the risk of lung hypoplasia. The technique of achieving reliable, complete and reversible trachael occlusion has evolved. Initially, it could only be accomplished by open fetal surgery and fetal neck dissection (taking care to avoid the recurrent laryngeal nerves) and placement of occlusive hemoclips. Next, a fetoscopic technique was developed to accomplish the same neck dissection and tracheal clip (the Fetendo Clip Procedure).[21,22] While successful, it proved difficult with a significant learning curve. Attempts to simplify the procedure by developing an appropriate polymer to

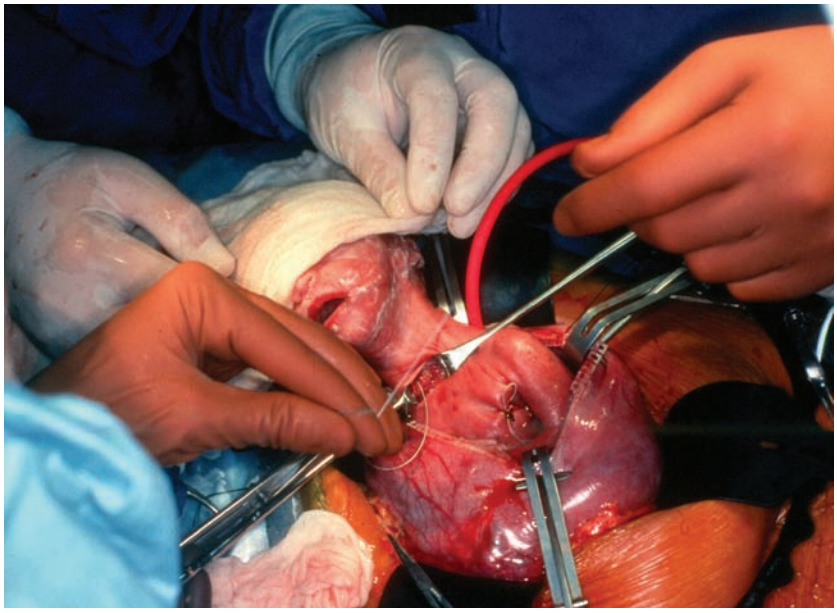

Figure 74.3 Surgical isolation of the fetal trachea prior to placement of hemoclips in a tracheal occlusion procedure for CDH.

use as a tracheal plug inserted through the fetal mouth were unsuccessful. Experience quickly showed that unless there was complete occlusion, the pulmonary secretions would leak, thereby defeating the purpose of the plug. Finally, a relatively simple technique was developed in which a fetoscope passed through a single port is advanced into the fetal trachea (fetal bronchoscopy) and a detachable silicone balloon is inflated to occlude the trachea.

CDH has been a classic example of rapid changes in technology clouding any simple attempts to understand the role for fetal surgery. With increasing sophistication of the surgical approach as well as concomitant improvements in neonatal care using extracorporeal membrane oxygenation, it was impossible to accurately determine the relative benefits of each approach without a prospective, randomized comparison that held all other details constant. Thus, after much debate, a randomized trial of surgery for CDH vs. optimal postnatal care was funded by the National Institute of Child Health and Human Development.[17] The principle component of the trial was that patients in the postnatal care (control) arm would receive the same neonatal care by the same center as the surgical arm.

It was originally expected that patients undergoing surgery would have a survival rate of about 70% as compared to the best data on controls expecting about 35%. The surgically treated patients achieved expected survival. However, the trial was stopped prematurely, when by having the controls cared for at the same tertiary specialty centers as the surgical group, survival in the controls was essentially the same as the surgical group. Such data show conclusively the principle of 'the moving target' and how our use of technology must continually adapt to changing conditions.[23]

Congenital cystic adenomatoid malformation (CCAM)

CCAM is a space-occupying congenital cystic lesion of the lung, which may grow and induce hydrops by causing mediastinal shift and compromise venous return to the heart. When fetuses with CCAM develop hydrops, the fetal mortality approaches 100%[25–27] (Figure 74.4). Fetal resection of CCAM reverses hydrops and has improved survival dramatically.[25–27] The fetal operation is performed by exposure of the arm and chest wall on the side of the lesion through the maternal hysterotomy. A large muscle sparing thoracotomy is performed through the midthorax of the fetus and the lobe containing the CCAM is isolated. The attachments of the lobe to the adjacent lung tissue are bluntly divided and the lobar hilum is divided by the use of a TIA stapler or a bulk ligature. During the remainder of the pregnancy, the remaining normal lung shows compensatory growth that fills the space left, showing mass removal.

Sacrococcygeal teratoma (SCT)

Fetal SCT arises from the presacral space, which may grow to massive proportions and in some fetuses induce high-output failure from tumor vascular steal. Fetal SCT with high-output physiology with associated placentomegaly or hydrops uniformly result in fetal demise[28,29] (Figure 74.5). The pathophysiologic rationale for fetal surgery is to ligate the vascular connections to the tumor, remove the vascular 'sin', and reverse the high-output physiology. The fetal operation is performed by exteriorization of the fetal buttocks with attached tumor.[28] Every attempt is made to keep the head, torso, and lower extremities of the fetus in the uterus. Since the tumor can sometimes be larger than the fetus, a significant loss of uterine

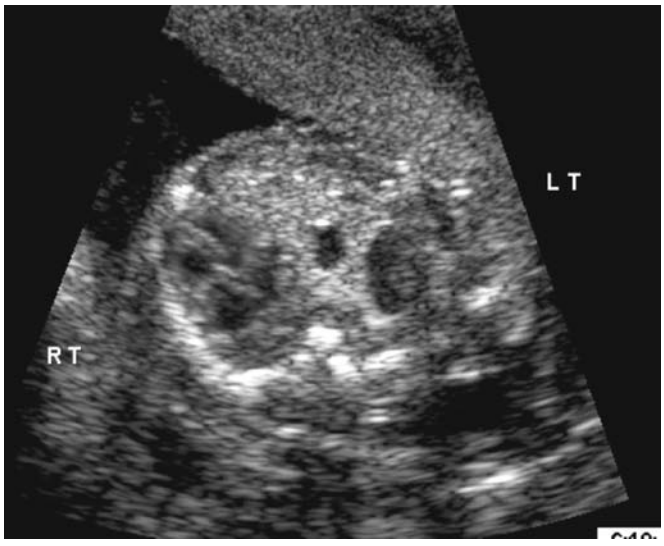

Figure 74.4 Microcystic congenital cystic adenomatous malformation (microcystic) with the beginnings of hydrops.

volume occurs, and the uterus may contract, increasing the risk of placental abruption, placental dysfunction because of compression, or postoperative preterm labor. Once exteriorized, the anus is identified and the fetal skin incised posterior to the anorectal sphincter complex to avoid injury to the continence mechanism. A tourniquet is then applied to the base of the tumor and brought down gradually as the tumor is finger fractured down to its vascular pedicle. The vascular pedicle is then ligated with suture ligatures or TIA device stapled depending on the width of the pedicle. The entire fetal procedure can be performed in less than 15 min with minimal blood loss. Because of the increase in afterload following ligation of the low resistance tumor circuit, the fetal hemodynamic status must be monitored by fetal echocardiography during and in the immediate period following the ligation.

ex utero intrapartum treatment (EXIT) procedure

The EXIT procedure is a modified cesarean delivery and may be applied to deliver fetuses after fetal surgical procedures, such as tracheal ligation, or for fetuses with difficult airway problems, such as massive cervical teratomas or cystic hygromas.[30,31] The most important component of the EXIT procedure is the maintenance of uteroplacental perfusion until the fetal airway is secured and ventilation is established. In direct contrast to cesarean section where uterine contraction for hemostasis is encouraged, uterine relaxation is maintained by deep general anesthesia. The fetal manipulations are then performed with maternal support via the placenta. Clips can be removed, chest masses removed, bronchoscopy performed, and stable airway access established in otherwise very difficult circumstances with this approach. Once the fetus is ready for transport to the nursery or adjacent operating suite following these preliminary steps, the cord is clamped and cut and the cesarean delivery completed.

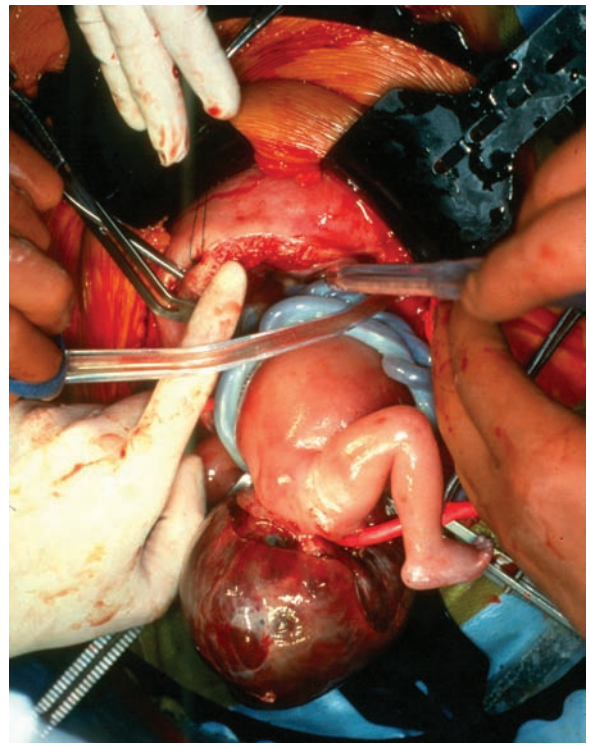

Figure 74.5 Saccrococcygeal teratoma in a fetus.

Meningomyelocele

Babies with myelingomyloceles have impaired lower motor function and loss of bowel and bladder control. A significant percentage develop obstructive hydrocephalus which requires ventriculoperitoneal shunting.[32] Experience from the 1970s and 1980s showed that babies with meningomyelocele delivered atraumatically by cesarean section had a better level of motor function for the given level of anatomic defect, than those babies delivered through the vaginal canal.[33] Such data suggest that compression and trauma to the cord in the delivery process can have permanent long-term sequelae to motor function. It therefore follows that trauma to the spinal cord *in utero*, either from banging into the uterine wall, or the toxic effects of the amniotic fluid in the third trimester, *per se*, could be detrimental to the function of the spinal cord. Furthermore, the traditional dogma that the pathogenesis of meningomyelocele was that an abnormally developed spinal cord, which did not in turn, engender the proper development of the bony spinal column, may not be the whole story. It is possible that the primary defect is in the bony spinal column, which exposes a presumptively undamaged spinal cord. The cord is then damaged by the toxic affects of amniotic fluid and trauma from the uterine environment and repeated contact with the uterine wall. Thus, the rationale for attempts to cover and protect the spinal cord in utero, to minimize the sequelae.[34]

Three groups have done most of the work in this area and have attempted to repair meningomyeloceles in utero, both as an open surgical procedure and endoscopically, with the stated attempt to reduce long-term morbidity and mortality.[35,36,37]

The principal benefit of the surgery is likely secondary, i.e. a significant reduction in the number of babies requiring ventriculoperitoneal shunting for obstructive hydrocephalus.[38,39] There is still much controversy surrounding the data.[32] A randomized, prospective trial comparing fetal to postnatal neurosurgical closure began in 2003, but will take several years to be completed. A major milestone of this trial has been the agreement among the participating centers not to perform any cases outside the trial, and other centers around the country have agreed not to start programs until the trial is completed.

Conclusion

There are an increasing number of congenital and genetic abnormalities for which *in utero* treatment is possible, and in some cases, now relatively routine. Advances in therapies have progressed at different paces for different disorders, but there is a great hope and enthusiasm that progress will continue to expand the number of disorders for which therapy can be effective.

SECTION VIII

Screening and risk assessment

Section Editors: **G. Monni and S. Chasen**

75 First-trimester ultrasound screening for fetal malformations

S. T. Chasen

The most significant advance in first-trimester ultrasound screening has been the recognition of nuchal translucency (NT) as a potent marker for fetal aneuploidy.[1] Abnormal NT in a euploid fetus is also associated with structural fetal abnormalities that can be diagnosed in the second-trimester.[2] Thus, measurement of NT can lead to earlier and targeted screening in the second trimester.

While abnormal NT can suggest the possibility of a structural abnormality, advances in ultrasound imaging have made the direct diagnosis of some anomalies possible.[3,4] Evaluation of other anatomic structures in the first trimester can diagnose anomalies or identify useful markers for anomalies that may be diagnosed later in pregnancy. As more women will be presenting for NT measurement at 11–14 weeks' gestation, it is important to consider other anatomic structures amenable to evaluation at this time.

Evaluation of first-trimester anatomy

Fetal head

Structures that can be well visualized in the first trimester include the calvarium and portions of the developing brain. Midline structures, including a falx cerebri and thalamic bodies, are easily visualized. Choroid-filled lateral ventricles can be identified as well. The cavum septum pellucidum and structures in the posterior fossa cannot be reliably evaluated in many cases, though visualization becomes more likely by 14 weeks.

Fetal face

The profile is well imaged in most fetuses from 11 to 14 weeks, and this has led to the use of nasal bone evaluation in Down's syndrome screening.[5] The orbits can be identified as well. While the lips can be seen at these gestational ages in some fetuses, they cannot be reliably evaluated in a significant proportion of cases.

Fetal spine

The cervical and cervical spines can be evaluated in the first trimester. Unfortunately, the lumbar and sacral spines, in which spina bifida are much more likely to occur, are often not well imaged prior to the second trimester.

Fetal heart

Aside from cardiac axis, the structure of the fetal heart is generally not well evaluated at 14 weeks' gestation or earlier. Four-chamber view, outflow tracts, ductus arteriosus, and the aortic arch cannot be evaluated in many cases at these gestational ages.[6]

Abdomen

An intact diaphragm and stomach bubble are visible at 11–14 weeks in most cases. The umbilical cord insertion in the ventral wall and the urinary bladder just below the site of cord insertion can be seen in the vast majority of fetuses as well. The kidneys can usually be identified, though this is not possible in a small proportion of cases.

Extremities

By 11 weeks, high-resolution ultrasound can document the presence of all long bones in the extremities in most fetuses. Reference ranges for limb measurements early in pregnancy have been published.[7] The hands and feet are usually easily identified. Evaluation of the fingers is possible, though this may be limited prior to the second trimester.

Diagnosis of fetal anomalies at 11–14 weeks

While we can identify many structures by the end of the first trimester, sonographic diagnosis of abnormalities in these structures is limited. Although first-trimester sonographic diagnosis has been reported for a wide variety of anomalies,[4,8–10] relatively few can be reliably diagnosed or excluded with confidence. The following anomalies can be reliably diagnosed or excluded sonographically in most cases at the 11–14 weeks' scan.

Anencephaly/acrania

Anencephaly and acrania are characterized by the absence of a cranial vault. Both conditions are easily identified or excluded after 10 weeks' gestation.[11] While anencephaly is characterized by absence of the cranial vault and the cerebral cortex, the latter structure can be seen in acrania (Figure 75.1). Both conditions are uniformly lethal. While there is some controversy as to whether acrania is due to failed closure of the rostral portion of the neural tube (as is anencephaly), women should be counseled to take high doses of folic acid starting prior to conception in future pregnancies to prevent open neural tube defects.

Figure 75.1 Acrania at 11 weeks' gestation. No bony structures are seen above the level of the orbits. Brain tissue can be seen. This would not be visualized in the case of anencephaly.

Holoprosencephaly

This condition is due to the failure of the forebrain to cleave into hemispheres early in gestation. Alobar holoprosencephaly, in which no midline structures are noted and only a single ventricle is present, is the most severe variant. This condition should be strongly suspected when two separate choroid plexuses are not seen in a transverse view through the fetal brain. Alobar holoprosencephaly can be diagnosed or excluded after 10 weeks' gestation[12] (Figure 75.2). Semilobar and lobar holoprosencephaly, in which some form of midline division has occurred, cannot always be detected prior to the second trimester.

While not lethal in all cases, alobar holoprosencephaly is associated with virtual absence of cognitive function. Cytogenetic studies are indicated, as this abnormality is associated with trisomy 13 as well as other less common forms of aneuploidy. As holoprosencephaly has been described to have autosomal recessive inheritance in some families,[13] recurrence can be excluded with identification of normal midline structures by the end of the first trimester.

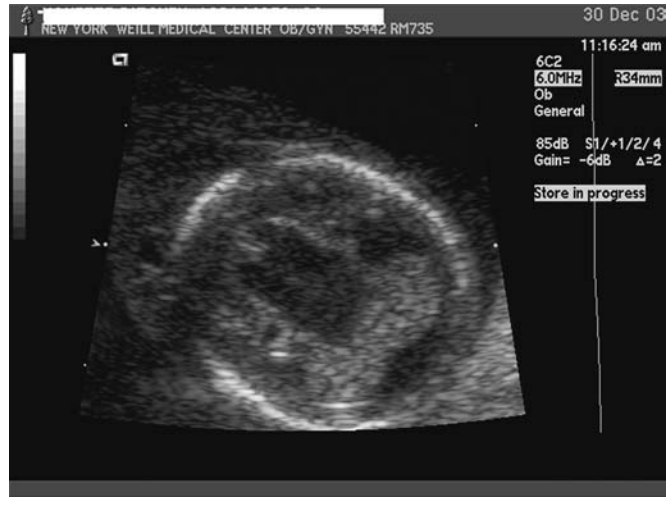

Figure 75.2 Alobar holoprosencephaly at 12 weeks' gestation. A single, small crescent-shaped holoventricle is seen anteriorly. The thalami are large, and not divided by a third ventricle. Separate choroid plexuses are not seen.

Cephalocele

Cephalocele is characterized by a defect in the skull, with protrusion of the meninges. In most cases, there will be brain tissue in the meningeal sac (encephalocele). Most midline cephaloceles are open neural tube defects, though they are much less common than either anencephaly or spina bifida. When a non-midline cephalocele is detected, amniotic band syndrome may be present.

Ultrasound can detect cephalocele at 11–14 weeks (Figure 75.3). Large cephaloceles are easily identified, though smaller ones may not be seen early in pregnancy. In patients with a prior fetus with Meckel–Gruber syndrome, which is characterized by cephalocele, multicystic kidneys, and polydactyly, first-trimester ultrasound can be used to detect early signs of recurrence of this autosomal recessive condition.[14]

Figure 75.3 Encephalocele at 12 weeks' gestation. In this profile view, a midline skull defect is seen above the level of the occiput.

Figure 75.4 Omphalocele at 13 weeks' gestation. A large sac containing bowel and liver is seen.

Omphalocele

Omphalocele is a midline ventral wall defect. All layers of the abdominal wall are absent at the site of the umbilical cord insertion, and a sac can be seen protruding from this site. The sac usually contains bowel and stomach. In larger lesions, liver may be present. The umbilical cord can be seen inserting into the sac.

It is important not to confuse physiologic midgut herniation, which occurs prior to 11–12 weeks' gestation, with omphalocele.[15] After 12 weeks' gestation, omphalocele, particularly if a large defect is present, is easily identified (Figure 75.4). Omphalocele is frequently associated with trisomy 18 or trisomy 13.

Figure 75.5 Megacystis at 11 weeks' gestation. A cystic midline mass is seen in the pelvis.

Skeletal defects

Though fetal long bones can be identified and measured late in the first trimester, most skeletal dysplasias that are characterized by abnormal limb growth cannot be reliably detected or excluded early in pregnancy.[16] Limb reduction defects, which occur sporadically, are characterized by the absence of all or a large part of an extremity, which can be identified at the 11–14 weeks' scan.

Megacystis

In this condition, the fetal urinary bladder is markedly enlarged (Figure 75.5). A longitudinal diameter of > 7 mm has been suggested to establish the diagnosis.[17] While the presence of megacystis does not indicate a specific diagnosis, high rates of fetal aneuploidy (especially when NT is abnormal) and obstructive uropathy have been reported.[18] The presence of megacystis is an indication to evaluate the genitourinary tract for obstructive uropathy early in the second trimester.

Approach to screening

In patients who present for ultrasound late in the first trimester, evaluation of fetal anatomy can provide valuable information. This information can be obtained in a relatively short amount of time in most patients.[4,6] While certain findings (such as nuchal edema or megacystis) are not diagnostic and require second-trimester follow-up, some conditions can be diagnosed or excluded at this stage in pregnancy. This may be especially useful to those at high risk of

having a fetus with malformations detectable in the first trimester.

Studies evaluating the detection rates for anomalies in the first trimester suggest that the majority of major structural anomalies can be identified or suspected.[4,8,9] As these studies have been done in large perinatal centers, however, it is not clear that similar outcomes can be achieved outside this setting. The experience of the examiner is important, as a learning curve for prenatal diagnosis in the first trimester has been demonstrated.[9]

While evaluation of anatomy at 11–14 weeks is recommended when NT is measured, this examination cannot replace routine second-trimester ultrasound. Comparison of detection rates of fetal anomalies demonstrates higher sensitivity at 16–20 weeks.[9] This is particularly true for cardiac abnormalities, the most common category of malformations.

Conclusion

With the emergence of first-trimester risk assessment for aneuploidy, many patients will be undergoing ultrasound late in the first trimester. If the sole objective of this examination is to measure NT, the opportunity to assess fetal anatomy will be lost. With experience, examination of the fetus at 11–14 weeks' gestation can be accomplished in a short period of time, and patients will have the benefit of early diagnosis of certain anomalies.

76 Fetal nasal bone in screening for Down's syndrome

S. Cicero, J. D. Sonek, G. Rembouskos and K. H. Nicolaides

Introduction

Chromosomal abnormalities represent a major cause of perinatal death and childhood disabilities. Prenatal diagnosis of chromosomal defects necessitates invasive testing. All of the commonly used invasive techniques such as chorionic villus sampling, amniocentesis, and cordocentesis, are associated with a risk of fetal loss risk of about 1%. For this reason, invasive procedures are reserved for pregnancies considered to be at high risk for chromosomal defects. The methods of screening to identify the high-risk group are described in Table 76.1. Screening using ultrasound is based on the fact that most fetuses with chromosomal abnormalities deviate phenotypically from euploid fetuses and many of these deviations can be detected by prenatal ultrasound.

Improvements in ultrasound resolution have allowed us to evaluate and measure very minute fetal structures with a concomitant decrease in the room for error. If they are to be included in prenatal screening protocols, their evaluation must be done with a high degree of precision and accuracy. This can be accomplished only through strict standardization of the fetal image and with appropriate training and an ongoing quality assurance. It is only by strictly adhering to these principles that ultrasound markers can be incorporated into any screening protocol.

Calculation of the individual patient-specific risk of chromosomal defects requires the incorporation of several factors. The first is the background risk, which is based on the maternal age, gestational age, and historical factors such as a previous offspring with aneuploidy. The background risk is then modified by multiplying it by a series of likelihood ratios, which are based on the results of screening tests (ultrasound and biochemical) carried out during the course of the pregnancy. A series of likelihood ratios can be used in such a fashion to adjust the risk of aneuploidy either at the same time in pregnancy (combined screening) or at different times in pregnancy[1] (disclosure and nondisclosure sequential screening).

Table 76.1 The screening performance of the various tests is compared by examining the detection rate (DR) for a fixed screen positive rate of 5%

Screening test	DR (%)
MA (≥37 years)	30
Maternal serum biochemistry at 16 weeks (AFP and β-hCG and uE3)	65
NT at 12 weeks	80
NT and β-hCG and P-APPA at 12 weeks	90
NT and NB and β-hCG and P-APPA at 12 weeks	96

MA, maternal age; AFP, α-fetoprotein; β-hCG, free β-human chorionic gonadotropin; uE3, unconjugated estriol; NT, nuchal translucency; PAPP-A, pregnancy-associated plasma protein-A; NB, nasal bone.

Background

The physical characteristics of individuals affected by trisomy 21 were initially described by Langdon Down[2] in 1866. He reported that their skin is too large for their body, their face is flat, and the nose is small.[2] In recent years it has become possible to observe these features by ultrasound examination even as early as in the third month of intrauterine life. Extensive studies over the last 15 years have demonstrated that the most effective sonographic marker of trisomy 21, and other chromosomal abnormalities, is increased nuchal translucency (NT) at 11–13^{+6} weeks' gestation. Another promising marker for trisomy 21, which has been extensively studied over the past 5 years, is the absence and hypoplasia of the fetal nasal bones (NB).

This chapter reviews evidence for the association between absence or hypoplasia of the fetal nasal bones and Down's syndrome in the first and second

trimester of pregnancy, and examines the value of incorporating this novel marker in screening policies.

Development of the nasal bones

During the fourth week of gestation, collections of neural crest cells undergo proliferation, forming the nasal placodes. In the sixth week, the nasal placodes of the frontonasal prominence invaginate to form the nasal pits and the lateral and medial processes. The medial nasal processes eventually fuse with the nasofrontal process to form the nasal septum, which in turn grows toward the forming palate, defining the left and right nasal cavities. The cartilaginous frame of the nose is developing at the same time. During the eighth week, initial centers of ossification of the NB appear in the membrane covering the cartilaginous nasal capsule.[3–7]

In 1994 Sandikcioglu *et al.*[8] established standards for the normal prenatal development of the NB. This study showed that the left and right NBs appear as a thin bony contour ventral to the cartilaginous nasal septum in the sagittal plane, and change gradually during growth to wedge-shaped bones. The initial appearance of the NB occurred at different developmental stages in normal fetuses. The smallest crown–rump length (CRL) at which NB was observed histologically was 42 mm corresponding to approximately 10.9 weeks' gestation. Furthermore, the NB was noted to increase in length with advancing gestation and its morphology changes, being overall wider and coming to a sharp point at the anterior tip in the most mature specimens.[8]

Anthropometric and radiological studies

An anthropometric study of 105 patients with Down's syndrome at 7 months to 36 years of age reported that the nasal root depth was abnormally short in about 50% of cases.[9] Keeling *et al.*[10] investigated the abnormal development of the NB in aborted Down's syndrome fetuses. They examined the development of the axial skeleton in 31 human trisomy 21 aborted fetuses at 12–24 weeks' gestation and found a 60% incidence of either NB absence (26%) or NB hypoplasia (34%).[10] Stempfle *et al.*[11] conducted a radiological study and found that the NB was absent in 23% of the 60 Down's syndrome aborted fetuses between 15 and 40 weeks' gestation. The authors also observed that, when present, the NB in the Down's syndrome fetuses was short.[11]

Sonographic, radiological, and histological correlation

Tuxen *et al.*[12] conducted a postmortem radiological study to investigate the presence of the NB in 33 aborted Down's syndrome fetuses at 14–25 weeks' gestation. They found that 30% (10 of 33) of fetuses had either bilateral or unilateral absence of NB. They also performed a histological evaluation of the specimens, which confirmed a complete NB absence in 7 of 10 fetuses. Histological evaluation was not performed in the remaining three, including the two that had unilateral absence of the NB. Presence of an NB was confirmed in all 23 fetuses that had a radiological evidence of NB formation.[12]

Minderer and his colleagues[13] compared prenatal sonographic evaluations of the NB in 17 Down's syndrome fetuses between 11 and 14 weeks' gestation, to those obtained by histological study performed after termination of pregnancy. In this report, the NB could not be examined sonographically in 1 of the 17 cases, due to fetal position, and in the remaining 16 cases the NB was either absent or hypoplastic. By contrast, the histological evaluation of the NB area showed evidence of NB formation in 16 of the 17 cases. Armed with the knowledge of the results of the histological evaluation, the investigators reviewed the ultrasound images of the fetuses originally classified as having an absent NB. They claimed that they were able to now detect evidence of an NB albeit 'smaller, less distinct, and less echogenic'.[13]

A study by Larose *et al.*[14] compared sonographic and radiological findings on the NB in 21 aborted fetuses with trisomy 21. The ultrasonographic evaluations were done between 11^{+3} and 13^{+5} weeks' gestation. The subsequent radiological studies on the aborted fetuses were performed between 13 and 25^{+5} weeks' gestation. Interestingly, the incidence of NB absence on ultrasound was very similar to the one noted on x-ray. However, the ultrasound and x-ray findings were discordant in 9 of the 21 cases (43%). Four of the cases where the NB was present on ultrasound showed no evidence of an NB on x-ray, indicating a possible wrong assessment of the fetal profile by ultrasound. In the other five cases where the NB was noted to be absent on ultrasound, an NB was seen on the x-ray. However, radiological examinations were performed at a later gestational age than that of the ultrasound examination,[14] allowing time between the two examinations for further NB development.

The apparent discrepancies in the NB identification among the three modalities (ultrasound, radiology, and histology) have a number of possible explanations. It is likely that small areas of calcification can be seen on histological evaluation even if those cannot be detected on either ultrasonography or x-ray. The likelihood of picking these up will depend on the number of sections done. Different types of staining were used in the two studies[12,13] mentioned above possibly contributing to the contradictory results. In the study by Larose *et al.*,[14] the ultrasounds and the x-rays were done at very different gestational ages (11^{+3}–13^{+5} weeks for ultrasound and 13–25^{+5} weeks for x-ray). Since the prevalence of NB absence

changes with gestational age, they are not truly comparable. Just as is the case with the ultrasound examination, controlling for the gestational age and standardization of the technique for both the radiological and the histological examinations is crucial.

Sonographic studies

The observation that in fetuses affected by trisomy 21 sonographic examination may reveal absence of the NB was only made at the beginning of 2001. In the initial description by Sonek and Nicolaides,[15] three Down's syndrome fetuses were evaluated in the second trimester. Two of them had no identifiable NB and one had a hypoplastic NB. A review of the videotaped exam from the first trimester examination of one of the fetuses at the time of the NT evaluation revealed that the NB could not be identified at that point in pregnancy.[15] Armed with this information, observational studies were undertaken to investigate the role of NB examination in screening for Down's syndrome.

First trimester: the 11–13^{+6}-week scan

Several studies have demonstrated that the fetal NB can be visualized by sonography in the first trimester of pregnancy, and that there is a high association between absent NB at 11–13^{+6} weeks and trisomy 21, as well as other chromosomal abnormalities.[16–25]

Cicero *et al.*[16] reported for the first time on the absence of the NB in trisomy 21 fetuses in the first trimester of pregnancy. In this observational study, ultrasound was used to determine the presence or absence of the NB in 701 fetuses at 11–13^{+6} weeks' gestation following screening by maternal age and NT, and immediately before chorionic villus sampling. The NB was noted to be absent in 73% (43 of 59) of Down's syndrome fetuses and in only 0.5% (3 of 603) of chromosomally normal fetuses. In this initial study, presence or absence of the NB was found to be independent of other fetal and maternal variables. It became clear that incorporation of the examination of the NB into screening for trisomy 21 by maternal age and NT could increase the sensitivity of the test and reduce the false positive rate.[16]

In an extended series[18] of 5918 fetuses undergoing prenatal diagnosis by chorionic villous sampling at 11–13^{+6} weeks, the fetal profile was successfully examined in 5851 (98.9%) cases. The NB was absent in 129 of 5223 (2.5%) chromosomally normal fetuses, in 229 of 333 (68.8%) fetuses with trisomy 21 and in 95 of the 295 (32%) with other chromosomal defects. An additional important finding of this study is that the prevalence of NB absence was higher in fetuses of Afro-Caribbean origin than in Caucasians (Table 76.2). The prevalence was also noted to decrease as the gestational age increased (Table 76.3) and to increase as the NT measurement increased beyond the normal range (Table 76.4). Consequently, in the calculation of an individual patient-specific risk for trisomy 21 it is necessary to take into account these demographic and ultrasound findings.[18]

The fact that ethnic origin of the mother may play a role on the evaluation of the fetal NB, was also suggested by Prefumo *et al.*[26] The authors conducted a prospective study in 4492 fetuses and demonstrated that having a mother of African origin is significantly associated with an increased likelihood of absent fetal NB compared with Caucasians, even after correcting for maternal age, parity, and CRL.

There are seven additional studies[19–25] that support the high association between trisomy 21 and absent NB at 11–13^{+6} weeks. In their combined data on 12,315 fetuses the fetal profile was successfully examined in about 97% of cases. The NB was absent in

about 1% of chromosomally normal fetuses and in 67% of the fetuses with trisomy 21.

Malone *et al.*[27] reported the results of a multicenter study which included 6316 fetuses scanned at 10–14 weeks' gestation. The nasal bone could be evaluated in only 75.9% of the cases. The NB was apparently present in all nine of the trisomy 21 fetuses where the NB could be evaluated. Their results contrast with the above published studies in a number of ways. The fact that the fetal nose could be examined only in 75.9% of the cases bring up questions regarding the level of training involved in this study and the fact that the NB was reported as being present in all nine trisomy 21 fetuses bring up questions regarding the technique. Furthermore, images published by the lead authors of this study suggest that their technique may not be consistent with that used by others.[28] Similarly, De Biasio and Venturini,[29] who retrospectively examined the images obtained for measurement of NT, reported that the NB was present in all five fetuses with trisomy 21. However, the five images that they published did not meet accepted criteria for either the measurement of NT or for examination of the NB.

Based on the vast majority of the currently available data (Table 76.5), it can be concluded that at $11–13^{+6}$ weeks the fetal profile can be successfully examined in about 98% of cases. The NB is absent in about 65% of trisomy 21 fetuses but only in about 1% of chromosomally normal fetuses.[16–25] Consequently, absence of the NB is an important marker of trisomy 21. However, appropriate adjustments need to be made on the basis of maternal ethnic origin, fetal CRL and NT when calculation of individual patient-specific risk for trisomy 21 is performed.[18]

Second trimester: 15–24-week scan

Absence or hypoplasia of the NB represents a new ultrasound marker in the second trimester of pregnancy as well, and it is likely to have a major impact on screening for trisomy 21 during the 16–24-week scan. Its benefit has now been confirmed in large trials.

Bromley *et al.*[30] assessed the NB using ultrasound in 239 fetuses between 15 and 20 weeks' gestation. Six (37%) of the 16 Down's syndrome fetuses had no

detectable NB. Among the fetuses with a normal karyotype, absence of the NB had a prevalence of 0.5%. In this study, absence of the NB was associated with a likelihood ratio for Down's syndrome of 83. Interestingly, in 2 of the 16 (13%) Down's syndrome fetuses, NB absence was the only abnormal finding. In addition, the NB length was found to play an important role. Biparietal diameter (BPD) to NB length (NBL) ratio was generated to control for the gestational age and the size of the fetus. This ratio increases as the NB becomes shorter. Using the BPD/NBL ratio of 10 or greater as a cut off in screening for Down's syndrome gives this test sensitivity of 81% with a false positive rate of 11%. This study confirmed that NB length increases linearly with gestation in chromosomally normal fetuses. However, the NB length in Down's syndrome fetuses was found to be uniform over the gestational age investigated (3.5 ± 0.47 mm) suggesting the possibility that a single cut-off value for NB length may be appropriate in Down's syndrome screening in the first half of the second trimester.[30]

Such approach was used in another study[31] looking at the utility of NB evaluation in the second trimester (15–22 weeks). The authors examined the fetal profile in 1046 singleton pregnancies undergoing amniocentesis for fetal karyotyping at 15–22 weeks. The NB was absent or hypoplastic (< 2.5 mm) in 21 of the 34 (61.8%) fetuses with Down's syndrome, in 12 of 982 (1.2%) chromosomally normal fetuses, and in 1 of the 30 (3.3%) with other chromosomal defects. It was noted that the prevalence of NB hypoplasia was higher in the euploid Afro-Caribbean population (8.8%) in comparison to the Caucasian population (0.5%), suggesting for the first time that adjustments based on ethnicity may need to be made when using the NB for screening in the second trimester as well. Furthermore, the overall likelihood ratio for trisomy 21 for hypoplastic NB was 50.5 (95% CI 27.1–92.7) and for present NB it was 0.38 (95% CI 0.24–0.56).[31]

Bunduki *et al.*[32] looked at the utility of NB measurement in the second trimester (16–24 weeks' gestation) in 1631 patients. The association between hypoplasia of the NB and Down's syndrome was also demonstrated. Using the 5th percentile of the normal curves generated in the same study as a cut off for screening for trisomy 21, a sensitivity of 59% was achieved.[32]

Vintzileos *et al.*[33] looked retrospectively at profiles of 29 Down's syndrome fetuses between 17.7 and 20.7 weeks' gestation. The NB was absent in 12 of the 29 (41%) fetuses with trisomy 21 and in none of the 102 chromosomally normal fetuses.[33]

A prospective study involving ultrasound evaluation of the fetal NB between 19 and 22 weeks' gestation[34] also looked at the utility of NB length and its presence or absence in screening for Down's syndrome. The normal NB ranges were based on examinations of 1913 fetuses. All five Down's syndrome fetuses in the study had either an absent NB or a NB length below the 2.5th percentile. None of the fetuses with other chromosomal abnormalities had a short or absent NB.[34]

It is premature to speculate on the precise detection rates that could be achieved in the second trimester

by a combination of maternal age, serum biochemistry, and ultrasound examination for the fetal NB and other sonographic markers. Nevertheless, on the basis of currently available data, nasal hypoplasia is likely to be the single most sensitive and specific second trimester marker of trisomy 21.

Ultrasound examination of the nasal bone: technique

Ultrasound evaluation of the NB requires strict adherence to standard criteria and it is essential that the operators performing this examination undergo adequate training and gain extensive experience.[35,36]

The need for adequate training is highlighted by a study published in 2003,[37] which looked at the extent of training needed for 15 sonographers experienced in measuring fetal NT, to become competent in examining the fetal NB at 11^{+0}–13^{+6} weeks' gestation. The study demonstrated that the number of supervised scans required to achieve proficiency is on average 80 with a range of 40–120. However, evaluation of the NB does not appear to significantly impact the length of the ultrasound examination.[37]

This was confirmed in a study of 501 consecutively scanned fetuses by experienced sonographers. The authors reported that the fetal NB could be successfully examined and measured in all cases without extending the length of time required for scanning.[38]

With a few minor exceptions, the method of NB evaluation is very similar in both the first and second trimesters of pregnancy. The NB should be seen as an echogenic line within the nasal bridge, i.e., underneath the nasal skin. This is usually not a difficult task in the second trimester. The following is a description of the technique at 11–13^{+6} weeks' gestation:

1. The fetal CRL should be 45–84 mm. There is no value on examining the fetal NB before this gestational age, as the NB first appears at a CRL of 42 mm.[8]
2. The image should be magnified so that the head and the upper thorax only are included in the screen (Figures 76.1 and 76.2).
3. A mid-sagittal view of the fetal profile should be obtained with the ultrasound transducer held in parallel to the direction of the nose (i.e., ultrasound beam perpendicular to longitudinal axis of the NB). The ultrasound transducer should then be gently tilted from side to side to ensure that the NB is seen separate from the nasal skin. The fetus should be facing the transducer.
4. When the correct view is obtained, three distinct lines will be visualized: the first two lines, which are close to the forehead, are horizontal and parallel to each other resembling an 'equal sign' (Figure 76.1). The top line represents the skin and the bottom one, which is usually thicker and more echogenic than the overlying skin, represents the NB. Therefore, it is the absence of the bottom line of the 'equal sign' that represents absence of the NB (Figure 76.2). A third line located distally to the 'equal sign' and at a slightly higher level, represents the tip of the nose.
5. If the bottom line of the 'equal sign' is completely absent, the diagnosis of NB absence is fairly straightforward. Occasionally, a line that is thinner and less echogenic than the skin line is noted within the nasal bridge. This may either represent a NB that is not yet ossified or an unusually prominent cartilage. Either way, this finding should also be classified as nasal bone absence. Similarly, the

Figure 76.1 Fetal profile at 12 weeks of gestation in a normal fetus showing the nasal bone.

Figure 76.2 Fetal profile at 12 weeks of gestation in a trisomy 21 fetus showing absence of the nasal bone.

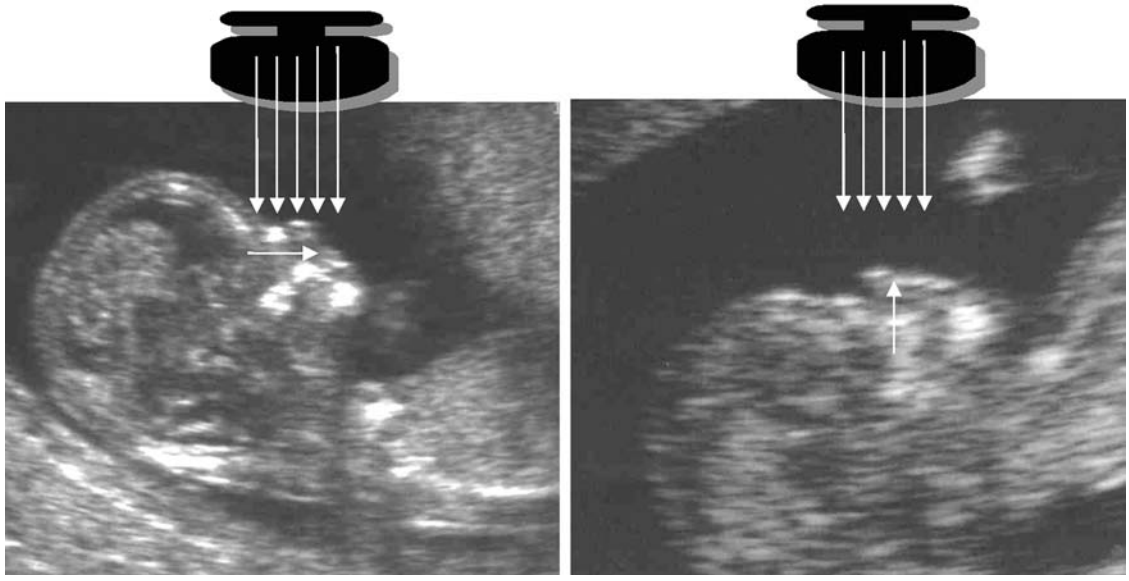

Figure 76.3 The best angle of insonation to assess the nasal bone in the first trimester is 90° to the longitudinal axis of the nasal bone (i.e., the beam of the ultrasound perpendicular to the longitudinal axis of the nasal bone) (left). Evaluation of the nasal bone should not be attempted with either a 0° or 180° angle of insonation (i.e., with the ultrasound beam parallel to the longitudinal axis of the nasal bone) (right).

presence of a tiny echogenic dot that can occasionally be seen in the area of the nasal bone should not be interpreted as NB presence.

6. If the NB is noted to be absent at 11–11^{+6} weeks' gestation, it is our recommendation to repeat the examination 1–2 weeks later because of the relatively high false positive rate at this early gestational age. Risk assessment is based on the results of the repeat examination.

Two techniques for caliper placement have been employed to measure the NB in the first trimester of pregnancy: measuring the central hyperechogenic region only or including the entire length of the echogenic line.[21,39]

The angle of insonation used to evaluate the NB is extremely important. The best angle of insonation used to simply differentiate between the presence and the absence of the NB is 90° to the longitudinal axis of the NB (i.e., the beam of the ultrasound perpendicular to the longitudinal axis of the NB) (Figure 76.3). Evaluation of the NB should not be attempted with either a 0° or 180° angle of insonation (i.e., with the ultrasound beam parallel to the longitudinal axis of the NB) (Figure 76.3). At this angle, the NB is insonated at its thinnest dimension and the lateral resolution of the ultrasound equipment available today is not sufficient to reliably detect the NB in this view. When the transducer is adjusted to an angle of insonation approaching 45° or 135°, the lateral scatter at the ends of the NB is reduced rendering the NB ends as more sharply delineated (Figure 76.4). This is helpful in the second trimester to improve the accuracy of NB length measurement. Figures 76.5–76.7 show absence, hypoplasia, and presence of NB in the mid-second trimester.

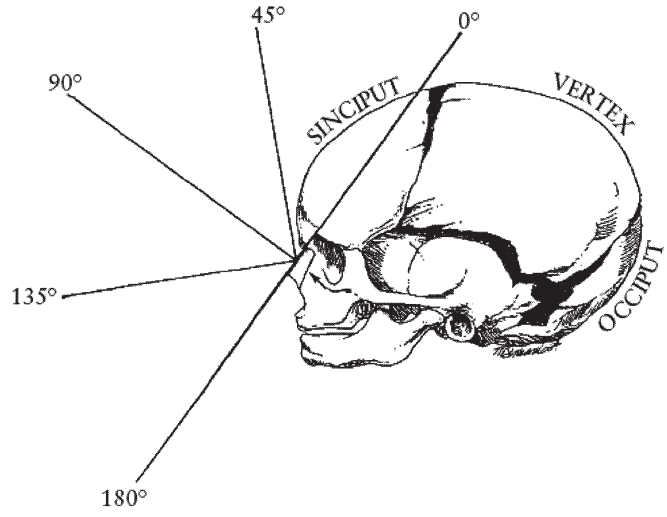

Figure 76.4 Diagrammatic representation of the bony structures of the fetal face with angles of insonation. Reprinted and adapted with permission from O'Brien W, Cefalo R. Simpson J, eds. *Obstetrics: Normal and Problem Pregnancies*, 3rd edn. New York: Churchill Livingstone, 1996:393.

Several factors make the ultrasound examination challenging; the foremost of these are maternal habitus and an unfavorable fetal position, such as hyperextension or vertical position. Others factors, such as large uterine fibroids or, early in pregnancy, retroflection of

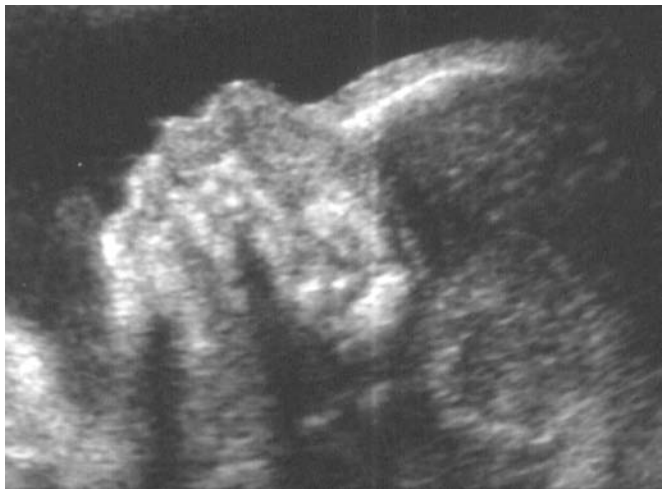

Figure 76.5 Fetal profile at 20 weeks of gestation in a trisomy 21 fetus showing absence of the nasal bone.

Figure 76.6 Fetal profile at 20 weeks of gestation in a trisomy 21 fetus showing absence of the nasal bone.

Figure 76.7 Fetal profile at 20 weeks of gestation in a normal fetus showing presence of the nasal bone.

the uterus can also make the examination difficult. Fetal small parts, especially the hand, often lie in close proximity to the fetal face, especially early in gestation. This can lead to erroneous results in two ways. If the digits are actually resting on the fetal face they can mimic the NB. Small parts in front of the fetal face, but not actually resting on it, can produce an obscuring effect and may create an erroneous impression of NB absence. Finally, fetal face contains other echogenic structures, which are located laterally to the NB, which can give the incorrect impression that the NB is present if the correct technique is not followed. These structures include the medial aspect of the orbis oculi and the maxilla. Being able to demonstrate either the presence or the absence of the NB from several different angles will make the correct diagnosis more certain.

Occasionally, the addition of transvaginal sonography can be a helpful adjunct. However, the directions and angles with which the fetus can be viewed using this approach are limited. Rarely, the patient may need to be asked to return for a follow-up if the initial examination is not satisfactory.

Three-dimensional assessment of the nasal bones

The role of three-dimensional (3D) sonography and its potential benefit in the assessment of the fetal NB, has been investigated in the last 2 years in the first, second, and third trimesters of pregnancy. The published studies have focused on trying to overcome the technical difficulties encountered during routine two-dimensional (2D) sonography, and on further investigating aspects of the NB development, by using different techniques such as multiplanar imaging and 3D rendering of the facial bones.

First trimester of pregnancy

The two major technical problems in the assessment of the fetal NB during the $11–13^{+6}$-week scan are the need to obtain a mid-sagittal view of the fetal profile and the need for the angle between the ultrasound beam and the fetal profile to be about 45° (i.e., ultrasound beam perpendicular to the NB). In the acquired

3D volume, multiplanar imaging permits to view a true mid-sagittal section of the fetus using the optimal angle. However, in the first study published on 3D assessment of the NB in the first trimester of pregnancy, Rembouskos *et al.*[40] found that the optimal visualization of the fetal NB in a reconstructed view of the nasal bridge by 3D multiplanar imaging, is entirely dependent on the initial 2D section. In this study, the authors demonstrated that in order to obtain a good quality volume, the initial section should be taken with a sagittal view of the fetal profile facing upwards, and that the angle between the fetal profile and the ultrasound beam should be in a range of 30–60°, with maximum quality at 45°. In volumes obtained in any other initial 2D view, the visualization of the fetal NB was poor at this gestation, and could lead to an erroneous diagnosis of absent NB. Consequently, the inability to examine the NB by 2D scanning because of the fetal position cannot be overcome by 3D ultrasound.[40]

In correctly acquired volumes, 3D multiplanar mode permits further assessment of both NBs. Peralta *et al.*[41] used this technique to examine the gap between the two NBs at 11–13^{+6} weeks of gestation, and compared the 3D findings to those obtained following 2D examination. The authors found that a gap between the NB is present in about 20% of the fetuses examined by 3D. When the gap measured 0.6 mm or more (40% of cases), it was possible to obtain a perfect mid-sagittal plane where the NB could erroneously be considered absent. By contrast, in all cases in which the gap was less than 0.6 mm, the NB was visualized in the perfect mid-sagittal plane. These findings can be explained by the limit of the lateral resolution of the ultrasound equipment. However, none of the cases with a gap was associated with a diagnosis of absent NB when the examination was performed with the 2D scan, and therefore the false positive rate would not increase. Furthermore, the authors observed that, when using the multiplanar mode, unilateral or bilateral absence of the NB could be demonstrated in about 1% of the chromosomally normal fetuses, and in 61% of the fetuses with trisomy 21. In about 10% of trisomy 21 fetuses only one of the two NB was absent. However, all the cases with unilateral absence demonstrated with the 3D scan, were classified as 'absent' NB during the 2D ultrasound examination, and therefore the sensitivity of the test, when performed by 2D sonography, would not decrease.[41]

In the original description of the technique for examination of the fetal NB by 2D ultrasound,[16] it was suggested that, once obtained the mid-sagittal section of the fetus, the transducer should be gently tilted from one side of the fetal profile to the other, in order to adequately examine the NB. Therefore, by using this technique, it is extremely unlikely that the presence of a gap can lead to a false positive diagnosis of absent NB when 2D sonographic assessment of the NB is undertaken.[16]

Second and third trimesters of pregnancy

The role of multiplanar imaging and 3D rendering of the NB have also been evaluated in the second and third trimesters of pregnancy. It has been suggested that 3D ultrasonography allows a better description of normal, absent, hypoplastic and unilaterally absent NB.[42–44]

Lee *et al.*,[42] used the multiplanar mode to evaluate the NB of 20 fetuses with Down's syndrome and 20 fetuses with normal karyotype, between 16 and 30 weeks' gestation. Two examiners independently evaluated the same images. The prevalence of absent NB in the fetuses with Down's syndrome was 40% (8 of 20) and 45% (9 of 20) by examiner #1 and examiner #2, respectively. These results were similar to those observed by 2D sonography. However, the prevalence of absent NB in the normal population was 20% (4 of 20) and 10% (2 of 20) by examiner #1 and examiner #2, respectively. These prevalences are much higher than those reported using 2D sonography during this gestational time period (< 1.3%). These data suggest that routine application of 3D assessment of the NB in screening for trisomy 21 could increase the false positive rate.[42]

More recently, Benoit and Chaoui[44] assessed the unilateral absence of NB by using 3D rendering of the facial bones in the second and third trimesters. Out of the 20 fetuses with Down's syndrome, 9 (45%) had nasal bone absence noted on the 2D ultrasound. Six had bilateral nasal bone absence documented on the 3D ultrasound and three had unilateral absence with the discernible nasal bone being hypoplastic in two fetuses and normal in length in one. None of the 18 euploid fetuses evaluated had an absent nasal bone on 2D ultrasound and all had both nasal bones present on 3D. In this study, similarly to what Peralta *et al.*[41] found in the first trimester, in all Down's syndrome fetuses with unilateral absent NB, that the 2D assessment of the nasal bridge was consistent with an 'absent' NB.[44] It appears that unilateral nasal bone absence does not increase the false negative rate.

Integrated first-trimester sonographic and biochemical screening

A retrospective case–control study,[45] comprising 100 trisomy 21 and 400 chromosomally normal singleton pregnancies at 11–13^{+6} weeks of gestation, and a subsequent study which extended this series of data[46] looked at the feasibility of combining the NB evaluation the NT measurement and maternal serum free β-hCG and PAPP-A in screening for Down's syndrome. Firstly, it was concluded that the presence or absence of the NB is independent of the serum biochemistries. Secondly, it was estimated that combining all four markers and maternal age would yield a Down's syndrome detection rate of 96% for a false positive rate of 5%.[45,46]

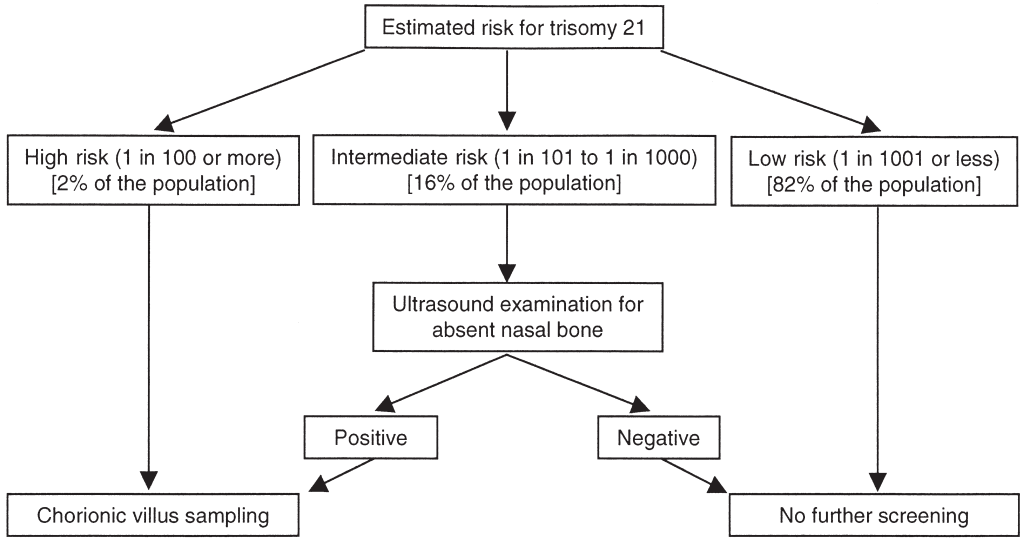

Figure 76.8 New individual risk orientated two-stage approach to first-trimester screening, (Nicolaides *et al.*[50]). Screening by maternal age, fetal nuchal translucency and maternal serum free β-human chorionic gonadotropin and pregnancy-associated plasma protein-A.

Nasal bone reference ranges by ultrasound

First trimester

Cicero *et al.*[39] reported that in the chromosomally normal group the fetal NB length increases significantly with CRL from a mean of 1.3 mm at a CRL of 45 mm to 2.1 mm at CRL of 84 mm. The Down's syndrome fetuses with a detectable NB tended to have a shorter NB than the chromosomally normal fetuses. However, the difference in the NB lengths was not sufficiently great to be of clinical utility.[39]

Second trimester

Guis *et al.*[47] published reference ranges for NB lengths, based on 376 cases, between 14 and 34 weeks' gestation. Sonek *et al.*[48] provided reference range based on a larger number of patients (3547) and for a wider gestational range (11–40 weeks) using the ultrasound technique described above was published in 2003.

Impact of the nasal bone evaluation in screening for trisomy 21 in the first trimester of pregnancy

This chapter reviews studies to date, which overwhelmingly support the significant contribution which NB evaluation makes to ultrasound screening for Down's syndrome. The clinical implementation of this method may take form in essentially two ways. The optimal approach would be for operators who perform NT screening to be also proficient in NB evaluation. However, since the preliminary data indicate that NB evaluation may require more expertise and experience than NT evaluation an alternative approach was recently proposed by Nicolaides *et al.*[50] Their proposed policy involves a two-stage screening approach (Figure 76.8). The first stage consists of screening using the combination of maternal age, fetal NT, and maternal serum free β-hCG and PAPP-A at 11–13^{+6} weeks' gestation. The results of the initial screen would be then divided into three categories: high risk (risk estimate of 1:100 or greater), intermediate risk (risk estimate of 1:101 to 1:1000), and low risk (risk estimate of 1:1001 or less). The authors proposed that the high-risk group should be offered chorionic villus sampling and that the low-risk group can be reassured that their fetus is unlikely to have a chromosomal abnormality. The intermediate group would undergo further ultrasound evaluation to determine the presence or absence of NB. The patients where the fetus is noted to have an absent NB would be offered chorionic villus sampling and those with a present nasal bone would be reassured. The authors modeled the performance of this approach on their prospective experience with combined screening in 75,821 singleton pregnancies and their published experience with NB evaluation. They estimated that using this approach the detection rate for an overall false positive rate of 2% would be approximately 92%. This compares favorably to using the combined screen alone where the detection rate is approximately 80% for the same false positive rate.[50–53]

Conclusion

Trisomy 21 is the most common chromosomal abnormality found at birth, with an incidence of about 1:600. However, the sonographic appearance of individuals with Down's syndrome, is often quite similar to those with normal karyotype, making screening for Down's syndrome more difficult compared to that of other chromosomal abnormalities. Hence the importance of a continued search for markers, that would accurately discriminate between affected and unaffected fetuses.

The sonographic appearance of increased NT and absent/hypoplastic NB could be due to connective tissue abnormalities.[54–56] The increased thickness of subcutaneous tissues in association with Down's syndrome has lead to the development of screening based on the NT measurement between 11 and 13^{+6} weeks of gestation, which is the most sensitive and specific ultrasound marker for this condition.[57]

Several studies have demonstrated that the best screening test for trisomy 21 in the first trimester of pregnancy is based on the combination of maternal age, fetal NT thickness, and maternal serum free β-hCG and PAPP-A. This test allows a detection rate of 90% for a false positive rate of 5%.[5,34,50] By adding the ultrasonographic evaluation of the NB, a sensitivity of over 90% could be achieved for a false positive rate of about 2%.[45,46,50] In the second trimester, the finding of an absent NB yields likelihood ratios for Down's syndrome of 51–83.[30,31]

Although extensive studies have demonstrated that absence of the NB is a highly sensitive and specific marker of trisomy 21, its examination in the first trimester requires highly skilled operators. Therefore, incorporation of this marker into the $11–13^{+6}$-week scan can come about only after extensive training and experience. It may be that this sonographic marker will be primarily used in specialized centers to reevaluate the risk in patients with an intermediate risk level category after an initial screening using fetal NT and maternal serum biochemistry as a part of a two-stage screening method.[50]

The introduction of individual risk-orientated two-stage screening for trisomy 21,[50] which includes examination of the fetal NB in those women with a individual risk between 1:101 to 1:1000, could increase the detection rate to more that 90%, and the false positive rate could be decreased to about 2%. This is important for three main reasons: firstly, the low false positive rate reduces the number of miscarriages of chromosomally normal fetuses associated with invasive testing;[58,59] secondly, the decrease in the number of invasive tests results in a reduction of economic costs; thirdly, this approach provides an early reassurance to pregnant women and, for those with an affected fetus, allows the possibility of an early termination of pregnancy.

In order to reproduce these results, it is imperative that sonographers receive appropriate training and adhere to a standard technique for the measurement of NT and the assessment of the NB. Furthermore, the success of a screening program necessitates the presence of a system for regular audit of results and continuous assessment of the quality of images such as the one established by the Fetal Medicine Foundation.[60]

77 Second-trimester ultrasound screening of fetal anomalies

L. Yeo and A. M. Vintzileos

Introduction

It is an unfortunate fact that birth defects sometimes occur in human development.

In fact, they are the single most common cause of perinatal mortality in many countries. It is important to detect fetal congenital anomalies prior to birth for various reasons, such as delivering at a tertiary care center, offering prenatal surgical correction, giving the option of invasive testing, and appropriately and accurately counseling parents.

While there are varying modalities that currently exist to screen for fetal anomalies (such as magnetic resonance imaging and fetoscopic examination), the most accepted method is ultrasonographic imaging. The concept of prenatal ultrasonography as a screening tool has received widespread acceptance among both physicians and patients. Unlike biochemistry screening, ultrasound is a very tangible and realistic tool that provides a visible assessment for patients. Accordingly, the second trimester is often utilized because fetal anatomic structures are readily assessed at this time of pregnancy. Once sonographic screening in the second trimester reveals the presence of abnormalities, further diagnostic testing may be offered to the patient such as amniocentesis or percutaneous umbilical blood sampling. Although the advantage of performing sonography in patients at high risk for fetal structural anomalies is clear, the benefits and cost-effectiveness of routine ultrasound screening in low-risk pregnant patients are not as clear.

This chapter focuses on the components of a normal fetal anatomic survey, second-trimester sonographic markers for aneuploidy, and describes the value of sonographic second-trimester screening.

Second-trimester fetal anatomic survey and its contents

Because ultrasonography utilizes sound waves to provide imaging capability, it has rapidly become the most commonly used method for imaging during pregnancy. Its major advantages include lack of adverse fetal effects,[1] the ability to view the fetus in real-time mode (with capabilities of observing and studying fetal behavior/movements), and most recently the ability to acquire a volume of data to generate three-dimensional imaging. With the introduction of two-dimensional static scanning in the early 1970s, physicians were allowed to view the fetus for the first time. Subsequently, in the late 1970s and early 1980s, real-time B-mode imaging became widespread as a clinical tool. However, despite its many technological advancements over the years, many in the USA still believe that the appropriate use of fetal sonography should be limited to only where there is an indication. This is despite the fact that detailed examination of the fetus for both aneuploidy markers and structural abnormalities has become a true reality. In contrast, many European countries perform ultrasound examinations routinely during pregnancy.

In order to screen for fetal abnormalities on a second-trimester ultrasound, the sonographer must be able to recognize normal fetal anatomy first. Accordingly, we will describe the features of a targeted, complete fetal anatomic survey on ultrasound. There are many possible indications to undergo an obstetrical exam, such as estimating gestational age and/or growth, vaginal bleeding, multiple gestation, history or prior congenital anomaly or syndrome, placental localization, adjunct to interventional or invasive procedures, biophysical profile, and evaluation of amniotic fluid quantity. In most cases, ultrasonography will provide reassurance of a normal and healthy fetus. Because most anomalies are sporadic and often occur in otherwise low-risk women, we believe that all patients regardless of risk should have uniform access to obstetrical sonography in the second trimester. Most importantly, this should be performed with a high level of expertise, since both false-positive and false-negative information can have a detrimental impact. A systematic fetal anatomic survey is able to detect the majority of fetal malformations,[2] and can

also evaluate fetal growth, amniotic fluid, placenta, and cervix. To be effective, the sonographic exam should be performed systematically, and with complete thoroughness.

Recently, we examined the value (from the patient's perspective) of a targeted ultrasound performed after an abnormal karyotype was discovered.[3] All patients valued the ultrasound because it provided visualization of anomalies, and this additional information influenced pregnancy management. Interestingly, all patients thought that the impact of sonography was superior to chromosomal diagnosis alone, and all believed that sonography should be utilized in patients facing likewise clinical situations. These patients found sonography invaluable because it provided more information and helped them to accept the diagnosis of fetal aneuploidy.

Published guidelines exist that describe the components of a complete obstetrical ultrasound. This involves both biometric measurements, which reflect gestational age, growth or size, and evaluation of specific organ structures for the absence/presence of anomalies. In 1994, the American Institute of Ultrasound in Medicine published standards for the performance of obstetrical ultrasound.[4] In the first trimester, the requirements include evaluation of the uterus, adnexa, cul-de-sac, gestational sac, crown–rump length, fetal number, and presence/absence of cardiac activity. In the second and third trimesters, the requirements include fetal life/number/presentation/activity (with multiple gestations requiring additional documentation), amniotic fluid, placental location/appearance/relationship to the internal os, fetal biparietal diameter (BPD) or head circumference (HC), limb measurement, estimated fetal weight (requires abdominal diameter or circumference), uterus, cervix, adnexa, cerebral ventricles, posterior fossa, four-chamber view of the heart and position, spine, stomach, kidneys, bladder, abdominal cord insertion site, and umbilical cord.

However, in order to increase the diagnostic sensitivity for fetal anomalies, a more comprehensive exam above and beyond what is required by the American Institute of Ultrasound in Medicine should be performed. Table 77.1 depicts the components of a second-trimester fetal anatomic survey that we routinely perform via ultrasonography. Of course, to carry out this task, other criteria should also be met. For instance, proper sonographic equipment and transducers with the highest-frequency probe should be utilized to maximize fetal anatomic resolution. The sonographers should be adequately and appropriately trained to ensure that these detailed exams are performed at the highest level. To properly recognize fetal anomalies, one must be familiar with normal fetal anatomy, normal variants, and the various sonographic landmarks.

Factors that can limit the ability to adequately examine the fetus sonographically in the second trimester include sonographer expertise, quality of

Table 77.1 Components of second-trimester sonographic fetal anatomic survey (at Robert Wood Johnson Medical School)

Anatomic structures

Head
- Cranial shape, degree of mineralization
- Cerebral hemispheres, cavum septum pellucidum, thalami, cerebral peduncles, lateral ventricles, choroid plexus, third and fourth ventricles, cerebellum and vermis, cisterna magna

Face/neck
- Orbits, nasal bone, lips/palate, profile, nuchal fold, ear length

Thoracic cavity
- Lungs
- Configuration of bony thorax, including ribs and clavicles

Heart
- Four-chamber views (apical and subcostal), both outflow tracts, aortic and ductal arches, inferior and superior vena cavae, valves, atria and ventricular septums

Abdominal
- Situs
- Stomach
- Liver, gallbladder, spleen
- Umbilical vein, portal vein
- Bowel
- Wall/cord insertion site

Genitourinary system
- Kidneys
- Bladder
- Genitalia

Spine

Extremities
- Upper (including bilateral hands)
- Lower (including bilateral feet)

Umbilical cord
- Number of umbilical arteries
- Placental insertion site

Biometry measurements
- Biparietal diameter
- Head circumference
- Atria of lateral ventricles, cisterna magna, nuchal fold (when applicable)
- Cerebellum
- Thoracic circumference (when applicable)
- Abdominal circumference
- Femur lengths, humerus lengths, radius and ulna lengths, tibia and fibula lengths
- Foot length
- Nasal bone length
- Orbital diameters

Other
- Estimation of dates or evaluation of growth
- Number of fetuses, position
- Placenta
- Amniotic fluid
- Cervix/lower uterine segment

ultrasound equipment, length of time spent scanning, incompletely filled or overfilled maternal bladder, maternal habitus, depth of penetration, tissue density, and other scanning characteristics, fibroids, early or advancing gestational age, ossification of fetal bony structures (later in the second trimester), fetal position, and amniotic fluid abnormalities (increased or decreased). Techniques that can improve fetal visualization include using various probes (including transvaginal scanning, for instance, in the obese patient) and changing maternal position (which effectively changes the fetal position).

The timing of scans in the second trimester may vary, depending on the scanning center, indication for the exam (amniocentesis), or physician preference. Later scans (for example, 23–24 weeks) can improve visualization of certain fetal anatomic structures such as the heart and improve overall sensitivity. However, scanning later in the second trimester of pregnancy may limit the window of opportunity for patients who desire termination of pregnancy for various reasons. On the other hand, patients who desire amniocentesis testing may choose to undergo a sonographic survey earlier, such as 16–17 weeks of gestation. Some patients who have had a previous child affected with structural anomalies or genetic syndromes may choose to undergo an initial early scan for some reassurance, and then a more detailed repeat exam later in the pregnancy. At our own center, we schedule fetal anatomy surveys around 18–21 weeks in order to optimize anatomy assessment, and yet still provide patients the opportunity for amniocentesis if necessary. Some studies suggest that among low-risk women, second-trimester ultrasound screening is easier to perform and less likely to require an additional scan at 20–22 weeks than at 18 weeks.[5] Fetal echocardiograms are best performed between 22 and 24 weeks when cardiac structures are large enough, and better visualization and assessment are possible.

With multiple gestations, not only should the fetal anatomy be evaluated, but the number, position of fetuses, and type of dividing membrane should be delineated. In addition, when screening for fetal anomalies sonographically, the placenta and amniotic fluid volume must also always be assessed. Placental appearance, thickness, echogenicity, location, and characteristics should be examined, along with amniotic fluid volume, to rule out polyhydramnios, oligohydramnios, or anhydramnios. These structures can provide clues to a potential anomalous fetus. For instance, polyhydramnios is associated with esophageal atresia, anyhydramnios is associated with renal agenesis, and a thickened placenta can be seen with fetal hydrops.

At the beginning of the examination, the entire uterus should be imaged both transversely and longitudinally to assess fetal position, amniotic fluid volume, and placental location. Determining the right and left sides of the fetus is crucial. Situs solitus is the term used when there is the usual arrangement of organs and vessels within the fetal body. Finally, examination of the lower uterine segment and cervix is important.

The examination of the fetal intracranial anatomy is extremely important since the presence of central nervous system abnormalities can have a major and devastating impact on perinatal morbidity and mortality. From the late first trimester until delivery, the calvarium can be identified. Thus, the BPD and HC can be readily measured. The calvarium should not be hypomineralized (which can indicate a skeletal dysplasia), and should be elliptical in shape. Reverberation artifact from properly mineralized bone will usually obscure the proximal hemisphere. ‘Strawberry’- or ‘lemon’-shaped heads can indicate the presence of trisomy 18 or neural tube defects, respectively. Brachycephaly (anteroposterior shortening) can also be a sign of fetal trisomy 21 or trisomy 18 (‘strawberry’ head). Dolicocephaly (elongation of the anteroposterior length) can be a normal variant, or secondary to decreased amniotic fluid and compression of the fetal head. Tangential imaging through the fetal calvarium may identify cranial sutures (hypoechoic spaces between bones), which are best visualized early in gestation since ossification progresses with time. In certain syndromes (such as craniosynostosis and skeletal dysplasias), premature closure of the sutures can be seen.

The transthalamic view (Figure 77.1) is an axial view through the cranium at the level of the thalami. At this level, the BPD and HC are obtained. Because of excessive variation in the BPD shape which can occur, when the head is either brachycephalic or dolicocephalic, the HC is the preferred measurement. The BPD is obtained with the cranial bones perpendicular to the ultrasound beam, and is measured from the outer margin of the near-calvarium to the inner margin of the far-calvarium. The HC is measured circumferentially at the outer margin of the calvarium. Other anatomic structures that should be assessed in the transthalamic view are the cavum septum pellucidum (fluid-filled midline structure anterior to the thalami and between the lateral ventricles), midline falx, third ventricle (located between the thalami), and frontal horns of the lateral ventricles. Visualization of the cavum septum pellucidum implies proper formation of midline intracranial structures. Its absence can be a sign of agenesis of the corpus callosum, holoprosencephaly, or other brain anomalies.

The transventricular view (Figure 77.2) is found just superior to the transthalamic view, and is marked by the lateral ventricles, which contain sonolucent cerebrospinal fluid. Within this system is the echogenic choroid plexus, which normally fills the body of the lateral ventricle extending into the atrium. The frontal horns are seen as prominent sonolucent anterior components of the lateral ventricles. Through an axial plane of the atrium, the cerebral ventricle is measured.

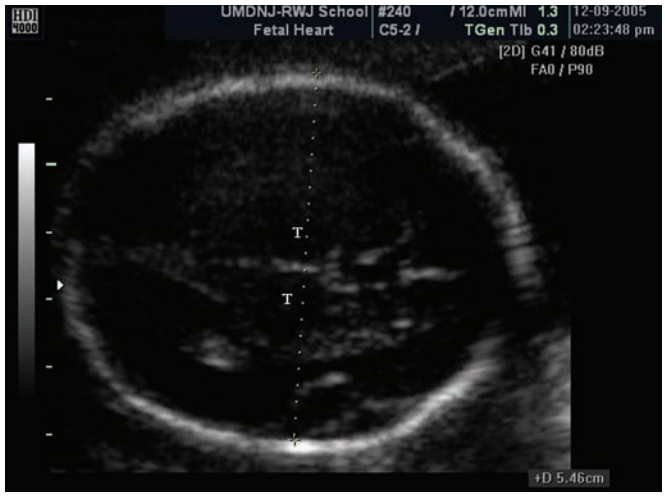

Figure 77.1 Axial view through the fetal head with calipers demonstrating measurement of the biparietal diameter. This is also the view for measurement of the head circumference. Both thalami (T) are also depicted.

Figure 77.2 Transventricular view of the fetal head demonstrating measurement of the atria of the lateral ventricle (0.42 cm) and the echogenic choroid plexus.

To rule out ventriculomegaly/hydrocephalus, normally it should be < 10 mm.

The transcerebellar view (Figure 77.3) contains the biconvex cerebellar hemispheres and midline vermis, cisterna magna (between the dorsum of cerebellar hemispheres and inner calvarium), and nuchal fold. Importantly, the transcerebellar diameter can also be measured and utilized as a one-point estimate of gestational age. The transcerebellar view is obtained by angling the scan plane down posteriorly from the transthalamic view. This area is of vital importance in ruling out open spina bifida, since obliteration of the cisterna magna and a 'banana' shape of the cerebellum may be seen with this disorder. Other anomalies that can be ruled out in this view include Dandy–Walker malformation/variant, cerebellar agenesis/hypoplasia, and occipital encephaloceles. The cisterna magna normally ranges from 3 to 9 cm.[6] On occasion, this measurement may be increased, but is a usually normal finding if the transcerebellar diameter is normal for gestational age and the vermis is well seen and intact. An incorrect scan plane can lead to a false-positive appearance of Dandy–Walker variant or to an abnormally large measurement of the cisterna magna.[7] An increased nuchal fold (6 mm or greater) may be secondary to fetal aneuploidy (especially Down's syndrome, DS) or may be falsely thickened due to breech presentation. In certain clinical scenarios, the intracranial major vessels (such as middle cerebral artery) can be identified with color and/or power Doppler imaging (Figure 77.4). This information may be quite useful in assessing for anemia (Rh isoimmunization, parvovirus infection) or intrauterine fetal growth restriction. On occasion, the fetal head may be low in the pelvis that it prohibits an adequate examination of the intracranial anatomy; transvaginal scanning may be quite useful and solve this dilemma.

Although examination of the fetal face is not required, we believe it should be examined routinely because it can add tremendous information when discriminating between genetic disorders/syndromes, including aneuploidy, and it completes the full examination of the fetus. Three distinct planes can be examined: axial, coronal (Figure 77.5), and sagittal (profile) (Figure 77.6) although a combination of these planes is the most optimal. In evaluating for cleft lip/palate (anterior palate), both axial and coronal images toward the anterior surface of the nose/upper lips provide the best visualization. The posterior or hard palate cannot be imaged sonographically, since it is obscured by overlying osseous structures. Other anatomic structures that should be evaluated include the chin (to rule out micrognathia), nasal bone (Figure 77.6), nose, lower lips, tongue, orbits (and diameters if necessary, to exclude hyper/hypotelorism), and ear length (which can be shortened in both aneuploid and non-aneuploid fetuses). Multiple studies have found sonographically absent or short fetal nasal bone in both the first and second trimesters to be sensitive for the detection of DS.[8–10] Structures in the anterior neck that may have to be examined on occasion include the fetal thyroid, and the fluid-filled trachea and hypopharynx.

Examination of the fetal spine should be performed in three planes: sagittal, transverse, and coronal. Each vertebral segment is composed of three echogenic ossification centers (two posteriorly and one anteriorly, which is the vertebral body), which are positioned in a symmetric triangular-shaped configuration in the transverse plane. In this plane, the posterior processes are also oriented toward the midline like the roof of a house. When these processes appeared splayed, a neural tube defect must be ruled out. Transverse imaging of the spine is perhaps the most sensitive method of examination for a spinal defect, since it allows a

simultaneous examination of posterior ossification centers and overlying soft tissue. Sagittal imaging of the fetal spine (Figure 77.7) should show two rows of approximately parallel ossification centers with overlying intact skin. Both sagittal and coronal views are useful to observe this 'lining up' of the ossification centers, and should be able to rule out scoliosis or hemivertebrae (which can cause disorganization or absence of ossification centers). The sacrum normally should curve slightly upward. The overlying skin and soft tissues should also be examined carefully to rule out masses/tumors, or open spina bifida.

In examining the fetal thorax, the scapulae, clavicles, and ribs should be assessed, especially when ruling out certain types of skeletal dysplasias. Abnormal lung tissue and echogenicity (such as bronchopulmonary sequestration, cystic adenomatoid malformations), diaphragm, pleural effusions, and thoracic circumference (to rule out pulmonary hypoplasia) should all be examined.

Performing an adequate and detailed fetal cardiac examination on ultrasound can be one of the most difficult and challenging tasks, since it is dynamic, complex, and can depend significantly on fetal position. First, the situs should be established along with the presence of a normal cardiac rate and rhythm. In a transverse image of the fetal chest, the heart should occupy about one-third of the fetal thorax, and its normal axis and position should be verified (apex points to the left, bulk of the heart occupies left side of chest, $45 \pm 20°$ angle of the heart relative to the midline). Any alterations in position, axis, or both can suggest intrinsic malposition or an intrathoracic mass. In order to sufficiently rule out cardiac defects,

Figure 77.7 Normal sagittal view of fetal spine. Note the overlying skin is intact, and the parallel features of the spinal centers.

Figure 77.8 Apical four-chamber view of the fetal heart, demonstrating left atrium and left ventricle (LV) and right atrium and ventricle (RA, RV).

multiple planes and views (in addition to the four-chamber view) should be examined in real-time imaging. A single static four-chamber view is no longer acceptable or adequate to completely examine the heart. Both outflow tracts should be evaluated to increase the sensitivity for cardiac defects, such as tetralogy of Fallot, transposition of the great vessels, truncus arteriosus, etc. In screening second-trimester fetuses, we advocate visualization of the four-chamber apical (Figure 77.8) and subcostal views, both outflow tracts, longitudinal parasternal arches (aortic and ductal), inferior/superior vena cava, valves, and the atria/ventricular septa. All chambers should have approximately equal sizes, the great vessels should cross each other, the pulmonary veins should be seen entering the left atrium, and there should be no pericardial effusion. Depending on the indication or clinical scenario, color, M-mode, or pulsed Doppler sonography can also be performed of the fetal heart and its great vessels. In about 3–4% of normal second-trimester fetuses,[11] an echogenic intracardiac focus can be seen, usually located in the left ventricle. It is caused by specular reflection from the papillary muscle and chordae tendinae. However, some studies have also confirmed an association between this and fetal DS in high-risk populations.[12]

Fetal abdominal organs that can be identified on second-trimester ultrasonography include liver (majority of the upper abdomen), gallbladder (right upper quadrant at inferior edge of the liver and 'tear-drop'-shaped), spleen (solid organ posterior to stomach), stomach, bowel, umbilical vein, and cord insertion site/adjacent anterior abdominal wall. The abdominal circumference (AC) is taken at the transverse level where stomach and spine are visualized, and the umbilical vein joins the right portal venous system, which should curve away from the stomach (Figure 77.9). If, however, the curve is toward the stomach, persistence of the right umbilical vein should be suspected. The AC has its greatest value in evaluating fetal growth later in pregnancy, and also comprises a parameter used for fetal dating. This is because AC deviations are a result of changes in both liver size and subcutaneous fat. The stomach should always be located below the diaphragm as a fluid-filled structure in the left upper quadrant. An absent or small stomach in the usual location despite prolonged scanning to allow for filling can be indicative of esophageal atresia with or without tracheo-esophageal fistula, or diaphragmatic hernia (stomach located within the chest). The rest of the abdomen is filled with bowel, with the appearance changing with advancing gestational age. In the second trimester, the fetal bowel appears as midlevel to increased echogenicity filling the abdominal cavity; when using higher-frequency transducers, it often appears mildly echogenic when compared to the liver.[13] True hyperechoic bowel is diagnosed when its echogenicity is similar to that of bone. It can be a normal variant, or associated with aneuploidy, infection, cystic fibrosis, fetus swallowing blood, intrauterine growth restriction, and bowel malformations/atresias. To exclude ventral wall defects such as omphalocele or gastroschisis, the umbilical cord insertion site into the abdominal wall (Figure 77.10) must be evaluated to confirm the cord penetrating the abdomen, with the adjacent abdominal wall intact. No fetal ascites or hydrops should be seen under normal circumstances.

The fetal genitourinary tract is a common site for fetal anomalies. The kidneys appear as bilateral, hypoechoic, paraspinal structures that contain the urine-filled renal pelvis and can sometimes be difficult to visualize. Dilation of the renal pelvis/calyx or ureter, renal masses, hyperechogenicity, parenchymal cysts, or enlargement/absence of the kidneys may reflect anomalies. To delineate the renal arteries, color

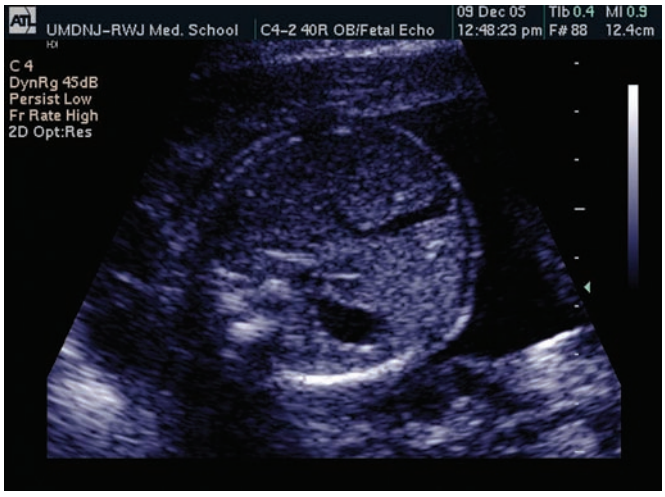

Figure 77.9 Correct view of taking the abdominal circumference measurement.

Figure 77.10 Transverse view of fetus depicting abdominal wall cord insertion site. The sonolucent bladder is also visualized with each of the two umbilical arteries starting to course around its periphery.

or power Doppler imaging is frequently used. The fetal adrenals can be seen cephalad to their kidneys. While the right adrenal lies immediately posterior to the inferior vena cava, the left adrenal lies lateral to the aorta. The fetal bladder is sonolucent (contains urine) and located in the midline, anteriorly, and low in the pelvis (Figure 77.10). Absence of the bladder may be secondary to recent voiding or bladder/cloacal exstrophy, while a very enlarged bladder may be a sign of lower obstructive uropathy. Male genitalia is confirmed only if penis and scrotum are seen. Occasionally, the hypoechoic umbilical cord lying between the thighs can be mistaken for the solid penis. Also, a prominent clitoris seen during the early second trimester can also sometimes be confused for a penis. The echogenic testicles usually do not descend into the scrotum until the seventh month. Female genitalia are identified by the presence of several parallel linear echoes, which represent the margins of the labia, and not by the observed absence of penis/scrotum. One should never forget that ambiguous genitalia may also be present.

Although routine evaluation of all fetal upper and lower extremities is not a part of routine obstetrical sonographic guidelines, it is our opinion that a complete survey of all extremities (including hands/feet) may provide important diagnostic information and can screen for abnormalities. Both the hands should contain five fingers, should be open (full extension of all fingers in the same plane as the metacarpals), have normal movement and tone, and the middle phalanx of the fifth digit must be visualized (Figure 77.11). The presence of clenched hands with overlapping digits is a highly sensitive (95%) sonographic marker of trisomy 18.[14] All the long bones (femur, humerus, radius, ulna, tibia, fibula) should be present and there should not be demineralized, shortened, fractured, contracted, or bowed bones. The ulna normally extends farther into the elbow, and the tibia extends farther into the patella. Routinely on our second-trimester surveys, we measure all long bone lengths. These measurements should be obtained with the long bone located horizontally within the image, since vertical measurements can falsely 'shorten' the actual length (Figure 77.12). Also, only the ossified portions of the bone should be measured, with the hypoechoic cartilaginous epiphyses excluded. Both lower extremities should not be clubbed, nor the plantar surface appear 'rocker-bottom'. Five toes should be present, and they should not appear dysplastic. Foot length (Figure 77.13) is also another biometric parameter than can be obtained.

Normally, the umbilical cord is comprised of three vessels: two smaller umbilical arteries and one larger umbilical vein; this can be confirmed by directly imaging the cord or by observing the umbilical arteries coursing around the fetal bladder. Depending on the clinical situation, an umbilical artery Doppler waveform can be obtained (Figure 77.14). Its flow is a reflection mainly of the placental resistance, and to a certain extent, of the fetal systemic circulation. Once the umbilical vein enters the fetal abdomen, it turns superiorly, enters the liver, and communicates with the portal vein. The umbilical vein also continues into the ductus venosus, and then the inferior vena cava and right atrium.

Sonographic aneuploidy markers in the second trimester

Aneuploid fetuses account for approximately 6–11% of all stillbirths and neonatal deaths.[15] Prenatal ultrasonography can often detect many abnormalities in fetuses with aneuploidy. These can include major structural defects or other 'soft' sonographic markers

Figure 77.11 Fetal hand demonstrating echogenic phalanges of four fingers, including the fifth digit.

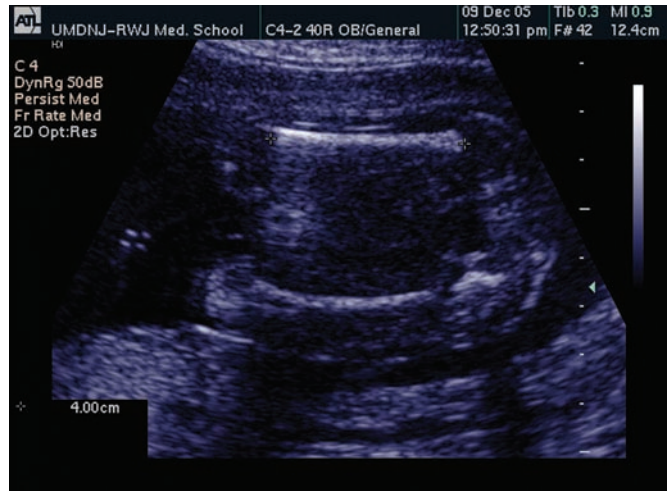

Figure 77.12 Femur length measured from proximal end to distal metaphysis, including only the ossified portions. Note the other femur lying parallel and directly below the measured femur length.

of aneuploidy. Aneuploidy 'soft' markers are usually non-specific, most commonly seen in normal fetuses, are often transient (such as choroid plexus cysts), and may not be significantly linked to perinatal outcome. The aneuploidy markers that we use in our institution include shortened long bones, pyelectasis, increased nuchal fold thickening, hyperechoic bowel, choroid plexus cysts, hypoplastic middle phalanx of the fifth digit, clinodactyly, sandal gap (wide space between first and second toes), two-vessel cord, echogenic intracardiac focus, short ear length, and absent nasal bone. Each marker alone has only low to moderate sensitivity for detecting fetal DS. Many of these sonographic findings when found in isolation in low-risk patients do not necessarily increase the risk for aneuploidy. However, when found in the context of multiple other sonographic abnormalities or markers (in low-risk patients), or when isolated markers are seen in high-risk patients, the risk for fetal aneuploidy may increase. In general, as the number of markers present increases, the risk for chromosomal abnormality also increases directly.

The presence of most fetal congenital abnormalities will increase the risk for underlying aneuploidy except for some disorders felt to be 'acquired' (rather than inherent) from tissue or vascular disruption. Such disorders include hydranencephaly, gastroschisis, tumors, amniotic band syndrome, limb–body wall complex, etc. Examples of specific structural anomalies that can be associated with fetal aneuploidy are cerebral ventriculomegaly, holoprosencephaly, agenesis of the corpus callosum, Dandy–Walker malformation/cerebellar hypoplasia, spina bifida, cleft lip/palate, ocular abnormalities, craniofacial anomalies, cystic hygroma, non-immune hydrops, cardiac abnormalities, diaphragmatic hernia, duodenal atresia, omphalocele, genitourinary anomalies, clubfeet, and extremity malformations.

The most common autosomal trisomy in liveborn infants is DS. Because only 25% of DS fetuses in the second trimester have a sonographically detectable major anomaly (unlike trisomies 18 and 13 where the majority will have anomalies visualized), several investigators have been searching to find aneuploidy ultrasonographic markers in order to increase the sensitivity for fetal DS.[16] Genetic sonography is performed in the second trimester, ideally between 18 and 20 weeks. It is a specific, targeted exam for fetal aneuploidy (most specifically for trisomy 21) where the examiner evaluates for abnormal fetal biometry, fetal structural anomalies, and other markers of aneuploidy. By combining multiple aneuploidy markers, the sensitivity for DS can be increased to >80%, with false-positive rates of 10–15% (by defining as abnormal the ultrasound exam with at least one abnormal marker present). Information derived from a normal genetic sonogram is used to generate an adjusted (lower) DS risk to guide a high-risk woman's decision on genetic amniocentesis. Thus far, many studies have been published that examine the accuracy of genetic sonography for detecting DS in high-risk populations.[17] By defining as abnormal the ultrasound with at least one abnormal marker, the overall sensitivity is 77% (50–93%) and the false-positive rate is 13% (7–17%).[17] In 1998, a large multicenter collaborative study involving 11 centers (including our own) examined the sensitivity of sonography in detecting fetal DS.[18] They found that 85% of DS fetuses ($n = 241$) had at least one abnormal finding on ultrasound. In 2003, an eight-center study (including our own) evaluated the utility of second-trimester genetic sonography among high-risk pregnancies, including 176 DS fetuses.[19] The sensitivity for DS was 72%, with a range from 64% to 80% at the various sites. Significantly, about half (47%) of DS fetuses had a thickened nuchal fold of 5 mm or

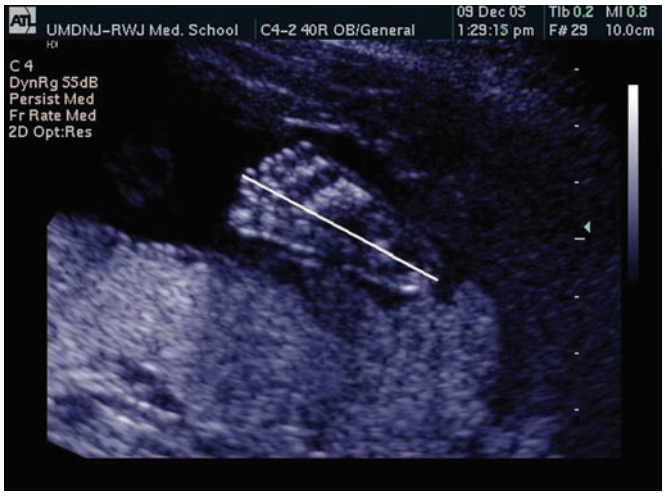

Figure 77.13 Measurement of second-trimester fetal foot length, with all five toes demonstrated.

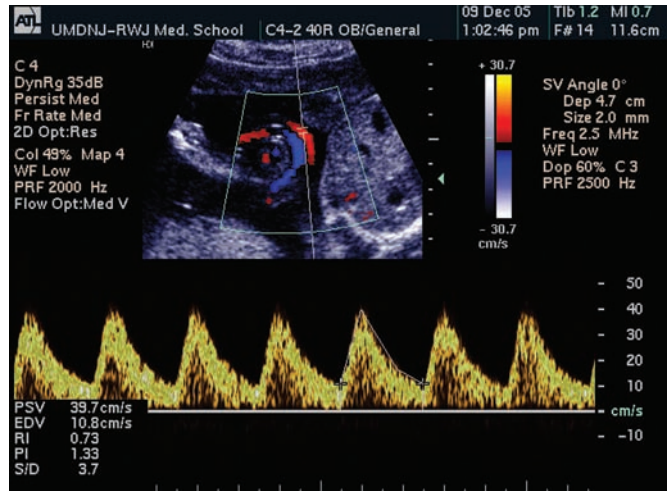

Figure 77.14 Normal Doppler waveform of umbilical artery in a second-trimester fetus. The systolic/diastolic ratio is 3.7.

more, making this marker the one with the highest sensitivity.

Nuchal fold thickening is the single most sensitive and specific marker for fetal DS (sensitivity 40% and false-positive rate of 0.1%),[20] although absent nasal bone has also recently been shown by us to have a 41% sensitivity and 100% specificity for fetal DS.[8] Short femur length (measured to expected length <0.91) has been found in 24% of DS fetuses,[21] while a short humerus (measured to expected length <0.90) identified 50% of DS fetuses, with a false-positive rate of 6.25%.[22] Unfortunately, there tends to be a large overlap in bone measurements between affected and normal fetuses. The sensitivity for pyelectasis (anteroposterior diameter renal pelvis >4 mm in second trimester) for DS is 25%.[22] Echogenic bowel has a reported sensitivity of 7–12.5%, while echogenic intracardiac focus has a sensitivity of 18%.[22] Recently, we examined the sensitivity for fetal DS by sonographic ear length.[23] We found that of 51 DS fetuses, 41% ($n=21$) had ear length $\leq$10th percentile. However, short ear length was not as sensitive a marker for DS as it was for trisomies 18 (96%) and 13 (100%). Although an association between choroid plexus cysts and trisomy 18 has been established,[24] the association with fetal DS has been controversial, especially when isolated. When the choroid plexus cyst(s) are isolated, obstetrical management should not be altered in the absence of any other high-risk factors.[25] Single umbilical artery has been found to be associated with aneuploidy and congenital malformations. The risk for fetal aneuploidy depends on the presence of associated anomalies: the greater the number of anomalies the greater the chances for aneuploidy. In a low-risk patient, an isolated single umbilical artery on ultrasound is probably not an indication for fetal karyotyping, provided that a search for additional malformations is negative.

In 1996, our group was the first to publish data on using second-trimester genetic sonography to guide clinical management of women at high-risk for fetal DS.[26] Subsequently, once we analyzed our 1999 data, in the presence of a normal genetic ultrasound, we counseled patients that the likelihood for fetal DS was reduced by at least 80% from the *a priori* risk (triple or quadruple screen, or if unavailable, maternal age).[17] Over almost a 10-year period (since November 1992), we have evaluated 5299 fetuses by genetic sonography; the overwhelming majority (85%) had no markers seen (normal scan), 12% had one abnormal marker present, and 3% had two or more markers present. When one or more abnormal sonographic markers were present, the sensitivity, specificity, positive and negative predictive values for DS were 87% (52/60), 91% (4395/4831), 11% (52/488), and 99.8% (4395/4403), respectively. Approximately two-thirds of DS fetuses had two or more abnormal sonographic markers seen.

Second-trimester ultrasound screening for fetal abnormalities

While there are numerous acceptable indications for performing a second-trimester sonographic exam during pregnancy, perhaps one of the most common indications is to rule out the presence of fetal abnormalities. While the advantages of performing a screening ultrasound in the pregnancies at high risk for fetal anomalies is clear, the benefits and cost-effectiveness of routine sonographic screening in pregnancy are not as obvious. In the USA, approximately 60–70% of all pregnant women undergo an ultrasound at various times in the gestation.[27] However, the efficacy of routine sonographic screening for fetal abnormalities varies widely. One of the first studies to determine the

diagnostic accuracy of ultrasonography in high-risk pregnancies was performed during the late 1970s and early 1980s in the UK.[28] It was around this time that real-time imaging became widespread as a clinical tool. This study found that 95% of malformations were correctly diagnosed.[28] Other published sensitivities have ranged broadly anywhere from 13.3% to 82.4%,[29] with the average collaborative world experience being 50%.[30] After reviewing these extremely wide and different detection rates, it becomes apparent why the reliability and utility of sonographic screening for fetal abnormalities have become very controversial in some countries. Even for those who already advocate routine sonographic screening, when to perform scans and the number of sonographic exams are debatable and inconsistent. Since 75% of patients with abnormal fetuses will be 'low risk', it is reasonable to review data in the literature that assess the impact of routine screening sonography.[29]

Diagnosing fetal anomalies prior to birth can provide many advantages. Prenatal sonographic diagnosis can lead to further diagnostic testing (such as amniocentesis), prepare parents for an adverse pregnancy outcome, alert the clinician to the possibility of other abnormalities, and determine appropriate management choices (such as intrauterine therapy, early delivery, delivery at a tertiary care center, or termination of pregnancy). However, all these advantages are achieved only if the ultrasound exam is performed by qualified, knowledgeable individuals, who possess expertise performing ultrasonographic exams. Sonographic screening done by individuals who are inexperienced and unqualified may not only increase the costs of health care, but can create high false-negative and false-positive results with significant consequences.

There are a multitude of biases and problems that can account for the sensitivity variation across various studies.[29] Fetal abnormalities that resolve, technical factors (obesity, fetal positioning), quality of sonographic equipment, and undetectability of certain anomalies comprise some of the reasons. In addition, each center has differing criteria and interpretations as to what exactly constitutes a detailed sonographic exam. There is no doubt that the less detailed the exam, the higher the chances are for having a lower diagnostic accuracy. Selection bias can also play an important role in affecting diagnostic accuracy, depending on whether the patient source is a hospital, or office practice-based. Perhaps the most important bias is the variation in sonographic skills, capability, and experience of individuals performing the ultrasound examination. In the Helsinki study that incorporated patient populations from two hospitals, the ultrasonographic sensitivity for detecting anomalies was more than twofold higher in the university hospital than in the city hospital (77% vs. 36%).[31] A study in Vienna examined the influence of the experience of the investigator on the rate of sonographic diagnosis of fetal malformations.[32] Of 323 cases of fetal malformations, obstetricians in private offices detected 22%, hospital examiners detected 40%, and examiners in the prenatal diagnosis and therapy center detected 90% of all fetal malformations.[32] The selection of pregnant women is also significant. Screening high-risk women is likely to be much more effective. In this scenario, the chances of discovering an anomaly is higher, and the sonographers may be more attentively focused. For instance, in one study they found that the average sensitivity in low-risk populations is 55%, while in high-risk populations it is 92%.[29]

The gestational age at the time of ultrasound screening also impacts sensitivity, since various anomalies are manifested at differing gestational weeks or may be easier to visualize/detect, and some anomalies may present only later in gestation (duodenal atresia). In general, the more sonographic exams a patient undergoes during the pregnancy, the higher the rate of anomaly detection. Levi found that the average sensitivity from studies including scans performed once before 20 weeks was 45%; when scanning was done several times during the pregnancy, the sensitivity rose to 60%.[29] The prevalence of specific malformations within a given population may also have a significant impact on the overall sensitivity of ultrasound. A low frequency of anomalies in a certain population can introduce bias in diagnostic accuracy. Studies that exclude certain anomalies because they are felt to be 'minor' or undetectable may have dramatically different sensitivities than when all fetal anomalies are included. In 1996, one study found that the sensitivity of sonography for diagnosing both minor/major anomalies was only 8.7%; however, if only major anomalies detectable by ultrasound were included, the sensitivity was increased up to 75%.[30] Finally, other factors that can affect the reported fetal abnormality detection rates in sonographic screening may be related to ascertainment biases, such as lack of autopsies (considered the 'gold standard'), suboptimal or incomplete neonatal evaluation at birth, and insufficient length of neonatal follow-up since some abnormalities may not express themselves immediately after birth and can take time to manifest.[29]

In the USA, the RADIUS (Routine Antenatal Diagnostic Imaging with Ultrasound) study was the first randomized clinical trial of second-trimester ultrasound.[33] This trial was performed to determine the benefits, if any, of routine sonograms among pregnant women at low risk. It compared routinely scanned pregnant women to those having ultrasounds only when indicated. An additional ultrasound exam was performed in the early third trimester in the study group. Although the identification rate of anomalies was found to be three times better with routine ultrasound vs. indicated ultrasound (35% vs. 11%, respectively), the sensitivity in detecting anomalies by ultrasound performed between 15 and 22 weeks was extremely low (17%). A possible source of bias was that practice-based patients were utilized, which

may have created an inadvertent selection bias (rather than a community or hospital-based population). This study reported a relative detection rate of 2.7 (95% CI, 1.3–5.8) in tertiary vs. non-tertiary ultrasound units.[33] Within a subgroup evaluated at tertiary care centers, the detection rate of anomalous fetuses was 35% vs. 13% in non-tertiary centers. This trial found that sonographic screening did not significantly influence the management or outcome of pregnancies complicated by congenital malformations. A 1998 study at a tertiary care center found that the sensitivity of anomaly detection in women at risk for anomalies was very high (89.7%).[34] In the screening group, or lower-risk population, although the sensitivity was less (47.6%), it was still sufficient to ensure cost-effectiveness for their patients.[34]

In 1999, the Eurofetus study was designed to evaluate the sensitivity of routine sonographic screening for fetal malformations.[35] In the largest among screening studies, ultrasound screening was applied to almost 200,000 pregnant women in 60 hospital laboratories and 14 European countries. They found a sensitivity rate of 64% (2363/3685), which at first glance, was much higher compared to the RADIUS study. However, for various reasons these two studies may not be exactly comparable. For example, patients studied in the RADIUS trial were low risk (and probably not relevant to the average population), since very strict exclusion criteria had been applied prior to patient recruitment. The criteria used to designate major fetal anomalies (gold standard) were also very liberal, and both of these facts could have lowered the sensitivity. On the other hand, in the Eurofetus study, all patients were studied regardless of their risk status, and only 'truly' major abnormalities were considered as endpoints. This could have artificially raised the sensitivity of the sonographic screening.

The Helsinki trial had patients undergo one ultrasound screening exam within the second trimester; 40% of major fetal anomalies were detected.[36] Although screening did detect most anomalies of the central nervous system, genitourinary system, and cases with multiple anomalies, it was less satisfactory in detecting cardiac and gastrointestinal tract anomalies.[36] The Belgian Multicentric Study found that of 381 structurally abnormal fetuses, 154 were correctly detected by ultrasound (sensitivity 40%).[37] The specificity, positive and negative predictive values were 99.9%, 95%, and 98.6%, respectively.

In 2002, we examined the value of our aforementioned complete anatomic sonographic survey in detecting fetal abnormalities, and correlated our sonographic findings with perinatal autopsy results.[38] Autopsy findings were considered the 'gold standard'. Of 88 abnormal autopsies, 85 fetuses had one or more abnormal structural sonographic findings, for a sensitivity of 97% (for anomalous fetuses). From autopsy, a total of 372 separate abnormalities were found; of the 299 major and 73 minor abnormalities, prenatal ultrasonography detected 75% and 18%, respectively. Thus, we found that the sensitivity for detecting minor abnormalities was poor, even when utilizing a complete sonographic survey. We found either complete agreement or only minor differences between sonographic and autopsy findings in 65% of the cases.[38]

In examining the literature, it is evident that there is a wide range in sensitivity of ultrasonography to detect fetal anomalies, and it depends highly on the clinical setting in which the exam is performed, along with the varying skills, expertise, and experience of those performing the sonographic exam. Therefore, there appears to be insufficient evidence to comment on a single estimate of the sensitivity of routine ultrasound in screening for fetal anomalies. However, in many studies, the specificity of a fetal anatomic survey has been found to exceed 99%.[33,39–41] This fact indicates that in the low-risk population, sonography may be helpful in ruling out abnormalities and detecting the normal, but may not be equally reliable in detecting abnormalities. It is expected that with time, the sensitivity of sonographic screening programs should improve. This can be partly attributable to improvements in equipment quality, training, and experience of sonographers, along with the emergence of new technological advances such as three- and four-dimensional sonography. It is thought that uniform and detailed training for practitioners is the best guarantee for an efficient screening program.[29] In addition, standardization of the scanning process for each and every scan should also improve overall sensitivity. In a 1996 review article, Seeds argues that the diagnostic sensitivity of the screening obstetrical ultrasound examination appears to be highest in high-risk patients examined by highly specialized and experienced personnel.[42] However, diagnostic sensitivity may be quite good even in low-risk patients with a basic or routine examination if recognized guidelines for content are followed and referral to experienced referral resources for unclear or suspicious images is liberally practiced.[42]

A common and often touted benefit of the prenatal detection of fetal abnormalities, especially those that are life-threatening, is the delivery of these infants in tertiary care centers that are capable of providing immediate and appropriate care. A valid and legitimate question often asked is whether routine sonography improves the survival rates of anomalous neonates. Ten years ago, the RADIUS study examined this question.[33] Screening ultrasound was not found to have any impact on the detection, management, and outcome of fetuses with anomalies. Although survival rates for fetuses with anomalies were not affected by sonographic screening, in an analysis of infants with life-threatening anomalies, 75% (21/28) in the routinely screened group survived, vs. 52% (11/21) in the routine-care group.[33] While this difference did not reach statistical significance, this may be attributed in part to the small sample sizes.

At present, there is insufficient evidence to either refute or support the benefit of routine sonography in reducing mortality of those neonates with life-threatening anomalies, although this may not be intuitively apparent to those families affected with these problems. It is clear that further studies are required to address this issue.

A significant question regarding routine ultrasonography is whether this improves overall perinatal morbidity and mortality. It is known that routine diagnostic sonography can lead to accurate determination of gestational age, multiple gestations, and placental abnormalities, thus theoretically improving perinatal risk. Three trials have examined perinatal morbidity and mortality in patients undergoing routine ultrasonography. In both the RADIUS and Stockholm trials, perinatal mortality rates were similar between the routine sonography and control groups.[27,43] However, the Helsinki trial found that the perinatal mortality rate was significantly improved in the routine ultrasound group (4.6/1000 vs. 9.0/1000); this 49.2% reduction was mainly attributable to improved early detection of major malformations, which led to termination of pregnancy.[31] In all three trials, no differences were found between the study and control groups in terms of perinatal morbidity.[27,31,43] Perinatal morbidity was defined as admission to the neonatal unit,[31,43] moderate morbidity (neonatal sepsis, grade I or II intraventricular hemorrhage, stay of > 5 days in neonatal unit), or severe morbidity (ventilation > 48 h, stay of > 30 days in neonatal unit).[27] In terms of birth weight and number of low birth weight (< 2500 g) infants, the RADIUS and Helsinki trials found a similar birth weight distribution between the routine ultrasound and control groups.[27,31] However, the Stockholm trial found fewer births of < 2500 g (2.5% vs. 4%) in the routine ultrasound group.[43] Finally, this same trial found that for women smokers, there was a higher mean birth weight (3413 vs. 3354 g) in the routine ultrasound group, and the authors surmised that this improvement could be attributed to healthier maternal behaviors after women visualized their fetuses on ultrasound.[43] The RADIUS trial investigators concluded that adopting sonographic screening in the USA would increase health-care costs without either improving perinatal outcome or providing any measurable benefit from early detection of fetal anomalies. In contrast, however, another group found that routine abnormality screening improves perinatal outcome by leading to termination of pregnancies for certain anomalies, and selected delivery at tertiary care centers for life-threatening malformations.[34]

An important issue to examine is the cost–benefit analysis of routine second-trimester sonography. Our group recently performed a cost–benefit analysis based on the RADIUS results, and compared a policy of routine second-trimester sonography in low-risk pregnant women vs. not offering such screening.[44] We concluded that routine second-trimester sonographic screening is associated with net benefits only if the ultrasound was performed in tertiary care centers. Another tertiary center also assessed the cost-effectiveness of anomaly screening in their patient population, and found that routine screening appeared cost-effective.[34] Leivo and associates demonstrated that a one-stage second-trimester screening ultrasound was cost-effective, and was associated with fewer perinatal deaths.[45] In the UK, a prospective study was performed to evaluate the cost–benefit of changing from selective to routine ultrasound screening for fetal anomaly.[46] They found that routine sonography was the sole method of detection for 11 major and 18 less severe congenital abnormalities found in low-risk pregnancies, which would not previously have qualified for selective ultrasound. They felt that routine fetal anomaly ultrasound would seen to be economically justifiable.[46] In 2002, Roberts reviewed evidence from the literature and found a need for more data on the costs and cost-effectiveness of routine sonographic screening for fetal anomalies.[47]

All published trials have shown that more twin pregnancies are diagnosed earlier with routine ultrasound. The Helsinki trial found that with the routine ultrasound group, 100% of twins were detected prior to 21 weeks, compared with 76% in the control group.[31] In addition, they found that the perinatal mortality for the twins was 27.8/1000 vs. 65.8/1000, respectively. The RADIUS trial also performed subgroup analyses for small for gestational age infants and neonates born at 42 weeks.[27] The data did not show improvement in overall outcome for these conditions when routing sonography was performed.

In conclusion, examination of the available evidence shows that in low-risk pregnancies, routine ultrasonography may reduce perinatal mortality because of induced abortions following the detection of fetal abnormalities. In the USA, the current standard of care remains at performing ultrasound only for specific indications. However, some would argue that every obstetrical patient should have an ultrasound examination only if it is competently performed, properly recorded, and if the patient is aware of appropriate goals and limitations.[42]

Although ultrasonographic screening for fetal abnormalities may have widely varying sensitivities depending on the particular unit, in our opinion it still offers great value to both patients and physicians that may not be quantifiable. Psychological reassurance, referrals, genetic counseling, antepartum management, and preparation of families and health care providers are just some examples of the possible advantages. Overall, these reasons may outweigh the 'risks' of ultrasound, such as false-positive diagnoses. If patients are given the choice and counseled regarding the diagnostic capabilities of present-day sonography, most would choose to undergo fetal anomaly screening. It is important to

remember that pregnant women often do not perceive ultrasonography as a 'test', but rather utilize it as a tool to evaluate their fetus as a patient. We concur with this philosophy, and would also argue that examining the fetus as a patient via ultrasound should be offered routinely, as in all other aspects of adult medicine.

Conclusions

Second-trimester sonographic screening for fetal anomalies and prenatal diagnosis is performed for many reasons. It can provide useful information and knowledge for patients, may give them reassurance regarding their pregnancy and the health of their fetus, provides the opportunity for further diagnostic testing such as amniocentesis, provides counseling regarding prognosis, and can modify management (such as location and method of delivery, termination, fetal surgery). Some patients will utilize this information to prepare ahead of the delivery date by consulting geneticists, pediatric surgeons, neonatologists, and other specialists. In addition, for the physician, information regarding specific abnormalities or aneuploidy can optimize pregnancy management, along with the labor and delivery process. Importantly, knowledge of anomalies can raise the possibility of genetic syndromes, can impact future pregnancies, and can influence counseling regarding genetics and prognosis. Therefore, because of its many advantages, it is our opinion that all patients should have access to sonographic screening within the second trimester of pregnancy, and a complete, targeted, and thorough exam should be performed to increase sensitivity.

78 First-trimester maternal serum markers of fetal anomalies

D. A. Krantz, T. W. Hallahan and J. N. Macri

Historically, prenatal screening for Down's syndrome and other chromosomal abnormalities had been conducted in the second trimester of pregnancy with results available between 16 and 18 weeks of pregnancy. Such screening can detect 60–70% of Down's syndrome cases with a false-positive rate of 5%.[1] Now, first-trimester Down's syndrome screening has become an important option for prospective parents providing risk information as early as 11–12 weeks of pregnancy and detecting up to 90% of Down's syndrome cases at the same 5% false-positive rate.[2–16]

The advantages of first-trimester screening are that most patients (95%) receive very early reassurance that they are at low risk, the test provides a significantly higher detection efficiency compared to most second-trimester screening methods, patients have more time and more diagnostic options to consider, and in cases where patients choose to terminate an affected pregnancy safer procedures are available in the first trimester. Further, pregnancies that may have ended in an unexplained fetal loss may now have karyotype information available.

First-trimester Down's syndrome and trisomy 18 screening includes the biochemical analysis of free beta human chorionic gonadotropin (free beta hCG) and pregnancy-associated plasma protein A (PAPP-A) combined with the ultrasound evaluation of nuchal translucency. This protocol has been studied extensively, and the first-trimester risk estimates have been validated.[17]

Free beta hCG

During normal pregnancy free beta hCG rises to peak levels at 8–9 weeks of pregnancy and then steadily declines to about 20 weeks when concentrations begin to level off. In second-trimester Down's syndrome pregnancies, free beta hCG is significantly elevated with a median MoM (multiple of the median) of 2.64.[18] By contrast, free alpha hCG has been observed to be unchanged (median MoM = 0.99)[19] or marginally elevated (median MoM = 1.31)[20] in cases of Down's syndrome. This proportionally higher increase observed in the beta subunit relative to the alpha subunit observed at the protein level is reflected at the mRNA level. Indeed, Eldar-Geva *et al.* demonstrated that the beta subunit MRNA content was proportionally increased compared to the alpha subunit in cultured second-trimester trophoblasts.[21] This suggests that the increase of the beta subunit in maternal serum may be due in part to increased synthesis. More recently, beta subunit MRNA has been detected in maternal serum and has also been demonstrated to be elevated in cases of Down's syndrome.[22]

In the first trimester, free beta hCG is significantly elevated in Down's syndrome pregnancies and is the only Down's syndrome marker that is effective in both first- and second-trimester screening. In two recent studies the median free beta hCG MoM in Down's syndrome increased with increasing gestational age from about 1.5 MoM at 9 weeks' gestation to 2.1 MoM at 13 weeks 6 days' gestation.[23,24] In the Serum, Urine and Ultrasound Screening Study (SURUSS) case–control study the median MoM of free beta hCG in Down's syndrome cases increased from 1.6 MoM at 10 weeks' gestation to 2.6 MoM at 13 weeks 6 days.[25] Therefore, free beta hCG becomes more effective with increasing gestational age. In trisomy 18 affected pregnancies, a study of 28 cases showed the median free beta hCG MoM to be 0.18 in the first trimester representing an 80% reduction from normal pregnancies.[7]

Pregnancy-associated plasma protein-A

Pregnancy-associated plasma protein-A (PAPP-A) is a 750 kDa zinc metalloproteinase. It is produced by the trophoblast and exists in maternal circulation as a disulfide bridged dimeric glycoprotein and as a 2:2 complex with the proform of eosinophil major basic protein (proMBP). Circulating levels are

detectable as early as 4 weeks in pregnancy and double approximately every 6 days throughout the first trimester. PAPP-A concentrations rise exponentially in the second trimester to reach approximately 50 mg/l in the third trimester.

In the first trimester, PAPP-A is significantly decreased in Down's syndrome pregnancies. The discrimination between unaffected and Down's syndrome pregnancy is greatest earlier in pregnancy. Our own data on 163 cases of Down's syndrome showed a median MoM of 0.3 at 9 weeks and 0.8 MoM at 13 weeks 6 days.[23] Spencer *et al.*[24] showed a median MoM of 0.37 at 9 weeks and 0.70 at 13 weeks 6 days while the SURUSS study showed a median MoM of 0.29 at 9 weeks and 0.62 at 13 weeks 6 days.[25] Therefore, PAPP-A becomes less effective with increasing gestational age and by the second trimester is no longer a marker for Down's syndrome. In trisomy 18 pregnancies, the median first trimester level of PAPP-A is 0.33 representing a 2/3 reduction from normal levels.[7]

Combining free beta hCG and PAPP-A

The levels of both free beta hCG and PAPP-A in Down's syndrome affected pregnancies tend to increase with increasing gestational age. As a result, with increasing gestational age free beta hCG becomes more effective while PAPP-A becomes less effective. These two trends tend to offset each other, such that the combination is effective in screening for Down's syndrome between 9 weeks and 13 weeks 6 days. However, the combined performance of free beta hCG and PAPP-A is optimized in the earlier gestations. For example, at a 5% false-positive rate, the detection rate is 69% if the blood is drawn at 10 weeks while it is 63% if the blood is drawn at 13 weeks.[26] These detection rates are as good as or better than those seen with second-trimester triple test.

Dried blood collection

Maternal serum screening has largely involved venepuncture collection of whole blood into red-top tubes. Recently, whole blood sample collection using finger-stick lancets and filter paper has become more common. The ease of collection and transport of dried blood specimens allows for greater flexibility in screening logistics. Since no phlebotomist is required, the simple finger-stick procedure can easily take place in the physician's office, ultrasound lab or ultimately in the patient's home. Quantitative analysis of prenatal screening markers in dried blood samples is highly correlated with liquid serum samples.[27] In addition, dried blood technology stabilizes serum proteins and therefore provides better overall analyte precision leading to both higher detection rates and lower false-positive rates.

Table 78.1 Impact of training and quality review of nuchal translucency measurements on first-trimester Down's syndrome screening detection rates

Detection rate	77%	31%

Results based on nuchal translucency only without biochemistry

Combined biochemistry and ultrasound screening

In addition to maternal serum markers, the evaluation of fetal nuchal translucency in ultrasound has been demonstrated to be a highly effective marker for Down's syndrome.[28] As a result, for the first time, biochemical and biophysical markers are combined in a single screening protocol for the detection of Down's syndrome. The challenge has been to introduce nuchal translucency assessment in a standardized, quality-controlled fashion to allow for efficient population screening. Laboratories perform a significant number of quality control procedures prior to releasing the results of biochemical tests to the clinician. Nuchal translucency, as a quantitative marker in the screening process must meet similar standards of quality control as biochemical markers. Therefore, sonographers must be specifically trained to perform nuchal translucency measurement using a standardized methodology and their results audited on a regular basis. The improved effectiveness of nuchal translucency screening when a quality control program is in place is dramatic (Table 78.1). In the study of Snijders *et al.*,[28] in which sonographers underwent training and quality review, nuchal translucency detected 77% of Down's syndrome cases while in the study of Haddow *et al.*,[29] in which there was no specific training or quality control, the detection was only 31%.

Currently, the standard first-trimester Down's syndrome and trisomy 18 screening protocol combines the biochemical analysis of free beta hCG and PAPP-A with the ultrasound evaluation of nuchal translucency. A summary of 15 studies encompassing over 80,000 patients using the free beta hCG, PAPP-A and nuchal translucency protocol demonstrates a

Additional marker(s)	Free beta hCG	PAPP-A	NT	Free beta hCG + PAPP-A
C. Combined detection (%)	91%	91%	91%	91%
D. Extra detection with inclusion of additional marker(s) = (C − A)	10%	11%	28%	17%
E. % of remaining undetected cases detected with inclusion of additional marker(s) = (D ÷ B)	53%	55%	76%	65%

88% detection rate for Down's syndrome at a 5% false-positive rate (Table 78.2).[2–16]

Combined biochemical and biophysical screening significantly improves the detection and false-positive rates for Down's syndrome compared to either mode alone. The study by Krantz *et al.*,[7] for example, showed the additional detection rate attributable to each marker in the protocol. In that study, free beta hCG added 10%, PAPP-A added 11% and nuchal translucency added 28% detection beyond that achieved by the corresponding other two markers alone (Table 78.3). Therefore to reach the optimal detection rate it is necessary to include all of these markers in the analysis.

Combined screening is also highly effective in detecting trisomy 18 and other chromosomal abnormalities. Using an independent algorithm for the calculation of patient specific trisomy 18 risk detects 97% of trisomy 18 cases with only an additional 1.2% false-positive rate.[7] In the biochemistry and ultrasound nuchal (BUN) translucency study, all 11 cases of trisomy 18 and 16 of 29 (55%) cases of other chromosomal abnormalities were detected.[12] Spencer *et al.* have shown that triploidy is associated with abnormal combined screening results with triploidy types I and II having different patterns of marker levels.[30] Type I triploidy, in which the additional chromosome is of paternal origin is associated with extremely high free beta hCG, mildly decreased PAPP-A and increased nuchal translucency. Type II triploidy, in which the additional chromosome is of maternal origin is associated with extremely low free beta hCG, extremely low PAPP-A and normal nuchal translucency.

Other perinatal risks

Abnormal free beta hCG and PAPP-A are both associated with increased perinatal risk. Low levels of PAPP-A are associated with increased risk of intrauterine growth restriction.[31–37] For example, Krantz *et al.*[31] found that PAPP-A values less than the 1st percentile were associated with a 5.4-fold increase in the odds of intrauterine growth restriction with a positive predictive value of 24.1%. Krantz *et al.*[31] also found that free beta hCG values less than the 1st percentile were associated with a 2.7-fold increase in the odds of intrauterine growth restriction with a positive predictive value of 14.3% while other studies that evaluated less extreme cut-offs for free beta hCG or treated free beta hCG as a continuous variable did not find an association with intrauterine growth restriction.[32,33,36–39] Goetzl *et al.*[40] have found that low levels of both free beta hCG and PAPP-A are associated with increased risk of spontaneous abortion. Free beta hCG levels below the 1st percentile were associated with an 8.5-fold increase in the odds of spontaneous abortion while levels below the 5th percentile were associated with a 4.3-fold increase in the odds ratio. PAPP-A levels below the 1st percentile were associated with a 5.4-fold increase, while PAPP-A levels below the 5th percentile were associated with a 2.4-fold increase in the odds of spontaneous abortion. Most importantly, patients with normal free beta hCG, PAPP-A and nuchal translucency (i.e., those with levels between the 5th and 95th percentiles) had a very low risk of fetal loss before 20 weeks (0.36%). Yaron *et al.*[34,38] found a similar association between free beta hCG and PAPP-A with fetal loss.

Maternal factors

As with second-trimester screening, maternal factors play a role in first-trimester Down's syndrome screening. Several studies have shown that patients with increased maternal weight tend to have lower free beta hCG and PAPP-A levels.[41–43] Spencer *et al.*[42] showed that there can be a twofold difference in Down's syndrome risk estimates if maternal weight is not accounted for. The effect on trisomy 18 risk can be even greater since heavier patients would have lower levels of both free beta hCG and PAPP-A which would increase the trisomy 18 risk based on both markers.

Ethnic differences in biochemical results have also been observed.[43] After weight adjustment, free beta hCG levels are higher for African Americans (15%) and Asians (6%) but lower for Hispanics (11%) compared to Caucasians. For PAPP-A, African Americans have 30% higher levels than Caucasians after weight adjustment.

The effect of assisted reproduction techniques on first-trimester combined ultrasound and biochemical Down's syndrome screening is minimal. Orlandi *et al.*[44] found that the false-positive rate for intracytoplasmic sperm injection (ICSI) (5.2%) and IVF pregnancies (4.2%) was only slightly higher than the false-positive rate in naturally conceived pregnancies (3.3%). Similarly, Liao *et al.*[45] found that the false-positive rate increased by only 1.2 percentage points in IVF pregnancies. Wojdemann *et al.*[46] found no significant difference in the false-positive rates among a group of naturally conceived pregnancies (4.9%), in vitro fertilization (IVF) pregnancies (4.7%) and ovulation induction pregnancies (5.1%).

Screening in twin pregnancy

First-trimester screening of twin pregnancies offers a distinct advantage over second-trimester screening in that it can be used to evaluate the risk of each individual fetus. In second-trimester screening, which is based on biochemical markers alone, the risk is pregnancy specific. For monozygotic twins, in which either both are affected or both are unaffected, second-trimester detection efficiencies can be expected to be similar to that observed in singleton pregnancies. However, 67% of naturally conceived and 93% of assisted reproduction twin conceptions are dizygotic, and therefore the majority of Down's syndrome affected twin pregnancies can be expected to be discordant. In such cases, since the observed maternal serum marker levels are the sum contributions from each fetus, not only is it impossible to determine which fetus is contributing abnormal analyte levels but the detection efficiency will be decreased due to a dilution effect from the contribution of the normal fetus. Indeed the detection of Down's syndrome in twins by second-trimester maternal serum screening is estimated at about 50%, significantly lower than that expected in singletons at a 5% false-positive rate.[47]

In first-trimester screening, nuchal translucency, a biophysical marker, is fetus specific. Fetus-specific

risks can be calculated based on nuchal translucency and the detection rate should be similar to that observed in singleton pregnancy. However, each fetus will carry an approximate 5% false-positive rate and therefore the false-positive rate per twin pregnancy based on nuchal translucency only is significantly greater than in singleton pregnancy. For example, in a study by Sebire *et al.*,[48] 7.3% of fetuses had an increased nuchal translucency. However, among pregnancies, 11.6% had at least one twin with an increased nuchal translucency.

Incorporating biochemistry into the first-trimester protocol along with nuchal translucency can reduce the false-positive rate. In our own data on a group of 212 twin pregnancies the false-positive rate was reduced from 13.2% using maternal age and nuchal translucency to 6.6% by also including the biochemistry.[49] Detection efficiency in twin pregnancy is difficult to document because Down's syndrome affected twin pregnancies are rare. However, modeling indicates that combining free beta hCG and PAPP-A with nuchal translucency can result in 80% detection rate for a 7% false-positive rate in twin pregnancy.[49] Therefore it is feasible to screen twin pregnancies for Down's syndrome in the first trimester. However until larger datasets of affected twin pregnancy are available a caution that risk estimates in twin pregnancy are less precise than in singleton pregnancy should be indicated on patient reports.

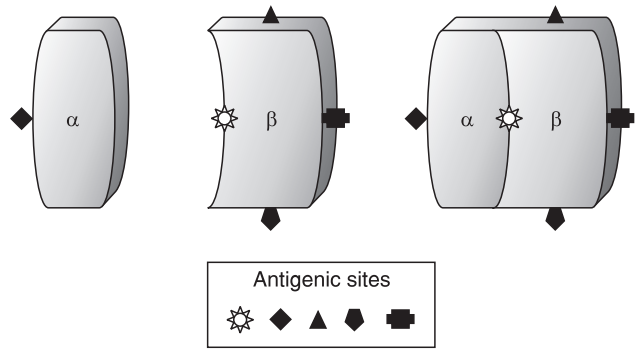

Figure 78.1 Schematic representation of hCG and its free subunits.

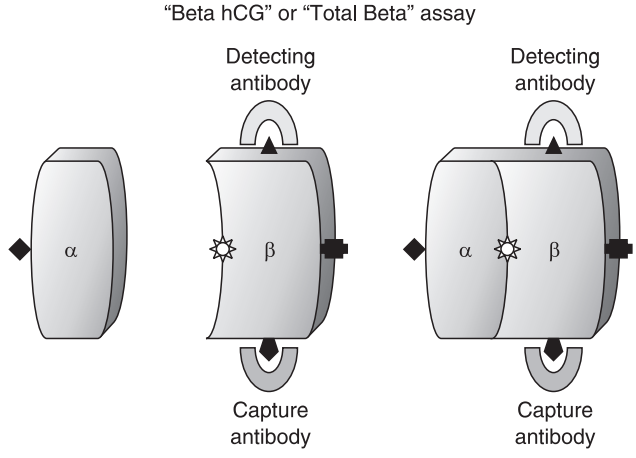

Figure 78.2 Schematic representation of assay commonly used to measure intact hCG.

Free beta hCG vs. intact hCG

HCG is a noncovalently bound heterodimeric glycoprotein consisting of an alpha and beta subunit. It exists in maternal circulation predominantly as the biologically active intact dimer. It is also found in the unbound state as both the free alpha and free beta subunits (Figure 78.1). The genes for the alpha and beta subunits of hCG are separate and distinct with the alpha subunit located on chromosome 6 and the beta subunit located on chromosome 19.[50] The separate synthesis and unbalanced secretion of subunits provides the rationale for monitoring levels of hCG subunits in obstetrical and gynecological disorders. Thus, assays for free beta hCG and intact hCG measure distinct proteins in the maternal blood.

Assays used to measure intact hCG are commonly called 'total beta' or simply 'beta hCG' assays. These assays use a capture antibody directed to the beta subunit of hCG and a detecting antibody directed to another epitopic site on the beta subunit (Figure 78.2). As a consequence, these assays detect both intact hCG and free beta hCG. However, since the intact molecule is present in a 200-fold molar excess relative to the free beta subunit, these assays reflect the concentration of intact hCG. During pregnancy intact hCG is measurable as early as 5 weeks in pregnancy making it an excellent indicator of pregnancy. An immediate and steep increase is observed with hCG levels peaking at about 120 IU/ml at 9 weeks followed by a steady decline to about 20 weeks when concentrations level off at 10–20 IU/ml.

Free beta hCG exists in maternal blood at a level of about 1/200th that of intact hCG. Assays that measure free beta hCG utilize an epitopic site that is located at the interface with the alpha subunit such that it is covered in the intact hCG molecule (Figure 78.3). As a result, antibodies directed toward this site capture free beta hCG but not intact hCG which is washed away in the assay procedure.

Prior to the prospective evaluation of the first-trimester combined screening protocol free beta hCG and intact hCG were evaluated in a number of studies.[29,51–76] Overall, it was seen that intact hCG was not an effective marker in the first trimester of pregnancy with a median MoM in 463 cases of Down's syndrome of just 1.30 while free beta hCG was an effective marker with a median MoM of 2.0 based on 858 cases of Down's syndrome (Tables 78.4 and 78.5). Hallahan *et al.*,[64] summarized seven case–control studies[57–60,64–66] in which both intact hCG and free beta hCG were measured in the same samples and showed that free

beta hCG detected nearly twice as many cases of Down's syndrome as intact hCG (Table 78.6). On the basis of these results prospective first-trimester screening studies using the combined protocol have all included free beta hCG.

Recently, Spencer *et al.*[24,26] have suggested that the evaluation of all the Down's syndrome markers should be conducted on a week by week basis since the performance of the markers varies by gestational age. Spencer *et al.* showed that the combination of free beta hCG and PAPP-A had detection rates that were

7–11% better than the combination of intact hCG and PAPP-A at each gestational week from 10 to 13 weeks at a corresponding 5% false-positive rate (Table 78.7).

In a case–control study, Wald *et al.*[25] modeled the performance of free beta hCG and PAPP-A in combination with nuchal translucency. The model indicated that free beta hCG significantly outperformed intact hCG within the combined protocol at 10 and 11 weeks' gestation but that at 12 weeks the two markers had similar performance and that at 13 weeks intact hCG performed better. However, Krantz *et al.*[77] determined that a more appropriate analysis would show that free beta hCG was better than intact hCG at 10, 11 and 12 weeks and that the two markers only appear similar in the model at 13 weeks. In response, Wald *et al.*[78] concluded that their data at 13 weeks were probably due to chance and that there was an advantage to using free beta hCG compared to intact hCG in the first trimester. An analysis[79] combining the results from Spencer *et al.*[72] and Wald *et al.*[23] demonstrated that using free beta hCG was better than intact hCG in a protocol that includes PAPP-A and nuchal translucency at 10–13 weeks. When false-positive rates were evaluated the difference between the two markers was even more apparent. For example at 10 weeks, the false-positive rate with free beta hCG was half that of intact hCG (Table 78.8).

Screening strategies

First-trimester screening is usually conducted between 11 weeks 1 day and 13 week 6 days' gestation. In general, the patient comes in for an ultrasound exam, crown–rump length (CRL) is measured for accurate gestational dating and a nuchal translucency value is obtained. At the time of the ultrasound exam a blood specimen is collected and forwarded to the laboratory along with the ultrasound information. The biochemical analytes are analyzed in the laboratory and risk results based on free beta hCG, PAPP-A and nuchal translucency are available usually within a few days.

One-stop clinic for the assessment of risk

The one-stop clinic for the assessment of risk (OSCAR) approach represents a procedural variation of first-trimester screening in which the blood sample is collected and analyzed on a rapid assay instrument during the patient's ultrasound appointment. The advantage of this modality is that the biochemical result is ready during the patient's visit allowing her to have her combined risk result immediately with the option of having chorionic villus sampling (CVS) the same day. This screening strategy is currently practiced very effectively in many European clinics.[11,13] The disadvantage is that in order to analyze the biochemistry specialized equipment and personnel are required at the ultrasound center. Therefore, this strategy is best suited for settings with high volume in order for the biochemical screening to be cost effective. The rapid assays needed to provide a blood result in under a half hour have not yet been approved by the Food and Drug Administration (FDA) and are therefore not currently available in the United States. Even with the rapid assays the total time required to interview the patient, draw a blood specimen, allow time for clotting and centrifugation, perform the biochemical assays and conduct the ultrasound examination could easily last more than 1 h. Further, the burdens of data entry, quality control and risk assessment in this modality are all the responsibility of the ultrasound clinic.

Table 78.8 Free beta hCG vs. intact hCG within a Down's syndrome protocol including PAPP-A and nuchal translucency and maternal age

Gestational age (weeks)	Detection rate at a 5% false-positive rate		False-positive rate at a fixed 85% detection rate	
	Intact hCG	Free beta hCG	Intact hCG	Free beta hCG
10	84%	88%	6.0%	3.1%
11	83	86	6.7	4.1
12	82	86	6.9	4.3
13	85	85	5.1	4.7

Analysis[79] performed using results from Spencer *et al.*[24,26] and Wald *et al.*[25]

Finger-stick blood collection with instant risk assessment

Instant risk assessment (IRA) is a variation of the OSCAR approach that takes advantage of the simplified blood collection and transport of dried blood. In this approach, patients draw their own blood at home about 1 week before their ultrasound appointment using a sterile lancet and a dried blood collection card. The sample is mailed to the laboratory and the biochemical results are ready in time for the ultrasound exam. Like the OSCAR approach the risk results are available immediately at the conclusion of the ultrasound exam but with IRA the ultrasound center has no need for specialized equipment and personnel. Additional time is not required for drawing blood and waiting for a biochemical result. That time may be better spent performing more detailed ultrasound evaluations such as ductus venosus, nasal bone and tricuspid valve regurgitation for those specific patients that have a borderline risk.

Independent sequential screening

The first-trimester combined screening test with free beta hCG, PAPP-A and nuchal translucency can detect approximately 90% of Down's syndrome pregnancies with a 5% false-positive rate. In sequential testing both first-trimester screening and second trimester multiple marker screening are performed independently. In this case, the false-positive rate in first trimester is additive with the false-positive rate in second trimester. For example, in the BUN study, a group that contained about 50% advanced maternal age patients, 9.9% of patients had increased risk results in the first trimester and another 9.0% had increased risk results in the second trimester.[80] Thus, the overall false-positive rate for the screening program using data in both trimesters was nearly doubled.

Modified sequential screening

Alternatively, the Down's syndrome risk can be calculated based on both the first- and second-trimester markers. Such an approach can reduce the increase in the false-positive rate compared to the independent sequential approach described above. However, sophisticated software is required to ensure that the patient's results in the second trimester are appropriately matched with those from the first trimester.

The modified sequential screening approach requires 95% of the population to return for second-trimester multiple marker screening. A refinement to this approach could be to offer second-trimester screening only to those patients with a borderline result.[81] For example, those patients with very high risks (e.g., greater than 1 in 100) in the first trimester can be immediately offered CVS. Those patients with low risk (e.g., less than 1 in 1500) can be reassured that no further screening is necessary. Patients with borderline first-trimester risks (e.g., between 1 in 100 and 1 in 1500) could be offered second-trimester multiple marker screening and have their final risk calculated based on the marker results in both the first and second trimester. This so-called 'contingency' screening approach has the advantage of reducing by as much as 75% the number of second-trimester screening tests that are performed, reducing the overall cost of the screening program and minimizing the number of added false positives generated by second-trimester testing.[81]

The sequential screening approaches outlined above have been described with respect to multiple marker serum screening in the second trimester. Nyberg *et al.*[82] and Bromley *et al.*[83] have determined likelihood ratios for second-trimester ultrasound markers. Any of the sequential screening methodologies described above could be conducted by substituting the second-trimester serum markers with second-trimester ultrasound markers. More data is needed to determine whether one approach is superior to the other. However, in settings where a second-trimester anomaly scan is common practice, use of the ultrasound screen may provide significant logistical advantages.

Future improvements

Future goals are to improve upon the already excellent screening performance while still maintaining screening in the first trimester. The most promising advancement may be the inclusion of ultrasound assessment of fetal nasal bone. Cicero *et al.*[84] observed that 73% of Down's syndrome cases had absent nasal bone while only 0.5% of unaffected cases had absent nasal bone in the first trimester of pregnancy. The results of Cicero *et al.* have been confirmed in several studies.[23,85–90] but one study by Malone *et al.*[91] had divergent results. The promising results with the nasal bone marker open up the possibility of significantly reducing the false-positive rate of first-trimester Down's-syndrome screening while maintaining a 90% detection rate or alternatively increasing the detection rate to better than 95%.

Conclusion

One of the first questions that expectant parents ask after discovering they are pregnant is 'Will my baby be normal?' Although there are no guarantees that a baby will be healthy, screening can reassure the vast majority of couples that they are not likely to have a baby with a major birth defect. Along with the benefits of early reassurance and diagnosis, first-trimester screening with free beta hCG, PAPP-A and nuchal translucency has raised the standards in terms of detection efficiency. As a result, the ability to screen for Down's syndrome and trisomy 18 in the first trimester of pregnancy represents the most significant advancement in prenatal screening in the past 10 years.
